The most challenging ethical issue associated with public data files is their creation; that is, de-identification of the data. Federal agencies, research organizations, and public archives (e.g., the Inter-University Consortium for Political and Social Research) take extreme precautions to de-identify the data before making them publicly available via the Internet or other media. Federal agencies and research archives that are responsible for holding data and making them accessible have the responsibility to ensure that data are de-identified if they are to be in public data files. The agencies and research archives are responsible for removing direct or indirect identifiers which could individually or jointly identify a person, such as detailed geographic information, birth dates, Social Security numbers, and exact income. A number of techniques are used by these data providers to remove both direct and indirect identifiers including eliminating variables entirely, aggregating categories instead of using exact values (e.g., using income brackets) or adding random noise to variables. De-identifying data files can be a complex process, and obtaining the advice or assistance of experts in this area is wise if the data preparation work is not being done by a professional archive or other data provider.

The process of de-identification to permit researchers' access is applicable to other forms of protecting confidential information beyond what is obtained in surveys and other systematic studies. In accordance with provisions in the Health Insurance Portability and Accountability Act of 1996 (HIPAA), researchers may be provided with individual health information without the individual's authorization if the data have been de-identified, an IRB or a privacy review board waives authorization, and the research is of minimal risk.^{111,112} Two approaches are available under HIPAA: the first identifies 18 categories of data elements that must be stripped (limiting the usefulness of the data), and the second requires a separate determination by a statistical expert attesting to the fact that the risk of identification from the data being sought is very small.

Although the use of de-identified public data poses little risk, researchers may at times want to combine a public data file with a nonpublic data file. An enhanced file can increase the risk of identifying people, so further analysis of disclosure risk and de-identification are in order if these data are to become public use files. In circumstances in which individuals can be identified through the secondary use of extant data, or through linking of public use data sets that are otherwise de-identified, further data protection procedures are required to reduce disclosure risk. Archives like the Inter-University Consortium for Political and Social Research work with investigators on data preservation, data sharing, and the forms of data release in order to maximize research access when threats of disclosure warrant stronger protections. Restricted use contractual data, site licenses, and secure data enclaves are vehicles for allowing access to identifiable data under strong guarantees of confidentiality.

Cross-Cutting Ethical Issues

The above discussion of ethical considerations, through the lens of the methods used in behavioral and social science research,

emphasized issues of consent, privacy and confidentiality, and risk and harm. There are two other cross-cutting issues—deception and incentives—that merit additional consideration because they speak to the autonomy of human participants to determine whether to be part of research. Deception is best understood in the broader context of the amount of information available to research participants and at what point information is revealed consonant with ethical considerations. Incentives, too, have ethical implications because undue incentives may alter or influence the actual autonomy that research participants experience.

Deception

The provision of information about the nature and purposes of the research is intended to be respectful of the autonomy of persons to decide if they wish to be involved in a study and to allow them to make a meaningful decision. There has been a great deal of discussion and debate about the appropriateness of deception—providing misinformation—and the relationship between deception and partial or delayed information about the research. Willingness to participate in research and consent to do so require that research participants understand what they are being asked to do, even if they do not know at the outset the full purpose of the research. As summarized by Sieber,¹⁰⁴ typically researchers using deception seek to do the following: enhance stimulus control or random assignment; study responses to low-frequency events; obtain valid data without serious risk to subjects; or produce data that would otherwise be unobtainable. When deception is used, it is accompanied by debriefing at later stages of the study to inform participants about the fuller purposes of the research.

In *Planning Ethically Responsible Research*, Sieber allowed for the potential use of deception but considered alternatives including simulation studies and role playing.¹⁰⁴ She also set forth options in which information is concealed, but deception does not need to occur. These included informed consent to participate in one of various conditions, consent to be deceived, and consent to waive the right to be informed. The emphasis of these options is to gain agreement to participate, while making research participants aware that information about the study may be incomplete or inaccurate as an essential part of the work.

Federal regulations do allow the use of deception in research. Section 46.116(a)(1) of the federal regulations requires that participants be provided with a statement regarding the purpose of the research and the procedures involved. Yet Section 46.116(d) permits an IRB to waive elements of informed consent (even informed consent altogether) provided the IRB finds and documents that:

1. The research involves no more than minimal risk to the subjects;
2. The waiver or alteration will not adversely affect the rights and welfare of the subjects;
3. The research could not be practicably carried out without the waiver or alteration; and
4. Whenever appropriate, the subjects will be provided with additional pertinent information after participation.⁶

Importantly, the regulations attempt to balance the risks to participants (e.g., allowing deception waivers only in minimal risk research that does not affect the welfare of the participants) with the need to understand how human beings behave. For example, an investigator may be interested in examining the effects of mood

on memory. Informing participants of the purpose of the study would defeat its purpose. Such a full disclosure, for example, might tell participants something like this:

In this study, you will first watch a videotape of either a happy or sad film in order to put you in a good or bad mood. Then you will see a list of words that you will rate on a pleasantness scale. We don't really care about the ratings but we want you to think about the words. Then you will do some math computations that we really don't care about either, but we need some time to pass for you to forget some of the words. Then we will test your memory for the words. We are trying to discover the relationship between mood and memory for items that have the same or opposite feeling as the mood you are in.¹¹³

Instead of such a frank and self-defeating disclosure of the study's aims, a researcher could inform the participant about the procedures involved and any risk associated with those procedures, and something about the overall goals of the study (i.e., to better understand memory), leaving the explanation of the full purpose until later in the study.

It is important to note that deception in research can be used only if the research procedures pose no more than minimal risk and if the information cannot practicably be obtained in another way. In addition, the investigator must make a case to the IRB and obtain its approval before deception (or delayed disclosure) may be used in research. The federal regulations, the principles articulated in the Belmont Report, and professional codes of ethics provide a framework for the investigator and IRB members when evaluating the risk and benefit to participants. Irrespective of the methodology, evaluating the sensitivity of the study topic and participant vulnerability can assist investigators and the IRB in determining whether a waiver of informed consent is appropriate.

Allowing the use of deception within ethical boundaries can yield important insights into human behavior. Indeed, in both biomedical and social science research involving experimentation, participants typically are not informed whether they will participate in the treatment or the control/placebo condition. Deception used for the purpose of gaining an individual's participation in research or obtaining information that participants do not wish to divulge is, however, outside of the boundaries of ethical research.

Incentives

Incentives should compensate participants for their time and serve as a means to thank them for participating, but must be structured such that they do not coerce participation. Researchers should consider when to pay participants, how often payments are to be made, how much of an incentive to provide, and what the meaning of the incentive is. Incentives can be financial or nonfinancial (gift certificates, provision of a service), and the type of incentive may have different meaning for different groups of people. For example, a \$10 payment in cash may not be excessive in the United States, but may be so in a developing country. A lottery ticket may be an appropriate, inadequate, or excessive incentive depending on a participant's knowledge regarding the odds of winning. Similarly, deferring all payments until the end of the study may encourage participants to continue to expend the time, but it could also induce participants to complete a study when they would otherwise prefer to terminate their participation. Smaller

incentives throughout the study might provide the right balance and decrease participant vulnerability.

In some instances, group-based incentives may be more appropriate. For example, when studying student behavior in a classroom, it may be more ethical to provide incentives to the entire class, rather than individual students. In this way, all students benefit, even those who do not wish to participate. In addition, when studying groups of any size, researchers must be aware that the decisions of a few (especially a vocal or popular few) may have a significant impact on others' decisions to participate (probably of most concern when studying adolescents). Although some degree of peer influence is probably acceptable, the researcher must consider whether the pressure to participate is a factor in the group process.

It is important to consider that incentives may be needed in order to ensure that the study population is sufficiently representative of the larger population from which participants are drawn. Just as vulnerable populations may be overincluded in studies because they are readily accessible or easier to manipulate, some populations may be underincluded because they do not have the wherewithal to travel to a research site, donate their time, or find the help they need with child care or elder care in order to participate. Incentives can serve to adjust for such imbalances. Because researchers are ethically obligated to ensure that the sample size is adequate for the research, incentives may ensure that the research as a whole is not undermined. Finding the right balance for encouraging, but not coercing, participation may not be easy, but it is ethically necessary.

Evolving Challenges

At any point in time, new scientific issues and methodological and technological advancements can raise ethical considerations in the conduct of human research that are uncharted, ambiguous, or controversial. As in the biomedical sciences, behavioral and social sciences face new ethical challenges, or understand old challenges differently, in the course of advancing knowledge in these fields. In our prior discussion of the use of observational methods in behavioral and social sciences research, for example, we raised issues regarding how investigators' use of video recording devices in public places, even when there is otherwise no interaction or intervention, changes the research from exempt to classified as human subjects research, as defined by 45 CFR 46, because recorded data are more readily identifiable. When new challenges first surface, ethical issues can seem formidable; typically, however, they become more tractable as scientists and those with expertise in the ethics of research unpack issues of risk of harm, privacy and confidentiality, and requirements of consent or the appropriateness of its waiver. A few illustrations make this point.

Internet Research

The Internet has expanded opportunities both to conduct research (e.g., surveys, experiments) and to study online behavior and human interaction. Earlier, we noted some of the complexities involved in using observational methods in the context of Internet chat rooms and considered the potential intrusiveness of such observation as well as the conditions under which Internet be-

haviors might be considered public or private. The Internet permits research on a global scale using extant data sources, using the Internet as a tool to collect data, and using the Internet context to study behavior in real-time and from web-based archives (e.g., transaction logs). Although the rapid transmission of information across time and space increases the salience of ethical considerations, the ethical issues that need to be weighed are not in general unique to Internet research.

Some Internet-based research presents few human research protection issues at all. If the data already exist as public records, there may be issues of appropriate reporting, but research on such records would typically fall outside of the regulatory definition of research with humans. In other instances, using the Internet to conduct research involves human research protection issues, including consent, confidentiality, and a weighing of benefits and risks. For example, when research is being conducted online, is awareness and continued participation a sufficient indicator of consent? Are there times when the sensitivity of the inquiry requires affirmative agreement to participate (for example, activating a radio button)? How can consent be documented especially given preferences for online anonymity and the frequent online use of pseudonyms? Are there areas in which Internet technology could increase risk (e.g., sharing of e-mail accounts, saving of documents by service providers)? And, do confidentiality protections need to be strengthened given the sensitivity of the data and the possibilities of compromising data security during data transmission or storage?

Internet technology also opens up new opportunities to study human behavior or interaction online. The nature of the Internet environment being studied; whether it might be presumed to be public or private (e.g., the rules governing the listserv, chat room, or discussion board); whether consent can or will be obtained; whether the confidentiality of the information can be protected (e.g., password protection for computers, encryption of data); and even how much the researcher reveals about her or his identity or presence all come into play in the ethical design and implementation of such research. The boundary between public and private is a particularly complex determination to be made in studying Internet communities, but rules of thumb are already being articulated to permit ethically responsible research in this environment (e.g., whether registration is required to be part of the forum; how many participants are in the forum; what are participants' perceptions of privacy).¹¹⁴

Most helpful in this rapidly emerging area of research on the Internet are the issues raised for investigators and for IRBs in reports by the American Association for the Advancement of Science (AAAS)¹¹⁵ and the American Psychological Association (APA).¹¹⁶ The AAAS and the APA reports point out the opportunities of using and collecting data and studying human interaction on the Internet. The AAAS report also addresses the basic principles of conducting human subjects research (e.g., informed consent, benefits and risk, privacy and confidentiality) in the context of this technology and also offers recommendations for undertaking research on the Internet and for undertaking studies and education that can further advance knowledge about human research ethics. The APA report, too, examines the benefits and challenges of conducting research on the Internet and provides advice on a wide-ranging set of issues from identifying potential harms and debriefing procedures to taking precautions when dealing with research involving minors.

Geospatial Measurements and Other Tracking Methods

In recent years, technological advancements in remote sensing and global positioning systems have permitted fine-grained geospatial measurements of latitude and longitude coordinates that allow for new and important studies of individuals over time and space.¹¹⁷ Geospatial data on individuals' residences, workplaces, schools, or other locations are being linked with social surveys and other forms of social, environmental, and health data to study a range of issues from the distribution or transmission of disease¹¹⁸ to how use of time is affected by travel and mobility patterns between locations.¹¹⁹ Such data have enormous scientific potential, but also have embedded in them considerable potential for personal identification. In addition, unlike identifiers like name or Social Security number that can be more readily stripped from data sets, geospatial coordinates are themselves important data that can help to explain important behaviors and interactions and thus need to be preserved at some fine-grained level (even after statistical manipulation and masking) in order to remain of use.

As geospatial research has progressed, behavioral and social scientists are giving considerable attention to the ethical issues involved in working with such data aligned with other social data and how to maximize the scientific benefits of using this information while protecting the privacy of research participants or the confidentiality of the information obtained.¹²⁰ Primary data producers and researchers are addressing issues of consent and confidentiality at the data acquisition stage, and they and secondary users are examining the specification of strong data disclosure plans and strategies that can allow for meaningful data use while protecting data confidentiality. Because highly sensitive data can be involved, licensing agreements, enclaves that provide restricted access, and other mechanisms that maximize use yet minimize risk are being assessed by the behavioral and social science research community, including, in 2006–2007, the National Academies' Panel on Confidentiality Issues Arising from the Integration of Remotely Sensed and Self-Identifying Data.¹²¹

Although advanced technologies allow for the collection and preservation of very large amounts of geospatial measurements over large spans of geography, the ethical issues of confidentiality and risk reduction are akin to those that the behavioral and social sciences have been considering about microlevel data linkages for over a decade.¹²² Even in this context, much research using such measurements is of minimal risk (depending upon the nature of the inquiry and the strength of the data protection plan). Yet behavioral and social scientists working in this milieu are giving considerable attention to how best to protect confidentiality and promote data use.

Beyond geospatial measurements, there are other new technologies for tracking behavior that have scientific potential for studying human interaction and social exchange. Some investigators have research participants use wearable computers to study how social relationships build and networks are formed. Sensor devices in computers permit recording sound, movement, and geographic locations with essentially continuous, fine time resolution for long periods of time over potentially large samples.^{122,123} Researchers working in this domain are addressing both privacy and confidentiality concerns (for example, they intend to reduce privacy concerns by focusing on the patterns of talk and not the

content of the talk). Some of the mechanisms being considered and honed for addressing privacy and confidentiality issues with geospatial data would have obvious relevance here.

Third Parties

The very nature of behavioral and social science research aims to understand how people act in their social contexts. For example, in order to fully comprehend the initiation and maintenance of drug use by young adults, a researcher may ask research participants about relationships with friends and family; contacts with social institutions such as a social or academic club, sports organization, or church; the strength of these associations; and the quality of social networks and relationships. The goal of such questions is to understand humans and their life circumstances, even though, in so doing, information about others is gathered from research participants in order to gain a more complete picture of these person's lives.

In 2001, a controversial case raised questions about the status of this information. The case, involving an adult daughter who provided a personal health history that included information about her father, raised questions about the appropriateness of providing this information without the father's consent. The term *third party* was used in this context to refer to the father, someone who was referenced by a research participant. Irrespective of particular aspects of this incident, the issue that became high profile was whether those who are referenced become research participants because someone in the study provided personal, identifiable information concerning them. The crux of the debate was about whether such persons met the regulatory definition of human subjects, and thus were entitled to the protections afforded by informed consent (unless a case is made for its waiver).

There is good reason to protect personal information provided by research participants—whether it is only about themselves or in relation to others in their social sphere. There is also good reason in terms of the integrity of research process and trust in science, as well as commitments to human participants, to be circumspect about alerting the identified human subjects in research. First, human subjects may be at increased risk if the fact of their participation in a study is known (e.g., study of victims in abusive marriage)—a necessity if third parties were required to give consent. Second, revealing participation of human subjects to others intrudes upon research participants' privacy and the confidential nature of information provided during the course of research. Thus, care must be taken to ensure that the rights of and responsibilities to human subjects are not compromised or eclipsed in considering whether consent from third parties should be sought.

The National Human Research Protections Advisory Commission (NHRPAC)¹²⁵—the first advisory committee established in 2000 by then DHHS Secretary Donna Shalala to advise the Office for Human Research Protections—provided in our view sound recommendations about third parties, although the issue still remains unresolved. The NHRPAC clarification states that “neither reference to a third party in a research design, nor the recording of information about a third party in research records suggests that a third party must be regarded as a research subject.” NHRPAC allowed for the possibility that third parties might be human subjects, but saw this determination to be a dynamic one

to be made by IRBs based on the substance of the research and not on the fact that personal information provided by research participants may also be considered personal information relevant to others.

In locating the determination with IRBs, the NHRPAC statement makes clear that third parties who are referenced in research are not necessarily considered human subjects but that third parties may become human subjects if the IRB, through careful analysis of a number of factors, determines that the focus of the research is really also on the third party and not on (or not only on) the designated human subject. NHRPAC's statement also makes clear that the requirement of consent, or waiver of consent, pertains only to human subjects of research as defined by 45 CFR 46, and not to third parties unless IRBs determine that these third parties are human subjects as well.

Although this issue remains unresolved from a federal regulatory point of view, the thrust of the NHRPAC recommendation is compatible with the general emphasis on individuals as human research participants in 45 CFR 46, delegating to IRBs the final determination in contested or highly ambiguous circumstances as to when multiple parties are the subjects of research. In behavioral and social science research, multiple parties or groups (e.g., studies of gangs, work teams, governance boards) may be the subjects of research. Couples and family research, for example, can raise complex issues regarding privacy, confidentiality, and consent accorded to each individual while still being respectful of the family unit under study.¹²⁶ Thus, behavioral and social scientists have experience in protecting multiple human subjects under circumstances where more than one party is the subject of the research.

Conclusion

There is no doubt that new research questions, contexts of study, or technologies will raise new questions and challenge the best of investigators' ethical judgments. To develop researcher savvy on ethical issues, it remains important to include training in ethics and human research protection as an integral part of research training. It is also important to foster the empirical study of ethical issues so that decisions about consent, risk perception, potential for harm, strategies for risk reduction, and so forth can be assessed based on meaningful data. Ethical decision making is an ongoing, dynamic process that can require of researchers and research fields extrapolation and translation of ethical principles to addressing new research questions, examining new or rapidly changing circumstances or contexts for research, or using new research capacities. To the extent that behavioral and social scientists embed ethical considerations in the ongoing design and implementation of methods, they can achieve the dual goals of advancing science and protecting human participants in their work.

Acknowledgments

This chapter benefited from the ideas and discussions of the Social and Behavioral Sciences Working Group on Human Research Protections supported by a contractual services agreement from the Office of Behavioral and Social Sciences Research, National Institutes of Health, to the first author and chair of the Working Group.

Phase I Oncology Research

Despite substantial improvements in treatments for individual cancers, 50% of people diagnosed with cancer—more than 550,000 per year in the United States—still die from it.¹ As the average age of developed country populations rises, both the absolute number and proportion of deaths from cancer will also rise in those countries. Therefore, research into finding novel therapies for most cancers remains an important priority. The process of translating basic research into clinical applications that could potentially lead to larger clinical trials and eventually to effective cancer therapies begins with Phase I oncology studies (see Table 33.1). Classic Phase I oncology studies are cohort studies in which patients are treated with increasing doses of investigational agents to learn about toxicities, maximum tolerated dose, and the pharmacokinetics of the agents, thereby permitting planning for Phase II studies of efficacy.^{2,3}

In other areas of medicine, Phase I trials often enroll healthy volunteers to test the pharmacokinetics and safety of drugs. Because of the potentially serious toxicities of cancer drugs, Phase I oncology trials enroll only patients with cancer, usually with cancers that are refractory to other chemotherapeutic interventions and, therefore, are terminal but with good performance status—that is, relatively normal energy and activity levels.

Since the process of testing new cancer drugs was formalized after World War II, there have been fundamental concerns about the ethics of Phase I cancer trials. These ethical challenges usually can be categorized into two main issues: the risk/benefit ratio and informed consent.^{4–9} One ethical challenge is that because Phase I oncology studies offer little therapeutic benefit but can have substantial, even life-threatening risks for patients, Phase I oncology studies seem to violate the ethical requirement for a favorable

risk-benefit ratio. Enrolling patients in research with high risks and few benefits seems to entail exploitation. Furthermore, knowing about the risk and low chance of benefit, it seems irrational for patients to participate in Phase I oncology studies. That patients do consent to participate suggests there must be a problem with the consent process. Disclosure of information must be deficient, or the patients must fail to understand the information disclosed, or they are pressured and coerced into enrolling.

Are these claims valid? Are Phase I studies unethical because they are highly risky with little benefit? Are patients who enroll in Phase I oncology studies uninformed, misinformed, and/or coerced? What are the ethics of Phase I oncology research?^{10–14}

Objections Based on the Risk-Benefit Ratio

A common concern regarding Phase I oncology studies is that they violate the ethical requirement for a favorable risk-benefit ratio. The purpose of Phase I studies is to evaluate safety and toxicity, not efficacy. Nonetheless, tumor response is often measured in Phase I studies, and tumor response is often seen as a benefit. Past meta-analyses of Phase I trials of anticancer drugs, mainly from research studies conducted between 1970 and 1987, showed an overall response rate of less than 5%^{15–19} (see Table 33.2). The majority of these were partial responses, with less than 1% of patients experiencing a complete response—that is, when the tumor completely disappears based on radiological and other diagnostic evaluations.

Several more recent analyses of Phase I oncology research studies from the 1990s and early 2000s demonstrated similar

Table 33.1
Phases of Studies

Phase	Intent of Trial	Typical Size of Trial
I	Safety and defining short-term toxicities and side effects. Determining maximal tolerated dose for Phase II efficacy studies and clinical pharmacology of dosing, including pharmacokinetics and pharmacodynamics. Collecting anecdotal clinical antitumor activity.	20 to 80 patients
II	Efficacy. Seeing if experimental agent(s) or combinations of experimental and proven agents have antitumor activity. Additional assessments of toxicities and side effects.	100 to 300 patients
III	Effectiveness. Comparing, usually in a randomized controlled trial, experimental agent(s) or combinations of experimental and proven agents with existing standard treatment(s) or, if no treatment(s), placebo to assess antitumor activity and side effects.	More than 400 patients

response data. Among 213 trials of single agent, investigational cancer drugs published as abstracts and full papers between 1991 and 2002, the overall response rate was 3.8%²⁰ (see Table 33.2). An analysis of all Phase I studies sponsored by the National Cancer Institute (NCI) between 1991 and 2002 showed that among those evaluating a single investigational chemotherapy agent, the overall response rate was 4.4%, with 1.5% being complete responses (CR) and 2.9% being partial responses (PR)²¹ (see Table 33.3).

What are the risks? Death from toxicity in Phase I studies is rare but definitely occurs. A study analyzing Phase I oncology studies between 1970 and 1987 showed an overall toxicity death rate of approximately 0.5%.¹⁶ Subsequent studies confirmed this finding, documenting overall toxicity death rates between 0.54% and 0.57%^{20,21} (see Table 33.2). Despite the perception that nausea, vomiting, and other debilitating side effects are common, their overall frequency, severity, and impact on quality of life have been poorly documented. One of the recent studies reported a rate of 10.3% for serious, that is grade 3 or 4, nonfatal, toxic events, although several toxicities could have occurred to a single patient²⁰ (see Table 33.2). Of these toxic events, 85% were reported as partially or completely reversible. The NCI data showed that for single investigational chemotherapy agents, 15.0% of patients had a grade 4—life-threatening—toxic event with an average of 1.6 grade 4 events per patient who experienced an event.²¹ In addition to these serious risks, there are frequent blood draws, radiological evaluations, physician visits, biopsies, all of which require a substantial, but hitherto unquantified, commitment of time and resources from patients and their families.^{5,6,22,23}

With a relatively low tumor response, a small but definite risk of death, severe life-threatening side effects, and substantial time commitment from patients, Phase I oncology studies have a very unfavorable risk/benefit ratio, according to critics. An unfavorable risk/benefit ratio violates the ethical requirements of clinical research, making Phase I oncology research inherently unethical. George J. Annas has claimed that under the guidelines of the Nuremberg Code and the Helsinki Declaration, “[Phase I] cancer drug research, for example, may not be performed on terminally ill subjects . . . because there is no reasonable probability that it will benefit the subjects.”²²

Response to Objections Based on the Risk-Benefit Ratio

Reassessing the Benefits of Phase I Oncology Research

Do the risk/benefit data as presented tell the whole story? What criteria ought to be used to evaluate whether a particular risk-benefit ratio is favorable or unfavorable?

In evaluating benefits, several additional considerations besides complete and partial tumor responses are relevant. An analysis of NCI Phase I studies between 1991 and 2002 found that the vast majority were not trials of single, novel, investigational chemotherapy agents (see Table 33.3). Many Phase I oncology research studies involved vaccines, immune modulators, antiangiogenesis

Table 33.2
Response and Toxic Death Rates and Other Side Effects of New Single Investigational Agents in Phase I Oncology Trials

Authors	Year Published	Number of Single		Total Number of Patients	Overall Response Rate	Complete Responses	Partial Responses	Toxic Death Rate	Rate of Serious Side Effects
		Investigational	Chemotherapy Agents						
Esty et al. ¹⁵	1986	66		6,447	4.2%	0.7%	3.5%	N/A	N/A
DeCoster et al. ¹⁶	1990	87		6,639	4.5%	0.3%	4.2%	0.5%	N/A

Combinations with investigational and FDA approved agents	1	3	0%	0%	0%	0%	0
<i>Vaccine</i>							
One investigational agent	15	265	3.4%	3.0%	0.4%	24.9%	0
Multiple investigational agents	7	198	1.0%	1.0%	0%	35.4%	0
Combinations with investigational and FDA approved agents	6	111	5.4%	2.7%	2.7%	19.8%	0

*For 630 of 10,402 participants, data on stable disease and less than partial response is not reported. The percentage is calculated using 9,772 as the denominator; **these percentages are calculated using a denominator adjusted to exclude participants for whom data on stable disease and less than partial response was unavailable.

factors, and signal transduction agents. These agents are widely perceived to be less toxic than chemotherapeutic agents, so the risk/benefit ratio may be different. In addition, their benefits may not be appropriately measured by evaluating tumor response; these agents usually control cancer growth rather than kill cancer cells, so different types of responses need to be assessed. Moreover, many of the 1991–2002 NCI Phase I studies combined investigational agents with proven chemotherapy drugs.²¹

When all these trials are aggregated, the overall response rate—including both complete and partial responses—was 10.6%. In addition to the complete and partial tumor responses, 34.1% of patients had stable disease or some minimal shrinkage of tumor, although less than the 50% tumor shrinkage that is required to be recorded as partial response (see Table 33.3). Although the significance of stable disease as a response to an investigational in-

tervention is controversial, it may well be a benefit to those patients whose tumors would otherwise be expected to grow.

Some critics object that response rate is not an important clinical outcome. At best, response rate is an “intermediate” or surrogate endpoint; what people care about is not whether their tumor shrunk but whether or not they will live longer. Since the 1980s, however, some data have emerged suggesting that at least for some cancers, such as lung cancer, response rate is related to prolonged survival. For instance, a 2004 study concluded that in non-small cell lung cancer, a 3.3% increase in response rate correlates with a one-week increase in median survival, and a 2% increase in response rate correlates with a 1% increase in one-year survival.²⁴ Consequently, response rate may be a reasonably good intermediate marker of benefit, or at least may be more meaningful than critics have hitherto acknowledged.

In a few notable cases, the benefits of Phase I research for patients have been more substantial. For example, when initially tested in Phase I studies in the 1970s, cisplatin for testicular cancer had a response rate of over 50%, and in a quarter of cases the tumor completely disappeared and was probably cured.²⁵ More recently, in Phase I testing, imatinib mesylate (Gleevec) for chronic myeloid leukemia demonstrated complete hematological response rates of 98%, of which 96% lasted beyond one year.^{26,27}

Overall, saying that only 5% of patients respond in Phase I oncology studies fails to acknowledge that in some Phase I trials response rates are higher, that stable disease may be a valuable and meaningful outcome for patients, and that in some cases substantial clinical benefits, and even cures, have been achieved in Phase I oncology trials.

In addition, among some terminally ill oncology patients there can be other important physical, psychological, and social benefits from participation in cancer research trials. Well-being, especially in very sick and terminally ill patients, is “not merely the absence of disease or infirmity” but includes psychological, social, and other dimensions.²⁸ Empirical study of these aspects of well-being among participants in Phase I studies has been limited. In considering other physical benefits, some data show that chemotherapy provides symptom relief among terminally ill patients even better than does supportive care. In one study, patients with metastatic colorectal cancer who had already failed one chemotherapy regimen were given another chemotherapy regimen that was associated with longer survival, fewer symptoms, and higher quality of life.^{29,30} Participating in Phase I oncology studies in some cases may stabilize patients’ quality of life compared to patients who receive supportive care and who typically experience declines in functioning as their cancer progresses.^{31–39} Most importantly, participating in Phase I studies does not exclude symptom management or palliative care. Participating in Phase I studies and focusing on quality of life are not necessarily—and should not be—inherently incompatible goals; indeed, enhancing quality of life should be one of the goals of Phase I studies.⁴⁰

Data also suggest that some cancer patients in Phase I studies experience psychological benefit. Daugherty et al. reported that 65% of research participants said they believed they would receive psychological benefit from being in the Phase I study.²³ One study showed that for terminally ill cancer patients, chemotherapy improves emotional function on measures of quality of life.⁴¹ For some participants, routine and regular physician contacts reduce psychological distress during a time of great uncertainty.^{13,42} In another study, 78% of patients enrolled in Phase I studies reported at least a moderate amount of comfort from having study-related diagnostic tests and physician visits.⁴³ An additional 56% reported that participating in research studies with new drugs gave them hope. For other patients, participation allows them to exercise some control over a situation they did not choose. Some patients also receive comfort from knowing they are helping future patients with cancer.^{11,13,43}

[There is] a complex relationship between knowing the reality of their situation (that they had incurable disease) and hoping that there still might be a treatment that would have a positive effect, even cure. . . . Patients do not seem to be harmed by their experience of participating in a Phase I trial and may experience benefits, albeit not in terms of tumor control.¹³

Finally, because of concern about potential risks, the dose escalation design of many of these trials is intended to minimize toxicity—which, ironically, ensures that the majority of participants are treated at doses that cannot produce responses in human tumors. Indeed, over 60% of participants in Phase I oncology studies appear to receive biologically inactive doses.¹⁵ Consequently, participants face little risk, but also have little chance of benefits. Some investigators have proposed novel design strategies to allow more patients to be treated at biologically active doses, increasing the chances for a therapeutic response.^{2,3,44–46} The aggregate response rates reported in the literature underestimate potential response rates that could be achieved with these design strategies. Ironically, less than 15% of Phase I studies use these innovative methods, largely because of a concern about minimizing toxicities.^{2,20,47}

What Standard Determines a Favorable Risk-Benefit Ratio?

To determine when a risk-benefit ratio is favorable or unfavorable requires a standard of evaluation that is appropriate for patients with advanced cancer who are likely to decline clinically and die within months because of disease progression. What criteria should be used to define a favorable risk-benefit ratio for Phase I oncology studies?

No standard for what is an acceptable risk-benefit ratio for adult research subjects has been explicitly articulated.^{7,48–50} One approach is to elucidate a standard based on socially accepted determinations of risk-benefit already used for cancer treatments, such as in FDA approval of cancer agents. For example, high-dose interleukin-2 (IL-2) is an FDA-approved treatment for metastatic renal cell carcinoma. This IL-2 regimen has a response rate of 14% (5% complete responses, 9% partial responses) with a median response duration of 20 months.⁵¹ The possible toxicities of IL-2 are substantial, including a sepsis-like syndrome, requiring judicious use of fluids and vasopressor support to maintain blood pressure while avoiding pulmonary edema from capillary leak. Other chemotherapy treatments with relatively low response rates, such as topotecan with a 10% response rate for ovarian cancer, have also been approved by the FDA.⁵² Irinotecan and Erbitux are two treatments approved for metastatic colon cancer on the basis of less than a two-month prolongation of overall survival.⁵³ Furthermore, gemcitabine is the FDA-approved treatment of choice for metastatic pancreatic cancer because of demonstrated quality-of-life benefits, despite a response rate of only 5.4%.⁵⁴ In all these cases, society, through the FDA, has deemed the relatively low increases in survival, and the risk-benefit ratio, acceptable for routine clinical care. This suggests that an even lower level of benefit might be acceptable in research.

For nonterminally ill cancer patients, the use of chemotherapy with limited benefits is also widely accepted even if debated. For instance, among patients with newly diagnosed Stage I breast cancer, for whom five-year overall survival is greater than 90%, a two- or three-drug chemotherapy regimen lasting four to six months, with its side effects, offers an absolute survival benefit of just 1–2%.^{55,56} Yet the vast majority of women receive such chemotherapy.

The risk-benefit ratio found in many Phase I oncology studies is not clearly worse for individual participants—even excluding

the benefit of social knowledge—than risk-benefit ratios used by the FDA as a basis for approval of many chemotherapeutic agents or by many nonterminally ill patients in their decision making. Among patients for whom all standard therapeutic interventions have failed, even a small chance of therapeutic benefit may be reasonable. The risk-benefit assessment requires consideration of the available alternatives.

Furthermore, when social knowledge is added to these evaluations of the risk-benefit ratio, it seems that participation in a Phase I trial is even more beneficial. A Phase I trial adds to social knowledge, which is a good. More important, the available data suggest that contributing to social knowledge is a benefit for people. Research participants value being altruistic and therefore gain benefit from contribution to others.^{10,43} The focus on physical benefit by critics of Phase I research discounts this type of psychological benefit.

Who Decides What Constitutes a Favorable Risk-Benefit Ratio?

The lack of explicit criteria means that institutional review board (IRB) members and critics frequently rely on their intuitions to determine what constitutes an acceptable risk-benefit ratio for Phase I oncology studies.⁵⁷ But IRB members and critics tend to be healthy individuals. Substantial data demonstrate that patients facing serious illnesses make very different assessments of their own condition and the risks they are willing to confront than do healthy individuals. For instance, families consistently overestimate symptoms and underestimate satisfaction and quality of life of sick patients.^{58–61} Furthermore, Slevin et al. found that patients with cancer were willing to undergo intensive chemotherapy with substantial side effects for a 1% chance of cure compared to oncology nurses who said they would need a 50% chance, doctors who would need a 10% chance, and the general public who would need a 50% chance of cure.⁶² Healthy IRB members and critics are likely to view studies with few benefits and greater risks unfavorably, yet patients might view the same studies as having a risk-benefit ratio that they are willing to accept or even welcome.

It has been argued that in considering protocols involving vulnerable populations, such as children or patients with mental illness, IRBs should include such patients or their advocates as members to ensure their perspectives are included in deliberations.⁶³ Extending this logic suggests that the views of terminally ill cancer patients should inform IRB determinations of the acceptability of risk-benefit ratios for Phase I oncology studies. Just as having minorities or women on IRBs may expand the factors considered in evaluating a research protocol, having patients who are terminally ill and eligible for Phase I studies may expand the considerations of these IRBs. Such patients may not be narrowly focused on physical safety and might consider the psychological benefits to the patients, thereby viewing risk-benefit ratios more favorably.

Objections Based on Informed Consent

That patients consent to participate in Phase I oncology studies with such an unfavorable risk-benefit ratio is widely viewed as indicative of deficiencies in disclosure, understanding, or voluntariness in the informed consent process.^{5,23,64–66} First, com-

mentators have claimed that physicians exaggerate the benefits while minimizing the risks of research participation. One bioethicist is quoted as having said, “Informed consent documents make Phase I studies sound like the cure for your cancer.”⁶⁷

To date, no studies directly document deficiencies in disclosure, exaggeration of benefits, or minimization of risks. Nonetheless, critics note that despite response rates of just 5%, most participants in Phase I oncology studies are motivated to participate by hopes for stabilization, improvement, or even cure of their cancer^{12–14,42} (see Table 33.4). Such hope suggests that either patients are not given accurate information or they fail to understand the information they are provided. Perhaps researchers do not provide adequate disclosure because they themselves overestimate the potential benefits from Phase I oncology studies by three-fold.^{8,66} “These exaggerated estimates may represent ignorance, itself a worrisome finding given that the physicians in this study were the ones to invite patients to participate.”⁶⁸

In addition, many consent documents do not make prospective research participants aware of their alternatives, especially for palliative care and hospice. For instance, a study of consent forms for Phase I oncology research revealed that less than 1% included mention of hospice care as an alternative.⁶⁹

In addition to possible disclosure deficiencies, critics argue that most patients in Phase I studies have deficient understanding of the objectives, benefits, and risks of Phase I research. For instance, in one study 93% of the participants reported understanding most or all of the information given to them about the Phase I study in which they had agreed to participate, yet only 31% of them were able to state accurately the purpose of Phase I studies as dose-finding.¹⁰ Another study found that although 90% of cancer patients who participated in research reported being satisfied with the informed consent process, few understood the potential for incremental risk or discomfort from participating in research, or the uncertainty of benefits to themselves.¹¹

Finally, commentators also argue that even if patients are given accurate information and understand it, they are vulnerable, their judgment is clouded, and they are not to be trusted with their own decision making. Indeed, according to this argument, their decision to participate in such high-risk/low-benefit research is itself indicative of how vulnerable they are, their confused judgment, or coercion. As one critic put it, terminally ill patients who consent to Phase I oncology studies have “unrealistic expectations and false hopes.”⁶⁶ Another claimed,

Being ill brings with it a multitude of pressures, and a patient suffering from a life-threatening disease may feel as though she has little choice regarding treatment. Physicians should be aware of how vulnerable patients may be to the *coercive influence of unrealistic hope*, especially those suffering from chronic, life-threatening disorders [emphasis added].⁷⁰

Cumulatively, concerns about disclosure, understanding, and voluntariness make some commentators argue that informed consent is simply not possible with terminally ill patients eligible for Phase I oncology research.

Therefore, instead of being suspicious of experimentation, patients may demand access to experimental interventions as their right. . . . Respecting patient autonomy does not require that we accept demands for mistreatment, torture, or whatever the dying may want.²²

Table 33.4**Studies Evaluating the Quality of Informed Consent in Phase I Oncology Trials**

<i>Authors</i>	<i>Year Published</i>	<i>Sample Size</i>	<i>Methods of Evaluation</i>	<i>Reasons for Participating</i>	<i>Awareness of Study Purpose and Design</i>	<i>Satisfied With Informed Consent Process</i>	<i>Would Participate Again</i>
Rodenhuis et al. ¹⁴	1983	10	Interview 1 week after treatment began	50% hope for improvement of their diseases; 30% pressure of family	60–80% recalled, “experimental,” “so far only animal studies,” “effect uncertain”	—	—
Itoh et al. ¹⁷	1996	32	Questionnaire after enrollment but before drug administration	19% treatment benefit; 63% no benefit but participate anyway	43% knew goal is to determine recommended dose	81% said understood almost all information given to them	—
Yoder et al. ⁷²	1997	37	Quantitative and qualitative interviews at entry and exit of study	70% to get best medical care; 85% decreased tumor size	—	—	100%
Hutchison et al. ⁴²	1998	28	Interviews 2–4 weeks after consenting to participate	Majority hope for benefit	—	89%	—
Daugherty et al. ¹⁰	2000*	144	Interviews within 1 week of receiving drug	73% seeking anticancer response	31% knew purpose	96%	—
Tomamichel et al. ⁷¹	2000	31	Quantitative and qualitative analysis of taped interviews	59% possibility of medical benefit	—	96%	—
Moore et al. ¹³	2000	15	Pre- and posttreatment questionnaire and structured interviews	3 themes: (1) need to try everything; (2) maintain hope; (3) help others	—	—	—
Schutta et al. ⁷⁷	2000	8	Quantitative and qualitative analysis of taped focus group	Hope for therapeutic benefit	—	—	—
Cheng et al. ⁶⁶	2000	30	Questionnaire after enrollment	60% expect to benefit	—	—	—
Joffe et al. ¹¹	2001	50**	Mail survey 1–2 weeks after consent		75% knew trials done to improve treatment of future patients; 71% knew may be no medical benefit to themselves	90%	77%
Meropol et al. ¹²	2003	328; 260 enrolled in Phase I	In-person or phone survey within 3 days of signing consent or refusing participation in Phase I	77% estimated their chance of benefit was at least 50%; 39% thought maximal benefit was cure of cancer		78% reported discussing side effects of treatment; 79% reported discussing benefits of treatment; 29% reported discussing changes in length of life from treatment	
Agrawal et al. ⁴³	2006	163	In-person interview immediately after signing consent form		For 63% of patients, key information for deciding whether to participate in Phase I was whether drug killed cancer cells		90% even if 10% of dying from Phase I agent

*The initial publication by Daugherty et al.²³ of 27 patients is included in the 144 patients; **survey of patients participating in Phase I, II, and III studies. Total number of patients was 207 of which 50 were enrolled in Phase I studies. Unfortunately, the analysis of the responses failed to stratify according to phase.

Response to Objections Based on Informed Consent

Methodological Concern

Even though informed consent in Phase I oncology studies may be the most extensively empirically studied area of informed consent, the data are still limited (see Table 33.4). First, fewer than 1,000 total patients have been interviewed in 12 separate studies. Second, the studies are of limited size: All but three studies evaluated 50 or fewer patients in Phase I research trials, and all but two of the studies were from a single institution. Third, some studies combine responses from patients enrolled in Phase I, II, and III oncology studies making impossible interpretation relevant solely to Phase I studies.

More important, assessing understanding of patients is methodologically extremely complex. Most courts evaluating informed consent cases avoid trying to evaluate whether patients had adequate understanding because they do not know how to make this evaluation. One problem is timing. When the surveys are administered days or weeks after the patient signs the consent, these studies actually evaluate recall of information as opposed to the ethically relevant understanding at the time of decision making.

In addition to timing, people generally retain only the information salient to them, which may not be the same information ethicists and investigators think is important. In buying a house, for example, the information buyers care about is narrow and focused, and usually substantially less than the information the attorney describes about how the deed will be recorded or if the bank will sell the mortgage to another bank. Similarly, participants in Phase I oncology trials might not care about study design and might focus instead on factors they consider salient such as whether the drug kills cancer cells.

Finally, in the studies published to date, there are serious challenges involving question design and especially framing effects. Because there is no gold standard by which to judge the reliability or validity of questions about comprehension, they can be judged only on face validity. This places an even greater burden on the investigator to demonstrate that the questions asked are being interpreted and answered by the research participant in the intended manner. Many of the questions used to assess understanding by participants in Phase I research are posed primarily from an investigator's perspective rather than the patient's. The wording of the questions and interpretation of the responses fail to differentiate between two aspects of understanding: *comprehension*, that is, understanding of the factual components of the information, and *appreciation*, what the information means to a particular person. For example, one study asked, "Why did you decide to enter this research trial? (What was your main reason?)"²³ and reported that over 70% joined hoping for benefit. The fact that patients participate primarily for the chance of benefit is often seen as indicative of a deficiency in comprehension. Yet, this interpretation fails to recognize that patients could very well comprehend their limited chance for personal benefit and still hope that they may actually benefit.

The Quality of Disclosure

There are limited empirical data on the adequacy of disclosure of information to participants of Phase I oncology studies (see Table

33.4). One study evaluated the substantive content of 272 Phase I oncology consent forms and found that 99% explicitly stated the study was research and that in 86% this statement was prominent.⁶⁹ Furthermore, 92% indicated safety testing was the research goal. Overall, the mean length of the risks section was 35 lines in contrast with four lines as the average length of the benefit section; and, 67% of forms mentioned death as a potential consequence of participation in the study, whereas only 5% mentioned cure as a possible benefit. Only one consent form indicated that any benefits were expected. Although this study found that less than 1% of informed consent documents mentioned hospice as an alternative, 56% mentioned palliative or supportive care.

Defenders of Phase I oncology studies note that no empirical study has shown that physicians fail to accurately disclose the risk, benefits, and experimental nature of Phase I oncology trials. Although physicians may overestimate the response rates in Phase I studies, they overestimate the risk of death even more, by 20-fold.^{23,66} Importantly, as Tomamichel et al.⁷¹ report from recordings of physician-patient interactions, physicians told patients about the lack of known treatments and the investigational nature of the Phase I oncology study in over 90% of consultations, and about the lack of sufficient knowledge of toxicity of the drug in more than 80%. Two other studies report similar findings.^{14,65} Furthermore, surveys of physicians and patients considering Phase I research trials indicate that many recall having discussed risks, benefits, and other aspects of the trial. For instance, 92% of physicians and 78% of patients recall having discussed possible side effects from the Phase I treatment. Similarly, 90% of physicians and 79% of patients recall discussing possible benefits.¹²

Although substantially more data are needed to evaluate the disclosure of information in Phase I oncology studies, available data do not support the notion that disclosure either in consent forms or by oncologists is systematically deficient or distorted.

More important, surveys of people who enrolled in Phase I research demonstrate that the formal disclosure in the informed consent process, whether by the documents or by discussion with researchers, is not the only way prospective research participants obtain information. For instance, in one study, 84% of participants were aware of palliative care and 81% were aware of hospice care as alternatives to participation.⁴³ This indicates that patients obtain information about Phase I research studies and alternatives outside of the formal disclosure processes of the informed consent document and discussion.

Do Terminally Ill Cancer Patients Misunderstand?

Recent data show that many patients are aware that the chance of benefit is low, but believe that they are likely to be among the beneficiaries. Indeed, it may be this very belief that they will be among the lucky ones that keeps them going. For instance, Daugherty et al.²³ found that 85% of patients were motivated to participate in Phase I studies for possible therapeutic benefit, but 78% were either unwilling or unable to state whether they believed they personally would receive benefit from participating in a Phase I trial. Similarly, Itoh et al.⁶⁵ found that 63% of participants did not expect any benefit but wished to participate anyway. Likewise, although Joffe et al.¹¹ concluded that misconceptions about cancer trials are frequent among trial participants, their data show that 71% of research participants recognized there may not

be medical benefit to themselves from participation in the clinical trial, and 75% of them reported that the main reason cancer clinical trials are done is to improve the treatment of future cancer patients. Knowing the chances are low but believing that they could be among the few who do benefit is common. As other researchers put it, “Although subjects were told that fewer than 10% of patients in Phase I trials experience a tumor response, many of them believed that someone comprised the percentage of patients who experienced a response and that they might ‘be in the lucky group.’”⁷² Defenders of Phase I studies argue that such data suggest Phase I research participants do not misunderstand but have a form of adaptive denial that all people engage in to some degree.^{9,43,72}

Similarly, studies show that although over 90% of patients felt they understood the information about the Phase I trial, only about a third were able to state accurately “what are the doctors trying to find out in the Phase I cancer research trial in which [they’ve] enrolled.”²³ Defenders of Phase I studies argue that interpreting this as reflecting a lack of understanding by participants of Phase I oncology studies confuses the intent of a Phase I study and the probability of benefit from a Phase I study. Phase I studies are not designed or intended to produce benefit. Yet, what matters to patients is not the intent of a Phase I study but the probability of receiving benefit from participation. It is perfectly reasonable that investigators design and intend Phase I studies primarily to determine toxicity, whereas patients enroll because of a chance of benefit, without there being any misunderstanding.

Investigators and patients each may have their own purposes but they are not necessarily in conflict with one another and may in fact be complementary. If the patient’s tumor shrinks it does not adversely affect the purpose of the Phase I study, and if the trial determines the toxicity it does not thwart the patient’s goal of tumor response, although the goal may not be achieved. Thus patients’ failure to state the purpose of the Phase I study as a dose-finding study probably demonstrates that patients care more about the probability of receiving benefit, the risks, and the requirements of the study than the scientific methodology or the researcher’s intent in conducting the study. This interpretation is supported by data showing that although 84% of respondents reported that they read the consent form carefully, and 73% considered it an important source of information, only 37% considered the consent form important to their decision to participate in the Phase I study.¹¹

Questions in prior studies evaluating understanding offer limited answer choices that force only one primary reason for participating in a Phase I study. But, as in most decisions, there are usually several reasons to participate even if one reason is more important than the others. For example, in their instrument Daugherty and colleagues list nine reasons that might have been motivations for patients to participate in Phase I studies. For each reason, a patient can circle “major,” “minor,” or “not” depending on the role that reason played in their decision making. Only 33% said helping future people with cancer was a major reason for participating, leading the investigators to conclude that “altruistic feelings appear to have a limited and inconsequential role in motivating participants to participate in these trials.”²³ This interpretation fails to capture the multiplicity of motivations that drives the decision making of research participants. Other reasons—such as the need to do something, the comfort gained from the regularity of clinic visits, family circumstances, and re-

gaining a sense of control—which may contribute but may not be the main reason to enroll in the study, would not have been detected in prior studies because they were not asked.

Are Patients With Cancer Able to Choose Freely?

There is a widespread perception that even if patients with cancer are given full disclosure and understand the information, the fact that some still opt to receive experimental drugs is indicative that they are vulnerable, their judgment is clouded by their illness, or they are pressured into enrolling or unable to make truly voluntary decisions.^{6,22,70}

According to advocates for Phase I oncology trials, the view that terminally ill cancer patients are vulnerable seems not to accurately reflect the actual data. It is certainly the case that people with life-threatening cancers face bleak choices. But this is different from being vulnerable in the sense of not being able to make free choices. Vulnerability in research is often understood as meaning that people are unable to make free choices because of their social position, thus vulnerable groups include oppressed minorities, the poor, or those who are poorly educated.⁷³ Whether or not such a presumption is accurate—that is, whether minorities or the poor should be presumptively considered unable to exercise free choice—this hardly fits the characteristics of participants in Phase I oncology research. Phase I oncology study participants are typically white, well-educated, well-off, and well-insured. For instance, in one multicenter study of Phase I participants, the average age was nearly 58, 88% of individuals considering research were white, 51% were college graduates or had postgraduate training, 62% had incomes over \$50,000, and 96% had health insurance.⁴³ Other studies report similar demographic data.¹² This, it is argued, is not the picture of a vulnerable population.

Even if terminally ill patients who are considering Phase I oncology research are vulnerable in certain ways, it does not imply an inherent lack of capacity to give informed consent. When terminally ill patients draw up wills or request not to be resuscitated, these are treated as genuine, autonomous choices; the consent of patients that their organs be donated for life-saving organ transplants is not considered *prima facie* invalid because they are made by terminally ill patients who cannot think clearly. Advocates of Phase I studies claim that most people with advanced cancer are able to and do make rational, reasonable, and informed decisions. There will be some individuals who are unable to give adequate informed consent, just as is true for people without advanced cancer. But to conclude that patients with advanced cancer are, as a group, inherently vulnerable and therefore unable to give informed consent is demeaning.

To categorize the choice of patients with advanced cancer to participate in Phase I studies as inherently coerced is a serious confusion.⁷⁰ By definition, coercion is a credible threat exerted by one person that limits or adversely affects the options another person has available.^{74–76} Presumably, no person associated with Phase I research is issuing irresistible threats to terminally ill patients. Patients may feel pushed by nature, fate, and their circumstances to enroll. However, being in a situation with limited and difficult choices does not itself constitute coercion.⁷⁵ Unless the adverse choice situation was created by another person, the choice made by the patient should not be labeled as coerced. Indeed having poor options can be consistent with making an autonomous or even laudable choice.^{72,74}

Limited available data support this analysis. When asked, only 9% of patients enrolled in Phase I research studies reported moderate or a lot of pressure from family, and only 7% reported such pressure from the Phase I clinical researcher.⁴³ Conversely 75% reported “pressure” to enroll from the fact that their cancer was growing.⁴³ Whatever the pressure from a growing cancer is, it is not coercive because only people can coerce; nature cannot. Furthermore, many dying people want chemotherapy, even if there is very low chance of benefit and a reasonable chance of toxicity, because it offers them hope or fits with their life narrative to fight against the odds, to overcome challenges—because they feel that to die without trying everything would constitute being false to themselves and their values.⁷⁷ One participant in several Phase I oncology studies put it this way:

Letting a patient choose the poisons (under professional guidance) adds something to the will to struggle. We who are struggling to escape cancer do not, obviously, want to die of it. The enemy is not pain or even death, which will come for us in any eventuality. The enemy is cancer, and we want it defeated and destroyed. This is how I wanted to die—not a suicide and not a passively accepting, but eagerly in the struggle.⁷⁸

Advocates argue that these people are not coerced but have a different set of values from the critics.⁹

Conclusion

Phase I oncology trials are critical to improving the treatment of cancer. Critics have raised ethical concerns about the risk-benefit ratio and the adequacy of informed consent. A critical analysis of the risk-benefit ratio does not show it to be unfavorable. Empirical data on informed consent in Phase I oncology trials does not support the notion that consent is uninformed.

Surgical Innovation and Research

Surgery, like all crafts, evolves to build on its successes and make use of changing materials and techniques. It is a craft in which physical or invasive methods are used to try to relieve a patient's suffering, and therefore the surgeon needs a certain confidence and assurance in his or her ability to do what needs to be done without the cure causing worse havoc than the disease. There are four quite different situations in which innovative surgery is used on real patients, who thereby become de facto subjects of medical experimentation even though no formal clinical trial might be in progress. These situations are as follows:

1. The one-off desperate case
2. The use of an established operation for a novel indication
3. The promising development that modifies a standard or widely practiced operation
4. The genuinely new operation

Before we discuss these possibilities, we need to introduce some basic features of clinical surgery that distinguish it in many ways from general medicine. In many areas of clinical treatment, we aim to correct an abnormality that is producing an illness. Sometimes finding the abnormality and figuring out how to correct it are easy, and this is the area of medicine in which we find surgeons (among others). So much is this the case that some physicians say that if surgery wasn't simple surgeons couldn't understand it.

When causes of disease are structural and easily visualized, surgeons devise means of correcting the structural abnormality in the hope that this will cure the problem. Most of these means are fairly simple-minded. Lumps are removed, blockages are cleared, stenoses are corrected, pressure that compromises function or causes pain is relieved, and infections are eradicated. Sometimes

the corrective intervention is so obvious that there is no uncertainty, for example, removing a subdural hematoma causing pressure on the brain, cutting out a tumor obstructing the bowel, or clearing a blocked artery. These are transparently effective interventions: The clinician can see, at the time of surgery, that what was needed has been done well or badly. The standard of assessment can usefully be called *the appeal to the educated eye*.

Some diseases, however, are more complex than is apparent to the educated eye. Functional diseases, such as oversecretion of gastric acid or biochemical abnormalities, are detectable only by inference from tests indicating that something is going wrong in the body. In other cases the intervention's immediate or intended effect has gained it accepted status as good treatment, but its effect on the natural history of the disease requires clear and careful assessment. Procedures in this category include removal of prolactin-secreting adenomas of the pituitary, carotid endarterectomy for bruits, cholecystectomy, spinal decompression in malignant disease, endoscopic removal of bowel polyps, and so on. These accepted but unproven procedures are apparently effective, but we need more than the appeal to the educated eye because therapeutic efficacy must be gauged by some reliable method of tracking their impact on morbidity and mortality.

Some surgical techniques are supported by controversial theories, for example, gastric ulcer surgery, breast cancer surgery, hysterectomy for carcinoma in situ of the cervix, and so on. In such cases it is unclear whether a procedure is truly or only apparently effective. Once a question about the theoretical justification of a procedure is raised—usually because of evidence that seems to conflict with the theory—trials of that procedure must be done. But clinical trials of surgical procedures raise difficult ethical

questions. Physicians' *duty of care*—the commitment to provide treatment that is at least as good as that the patient would otherwise have received—seems to require that such trials preserve the option of the best current treatment for those who need it. That would (prima facie) rule out the “gold standard” for evidence-based medicine—double-blind randomized controlled trials using placebos. Therefore, the ethical justification for trials of surgical techniques needs to be carefully examined in terms of the risks and benefits involved.

The Desperate Case

Surgical patients present unique challenges, some of which resemble but are not the same as those presented by other patients. The first time that it occurred to somebody that a heart could be transplanted to replace one that was failing the situation was indeed desperate, but the operations were doomed to failure.¹ If we project ourselves back into the life stories of patients with intractable heart failure due to severe valvular disease or high grade stenoses of the coronary arteries, we find ourselves contemplating dire prospects. Such a patient has not a lot to lose and a great deal to gain, but there are either no statistics to support the surgeon or very bleak reports of surgical deaths due to one or another of the many causes of failure for major heart surgery. In such a case, one can hardly deny the patient the faint hope offered by a procedure radical in nature and adventurous in the extreme but overwhelmingly likely, apart from the glimmer of hope, to result only in pain and death. Provided such patients understand the dire realities, then their decision to allow this throw of the dice on their behalf seems ethically unproblematic even though it clearly serves the interests of future potential patients and the surgeon in a more certain and evident way than it does the patient who is trying to defy the odds.

Here altruism, to which I shall come, clearly has a role, as does the fact that the journey to a new technique must begin somewhere even when the risks are stark and unattractive. Successive patients may face prospects not significantly different, but such is the nature of surgery that these “blood sacrifices” will almost certainly help to provide life-saving opportunities for those who follow. The relevant benefits differ considerably from a narrow assessment of statistical harms and benefits versus current therapeutic options presented to an individual patient. But the problem is capable of rational resolution as long as there is openness of information sharing and a genuine commitment to partnership in the surgeon-patient relationship.²

A New Indication

The development and extension of surgical techniques is consistent with Hippocratic injunctions about medical knowledge. The Hippocratics stressed the need for careful investigation of phenomena noted in the course of clinical practice along with a refusal to be biased by preformed theories. “Physicians,” the writings say, “compare the present symptoms with similar cases they have seen in the past, so that they can say how cures were affected then.”³ The ability to transform chance observations into well-validated clinical therapies aimed at difficult problems is a valued aspect of surgery. The first treatments for Parkinsonism by lesions in the

basal ganglia followed this path, and the transition from observation to technique in an ethical way is centrally important for reflective surgical practice.

Indications can only be defined by carefully structured clinical trials of treatment versus nontreatment for various conditions. But for reasons already outlined, these trials are hard to do in surgery. Often when the chance observation occurs, some hypothesis about the functional interconnectedness of the system concerned suggests a tentative place for that observation in our corpus of medical knowledge and current understandings of pathophysiology. This may provide a rationale for what is done and a decision about new indications for the procedure, but often the place of the surgery remains unclear. This is an unhappy situation.

The Hippocratic writings describe the accumulation of careful clinical observations over time until conclusions can be drawn as to which methods are effective and which not. In surgery this is a somewhat varied business, so the gap between animal experiments and use of surgical techniques on humans tends to be filled by “informal research.”⁴ Evidence of safety and efficacy is often based on historical series despite the statistical hazards of such evidence.^{5–7} A reported case of headache and neck stiffness from cervical spondylotic stenosis (CSS) followed this Hippocratic path, and its deficiencies against a placebo-controlled trial are evident.⁸

The surgeon began doing a posterior decompressive operation on the cervical spine for standard reasons, but out of a sense of partnership with his patients, he heard a lot about the operation and its effects. He noticed that many patients spontaneously reported resolution of tension-type headaches after their operations; for some, this was the most significant result of surgery. He began to regard severe and persistent cervicogenic or tension-type headaches as a relative indication for surgery. Eventually the results seemed so compelling that he operated on some patients who wanted the operation mainly in the hope of getting rid of their headache, with due warnings about the uncertainties and their entitlement to an alternative opinion quite possibly differing from his own. Patients were increasingly referred as “domino” cases: They or their doctor knew somebody with a similar syndrome who had been dramatically relieved.

What, from an ethical point of view, should the surgeon do at this point? Obviously, there are a number of people who seem to have gained a significant change in morbidity and functional status by opting for a relatively novel operation for controversial reasons. He cannot, in service of his Hippocratic duty of care, just ignore these observations. But it seems that he should do something to elucidate the safety and efficacy of the procedure in comparison with existing alternative treatments to ensure that he does not violate his duty to do no harm. In fact, it seems that the claim that symptom relief is truly related to surgery ought to be submitted to rigorous statistical testing in view of the subjective nature of the effect of surgery and the prevalence of placebo effects in the treatment of such symptoms.

Developing an Existing Technique

At this point we should note that some surgical techniques are no more than technical improvements on accepted treatments, which may themselves be well grounded in evidence or just accepted as normal practice. In such cases, it is reasonable to put considerable weight on the opinions of surgeons actually using the new tech-

nique as to whether it serves their surgical need better than the procedure it has replaced. However, in addition to the impressions of surgeons, a review of the outcomes of operations using both the new and traditional techniques—not necessarily a placebo-controlled, randomized trial—ought to be conducted to ensure that any modifications or technical improvements do not cause unforeseen complications and problems, perhaps at some time removed from the surgery.

The relevant studies would assess the new technique with respect to the achievement of the technical goals of the surgery and its safety, and in light of medical and surgical knowledge at the time. Thus the same doubts as to clinical indications and efficacy in altering the natural history (in terms of morbidity and mortality) would apply to the modification and to the basic technique.

Throughout the practice of surgery there is a strong presupposition in favor of a consensus of practicing surgeons (a standard of validation that has a very low ranking on the Cochrane scale of evidence). In fact this is not totally irrational when one considers that the techniques of surgery develop in a progressive manner and that initial attempts to correct an abnormality are likely to be refined by cumulative experience until surgeons can do the job safely and well. It is therefore a question of degree as to whether a modification of an existing technique requires only the educated eye test or a total reevaluation.

These facts make it understandable that a surgeon might do a certain kind of operation in a certain way and believe that it is superior in technical terms to his or her previous practice, without having good evidence either that the standard practice is beneficial or that the modification is a genuine improvement in anything more than intraoperative technique. We ought, therefore, to ask, why are modifications introduced?

A surgeon may notice that the existing techniques lack safeguards against common complications or deficiencies, or that they are time consuming and difficult, or that the morbidity of the operation can be obviated by a change of technique. In many such cases a technical comparison is appropriate, and the surgeons doing the operation should be consulted as to whether a new technique is better. But in other cases the new operation should be used only with suitable monitoring of the points of modification (and therefore of potential risk).

The Genuinely New Operation

An entirely new procedure may occur in two quite different situations:

1. The aim of surgery in terms of correction of abnormal structure has itself proven to be effective in treating the disease—as, say, in removal of a life threatening tumor of the brain.
2. The aim of the surgery has never itself been well proven but is a matter of accepted practice.

In both cases, the new technique should be compared in a clinical trial against the best available current treatment so that its advantages—or at least its equivalence—can be examined. But how should such a clinical trial be structured?

In order to compare the way we test surgical innovations with the more common clinical trials with which we are familiar, we should compare surgical trials with the phases of drug treatment

trials. We cannot do early experimental operations on healthy volunteers, so Phase I studies of drugs have no counterpart in surgery—apart from animal trials and ancillary investigations, such as mechanical or laboratory testing.

Phase II studies investigate *prima facie* efficacy, and this is as far as formal trials of surgical innovations usually get. Surgical procedures are often introduced because they appeal to “the educated eye,” which is attuned to a visible abnormality and a visible (or palpable) correction of that abnormality. There is no equivalent of the educated eye in nonsurgical medicine; biochemical and physiological functions are not surveyable in any obvious and simple way, and placebo-controlled trials are needed to prove the efficacy of an intervention aimed at a complex abnormality of function.

In surgery, Phase II success often leads directly to wide clinical adoption and, in effect, Phase IV testing. We seldom step back and ask whether correcting the obvious anomaly in accordance with the educated eye actually helps the patient. An audit of large numbers of procedures done as part of a Phase II demonstration of safety in patients might be the closest we usually get to a Phase III trial. Such an audit shows us something about risks and benefits of clinical use, but it lacks the evidential force of a proper clinical trial because of biases that a formal trial is designed to overcome.

Even though surgical techniques are commonly studied in something that looks like a Phase IV study, as Evans and Evans note: “We must try to pick out serious follow up work from mere marketing ploys.”⁹ Marketing ploys arise because innovation often involves new devices or marketable commodities, resulting in profits and royalties for their creators, and a common way to encourage widespread usage is to enlist surgeons in “research trials.”

Placebo-Controlled Trials in Surgery

It is now time to turn to the reasons that placebo-controlled trials are needed for some surgical innovations. For most surgical procedures, a wide range of results have been reported and for a number of reasons, the interpretation of the relevant data is not at all straightforward. First, the indications for surgery often differ between surgical series, and they are not always clearly defined in published studies. Second, outcome measures vary from study to study and are often not reported in any detail. Third, assessment of the patient before and after surgery is often carried out by the surgical team doing the procedure, and therefore there is a well-recognized possibility of bias in the results. Fourth, we often are not told of inclusion and exclusion criteria for such a surgical series, nor whether there has, in fact, been a declared or undeclared selection of patients.

However, a controlled trial requires surgical equipoise, a contentious concept^{10,11} (see Chapter 24). One might expect equipoise to exist when the clinician has no valid reason to believe that one of the treatments will confer any advantage. But this simple and rational definition is clouded by debates contrasting theoretical equipoise, somewhat vacuously defined as a condition in which the existing evidence is equally balanced between the two procedures, and clinical equipoise, a concept based on the existence of significant clinical disagreement.¹² Equipoise seems best defined as a position in which *there has been no clear-cut and sustained demonstration of the superiority of one treatment over another.* The

standard then becomes objective and historically sensitive to the accretion of statistically valid evidence. In fact, we are often in this position, and surgeons tailor their advice to their own capabilities and to the opportunities open to a patient in their patient's position (because of geography, urgency, cost, antecedent clinical fitness for surgery, and so on). Prolonged debates about definitions of equipoise are therefore a waste of time, and the best we can do is note that in surgery, some disturbances of equipoise are based not on remote clinical outcomes but on factors proximate to the surgery, such as pain, time of operation, and worries based on the educated eye. And so we come to the nub of the problem.

Should We Perform a Randomized Controlled Trial of a New Surgical Procedure?

The question is difficult to answer for a number of reasons.

1. The surgeon has usually introduced the innovation for what he or she considers to be good reasons, so the surgeon is not in an equipoise condition unless that is narrowly interpreted overlooking, for instance, the educated eye and technical adequacy.

2. The fact that any given surgeon will have his or her own favored technique for a procedure means that the best comparisons that can be achieved are usually either prospective contemporaneous trials of patients allocated to different treatments nonrandomly or comparisons between historically distinct retrospective series. Both of these study designs present problems because they fail to control for the differing skills of different surgeons. Such trials also may fail to achieve comparability on other measures such as the clinical status and management of patients.

3. The idea of blinding and placebo control is hotly contested in surgery because placebo operations are ethically problematic.^{13,14} I will consider this at length below.

Some of these problems can be ameliorated by such measures as careful attention to the clinical status of patients in each series, adjustment of morbidity and mortality statistics in retrospective series by using a marker procedure of similar difficulty to that contemplated (such as anterior discectomy rather than discectomy with implantation of an artificial disc), standardized questionnaires and instruments for measuring indications and outcomes, and careful assessment of diagnostic and other parameters used in the series. They are also addressed in part by what is known as the uncertainty principle.¹⁵ This requires doctors to be genuinely reflective about the standard of evidence they have for their beliefs and—when they acknowledge that they are uncertain, or the evidence is inconclusive, about the best treatment—to seek to be part of a well-designed trial to address that uncertainty. This orientation is clearly needed in many areas of surgery, provided only that uncertainty is not defined in a way that neglects the collective wisdom of current practice.¹¹

Placebo-Controlled Surgical Trials: The Problem of Sham Surgery

The idea of placebo arms of double-blind clinical trials in surgery makes most surgeons wonder what the world is coming to. However, when we consider the increasing move toward quality of life surgery and the importance of the placebo effect in that area, along with diminishing surgical morbidity, the idea of placebo-

controlled trials looks more attractive. Adequate information and consent, the possibility of altruistic decision making, and the rational examination of surgical choices in the face of uncertainty may blunt some of the ethical worries that spring to mind. We should also recall, however, that prospective randomized double-blind placebo-controlled clinical trials may not be necessary for all surgical innovations because a considerable proportion of surgical innovation involves learning to operate in a less risky, more efficient, or more elegant way.

A 1999 issue of the *New England Journal of Medicine* addressed the ethics of placebo-controlled trials of surgery by examining the implantation of fetal brain cells in patients with Parkinson's disease.^{16,17} All patients, both in the placebo and treatment groups, had a stereotactic frame fitted under general anesthetic, burr holes drilled in the skull, low dose cyclosporin for immune suppression, and repeated neurological assessment. But is submitting patients to the sham operation (and cyclosporin) as a placebo ethically justifiable? Ruth Macklin is quite clear that "it is unethical" to do operations that involve cutting into people and sewing them up again. She argues that sham surgery violates our duty to minimize the risk of harm to participants in research.¹⁷

The Tension Between Ethics and Science

Macklin contends that there is "a tension between the highest standard of research design and the highest standard of ethics."¹⁷ This is an odd claim given that ethics concerns the making of good decisions and should attend to both the scientific merit of what we are doing and the best interests of the patient. Therefore the correct contrast can be only between good research design and the desire to minimize harm to the individual. But the risk of individual harm is not confined to the study. All surgical treatment is invasive and, if unproven, may cause harm without correlative benefit. So purely on the basis of harm, it is unethical to apply any unproven treatment to any patient. What is more, the wound associated with a sham operation is of a different order from the potential harm attendant on a full operation. Arguably, then, it is misleading to lump all surgical harm into one grab bag. It is not such an open-and-shut case as it initially appears, and some careful thinking is required about the ethics involved.

Why Placebo-Controlled Studies?

There is undoubtedly a need for rigorous testing of new procedures in surgery just as there is for new drug treatments. The baseline data against which new surgical techniques are assessed are problematic. We often rely on historical controls involving a range of different techniques and noncomparable clinical settings in terms of diagnostic facilities, surgical expertise, and the dynamic relationship between biomedical knowledge and the understanding of the indications and rationale for surgery. These problems are compounded by the lack of independent assessment of outcomes and inadequate reporting of the results of surgical series.

Moreover, two new developments are of particular relevance to placebo-controlled clinical trials of surgery. The first is the growth of surgery for quality of life indications—whose "success" requires subjective judgments that are particularly vulnerable to placebo effects—rather than for immediately life-threatening conditions

whose outcomes are readily evident. Macklin discusses an operation aimed at controlling Parkinson's disease. It is similar to quality of life surgery in a number of other areas such as spinal surgery and orthopedic surgery in general, although the aim was to produce a cure. And as distinct from acute rescue or life-saving surgery, we might expect placebo responses to be particularly important. Therefore controlling for the placebo effect is a real issue in assessing many surgical innovations.

In addition, surgery is becoming safer. Operations have become cleaner, quicker, more closely monitored, and they threaten less morbidity and mortality than those in the past, a fact that justifies, at least for many patients, exploratory surgery with an uncertain promise of significantly improving quality of life. This fact also defuses, in part, the argument that placebo surgery is "too risky" to be ethically permissible. There are, however, other arguments that cannot be dealt with quite so definitively.

Vulnerable and Desperate Patients

People with diseases for which we have only relatively ineffective interventions are vulnerable and may be coerced by the hope of treatment, even when that hope is based on nothing but speculation or very poor evidence. We see this every day in clinical practice, when patients with cancer or AIDS turn to alternative and unproven treatments—or even barefaced quackery—searching for answers.

Despite the fact that the standards of evidence and efficacy for allopathic or orthodox medicine may not be fully applicable to the problems that present themselves to holistic practitioners, and despite misgivings about venerating the placebo-controlled trial, we do need clinical rigor. Significant worries about patient bias, placebo effects, observer bias, and subjective end points seem to require the use of placebos in some contexts. The articulation of ethical constraints on their use is therefore required.

General ethical considerations suggest that the first requirement is absolute honesty about the treatment proposed and the structure of the trial. Only disclosure of this kind allows the patient to give informed consent to participation. In a placebo-controlled study, such honesty demands an explanation of the actual chances of the surgery being "real" or "sham" and the importance of the use of placebos in the trial. It seems, however, that we cannot always rely on this being carried out well.

Macklin observes that "some researchers performed sham surgery without obtaining informed consent from patients" and notes that in a trial of coronary artery surgery, "the patients were told only that they were participating in an evaluation of this operation; they were not informed of the double blind nature of the study."¹⁷ Notice that it is the use of placebos that is of most concern, and the probabilities must be clearly explained. Macklin recounts cases in which "the misconception that research is designed to benefit the patients who are the subjects is difficult to dispel," and she concludes that "the protection of human subjects cannot rest solely on the ethical foundation of informed consent."¹⁷

Before approving surgical research protocols, institutional review boards or other ethics committees should reassure themselves not only that patients will be appropriately informed, in an unbiased manner, but also that the surgeons involved are competent and held in good regard by other specialists in the relevant specialty. This would presumably include evidence that the tech-

nique had been presented at professional meetings and is subject to ongoing audit.

However, such an assessment could mean that some major medical advances might never have been made (for instance, in kidney transplantation and open heart surgery).¹ Therefore the needs of desperate patients and their willingness to contribute to future benefits for others must be balanced against the sometimes bleak prospects of the surgery that they are offered in its present state of development.

The Reasonableness of Ordinary Folk

Macklin identifies a tension that rests, in part, on the thought that people should never make self-harming choices. However, a moment's reflection reveals that this is not so. Consider, first, that surgeons often propose operations for which rigorous scientific evidence—in the form of a randomized placebo-controlled trial—is not available. The acceptability of most surgical procedures is based on favorable outcomes in historical series, not on evidence from placebo-controlled trials. Therefore, many patients opt for potentially harmful interventions that have never been strictly validated in terms of their efficacy or benefit. Refusing to allow volunteers to choose the minimal harm associated with placebo surgery would require many patients outside the clinical trial to go on submitting themselves to unproven (strictly speaking) and potentially harmful surgery, with no rigorously scientific way of determining the merits of that surgery. But it is clearly unethical to submit 1,000 people to an unproven and potentially harmful procedure when its merits or otherwise might be revealed by exposing 100 people (or, more probably, 50) to a much lesser risk than that involved in undergoing the real operation.

This is likely to be an ethically defensible approach when our general understanding of human function makes us sure that we are doing good, as, for instance, when we take out a blood clot that is killing a patient from raised intracranial pressure. In such a case the Hippocratics were content to allow the judicious use of reason to help good clinical decision making when we lacked the evidence to be more exact in our assessments of optimal management.³ But recall that there is sometimes a gap between what seems intuitively to be the right thing to do and what can be proven beneficial by evidence, for example, lowering intracranial pressure after acute diffuse brain injury is intuitively correct but unproven in the management of acute head injury. Not only does the obtaining of good evidence make sense in terms of the greatest good for the greatest number, but it makes sense in terms of doing real good (not harm) in future individual cases.

Some thinkers are not swayed by the idea of collective harms and benefits even when the ultimate goal is to refine our ability to benefit identifiable individuals. They protest against utilitarian approaches on principle because they regard acting for the good of the individual as an absolute duty. At this point, we need to examine more closely the ethical basis of their claim.

It is clear that a narrow focus on the best interests of the individual gives certain weight to self-interest, autonomy, and paternalism. But the balance commonly struck is fraught with internal inconsistencies. Autonomy or self-rule generally means that we ought to respect the reasonable wants and intentions of an individual, in which a "reasonable" want or intention means that it is endorsable by a rational person and it is not unjust (in the sense

that it does not infringe the rights of others). Among a person's reasonable interests are those which put a value on serving others, usually referred to as *altruistic intentions* and generally reckoned not only to be reasonable but morally commendable.

Given that concession, voluntary or even enthusiastic participation in a placebo-controlled surgical trial seems reasonable on at least two counts:

1. A 50% chance of a treatment that might help is arguably as good as a treatment whose effect is (strictly speaking) unknown.
2. The thought that our ignorance about the efficacy of a potentially helpful treatment would continue to dog future sufferers of a condition one suffers is itself unreasonable.

The chance of availing myself of the statistical opportunity of possible benefit (50%), combined with the possibility of uncovering important information for the treatment of others like me, arguably outweighs the harm of a relatively innocuous surgical intervention if I am in the 50% who get a placebo operation.

This might provide some people, and patients in particular, with a significant motivation for altruistic behavior. We have applauded altruism in the past, particularly in medical pioneers experimenting on themselves. But to deny patients the chance of participating in placebo-controlled surgical research would be to say, in effect, that altruism is no longer endorsable as a rational motive. The view of human motivation as narrow self-interest, which is reflected in (and possibly encouraged by) this ethical stance, is lamentable. It seems ironic that ethicists, of all people, should condemn altruism, which some would regard as a fundamental pillar of ethical behavior.

Safeguards for Patients

Despite the weaknesses in the argument against placebo-controlled surgery, there are safeguards that need to be in place for us to allow such a trial design to be ethically approved. The most important safeguard concerns patient information and consent. Patients should know that there is a 50% chance of undergoing sham surgery, but they should also be told that we do not actually know if the "real surgery" is of any benefit (which is why the study is being done in the first place) and that continuing in ignorance involves even more substantial risks not only to them but also to others. If the patient decides to go ahead and participate in the study, then it seems to me that a realistic "cooling off" period should be scheduled and/or that they should be provided with access to a medical opinion distanced from the surgical enthusiasts committed to doing the trial. If such conditions are met, then no reason remains to ethically disapprove of the altruistic participation of some patients in trials to advance the search for a well-grounded, scientifically proven response to their condition (given that they also have a chance of obtaining benefit from the experimental treatment).

Advances in Surgery and the Dogma of the Placebo-Controlled Trial

Placebo surgery addresses the question posed by the fundamentalism that venerates placebo-controlled trials above everything

else in clinical medicine. This is not necessarily the core of evidence-based medicine, which is "the conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients."¹⁸ The fundamentalism involved is a product of clinical epidemiology conceived as a science wedded to the concept of provable causal efficacy from an equipoise situation.

However, medicine, and particularly its surgical arm, is a science-based art with elements of creativity and imagination involved, so flatfooted application of a generic and uniform intervention like a drug or a standardized procedure is not always appropriate. Many surgical procedures are, effectively, unique solutions tailored by the surgeon to suit the needs of the individual patient, although based on a generic technique. Of course we need evidence for the efficacy of these procedures, and we need to remove or negate potential biases in gathering that evidence. But surgery has a history of incremental innovation and cumulative refinement of its techniques and is therefore allied in some ways with the crafts practiced by skilled craftspeople. We must therefore ask when and what version of a technique or its refinements ought to be tested in a placebo-controlled trial. To some extent, surgeons are the best judges of this threshold, in the light of considerations such as those above about the possibility of new harms and benefits.

At one end of the continuum there are going to be new operations, even involving new, patented devices, which are better ways of doing the job that has to be done—as, for instance, might be the case with the current generation of aneurysm clips compared with their more remote ancestor devices. We then need to consider some developments, such as intra-arterial or interventional radiological occlusion of cerebral aneurysms, as alternatives to surgery when the procedures are so different that a comparative clinical trial could hardly proceed with equipoise except in relation to serious outcomes. In such a situation, some other kind of comparison is going to be required to establish exactly which patients will be more suitable for which procedures. But there are also interventions based on belief and theory, such as the use of prophylactic antibiotics, when the results are not always accessible to the intuitive technical judgment of a skilled practitioner and the solution is generic and uniform so that a standard clinical trial methodology is appropriate.

In between the innovations clearly in one camp and those clearly in the other, there are some that fall in the middle, like the resection of the gyrus rectus in clipping an aneurysm of the anterior communicating artery—a detail that is seemingly innocuous but which should be evaluated more thoroughly than just by making bedside assessments on a ward round. Similar points could be made in relation to developments in spinal fusion techniques, an area in which practice has shifted to suggest that active fusions are required in more and more cases without there ever having been a thorough validation of their necessity or effects.

Therefore the differences between the craft of surgery and the science of medicine in general suggest that we need to develop a more Hippocratic method of evolving and assessing techniques in surgery. Some techniques seem to confer technical advantages, but often the baseline of standard practice against which they are assessed is not well documented. In such a case we need to do what the Hippocratic practitioners did: document our baseline, do audits on our techniques, and document shifts in practice so that, despite the historical, nonblinded, nonplacebo-controlled meth-

odology being used, we monitor what we are doing by careful case records and by audit (perhaps by independent assessors) of our results. There are some areas of surgery in which this approach, despite its nonconformity to the dogma of placebo-controlled trials, may be the correct way to proceed. In other cases, a placebo-controlled trial is the right way to go, and some groups are now using mixed designs that allow surgeons to exercise clinical judgment and yet study their techniques for efficacy.¹⁵ In any event it seems after careful scrutiny that we cannot dismiss out of hand either way of proceeding in the evolution of surgery.

We now come to some general questions that should concern all surgeons involved in actual clinical innovation and research.

Do the Patients Concerned Understand That They Are Receiving Innovative Treatment?

This is the most important ethical consideration. However, the possible weakness of a focus solely on informed consent is the vulnerability of patients and the unequal power relationships in the clinical encounter, therefore further questions must be asked, in particular about the standard of information required.

Given that evidence about efficacy of existing treatments might be very poor by epidemiological standards, all that we can ask of surgeons is that they should be open with their patients about what they are going to do, they should reasonably believe that what they are doing is comparable to existing techniques, and they should submit their procedure to peer review. Such peer review depends on a careful audit of results and an attempt to do some kind of valid clinical comparison that will yield the best possible evidence as to the relative scientific merits of the technique used.

The patients should be told of their options and should appreciate how to position the surgeon's advice in relation to a representative body of medical opinion. Many clinicians, and surgeons in particular, are bad at this. They will decide their preferred mode of therapy but will not inform the patient about uncertainties or other options for treatment. But patients must be empowered to make their own decisions, especially when clinical facts do not unequivocally point to one approach—adjuvant chemotherapy for gliomas, for example. The patient should understand any sources of bias that would not be obvious and should be aware that surgery is a journey that may take many paths to the same destination.

If this is done, then patients become participants in designing (and owning) their own treatment regimes and monitoring their own outcomes. Such a partnership allows medical innovation to proceed in a very fruitful way because the patients feel permitted to contribute their own observations no matter how odd or unusual these seem to be. The ongoing audit of practice allows such observations to be a rich source of truly Hippocratic data, a branch of the tree of knowledge on which advances in medicine have hung for over 2,000 years.

It may be that a relatively new technique, unlike most surgical procedures, does not have a clear-cut scientific rationale. The lack of a theory explaining why the innovative technique works can be understandable and is not, in itself, an absolute barrier to doing the procedure; theory often lags behind data. However, some systematic investigation should be pursued—perhaps through anatomy, animal physiology, and so on, or perhaps with a placebo-controlled trial—to fill the gap in our knowledge, par-

ticularly in an area in which the results of surgery are partly assessed on the basis of quality-of-life criteria that are highly susceptible to the biases that a placebo-controlled trial is designed to eliminate. Once the observation or anecdotal finding is then established as a genuine finding, theory usually comes to grips with it and sets about elucidating it.

Conclusion

We need innovation in surgery to make techniques safer. We need good research to check on what we are doing and to refine our indications for using surgery in various clinical situations. Surgeons and their patients need to go into these trials and undertake their respective roles in these developments with an open mind and a careful attention to the need for the rigor that is to be had in a primarily healing art. They must do so in a spirit of open and informed partnership in which the maximum is done to address the imbalances that exist in the clinical setting and the patient is regarded as a coinvestigator. When significant innovation is being studied, an independent ethical review committee ought to oversee the trials that are conducted to develop and test that innovation.

Having said all this, we ought not to delay nor unnecessarily obstruct surgical innovation by always insisting on orthodox and rigid adherence to the tenets of the placebo-controlled trial, especially when an educated eye might inform us that a procedural variation is more technically adequate than an existing method. There are undoubtedly other ways of moving ahead, such as trials done under the principle of uncertainty or systematic case-matched reviews, which can achieve much the same result as a placebo-controlled trial.^{5,6} But we should not altogether rule out the placebo-controlled trial on ethical grounds.

Participant Selection

Section A. Fair Participant Selection

This page intentionally left blank

What Is Fair Participant Selection?

Introduction: “Born in Scandal, Reared in Protectionism”

The U.S. regulations for the protection of humans in biomedical and behavioral research were, as Carol Levine notes, “born in scandal and reared in protectionism.”¹ Other chapters in this volume identify and discuss research projects that were condemned because they imposed undue risks on research subjects or because they failed to obtain voluntary, informed consent. In addition, some were criticized as violations of standards of fairness, justice, and equity in the selection of subjects, now increasingly called “participants.”

In Henry Beecher’s 1966 exposé in the *New England Journal of Medicine* of 22 clinical trials in which researchers had engaged in “unethical or questionably ethical procedures,”² the vast majority of cases involved research on soldiers, hospital patients, institutionalized mentally retarded children, newborns, the elderly, and the terminally ill. These studies were not anomalies, Beecher demonstrated, but examples of mainstream science: All were published in prestigious medical journals and most were conducted at university or government facilities with federal funding.

Although Beecher’s article accelerated the movement toward federal regulation of human experimentation in the United States, it was the media’s discovery of the Tuskegee Syphilis Study in 1972 that ultimately led to many of the guidelines in place today. In an attempt to study the natural progression of untreated syphilis, the U.S. Public Health Service (PHS) had sponsored a 40-year trial in which close to 400 poor, African American men with syphilis were systematically deprived of established treatments and led to believe that the lumbar punctures they received were therapeutic,

not diagnostic³ (see Chapter 8). Although this study was ethically flawed in several ways, one major ethical criticism focused on its unfair selection of subjects, a selection based in part on racist views that syphilis was a different disease in whites and in African Americans.⁴

In 1974, Congress responded to these and other scandals by passing the National Research Act,⁵ which created the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (hereafter, the Commission). The Commission was charged, first, with identifying the basic ethical principles that should underlie the conduct of research with human subjects, and, second, with developing guidelines to ensure that these principles were followed in the future. In carrying out these tasks, the Commission was directed to consider, for the first time, “appropriate guidelines for the selection of human subjects for participation in such research.”⁶

Protection From the Burdens and Risks of Research

The Commission deliberated during a time in which clinical research involving humans had proven not only a risky enterprise but one that largely burdened vulnerable populations. An article published by Hans Jonas in 1969, which has since become one of the most anthologized essays in research ethics, is characteristic of this climate. One of the first authors to address the issue of subject selection directly, Jonas contended that in ruthlessly pursuing scientific progress, society had placed an excessively heavy burden on its most vulnerable members simply because they were readily

available and easily expendable. He argued that in a rightly ordered society, physician-researchers, who have the motivation and understanding necessary to freely enter research, would be the primary source of research participants. Other members of society could participate in research in “descending order of permissibility,” with society’s most vulnerable members included in research only as a last resort.⁷

When the Commission released its Belmont Report in 1978, it echoed Jonas’ protectionist attitude toward the selection of research participants (see Chapter 14). Recalling Tuskegee and other research scandals, the Commission wrote that

[c]ertain groups, such as racial minorities, the economically disadvantaged, the very sick, and the institutionalized may continually be sought as research subjects, owing to their ready availability in settings where research is conducted. Given their dependent status and their frequently compromised capacity for free consent, they should be protected against the danger of being involved in research solely for administrative convenience, or because they are easy to manipulate as a result of their illness or socioeconomic condition.⁶

The Commission grounded its view in the principle of individual and social justice. Individual justice, the Commission wrote, requires “that researchers exhibit fairness” in the selection of participants. Accordingly, “researchers should not offer potentially beneficial research only to some . . . or select only ‘undesirable persons’ for risky research.”⁶

The requirements of social justice added another layer to the conception of fairness. Social justice, the Commission stated, entails drawing a distinction between classes of people who should and should not participate in research “based on the ability of members of that class to bear burdens and on the appropriateness of placing further burdens on already burdened persons.”⁶ It also demands that research “not unduly involve persons from groups unlikely to be among the beneficiaries of subsequent applications of the research.”⁶ As a matter of social justice, then, researchers should prefer nonvulnerable populations to vulnerable ones and should not involve groups whose members do not stand to benefit from the results of the research.

In 1981, the Department of Health and Human Services (DHHS) and the Food and Drug Administration (FDA) issued separate federal regulations that reflected an attitude similar to the Commission’s toward protecting vulnerable persons in research.^{8–10} The DHHS regulations, Subpart A of which became the basis of the so-called Common Rule, required institutional review boards (IRBs) to ensure that the “selection of subjects is equitable.” In studies “where some or all of the subjects are likely to be vulnerable to coercion or undue influence,” the IRB reviewing the protocol is to ensure that “appropriate additional safeguards have been included in the study to protect the rights and welfare of these subjects.” At its inception, Subpart A included children, prisoners, pregnant women, mentally disabled persons, and economically or educationally disadvantaged persons among the class of vulnerable persons. Specific guidance for research involving pregnant women, human fetuses, and neonates (subpart B); prisoners (subpart C); and children (subpart D) was also integrated into the DHHS regulations.⁸ Most of the 18 federal departments and agencies that subsequently adopted the Common Rule, however, did not adopt subparts B, C, and D.

In the decade following Tuskegee, research participation was considered a heavy burden requiring stringent regulation. The paradigm was so-called nontherapeutic research; that is, research that does not offer the participant the prospect of direct benefit. The protectionist stances of the Belmont Report and the Common Rule, and their view of fairness in terms of the distribution of research burdens, reflect the era in which they were developed as well as the problems they faced. Looking back on this period, the Advisory Committee on Human Radiation Experiments indicated in 1996 that it “was troubled by the selection of subjects in many of the experiments we reviewed. The subjects were often drawn from relatively powerless, easily exploited groups, and many of them were hospitalized patients.”¹¹

Access to the Benefits of Research

By the mid-1980s, attitudes toward research participation had begun to change. Trials once regarded as burdensome and potentially dangerous came to be viewed as highly desirable opportunities for patients to access the latest benefits of medical science. Among the factors contributing to this transformed vision of clinical research were several studies demonstrating not only that research participation is relatively safe,^{12,13} but also that research subjects often enjoy better health outcomes than their peers receiving the same therapy outside of the research setting.¹⁴ At the time these data became public, the cost of health care in the United States was rising exponentially. Enrolling in a clinical trial was thus seen as a way to receive state-of-the-art medical care, improved disease monitoring, and access to the health-care system.¹⁵

Nowhere were the perceived benefits of participating in clinical research more pronounced than in the context of the HIV/AIDS crisis. First recognized in 1981, AIDS became one of the most feared diseases in modern times. Physicians had no standard treatment for the disease or the virus that caused it; and although antiretroviral therapy currently offers the best hope, the first antiretroviral drug was not available until 1986 and then only in clinical trials.

Individuals infected with HIV and those with AIDS clamored for access to clinical trials that offered even a slim chance at improvement. In the context of limited access to zidovudine (AZT), many HIV/AIDS activists argued that research was synonymous with health care, an argument that suggests there was a therapeutic misconception about the nature of these trials, many of which were placebo-controlled. Unlike critics of the previous decade who were preoccupied with protecting research participants from the burdens of research, the activist group AIDS Coalition to Unleash Power (ACT-UP) argued that people should have the right to decide for themselves what burdens to bear. From the perspective of AIDS activists, fairness demanded nothing less than unimpeded access to the potential benefits of research participation.¹⁶

Against this background, a different conception of justice in the selection of research participants began to emerge. The focus shifted from the fair distribution of research burdens and risks to the fair distribution of research benefits. Instead of asking how to protect certain vulnerable groups from the burdens of clinical research, the ethical question turned to how to ensure access to potentially beneficial research for vulnerable or underrepresented populations.¹ This ethical discourse occurred largely in the context of HIV/AIDS research.

Because AIDS was initially thought to be a disease primarily affecting gay men, those in the first several AZT trials were mostly white, homosexual men. The categorical exclusion of intravenous drug users from these trials, coupled with low inclusion rates for women and minorities, led to charges of discrimination and injustice.¹⁷ Ethical analyses began to recognize that the protectionist regulations of the 1970s were limiting enrollment among many of the populations (e.g., women of childbearing age, prisoners, infants, prostitutes) that stood to benefit from participating in HIV/AIDS research.¹⁸

Subsequently, the U.S. Office for Protection from Research Risks issued guidance for IRBs concerning the fair distribution of benefits among potential research participants. Although not codified in the federal regulations, the guidance recommended that IRBs ask the following three questions when reviewing clinical protocols:

To the extent that benefits to the subject are anticipated, are they fairly distributed? Do other groups of potential subjects have a greater need to receive any of the anticipated benefit? Has the selection process overprotected potential subjects who are considered vulnerable (e.g., children, cognitively impaired, economically or educationally disadvantaged persons, patients of researchers, seriously ill persons) so that they are denied opportunities to participate in research?¹⁹

This guidance illustrates the degree to which the ethics of clinical research had changed in just one decade. Instead of having to justify the *inclusion* of vulnerable populations in clinical trials, researchers were now asked to justify their *exclusion*. Fair selection in this ethical environment meant providing all prospective participants with equal opportunity for access to the potential benefits of participating in clinical research.

Proportional Representation in Research

In the early 1990s, an additional layer of ethical complexity was added to the discussion of fairness in the selection of participants. Several people argued that justice requires not only equal opportunity for access to benefits for individuals (through participation in research), but also equal opportunity for access to benefits for groups in the population at large (after the completion of research). To ensure fair or equitable distribution of the results of research among all groups, it was argued, people from those groups must be represented in the research. As numerous studies revealed, however, most research participants were middle-aged, white males who reported high or middle annual incomes²⁰—hardly representative of the diverse groups who hoped to benefit from the results of research.

The early HIV/AIDS trials again provided the backdrop for these discussions. Because the participants in those trials were mostly white men, some argued that clinicians lacked important information about the efficacy of AZT in the wider population of HIV/AIDS patients.^{17,18} Specifically, concern emerged that there could be relevant biological differences between white men and other groups with HIV/AIDS, such as women, racial minorities, and children.^{21,22} The failure to include these latter groups in clinical trials left unanswered questions about the progression of the disease and the effective treatment dose in those populations.

When an experimental drug ultimately reached the market, it was argued, understudied groups might receive ineffective or even harmful treatment.²³

In 1992, Rebecca Dresser's groundbreaking article demonstrated that the failure to include women and racial minorities in research was not limited to HIV/AIDS trials but, instead, was "ubiquitous."²⁴ During the 1970s and 1980s, for example, the National Institutes of Health (NIH) had funded several large-scale, male-only heart trials, including the now well known Coronary Drug Project,²⁵ Multiple Risk Factor Intervention Trial,²⁶ Coronary Primary Prevention Trial,²⁷ and Physicians' Health Study.²⁸ These studies systematically excluded women from participation; but even in studies that were not gender-restricted, female enrollment was low.^{15,29} One reason given for women's underrepresentation in research was that "their hormonal fluctuations 'confound' or 'confuse' research results,"³⁰ but other articles suggested that low enrollment simply resulted from unreasoned sex biases in participant selection.^{31,32} Just as these data were surfacing, so too were studies demonstrating that men and women respond differently to certain drug treatments.³³

Racial minorities were also underrepresented in the vast majority of clinical trials at this time, and almost no clinical trials existed to study diseases that primarily afflicted minority populations.^{34,35} There was also growing evidence that racial minorities respond differently from whites to certain drugs, such as antihypertensives,³⁶ and that they experience disease progression differently from whites, especially in the context of cancer.³⁷ As a result, there was legitimate concern that researchers were regularly extrapolating data from whites to racial minorities without any scientific justification for doing so.³⁸

The use of children in research was similarly rare. In the mid-1990s, for example, only 20% of drugs approved in the United States had been labeled for use in infants and children, and only 37% of new drugs with the potential for pediatric use had pediatric labeling at the time of approval.³⁹ Off-label use of medications was thus the norm in pediatrics, but with it came the risk of exposing children to unexpected adverse reactions or suboptimal treatment.

The government responded to the exclusion and underrepresentation of women, racial minorities, and children in clinical trials in a series of personnel and policy changes that took effect throughout the 1990s. During the Senate confirmation hearings for Bernadine Healy, director of the NIH from 1991 to 1993, gender representation in biomedical research was the focus of discussion. Healy stated that her intent was to make women's health a central aspect of her administration, and as NIH director, she upgraded the status of the NIH Office of Research on Women's Health (ORWH). The office had been established in 1990, the same year in which the NIH required the inclusion of women and minorities in study populations unless researchers showed "a clear and compelling rationale" for their omission,⁴⁰ a standard that has since been tightened.

In 1993, the FDA and the NIH both took crucial steps toward ensuring the widespread applicability of research results. The FDA withdrew its previous prohibition against including women of childbearing age in early clinical trials and issued new guidelines stating that research participants "should, in general, reflect the population that will receive the drug when it is marketed."⁴¹ This change in FDA policy dramatically affected drug companies, which were suddenly required to consider whether they had enrolled

adequate numbers of women to detect gender-related differences in drug response.^{42,43}

Echoing the FDA's message to researchers, Congress passed the NIH Revitalization Act of 1993, which mandated the inclusion of women and minorities in clinical research.⁴⁴ Under the Act, researchers conducting Phase III clinical trials were further obligated to enroll a sufficient number of women and minorities "such that valid analyses of differences in intervention effect can be accomplished."⁴⁵ The NIH justified this provision by pointing out that "[s]ince a primary aim of research is to provide scientific evidence leading to a change in health policy or a standard of care, it is imperative to determine whether the intervention or therapy being studied affects women or men or members of minority groups and their subpopulations differently."⁴⁵

Federal efforts to encourage the inclusion of children in clinical trials developed more slowly. In 1995, Congress expressed concern that the NIH was devoting inadequate attention and resources to pediatric research it conducted and supported.^{46,47} When a workshop convened by the National Institute of Child Health and Human Development and the American Academy of Pediatrics revealed that as many as 20% of clinical trials inappropriately excluded children,⁴⁸ Congress's fears were confirmed. In response to congressional demand, the NIH issued a policy in 1998 that required grant applicants seeking NIH support to include children in research, except in certain stated situations. The policy aimed "to increase the participation of children in research so that adequate data will be developed to support the treatment modalities for disorders and conditions that . . . affect children."⁴⁸ Following the same reasoning, the FDA implemented mirror regulations in 1998 that required all new drugs and biologics, absent a waiver, to be studied in pediatric research subjects.⁴⁹

By the turn of the millennium, the concept of fairness in the selection of research participants had evolved substantially from its roots in protectionism. Policy experts, investigators, and ethicists alike acknowledged that a combination of overprotection and discrimination had created homogeneous study populations that did not reflect the full range of patients likely to receive a marketed therapy. Without information about how different groups responded clinically to research protocols, it was thought that physicians would not be able to provide equal care to all of their patients. In this context, fair selection meant ensuring that research cohorts resembled target clinical populations. Exclusion or underrepresentation of women, racial minorities, or children unjustly affected those groups by denying them access to the benefits of participating in research (the concern of the 1980s) and by failing to provide them with the benefits of applicable knowledge from research, such as information about how treatment regimens might affect them differently than the study population (the worry of the 1990s). Determining what exactly counts as proportional or fair representation in research remained an unanswered question.

Present Challenges

Researchers, ethicists, and others continue to grapple with the delicate balance between protecting vulnerable populations from the burdens of research and providing all individuals and groups with an equal opportunity to benefit from research, both in particular studies and after their completion. During the past 10 years, however, new challenges have suggested that achieving fairness in

research may require fresh approaches. The continued underrepresentation of minorities in research, the exploitation of economically disadvantaged people, and the dearth of elderly research participants suggest that we need to look more thoughtfully at the factors that impede equitable participant selection. At the same time, the expansion of research in the international arena illustrates that although attention to participant selection is necessary for fairness in research, it is not always sufficient.

Ongoing Underrepresentation of Minorities

Despite U.S. federal regulations mandating the inclusion of racial minorities in clinical trials, recent studies demonstrate that African Americans, Hispanic Americans, and other minorities remain underrepresented.^{50,51} One explanation offered for the low representation of minorities in research is that investigators do not know what the congressional legislation requires of them with regard to minority enrollment.^{52,53} Although the 1993 NIH Revitalization Act was revised in 2000 and 2001, the provision that researchers must ensure the "appropriate inclusion" of minorities remains vague.

In highlighting this problem, one article suggested that "appropriate inclusion" could be interpreted in three different ways.⁵⁴ First, it could require researchers to use the burden of disease in a population to guide minority inclusion. If a group has a higher likelihood of disease, it should have greater representation in research, which translates into a greater likelihood of sharing in the benefits and burdens of the research. A second method for determining appropriate inclusion might be to use census data to guide the proportion of minorities included in research. On this view, a group's representation in a trial would be proportional to its representation in the population at large. A third option might be to use the demographic statistics of a region, rather than the country, to guide participant selection. This method would, for example, be more precise when the therapy being tested is intended to benefit people in a limited region of the country. Although these proposals demonstrate the need for clarity in the federal guidelines, the present ambiguity does not alone explain the continued underrepresentation of racial minorities in clinical trials.

An arguably larger impediment to minority enrollment in clinical trials is what has been called "the legacy of distrust"⁵⁵ or "Tuskegee fallout."²⁴ Both terms speak to the powerful deterrent effect that knowledge of past research scandals has on potential minority participation in research.^{56,57} In one survey, African Americans stated that they avoid clinical research because doctors "always use our race as guinea pigs" so that others in society can benefit.⁵⁸ Other studies have similarly documented the pervasive distrust many African Americans have toward the medical establishment.⁵⁹ In part, because self-referral is a primary mechanism for enrollment in present-day clinical trials, skepticism and suspicion among potential participants have hindered minority representation.^{60,61}

To be clear, the suspicion with which racial minorities view clinical research is not merely the result of research scandals from the 1960s and 1970s. Recent allegations of impropriety have likely increased the apprehension with which minorities view clinical research. In the mid-1990s, for example, it was revealed that the Centers for Disease Control and Prevention, in concert with Kaiser

Permanente of Southern California, had enrolled nearly 1,500 infants in a measles vaccine trial. The research subjects were largely members of minority groups: 44% were African American, 44% were Hispanic American, and 12% were from other unspecified groups.⁶² Investigators did not inform any of the infants' parents that the vaccine was experimental or that it was not licensed for use in the United States. This trial further exacerbated the distrust that many minority populations already felt toward clinical research.

Although some minorities may choose not to participate in research, there is compelling evidence that many are never even offered the option of enrolling in a clinical trial.^{15,60} Advertising for clinical trials on the Internet has increased self-referral among some populations, but many minorities do not have access to this information.¹⁵ They enter clinical trials largely because they are recruited by investigators or referred by primary care providers.

Because many minority patients seek care at their neighborhood institutions, rather than at research centers, it is the rare few who come into contact with investigators recruiting for new trials.⁶⁰ Moreover, limited data suggest that health-care providers, like the rest of society, harbor prejudicial attitudes toward minority groups that influence their decisions about referrals.^{50,63} Physicians may refer only "good study candidates" to trials: those who are likely to keep appointments, comply with drug dosing, and be otherwise reliable.²² Patients who do not speak English,⁶⁴ or those with chaotic lifestyles—like single mothers, people with multiple jobs, or those with substance abuse problems or who lack transportation or housing—may not be referred to clinical trials because their primary care providers believe they will have trouble keeping appointments and following the experimental regimen. All too often, minorities are deemed bad study candidates, thereby further limiting their representation in clinical research.²²

The reluctance among many minorities to participate in research, coupled with these impediments to minority recruitment, point to a need for greater education of both prospective research participants and researchers. Overcoming the pervasive distrust of the medical establishment among minorities will require substantial time and effort. Community-based education programs aimed at discussing concerns minorities have about research, providing information about federal safeguards intended to protect research participants, and sharing the results of relevant research with minorities are essential first steps. Including members of minority communities on research advisory boards, although rarer, has also proven an effective way to improve trust and communication between prospective participants and the research community.⁶⁵ At the same time, researchers must recognize that access to research participation is affected not only by eligibility criteria, but also by recruitment strategies and research biases.⁶⁶ Researchers must also be aware of and address prejudicial attitudes that prevent primary care providers from referring minorities to research trials.

Research With Economically Disadvantaged Persons

Although ethical analyses have devoted considerable attention to the underrepresentation of minorities in clinical research, far less has been written about the fair selection of those from economically disadvantaged populations. In 1978, the Belmont Report

acknowledged that economically disadvantaged populations may be overrepresented in research, "owing to their ready availability in settings where research is conducted," and the ease with which they can be manipulated "as a result of their . . . socioeconomic condition."⁶ The Common Rule, at 46.111, likewise includes economically disadvantaged persons as a subset of those "vulnerable to coercion or undue influence."⁸ As such, it calls upon IRBs reviewing research involving economically disadvantaged participants to ensure (a) that the "selection of subjects is equitable" and (b) that "additional safeguards have been included in the study to protect the rights and welfare of these subjects" (46.111(a-b)).⁸ A recent trial conducted on children in low-income housing suggests, however, that researchers, IRBs, and ethicists need to focus greater attention on the socioeconomic status of research participants and the meaning of the federal regulations designed to protect them.

In 1993 the Kennedy Krieger Institute (KKI), a Baltimore-based children's hospital affiliated with Johns Hopkins University, sought to measure the short- and long-term effectiveness of several different lead paint abatement procedures in low-income housing. KKI researchers estimated that as many as 95% of low-income housing units in Baltimore were contaminated with lead-based paint,⁶⁷ creating a risk for developing dangerous levels of lead in the blood of children who lived in those units. At low levels, lead poisoning can adversely affect cognitive development, growth, and behavior; extremely high lead levels can result in seizures, coma, and even death.⁶⁸

Because the cost of safely removing lead-based paint from these low-income housing units often exceeded the cost of the units themselves, landlords frequently closed the properties rather than repairing them, thereby producing a shortage of low-income housing. Researchers at the KKI hypothesized that more economical lead abatement procedures could effectively reduce lead contamination in affected units, thus preserving the availability of low-income housing. In order to determine the effectiveness of various levels of lead abatement, KKI researchers wanted to measure the lead levels in the blood of children living in units that had undergone different degrees of lead abatement.

The two-year KKI study was approved by a Johns Hopkins University IRB and funded by the U.S. Environmental Protection Agency. The study classified 125 low-income Baltimore rental properties into five groups. Housing in the first three groups received varying degrees of partial lead abatement. Housing in the two control groups had either previously undergone full lead abatement or had been constructed without lead-based paint. KKI encouraged landlords to rent these properties, if they were vacant, to families with young children who intended to remain in the housing until the completion of the study.⁶⁷ In the event that young children already resided in a study property, their parents were encouraged to remain on the premises.⁶⁷

KKI evaluated the success of each lead abatement method by measuring, at periodic intervals during the two-year period, lead levels in the blood of the children living in each housing group, and the extent to which lead dust remained in, or returned to, the housing. The consent forms signed by the children's parents indicated that lead poisoning in children was a significant problem in Baltimore, and stated that the purpose of the study was to measure the effectiveness of repairs that aimed to reduce, but not completely eliminate, the lead in their home.⁶⁷ In return for their participation, parents received periodic payments of \$5 to \$15 and

were told that KKI would provide them with the results of their children's blood tests.

In 2001, the Maryland Court of Appeals permitted two families with minor children that had participated in the study to bring a negligence action against KKI. The parents alleged that they had not been completely and clearly informed of the risks of the research; that KKI had delayed informing them of tests that revealed their children had dangerously high levels of lead in their blood; and that their children had contracted lead-related health injuries during the study. In its defense, KKI claimed that it had no legal duty to protect the research participants from injury, and therefore could not be found negligent. The court disagreed with KKI and held that by virtue of the informed consent agreement entered into between the parents and the researchers, as well as the special relationship created between researchers and research participants, KKI had legal obligations to protect the participants in the study.⁶⁷ The court further held that in Maryland, parents cannot consent to their children's participation in "non-therapeutic research or studies in which there is any risk of injury or damage to the health of the subject."⁶⁷

Most striking, though, was the court's comparison of the KKI study to the Tuskegee syphilis trial in its exploitation of economically vulnerable persons.⁶⁷ The court admonished the KKI researchers for recruiting families with limited access to low-income housing as research subjects, and it leveled strong words against the IRB that approved the research.⁶⁷ Although the court's comparison of the KKI study to the Tuskegee syphilis study has its limitations,⁶⁹ it serves as an important reminder that reliance on economically disadvantaged populations as a source of research participants is not merely a part of the past, but something we must actively safeguard against in the present and future. The disclosure in 2005 that NIH-funded researchers enrolled hundreds of mostly poor or minority foster children in HIV-related antiretroviral drug studies during the past two decades, often without advocates to act in the children's best interests, demonstrates the continued prevalence of economically disadvantaged children in research and underscores the need for safeguards to protect them.⁷⁰

The Common Rule offers only limited guidance in this area; it specifies neither what counts as the equitable selection of vulnerable research participants nor what qualifies as an acceptable level of "additional safeguards" to protect them. To hold IRBs, research institutions, and investigators ultimately responsible for the research they approve and engage in, as the Maryland court did, the research community as a whole must take steps toward discussing and further specifying what constitutes fair research with economically disadvantaged persons.

Exclusion and Underrepresentation of Elderly Persons

In the next 25 years, the number of people in the United States who are over the age of 65 will double, and the number of those over 85 will quadruple. Recent literature suggests, however, that the elderly are often excluded and underrepresented in research, even in clinical trials targeting diseases that mostly affect older patients. For instance, in the United States, more than 80% of patients hospitalized with heart failure are aged 65 or older and more than 20% are 85 or older. Yet in a series of 59 clinical trials

conducted with more than 45,000 participants, nearly one-third of trials excluded elderly persons from enrollment.⁷¹ Similarly, in a recent review of 1,522 people enrolled in cancer clinical trials, the enrollment rate for those aged 65 or older was unexpectedly low. Although 49% of breast cancers in the United States occur in people aged 65 or older, only 9% of women enrolled in breast cancer studies were aged 65 or older.⁷²

Several factors contribute to the exclusion and underrepresentation of the elderly as research participants. Many clinical trials have enrollment criteria that strictly exclude elderly persons—not always with clear justification. Some trials exclude elderly participants because their comorbidities make them more likely than other participants to experience substantial side effects from experimental interventions. For similar reasons, trials may exclude elderly participants until preliminary dosing and safety data are available from research with the general population. Even when the formal study design does not require aged-based exclusion, criteria that exclude people with conditions that are disproportionately found in the elderly, or that exclude people using medications often taken by the elderly, often function to eliminate older people from the pool of research participants. Elderly patients are also less likely to know or to ask about trials, and because Medicare does not fully pay for experimental trials, many elderly patients may assume (sometimes correctly) that they must pay to participate. Among elderly patients who do want to enroll in research, decreased mobility may make participation more difficult.

Although federal guidelines address the inclusion of women, racial minorities, and children in research, they presently neglect the equally important challenge of enrolling elderly persons in research. Because age affects drug metabolism and disease progression, the lack of older persons in clinical trials limits the benefits of applying research knowledge to the elderly population. Conversely, elderly patients are at greater risk to experience toxic or suboptimal effects of medications that have not been tested for use in their age cohort. Medical advances that prolong life, coupled with the aging of the baby boom population, have rendered the unique health-care needs of the elderly a prime concern in the present era. Fairness in the selection of research participants demands that society consider mechanisms for proportionally representing them in research.

International Clinical Research

In the last decade, ethical controversy erupted about U.S.-sponsored, funded, and conducted clinical trials in the developing world. Such research is not new, however. In the 1950s, U.S. researchers enrolled poor Puerto Rican women in a study to test the effectiveness of the oral contraceptive pill without informing them that they were in research or that there was a risk they would become pregnant.^{73,74} In the 1970s and 1980s, U.S. researchers conducted trials of Depo-Provera, a long-acting injectable contraceptive, on women in developing countries even though (and perhaps because) the FDA refused for safety reasons to license the drug in the United States.⁷⁵ But it was the work of U.S. researchers in the 1990s studying ways to reduce the perinatal transmission of HIV in the developing world that ultimately sparked the present controversy over the ethics of international clinical research. The debate quickly focused on whether the researchers had acted unethically when they used placebo controls instead of known,

effective treatment for preventing perinatal HIV transmission, as would have been required had the research been conducted in the United States.^{76,77}

Although that question remains critical to any discussion about the ethics of international research, and is indeed discussed at length in other chapters in this volume, it is equally important to address related concerns about fairness in participant selection. One commonly raised objection to international research is that it can exploit a vulnerable population, namely citizens of developing countries, when they are selected for research participation not for reasons related to the scientific question under study but rather because of their easy availability, their compromised position, and their ability to be manipulated by researchers.⁷⁸ To the extent that people living in developed countries are less likely to be exploited, international research often creates “an inequitable selection of research subjects across international boundaries.”⁷⁵ This inequity is further exacerbated when disadvantaged populations from developing countries bear the burdens of research without the opportunity to enjoy the benefits that may result from its completion.

These concerns suggest the need for stringent guidelines to protect populations in developing countries. As the history of participant selection in the United States illustrates, however, adopting an overly protectionist attitude can prevent vulnerable populations from enrolling in clinical trials from which they may benefit. Fifty percent of people in developing countries do not have access to even the most basic drugs, arguably making participation in clinical trials an attractive way to gain access to physicians and medications otherwise unavailable.⁷⁹ Fair selection in this context therefore requires a delicate balance between protection from research harms and access to research benefits, both during the trial and after its completion.

Future Directions

Conceptions of fairness in research participant selection have evolved dramatically during the last 40 years. Ultimately, though, fair selection is just one component in ensuring fairness in the distribution of the burdens and benefits of research across the whole population. Each step in designing, conducting, and concluding a research study marks a moment in which fairness should be considered.⁶⁶ Setting research priorities, developing research questions, and distributing research funding all affect fairness in research by determining what counts as medically or socially beneficial research and who should be the participants in and beneficiaries of such research. A decision to address a disease that affects a large segment of the population, such as heart disease, may compete with studies that address a disease primarily affecting a minority population, such as sickle-cell anemia.

Study design and recruitment also shape the fairness of any research trial. Avoiding scientifically unnecessary exclusion criteria raises the probability that diverse populations will participate in research. Similarly, employing a variety of recruitment mechanisms increases the likelihood that people of different backgrounds will enroll in research. Certain recruitment methods, such as those requiring a computer, may limit access to trials, whereas flyers, classified ads, television commercials, and radio announcements may reach broader segments of the population.

At each stage in a clinical trial, researchers and IRBs should carefully consider the fairness of the study. Admittedly, the federal

regulations offer far less guidance in this area than they do with regard to informed consent. And, to be sure, further conceptual, normative, and empirical work is needed to clarify and address exploitation as unfairly taking advantage of the circumstances, including the vulnerabilities, of particular populations.⁸⁰ Still, despite incomplete guidance and lingering ambiguities, investigators, IRBs, and research institutions must make practical efforts to ensure that research populations are selected equitably and represented proportionally. Any given research study should include people from diverse populations, where *not* scientifically inappropriate, without unduly burdening any particular population. Fairness in research demands nothing less than an ethically justified balance between protection and access.⁸¹

Incentives for Research Participants

History

The practice of paying research participants dates back at least to the early 19th century, when William Beaumont provided Alexis St. Martin with room, board, and \$150 per year for the use of his stomach in physiologic studies. St. Martin had been shot in the stomach and was left with a permanent gastric fistula, providing Beaumont with “access to the stomach and the opportunity to study the action of gastric juices.”¹ Later, Walter Reed offered \$100 in gold to participants in studies involving deliberate exposure to yellow fever. If successfully infected, participants received a \$100 bonus (payable to their family if they died).¹ Although a long-standing practice, payment in research seems to be increasingly common with the growing volume of research conducted today.

Paying research participants, however, remains contentious. Ethical concerns have appeared in the literature since the 1970s and are far from resolved;^{2–11} and the unfortunate deaths of Bernadette Gilchrist, Nicole Wan, and Ellen Roche have called attention to the practice of paying healthy participants.^{12,13} Stories appearing in the mid-1990s about homeless participants in Phase I drug trials conducted by Eli Lilly and Co. raised concerns about offering money and other incentives to the homeless in exchange for research participation.¹⁴ Analogous concerns have been raised with regard to the provision of otherwise unavailable health-care services when conducting research in the developing world.¹⁵ In the United States, advertisements on television and radio, in newspapers, and on the Internet offer money, medications, free medical care, and other incentives in exchange for participation in all types of research. Ads recruit the young and the old, the sick and the healthy. There have even emerged a number of professional re-

search participants, or “professional guinea pigs,” who make a living participating in research. Online ‘zines such as *Guinea Pig Zero* rate research facilities on criteria ranging from the amount of payment to the quality of food, and give potential research participants the “inside scoop” on how to be a successful participant.¹⁶

Core Conceptualization

Exchanging money and other goods for research participation can represent reimbursement or remuneration, compensation for time and effort, a gift or token of appreciation, or a recruitment incentive. These different ways of conceptualizing exchanges have distinct meanings and ethical implications. Here, we use the generic term *payment* to encompass all potential conceptualizations, and we discuss the different ethical implications of various conceptualizations.

Payment serves different purposes and occurs in numerous forms, many of which are nonmonetary. Payment has come in the form of sentence reduction for prisoners, academic credit for students, and toys or movie passes for children. Some studies offer free treatment for the condition under study or for unrelated medical conditions. Most literature has focused on cash payments, for two primary reasons. First, monetary exchanges are identifiable and fungible. Exchanges of health care or access to other studies may be less demarcated and even inseparable from the research. Second, there is a particular concern about offering money in a traditionally volunteer relationship, especially when patients who are ill are involved.^{7,17–19} For any research project, whether health care or other benefits are offered, participants must make the same

type of decision as when money is offered. They must decide whether to accept the risks, benefits, and inconvenience of research participation in exchange for valuable goods. The following discussion thus pertains to payment in multiple “currencies.”

It is important to consider why payment is offered in the first place. First, payment may encourage or allow individuals to perform a needed service. It may aid recruitment by lessening the burden of participation or presenting an opportunity for “profit.” The extent to which payment actually facilitates recruitment, however, is not well documented. Payment is known to facilitate response to surveys, but the relevance of such data to clinical research is uncertain.²⁰ The second reason payment may be offered is to recognize and compensate for the time, inconvenience, cost, or even risk of participation. Rather than paying to achieve recruitment goals, investigators may seek to recognize participants’ contributions and to thank them for it.

Elsewhere we have described three core models for paying research participants: a market model, a wage payment model, and a reimbursement model.³ We will review the ethical advantages and disadvantages of these models, as well as those of an additional posttrial appreciation model.²¹ Table 36.1 presents some core features of each of the models.

Market Model

If the primary purpose of payment is recruitment, the intuitively appropriate model is the market model. This model relies on the principle of supply and demand to decide the amount and type of incentive needed to recruit a sufficient number of qualified research participants in the desired time frame.^{3,22} If research is risky or unpleasant, incentives increase. If research is desirable, as in studies of new medications for diseases for which no treatment existed previously, payment may be low or nonexistent. Likewise, payment may increase or decrease relative to other local studies recruiting similar participants, or it may vary based on the time frame within which studies must be completed. Pay might be contingent on completion of the study or might increase over the course of the study as an escalating incentive. Although money is the paradigm, any “currency” can fit this model. Free physical examinations, medications, or academic credit can all be scaled to meet demand.

Wage Payment Model

The wage payment model regards research participation as akin to unskilled labor for which participants are paid an amount close to the standard hourly wage for other unskilled jobs in the geographic area in which the research is conducted.^{2,3,23} Completion bonuses or increases for inconvenience or discomfort may be employed, but payment is essentially based on the amount participants “work.” Wages can clearly act as incentives; however, the unskilled labor market sets wages, rather than individual preferences or pure market demand, and pay across studies is relatively standardized.

Reimbursement Model

The reimbursement model allows only for reimbursement of expenses actually incurred, based on the idea that research should be “revenue neutral.” This model could be applied in radically different ways. Out-of-pocket expenses such as parking and transportation could be reimbursed. Or research participants could be paid what they are normally paid for their work as reimbursement for wages lost while participating in research. If the latter standard were applied, a homemaker might receive nothing, whereas an executive would receive quite a lot of money for the same contribution to research. However, no participant would profit, supply and demand do not influence payment, and nonmonetary expenses, such as inconvenience or discomfort, are not reimbursed.³

Posttrial Appreciation Model

A fourth model is a posttrial appreciation model in which participants receive a gift or reward upon completion of a study. This model can apply to research with adults, but it is most popular in pediatric research in which the appreciation gift might be a toy or game.^{24–26} Although gifts are not always a surprise, in this model participants are not typically informed of the gift during the consent process or the study. To the extent that investigators keep potential research participants from knowing about the gift during decision making, the gift will not be an incentive to participate; it is a reward for participation. However, as rewards become known to potential participants, either through prior participation or word of mouth, they could also operate as incentives.

Table 36.1
The Four Models of Payment

	<i>Market Model</i>	<i>Wage Payment Model</i>	<i>Reimbursement Model</i>	<i>Posttrial Appreciation Model</i>
Justification for payment	Recruitment of research participants is vital to research; monetary incentives help to recruit the needed research participant pool	Participation in research requires little skill but takes time, effort, and endurance of uncomfortable procedures	Participation in research should not require financial sacrifice by research participants	Participation in research is a valuable service that merits recognition and appreciation
Function of payment	Pure incentive	Working wage	Reimbursement for expenses	Recognition of service
Strategy employed	Payment based on supply and demand; employment of completion bonuses and other end-loaded incentives	Payment based on standard wage for unskilled labor; augmented for particularly uncomfortable procedures	Payment determined by research participant’s expenses; can be payment for lost wages or for other expenses incurred	Goods of any kind offered to research participants after participation is finished; research participants not informed at time of consent

Ethical Concerns

These four models represent the essential conceptualizations surrounding the payment of research participants. Some may propose further divisions, and actual practice may employ variations or combinations;²¹ however, considering each model individually allows isolation of ethical concerns associated with each strategy. Table 36.2 presents the principal advantages and disadvantages of the four models.

Coercion and Undue Inducement

The principal concerns cited in the literature on payment relate to the possibility of coercion or undue inducement.^{6,7,10,11,22,27} Unfortunately, these terms are often confused or used inappropriately. Coercion is defined by the presence of a threat of harm or force that could make the coerced person worse off in some way.²⁸ Undue inducement, on the other hand, is not associated with threats but with offers.^{11,30} What makes certain offers undue is a subject of significant debate. We suggest that offers are unduly influential if they are so attractive that they lead individuals to participate in research studies to which they would normally have important objections.

True and morally problematic coercion in research is a rare phenomenon. Few investigators overtly threaten to make anyone worse off for refusing to participate in a study. Coercion may be an important concern in research with prisoners or other captive populations, in which refusal to participate in research could be met with punishment or retaliation. Though technically possible whenever a power differential exists between investigator and participant, most institutional review boards (IRBs) scrupulously prohibit threats of harm for refusal. People may sometimes fear that they will be treated worse for not participating in research, even when no threat exists. Such perceived coercion is a crucial consideration, but neither perceived nor real coercion has any direct or consistent connection to payment because payment is never (or should never be) a threat itself. In some cases, refusal to participate in a paid study could indirectly result in harm. For example, if the spouse of someone refusing to participate in a paid study threatens the refusing spouse, payment might facilitate third-party coercion, but the investigators themselves could not be charged with coercion. In a doctor-patient relationship, payment may actually reduce perceived coercion by transforming the exchange into one that is less personal, and unrelated to medical care.

Some writers have discussed omissive coercion, based on the concern that society “threatens” to remove or does not provide the

Table 36.2
Potential Advantages and Disadvantages of the Four Models

Model	Advantages	Disadvantages
Market	<ul style="list-style-type: none"> • Ensures sufficient research participant pool in desired time • Increases likelihood of research participants completing the study • Research participants profit from performing a social good • Lessens financial sacrifice of participation 	<ul style="list-style-type: none"> • High offers may be unduly influential • May provide an incentive to remain uninformed • May provide an incentive to conceal information • May particularly influence poor populations • May lead to recruitment of research participants with no concern for the ends of research • Leads to interstudy competition based on research participant payment • Commodifies research participation
Wage payment	<ul style="list-style-type: none"> • Offers profit commensurate with other unskilled jobs • Standardizes payment across studies • Lessens financial sacrifice of participation • Ensures minimum wage for paid research participants • Research participants may profit performing a social good 	<ul style="list-style-type: none"> • May not recruit sufficient research participant pool in desired time • Presents profit only to poorer populations • Requires financial sacrifice for wealthier populations • Commodifies research participation
Reimbursement	<ul style="list-style-type: none"> • Precludes undue influence from money • Provides no incentive to conceal information • Provides no incentive to remain uninformed • Does not preferentially induce poorer populations • Lessens financial sacrifice of participation 	<ul style="list-style-type: none"> • May not recruit a sufficient research participant pool in desired time • Requires financial sacrifice for uncompensated time <p><i>If time is reimbursed:</i></p> <ul style="list-style-type: none"> • May lead to targeting poorer populations • May increase the cost of conducting research • Pays differentially for the same function
Posttrial appreciation	<p><i>If hidden:</i></p> <ul style="list-style-type: none"> • Allows for profit with no potential for undue inducement • Rewards a valuable service • Expresses appreciation without undermining volunteerism <p><i>If not hidden:</i></p> <ul style="list-style-type: none"> • Rewards a valuable service • Expresses appreciation without undermining volunteerism • May allow for sufficient recruitment within time goals (if treated as a recruitment device) 	<p><i>If hidden:</i></p> <ul style="list-style-type: none"> • May not recruit sufficient research participant pool in desired time • May still require financial sacrifice • No basis for determining the magnitude of “reward” <p><i>If not hidden:</i></p> <ul style="list-style-type: none"> • No constraints on reward may lead to undue inducement • May lead IRBs to ignore potential power of the offer • Does not ensure volunteerism, which is its primary goal • No basis for determining the magnitude of “reward”

means to obtain certain basic goods unless those individuals participate in research.³¹ Although this is a legitimate concern, investigators' responsibility for background social conditions seems minimal, and calling this situation coercive seems a misnomer. Individual vulnerabilities resulting from societal failures are crucial considerations, but we believe these are really concerns about possible exploitation, not coercion. We discuss this further below.

Undue inducement is the predominant ethical concern in the literature and the focus of the sparse guidance in the U.S. Common Rule, as well as guidance issued by the Food and Drug Administration (FDA), the Office for Human Research Protections (OHRP) in the Department of Health and Human Services, and the Council for International Organizations of Medical Sciences (CIOMS).³²⁻³⁵ Yet there is significant ambiguity and disagreement about what constitutes undue inducement and how to avoid it.^{22,30,36,37} The classic scenarios involving undue inducement are studies that pose significant risk of harm and offer considerable incentives to research participants who often have limited means and opportunities. For example, a trial that administers general anesthesia to healthy research participants may pay quite a bit of money and involve significant risk. A challenge study investigating psychiatric disease may provide psychiatric treatment in exchange for the risk of a research challenge and enroll individuals with little or no access to health care. Although all concerns about undue inducement refer to attractive offers, different reasons have been put forth regarding when and why such offers are problematic. Some accounts have to do with the quality of judgment or voluntariness of decisions, whereas others focus on risks to research participants or to scientific integrity.

Several writers have expressed concern about the effect of payment on the quality of judgment or decision making.^{6,33,37,38} There are two ways that a participant's decision might potentially be compromised in the setting of significant inducement.¹¹ First, a research participant may ignore the risks of a study. A homeless man may be so eager to make \$500 that he neglects to read the consent form or ignores a research coordinator's description of study risks. Strictly speaking, his decision might be voluntary, but it would be uninformed and based on incomplete understanding. However, even though data show that informed consent is less than adequate in many ways, there are no data that show that payment exacerbates these inadequacies. In fact, some data suggest that it does not.³⁸ Furthermore, if the worry is about understanding, the more immediate remedy would be to take extra steps to ensure that participants are well informed rather than to ban payment for research participation.^{30,39}

Other concerns about the quality of judgment have more to do with the voluntariness of decisions.¹¹ The disagreement over this concern can hardly be understated. Some writers worry that large incentives may control individuals' decisions in a way that is morally objectionable,⁶ though exactly what constitutes "control" over decisions is unclear. Others have argued that it is absurd to talk about reducing voluntariness by giving someone what they want.^{22,27} After all, we rarely say that people offered a high salary for a job are being unduly induced. The fact that people "cannot refuse" an attractive offer speaks to the appeal of the offer and not to nonvoluntariness. Although we do not dismiss all concerns about undue inducement, we agree with the view of those who argue that voluntariness is not the right way to frame this concern.

Most worries about attractive offers likely stem from the view that money and other incentives ought not to be the only reasons

that an individual participates in research. At the heart of research ethics is a moral tension about "using" a person's body for research, rooted in the Kantian prohibition against treating other people merely as means. Many believe that research participants ought, in some way, to accept the ends of the research as their own.⁴⁰ However, there are deep questions about this view.³⁰

First, why are monetary or other goals advanced by payment illegitimate compared with the goals of the research? Second, Kantian theory particularly prioritizes respect for individuals' ability to determine their own values and to make autonomous, rational decisions. Although concerns about payment compromising voluntariness seem misdirected, using forms of payment to overcome important values that people hold is potentially problematic. A rich conception of respect for persons as autonomous agents, we believe, does include sensitivity to individuals' fundamental values and strong preferences. It thus entails a certain responsibility to allow people to live lives in accordance with their values and preferences, a responsibility that may be incompatible with making certain offers that knowingly challenge those values.

Consider, for example, a safety study of an investigational blood substitute that is derived from human blood but does not have to be matched. Investigators are conducting this study in an area in which a very high proportion of the population are Jehovah's Witnesses. Despite the fact that the new blood substitute is not whole blood, the use of this agent would constitute a major violation of this population's religious beliefs. Because investigators know that few people in the area will want to take part in this study, they decide to offer \$20,000 to participants, knowing that this amount of money will likely lead enough Jehovah's Witnesses to participate in the study because of the promise of significant financial reward.

We do not assert that Jehovah's Witnesses who would make this choice would be acting in an irrational, uninformed, or involuntary manner; nor would we necessarily criticize them for making the choice to enroll. We do, however, have deep concerns that the practice of offering such a reward with the aim of encouraging people to overcome important and deeply held values fails to respect those persons and their values in an important way. For the same reasons that many would suggest conducting the study in an area in which fewer people would find it objectionable, we submit that raising the offer to an amount that might induce people to set aside deeply held values in order to recruit an adequate sample is not compatible with respecting participants.

Other writers reduce the concern for undue inducement to a concern about risk to participants.^{7,30} Emanuel, for example, argues that undue inducement cannot occur in an appropriately approved study, because risks should not be unreasonable relative to the benefits for participants or society.³⁰ It does seem that essentially risk-free studies do not raise concerns about undue inducement; however, even in appropriately approved studies, risk-based concerns remain relevant for three reasons. First, IRBs must make determinations based on what reasonable people consider to be acceptable risks. Potential participants, however, lie on a spectrum from extreme risk aversion to extreme risk tolerance. Any given level of risk will surely carry different meanings for different participants. Second, actual risks vary among individual participants, and some risks are idiosyncratic. Third, risk tolerance may be an important aspect of individuals' values and preferences. Large amounts of payment at the end of the spectrum of approvable risk might induce individuals who are actually quite

averse to risks, or more susceptible to risks, to participate in studies that are otherwise problematic for them. For these reasons, concerns about undue inducement cannot simply be dismissed based on an IRB's finding that the level of risk is reasonable.

Another concern about undue inducement is that individuals, enticed by large offers, may conceal information about themselves that might otherwise disqualify them from studies (e.g., past medical history or medications). Similarly, they may be reluctant to report adverse events out of fear that they may be removed from the study and not receive their payment. The concern is that such misrepresentation may expose participants to increased risk or that it may compromise the data.^{3,6,27,32,36,39} One study suggests that people are unlikely to hide information in studies they perceive as risky but may be more likely to misrepresent themselves in lower-risk studies.⁴¹ The degree to which these concerns are real is largely unknown, and they warrant further empirical investigation and attention.

In sum, we argue that undue inducement may occur when offers are so attractive that they lead individuals to participate in research studies to which they would normally have strong objections, based on risk or other important values or preferences. This account has some similarities to that of Grant and Sugarman.³⁶ Importantly, a decision to participate does not have to be irrational or less than fully voluntary in order to be unduly induced. Rather, the key determinant is that the activity is one that participants find objectionable in a significant way. The proper focus of scrutiny is thus more on the research, and the likely participants, than on payment itself. Although the incidence of undue inducement is an empirical question, relatively few people are likely to have true, strong objections to most research projects, making real undue inducement a rare occurrence. IRBs should nevertheless consider its possibility—especially at the end of the spectrum of approvable risks and when people are likely to have strong values or preferences that conflict with the research. At the same time, IRBs also cannot avoid all potential cases of undue inducement, because strong objections to research may be very individual and idiosyncratic and therefore hard to predict.

On any account of undue inducement, the degree to which it is a concern varies by payment model. Because the market model contains no constraints on incentives, those most concerned about undue inducement will likely find the market model problematic. The reimbursement model, in which only actual expenses are reimbursed, and the posttrial appreciation model, in which the reward is not offered at the time of consent, do not raise the possibility of undue inducement. The wage payment model limits concern about undue inducement by capping, though not eliminating, the degree of incentive provided to participants and offering an inducement commensurate with other unskilled jobs available elsewhere. Although wage-like amounts of money may possibly be more attractive to low-income participants, the amount is unlikely to cause many people to compromise deeply held values or preferences.

Justice

Two considerations of justice are relevant when offering payment for research participation. First, justice requires that benefits and burdens of research be distributed equitably; therefore no population should bear a disproportionate burden. Second, justice requires that similar people be treated similarly.^{27,29}

Because incentives may be more attractive to poorer individuals, there could be overrepresentation of poor individuals in research.^{2,3,39} If so, an already disadvantaged segment of the population could bear a disproportionate share of the research burden. On the market model, it is easy to meet the “price” of poor people. On the wage payment model, unskilled wages are likely to be preferentially attractive to the poor. Even the reimbursement model might preferentially attract poorer research participants, as reimbursement is likely to provide more meaningful reductions in opportunity costs for poorer research participants.³ Similarly, the attractiveness of gifts, if known at the time of consent, may differ for members of different socioeconomic classes.²⁴

How much should we worry about differential effects of payment according to socioeconomic status, and how much is this concern borne out in practice? Wilkinson and Moore clarify the distinction between the question of group-level justice, which they term “pattern equity,” and concerns about exploitation, which involves inappropriately taking advantage of the predicaments of others. The pattern equity concern refers to the distribution of burdens and benefits across the population of potential research participants.²⁷ Most importantly, they argue, many paid research participants view participation and payment as beneficial, so it is strange to speak of a maldistribution of burden. In addition, poverty and the consequent attractiveness of research participation are problems with the way society distributes goods, not necessarily problems with the conduct of research.²⁷ Payment may even be a way to advance justice by increasing enrollment of underrepresented groups in research.^{36,37} Real ethical worries about enrolling poor participants are likely concerns about exploitation rather than pattern equity.

The second demand of justice, that similar cases be treated similarly, conflicts with concerns about pattern equity because one solution to pattern equity concerns is differential payment to different groups.^{2,3,36} Treating similar people similarly is arguably more important than pattern equity.

The concerns and demands of justice have different implications for various payment models. A market model could allow vastly different amounts of payment per participant or per study, depending upon supply and demand, and could allow for preferential recruitment of any type of person. The wage payment model is largely premised on the notion that similar work should be paid similarly, but low, standardized payments could preferentially attract poor people.^{2,3,36,39} A posttrial appreciation model might offer the same gift to each participant within a study but might not standardize across studies and could preferentially induce people with greater need or desire for the gift. Contrary to the assertions of Dunn and Gordon,³⁹ it seems that the only way to be sure to avoid preferential recruitment of poor people (and its consequent impact on justice and scientific integrity) would be to employ a strict reimbursement model involving different payments to every person in the study.

Exploitation

An important concern, often confused with and sometimes overlapping with concerns about undue inducement, is the potential for payment to be exploitative. Concerns about exploitation are often raised when investigators conduct research in developing countries or enroll poor individuals or sick patients who do not

have access to care. Though commonly discussed, the word *exploitation* is often loosely used, and there remains debate about exactly what constitutes exploitation. Alan Wertheimer argues that exploitation occurs in circumstances in which “A takes unfair advantage of B.” Simply put, unfair-advantage exploitation involves an unfair distribution of harm and benefit between the two parties, a possibility even in cases when both parties benefit.⁴² Wilkinson and Moore argue that payment for research participation is not exploitative in this sense, because it is not clear that research participants ought to be paid more. They also note that imbalances in benefits exist in almost every type of transaction.²² Furthermore, they claim, as Emanuel does, that the obvious fix to unfair exchange would be to pay participants more, not less.^{22,30} This solution illustrates an important tension between unfair-advantage exploitation and undue inducement, a tension clearly recognized in the *IRB Guidebook* in its discussion of payment to prisoners. Prisoners represent a population with few options for making money; thus they have the potential to be exploited by being significantly underpaid for their work. On the other hand, any offer to a prisoner is likely to be exceedingly attractive and eagerly accepted, resulting in concerns about undue inducement.³²

Although paying more may be appropriate in some situations, it may not always eliminate exploitation. Raising payment when recruiting and paying research participants with restricted options may make the transaction fairer in strict economic terms, but it ignores the potential incommensurability of payment with certain values that people hold. In this sense, the concern for exploitation closely parallels and may magnify concern for undue inducement. Wilkinson and Moore counter that investigators are simply not responsible for the background conditions that, often unjustly, leave people in such a state of need. Further, denying paid research opportunities will only exacerbate already existing needs²² (see Chapter 20).

Not surprisingly, different payment models address concerns about exploitation differently. The market model dismisses it as a concern because individuals are free to negotiate their price and investigators the amount they are willing to pay. Yet in the market model, poor research participants could still be exploited by being paid very little because of their weak bargaining position. A wage payment model sets a floor and a ceiling on the amount research participants are paid, limiting how much the situation of particular research participants can be exploited. Yet setting the limit too low may be taking advantage of people with few opportunities. Importantly, prohibiting payment to such research participants in the interest of “protecting” them is also exploitative, if one believes that participants provide a valuable service that can warrant some form of payment.^{3,22,30}

Commodification

In an often cited but now dated piece, Max Wartofsky likens the payment of research participants to prostitution. Just as sex ought not to be traded, Wartofsky argues that one’s body is not an appropriate “commodity” for use in research.⁴³ Similar arguments have been used against paid organ donation and surrogacy—assertions that these practices fail to respect or value human bodies in the appropriate way.⁴⁴ Providing incentives for any service involves, to some extent, “commodifying” people. Paying

for research participation and the accompanying risks does not seem inherently different from many other paid transactions accepted as normal parts of life. Modeling, sports, police work, and firefighting, for example, all involve the use of human bodies, and some entail significant risk. Furthermore, research participation is not as intensely personal as sexual intimacy or pregnancy. As with undue inducement, however, commodification may be a concern when individuals have important objections to research participation.

A related view conceptualizes research participation as an instance of gift giving.^{9,18,19} In his discussion of blood donation, Richard Titmuss argues that preserving gift giving is an important part of our social structure, and that commercialization can erode the social fabric of mutual dependency and altruism that is important for societal flourishing.¹⁹ We find these arguments unpersuasive with regard to payment for research participation. First, anyone can refuse to accept payment; volunteering for research without pay is still an option. The personal value of volunteering may even increase for some if payment is offered and refused. Second, payment does not necessarily obviate altruism. It may facilitate gift giving by making sacrifices less demanding. Finally, any potential harm to the social fabric should be weighed against the benefit of quality research with adequate numbers of participants. Empirical research could play an important role in assessing the effect of payment on total rates of participation, as well as on important elements of the social fabric.

If preserving volunteerism is the major concern, the market model might be particularly offensive. The wage payment model may enable gift giving for some, but treating research participation as a job may be viewed as insulting. The reimbursement model is unlikely to be objectionable, and posttrial gifts may be superfluous but not offensive.

Incentives for Risk

A common theme throughout the literature on payment, and echoed within national and institutional guidance, is that payment should not compensate for risk.^{7,45} In particular, researchers conducting risky studies should not offer more money than those conducting less risky studies involving similar effort or inconvenience. Some justify this view by arguing that risk simply ought not to be incentivized.⁷ Others have argued that allowing risk-based payment could reduce investigators’ incentive to minimize risks.³ On the other hand, proponents of payment for risk argue that prohibiting such payments constitutes simple, unjustified paternalism. More compensation is often offered for risky jobs, and prohibiting payment for risk in research fails to respect people’s ability to make decisions about acceptable levels of risk.²²

Although disagreement exists about whether risk ought to figure into payment amounts, there is widespread agreement that IRBs ought to consider whether the balance of risks to potential benefits of a given project is reasonable independent of payment.³⁰ Payment will thus not *make* any study approvable. Whether incentives can or should be offered to make otherwise approvable, but riskier, studies more attractive to potential participants is a matter of significant disagreement.

Oponents of risk-based incentives will find the market model most offensive, as payment could be increased until it overcomes any aversion to risk. The wage payment model does not base payment on risk, focusing instead on the nature of the “work”

research participants do. Some may argue, however, that risk is an important determinant of the value of “work.”

Special Populations

Certain populations present particular concerns regarding payment for research participation. Prisoners and other captive populations may be susceptible to coercion. Worries about justice and exploitation focus on the poor and homeless, as well as on participants in developing countries. Two populations, however, raise unique concerns: patients and children.

Patients

It is sometimes assumed that only healthy research participants are paid for participation in research and not patients with the condition being studied. This belief is simply incorrect. A review of protocols at major academic institutions and independent IRBs showed that over half of paid studies involved patients.⁴⁶ Some writers, nevertheless, argue that patient-participants differ from healthy research participants because they are particularly vulnerable and may benefit medically from participation.^{17,47} Patients' vulnerability stems either from an inability to distinguish between clinical care and research⁴⁸ or from a power differential between patients and investigators. Payment does not exacerbate either source of vulnerability in principle.³ Paying patients may in fact call attention to activities not designed to advance their medical interests by signifying that investigators are not functioning only as physicians providing medical care. Payment could also depersonalize the exchange, making it easier for patients to refuse and putting them on more equal bargaining terms with investigators. Though noncash “payment” by means of free or reduced-cost medical treatment may be thought to be more appropriate than other currencies, health-related offers have the potential to exacerbate any therapeutic misconception.

That patient-participants may already receive benefits from participating in some research should not warrant a prohibition of payment to patients. Many studies involving patients offer no potential for direct benefit. It seems odd to assert that patients ought not to receive payment in these cases while allowing payment for healthy participants. And although studies offering potential benefits may not need to pay to recruit patients, it is unclear why payment would be unethical.

Children

Payment certainly magnifies ethical challenges involved in conducting research with children. Several key factors make payment challenging in this setting. First, parents are the primary decision makers, but they are expected to make research decisions based primarily on children's interests. The greatest worry is that parents will use children as a source of revenue.⁴⁹ Consequently, payments to parents are often discouraged or limited. Incentive payments, in particular, have been flatly banned in Europe, a position echoed in a U.S. Institute of Medicine (IOM) report in 2004.^{49,50} The extent to which this concern is well-founded, however, is unclear. In addition, parents are more likely than the child to incur opportunity costs, and having a child participate in a study can be quite inconvenient. Wendler et al. argue that carefully calculated compensatory payments to parents for inconvenience and time, if calibrated to the resources of the least well-off families

among potential participants, are acceptable and unlikely to result in significant distortions in parental decisions, even if they result in some profit. Concerns about profit-minded parents, they argue, are also reduced by the strict limits on allowable risk in pediatric research regulations.²⁴ The IOM report, on the other hand, insists that compensation cover only actual expenses.⁴⁹ Other groups, such as the Therapeutics Development Network of the Cystic Fibrosis Foundation, support a standardized payment schedule resembling the wage payment model that likely entails small profit for some participants.^{49,51}

Paying children directly is another approach, and these are not mutually exclusive. Knowing how to pay children is difficult, particularly because children of different ages view payment differently, and children's roles in research decisions are often unclear. The American Academy of Pediatrics (AAP) recommends a posttrial appreciation model, suggesting that gifts not be disclosed at the time of consent.²⁶ This model allows giving children gifts that only they would appreciate, such as a toy or a stuffed animal. By not disclosing the gift at the time of consent, investigators make sure that children do not give their assent because of the gift. Wendler et al. have questioned the legitimacy of this method, asserting that parents and children are quite likely to be aware of posttrial gifts. They also point out that this method may lead IRBs to ignore the potential power of the gifts that are offered.²⁴ The 2004 IOM report also supports up-front disclosure of any payment, and it is known that many institutions ignore the AAP's approach.^{25,49}

When and how to pay children and their parents for research participation merits further empirical and conceptual study. Wendler and colleagues suggest that the acceptability of the payment should not depend on ignorance of payment at the time of consent, and that it may be appropriate to pay children and adults differently when both populations are enrolled in the same study. They also suggest using forms of payment that are unlikely to entice adults, avoiding large lump-sum payments and putting the money in an account to be accessed by the child at an older age.²⁴ The IOM report concurs on many levels. It also recommends that institutions develop policies on this issue and explicitly allows for “reasonable, age-appropriate compensation based on the time involved in research that does not offer the prospect of direct benefit.”⁴⁹ The primary discrepancy between these sets of suggestions seems to be tolerance for parental profit. Although there is no principled reason why parental profit should be prohibited, empirical work could help to determine whether the concerns with parental profit are borne out in practice.

Other Concerns

Additional concerns are practical in nature but carry significant ethical implications. As mentioned, the effect of payment on the quality of scientific knowledge is an important question warranting further investigation. Other practical concerns also have ethical implications. The market model, for example, could lead to competition among investigators for research participants, driving up research costs and potentially compromising the ability to recruit adequately for projects with smaller budgets. These outcomes are speculative and subject to dispute.^{3,27} Several writers have asserted that the wage payment model would require regulations more in keeping with other types of employment. For example, unionization, overtime, and health benefits may be needed if re-

search participants are treated as workers.⁵² Although the extension of the employment analogy is helpful in certain respects, such as the need for safe working conditions, most individuals do not participate in studies on a long-term basis or frequently enough to justify being considered employees warranting health insurance coverage or overtime.

Empirical Data

Though deep conceptual disagreements exist, the controversy over payment is perpetuated by the paucity of empirical data about the extent to which ethical concerns are borne out in practice.

Perhaps the most basic question is simply how payment affects recruitment. Are monetary incentives more effective than medications or health services? To what extent do completion bonuses retain participants? What amount of payment will maximize recruitment? These questions are largely unanswered. Conversations with representatives from contract research organizations (CROs) and private Phase I drug development units suggest that they have conducted local studies in developing their own policies, but these data are proprietary. Response rates to surveys are affected by both the amount and timing of payment.⁵³ However, few studies have looked explicitly at the effect of incentives in clinical research. Korn and Hogan showed some effect of increasing academic and small monetary rewards for participation in hypothetical experiments of varying types, but the effects were relatively small. The aversiveness of the intervention being tested had a much more important effect on willingness to enroll than the incentive offered.⁵⁴ In sum, we know very little about how payment affects recruitment for different types of clinical research.

Several studies have attempted to measure paid research participants' motivations for participating in research. Bigorra and Banos found that healthy participants from the general population were likely to report solely monetary reasons (90%) as the motivation to participate in research, in contrast to healthy medical students, who were more likely to report other motivations as primary (only 5% reported money as a primary reason).⁵⁵ Other studies have found that healthy research participants join research primarily for money (78.4% to 93%).^{56,57} Van Gelderen et al. found that younger research participants seemed more interested in monetary payment, and older research participants in free medical examinations.⁵⁷ Older studies with healthy subjects reveal similar variation in the importance of money.⁵⁸⁻⁶⁰ Aby et al. asked individuals participating in Phase III studies of allergy and asthma interventions to rate different potential motivations on a five-point scale of importance to their decision. Participants rated all "altruistic" reasons highly, and payment ranked fifth among nonaltruistic reasons. Health-related reasons were consistently more important.⁶¹

Conclusions from these studies are limited. First, only Aby et al. interviewed anyone other than healthy research participants. Second, the studies have important methodological differences and flaws. In many cases, people were asked only for their primary motivation to participate; there are surely multiple reasons why people decide to join a study. Only the Novak and Aby studies asked about a range of motivations. And in none of these studies is it really apparent how payment factored into participants' actual decisions. Most importantly, none assessed what types of trade-offs research participants are willing to make for varying amounts

or types of pay. This information, however, is crucial to assessing undue inducement.

Halpern et al. attempted to assess the effect of payment on willingness to participate.³⁸ They asked individuals eligible for participation in hypertension research to rate their willingness to participate in studies involving varying amounts of payment, likelihood of adverse effects, and chance of placebo assignment. They found that payment did increase willingness to participate at every level of risk, but the effect of payment remained relatively constant over different levels of risk. Thus, they argued that payment did not disproportionately affect willingness to participate in higher-risk studies. It is unclear, however, exactly what influence one would expect payment to have and what level of willingness to participate should be expected at any given level of risk.

Another study attempted to ascertain what level of payment adolescent asthma patients and their parents found to be appropriate in different types of hypothetical asthma studies.⁶² Researchers found, not surprisingly, that adolescents considered as "fair compensation" lower levels of payment than their parents did, as did participants with lower versus higher income. Participants' estimates of fair compensation were more likely to be greater than actual compensation in low-risk studies. The study shows that expectations regarding reasonable levels of payment differ based on the nature of the study, the socioeconomic situation, and age (parent vs. adolescent) of the potential participant.

Other empirical questions in need of further study are the effect of payment on informed consent and the extent to which payment leads to lying or concealing information in order to prevent exclusion or discontinuation from studies. Bentley and Thacker attempted to address both questions in a study involving U.S. pharmacy students.⁴¹ They found that payment did not impact participants' understanding of risks entailed by hypothetical studies. Payment appeared, however, to increase participants' willingness to conceal relevant facts about themselves in low-risk studies, but not their willingness to report adverse effects. The generalizability of this study, however, is limited in that pharmacy students are likely to have a more sophisticated understanding of research than the general public and may not be the best population in which to test the effect of payment on informed consent.

Other work has focused on institutional policies and practices regarding payment. In our study of U.S. research institutions, most endorsed the notion of payment for time, travel, and inconvenience; there was less agreement about payment for risk (31%) or as an incentive (58%). Few institutions (25%) had any prescribed, standardized method of determining when and how much to pay research participants; most IRBs and investigators make decisions with little substantive guidance. Moreover, few institutions track studies that offer payment. Institutions generally require that payment be explicitly described in consent forms, typically in a separate section, and that payments be prorated if individuals withdraw. And institutions usually pay healthy participants and patient-participants similarly.⁴⁵ A 2002 review of policies for payment of children revealed a significant division among institutions with respect to the AAP's recommendation that payment not be mentioned at the time of enrollment in the study.²⁵

A review of protocols at major academic institutions and independent IRBs demonstrates several important practice trends with regard to payment.⁴⁶ First, there is variability, within and

across institutions, in the amount offered for particular procedures, with little rationale given in protocols or consent documents for how payment is determined. Patients are paid for participation in many types of studies, including both potentially therapeutic Phase II and III studies and clearly nonbeneficial biologic or physiologic studies. Finally, although the range is wide, the amount of payment offered was usually relatively modest (median = \$155; range \$5 to \$2,000).

Policy Implications

Though contentious, payment to research participants is common and takes many forms. On the simplest level, payment enables and rewards individuals for making a valuable contribution to medical science. Prohibiting payment seems unnecessary and inappropriately paternalistic.

Because paying research participants has important ethical implications, there is a need for policy guidance. Existing data show that research participants are paid on a haphazard and inconsistent basis. In the United States, a national policy or set of guidelines with more substance than those currently in place, and which promotes standardization while allowing appropriate variation according to local conditions, would be helpful to investigators and IRBs. In the absence of a national policy, individual institutions might develop local policies to promote internal consistency and guide investigators and IRB members. Explicit attention to research regarding children and patient-participants should be included.

We believe that the wage payment model most effectively balances the needs to recruit and protect research participants. This model recognizes that payment may be one appropriate consideration in a decision to participate in research and compensates research participants at a level similar to other jobs requiring similar levels of skill, effort, and inconvenience. It also reduces concern about undue inducement and provides standardization within and across studies, reducing competition between investigators and avoiding further escalation in research costs.³

Unanswered Questions

Policy formulations are difficult to make because of currently unanswered conceptual and empirical questions. Deeper conceptual analysis of exploitation is warranted, particularly the tensions between exploitation and undue inducement. Another important conceptual question is the legitimacy of treating research participation as a job. Many are uneasy about the wage payment model precisely because it treats research participation as a form of unskilled labor. Yet why research participation is or should be different is unclear. More analysis of the ethical acceptability of providing incentives to children and their parents is also needed, as there is divergence within the field and a small body of literature on the topic.

Perhaps the most immediate need is for careful empirical work on issues related to payment at both institutional and individual participant levels. There is a surprising lack of institutional data tracking studies and participants, resulting in very little information about the demographics of the research participant

pool. We do not know who participates in studies or how paid research participants differ, if at all, from unpaid participants. The percentage of studies that pay participants, how much of the research budget is used, and the range of incentives employed in different regions are important data in assessing the large-scale impact of payment practices.

We also know little about how payment affects decisions to participate or to refuse participation in research studies, and what types of trade-offs research participants make for various types or amounts of payment. There are no data on whether paid research participants understand less about the studies in which they actually enroll than unpaid participants, and it is unknown how often research participants misrepresent their health status to meet eligibility criteria or to remain in paid studies if they experience adverse events. Finally, though we have argued that there is no inherent reason to treat patients and healthy participants differently, it would be valuable to study whether payment exacerbates or reduces any vulnerability that patient-participants might have.

Recruiting Research Participants

Clinical research promotes social value by means of producing scientific knowledge that can lead to improvements in public health and medical care. The social value that justifies clinical research also justifies using techniques of recruitment to enroll eligible participants in research protocols. However, recruitment strategies pose ethical issues insofar as they threaten to distort the physician-patient relationship, exploit potential research participants, interfere with informed consent, or violate confidentiality or privacy. As compared with study design and informed consent, participant recruitment has received relatively little attention in the bioethics and medical literatures. It is an important topic because recruitment techniques represent the initial communication or contact between potential participants and investigators or other members of the research team, which may influence participants' understanding of research and the voluntariness of their participation.

This chapter will address three ethical issues in the recruitment of research participants: (1) the role of physicians in recruiting their own patients for clinical research; (2) respecting confidentiality and privacy in the recruitment process; and (3) the use of advertisements to recruit potential participants. I will focus here mainly on the recruitment of "patients"—that is, individuals with a disorder under investigation. Recruitment of patients is ethically complex because research participation involves a status change from being a patient with a given medical condition, often seeking treatment in the context of clinical trials, to being a research participant in a study aimed at developing generalizable knowledge. Recruitment messages and interactions can either clarify or confuse the ethically important differences between medical care and clinical research.

Recruitment by Treating Physicians

Patients are recruited for clinical research by a variety of mechanisms. They may be referred by their treating physician to researchers conducting a study relevant to the patient's medical condition; they may respond to advertisements for clinical research in newspapers, on television or radio, in advocacy group publications, or posted in public areas; or they may learn about available research by examining Internet web sites. In addition, physician-investigators employed by academic medical centers traditionally have recruited their own patients for enrollment in clinical research. In recent years patients have increasingly been recruited by community physicians to participate in industry-sponsored clinical trials.^{1,2} Although this latter practice of treating physicians recruiting their own patients for research in which the physicians are involved is widely accepted and probably necessary to maintain adequate enrollment in valuable clinical research, it raises ethical questions that deserve careful consideration.

Historically, clinical research has been conducted in the context of the physician-patient relationship.³ The ethos of scientific medicine has made the activities of medical care and clinical research seem inextricably and properly connected.⁴ Prior to the late 1960s, physician investigators typically saw no ethical problems in enrolling their patients in clinical investigations without obtaining informed consent.⁵ Recognition of the ethically significant distinction between therapy and research has led to the understanding that there is a potential conflict of roles and role obligations between acting as a treating physician and acting as an investigator.⁶ The treating physician is devoted to promoting the medical best interests of his or her patients; the investigator is devoted to

producing generalizable knowledge about well-defined groups of patients. In some cases, research participation can be seen as promoting the medical best interests of a particular patient, for example, when the patient has failed to respond to available standard therapies and has a reasonable prospect of receiving medical benefit from an investigational treatment available only in the context of a clinical trial. In many cases, however, research participation will not serve the medical best interests of patients.

It does not follow that recruiting patients for research that is not likely to be medically beneficial (for some or all participants) is unethical. The question remains whether it can be ethical for a treating physician to request his or her patient to consider enrolling in a study when research participation does not offer the patient a prospect of net medical benefit that is as good as or better than standard medical care. It would seem that under these circumstances, loyalty to the best medical interests of one's patients would preclude a treating physician from inviting his or her patient to enroll in research. Recruitment is only one dimension of this issue of role conflict; the responsibility to monitor the condition of enrolled participants poses tensions between the duty to care for patients and the commitment to complete valuable research.

One response to this problem is to invoke the principle of clinical equipoise as a guide to when it is ethical for treating physicians to enroll their own patients in clinical research.⁷ As long as there exists uncertainty or an honest disagreement within the expert medical community between the experimental and control treatments being evaluated in a randomized clinical trial, then physicians can maintain their therapeutic obligations to their patients when inviting enrollment in the trial. The duty of competent medical care and enrollment in a clinical trial are alleged to coincide when clinical equipoise obtains.⁸

Apart from theoretical and practical difficulties with clinical equipoise (see Chapter 24), this solution to the problem fails for two reasons. First, it applies only to randomized clinical trials. Clinical equipoise has no bearing on clinical research that is not aimed at evaluating treatments. One might argue, accordingly, that treating physicians should not be permitted to recruit their patients for "nontherapeutic" research. This, however, would make it difficult, if not impossible, to conduct valuable studies aimed at improving the understanding of rare diseases in which the only available and competent investigators and eligible patients are those who stand in a therapeutic physician-patient relationship.

Second, clinical trials that satisfy the principle of clinical equipoise will often include research procedures such as blood draws, lumbar punctures, and biopsies that are aimed at determining participant eligibility, characterizing the study population, or measuring outcomes. These procedures carry some degree of risk without any compensating medical benefits to the enrolled participants. It is difficult to see how recruiting patients for research containing such nonbeneficial components is compatible with the obligation of the treating physician to always promote the medical best interests of the patient.

This ethical problem is also recalcitrant to a procedural solution by means of review and approval by an institutional review board (IRB). Competent independent review will endeavor to minimize risk to participants and determine that any risks not compensated by medical benefits are justified by the anticipated value of the knowledge to be gained from the research. Nevertheless, this will not guarantee that research participation is in the best

medical interests of patients who are recruited by their treating physicians, leaving the problem of divided loyalties intact.

We seem to be faced with a dilemma. On the one hand, precluding treating physicians from recruiting their patients would greatly hamper the conduct of valuable clinical research. On the other hand, permitting treating physicians to recruit their patients into clinical research often appears to violate the fundamental norm of medical ethics—prescribing unwavering loyalty of treating physicians to the best medical interests of their patients. There is no escaping the problem of divided loyalty when treating physicians recruit their patients for clinical research (and monitor them during research participation). Nonetheless, I suggest that the problem is ethically manageable if physicians who are subject to this divided loyalty face squarely the fact that their situation poses inherent ethical tensions, if they strive to help patients understand how research participation differs from patient care, if they are committed to protecting patients from harm, and if they respect the patients' right to withdraw from research without penalty.^{9,10} As Henry Beecher noted long ago, an important ethical safeguard relevant to this problem is "the presence of an intelligent, informed, conscientious, compassionate, responsible investigator."¹¹

Managing the tensions of divided loyalty with integrity requires that physician-investigators are honest with themselves and with patient-participants about how clinical research differs ethically from patient care. Across the range of ethically justifiable clinical research studies it is not possible to have it both ways—that is, to maintain fidelity both to promoting the medical best interests of patients and to conducting valuable research. It is tempting to see the relationship between physician-investigators and patient-participants as a fiduciary relationship, comparable to the doctor-patient relationship in medical care.¹² But this flies in the face of the fact that nearly all clinical research includes procedures that pose risks to participants without compensating medical benefits to them. Thus, physician-investigators cannot, and should not, promise explicitly or implicitly that during the course of research they will be functioning as a treating physician dedicated to promoting the medical best interests of their patients. What investigators can promise is that they will endeavor to protect the research participant from serious harm as a result of research participation and will always respect the right of the patient to withdraw from research.

A related problem associated with physicians recruiting their patients for clinical research is the potential for the prior physician-patient relationship to place undue pressure on patients to agree to research participation, thus compromising informed consent. If physicians are permitted to enroll their patients in clinical research, this potential for undue influence cannot be eliminated. Any recommendation by a physician to a patient to consider research participation may be perceived as pressure, because it comes from an authority figure whom patients are interested in pleasing or to whom they feel a debt of gratitude. This situation is most worrisome when the physician is directly involved in conducting the research in question. Nevertheless, informed consent does not require the absence of influence; rather, it is incompatible with controlling influence.¹³

Established guidance on this issue has been promulgated by the World Medical Association, in its Declaration of Helsinki, and by the Council on Ethical and Judicial Affairs of the American Medical Association (AMA). Principle number 23 of the Declara-

tion of Helsinki states “When obtaining informed consent for the research project the physician should be particularly cautious if the subject is in a dependent relationship with the physician or may consent under duress. In that case the informed consent should be obtained by a well-informed physician who is not engaged in the investigation and who is completely independent of this relationship.”¹⁴ The AMA’s ethical position is that “the physician who has treated a patient on an ongoing basis should not be responsible for obtaining that patient’s informed consent to participate in a trial to be conducted by the physician. . . . Instead, after the physician has identified that a patient meets a protocol’s eligibility and recommends that a patient consider enrolling in the trial, someone other than the treating physician should obtain the participant’s consent.”¹⁵

These two statements differ in details. The Declaration of Helsinki provision is less restrictive in one respect and more restrictive in another. On the one hand, the qualification that the patient is in a “dependent relationship” suggests that the separation between recruitment and obtaining informed consent is not required in all cases for treating physicians who desire to enroll their patients in research. The AMA’s position lacks any such qualification. On the other hand, when separation of recruitment and informed consent is indicated, Helsinki requires that consent be obtained by a physician not associated with the research. The AMA position permits another member of the research team to obtain informed consent, provided that he or she does not have a treating relationship with the patient. As the main concern is separating the informed consent process from the influence of a prior therapeutic relationship, the AMA position appears to offer more sound ethical guidance.

It is not clear, however, whether this separation between recruitment and informed consent constitutes a genuine protection for participants. The AMA statement notes in defense of its position that “patients may feel indebted to their physician or may hesitate to challenge or reject their physician’s advice to participate in research.” But these forms of pressure may be present regardless of whether it is the treating physician who obtains informed consent. An interview survey of 1,882 patients in medical oncology, radiation oncology, and cardiology clinics found “little evidence that patients felt coerced or manipulated by health care providers or scientific investigators to participate in research.”⁵ No data were reported comparing those with and without a prior physician-patient relationship with investigators. Empirical research is needed to clarify whether patients with a prior physician-patient relationship with the investigator feel greater pressure to consent than those lacking such a relationship and whether separation between recruitment and obtaining informed consent makes any difference in perceived pressure.

Undue influence is not the only ethical concern associated with physicians recruiting their own patients. The tendency of patient-participants to confuse research participation with medical care, known as “the therapeutic misconception,” is a widely discussed issue in the ethics of clinical research.^{16,17} It seems plausible to assume that this confusion, with the potential to interfere with informed consent, is likely to be more prevalent when physicians recruit their own patients into research as compared with recruitment that does not involve any prior therapeutic relationship. Whether this is true is a factual issue that could be addressed by empirical research. In any case, clarifying, or at least not obscuring, the differences between research participation and routine

medical care is an important component of the processes of recruitment and informed consent. The issue of the therapeutic misconception is discussed further below in the context of addressing advertising for clinical research.

Habiba and Evans have recently argued that treating physicians breach confidentiality when they use private information obtained from patients seeking their care for the purpose of recruiting these patients to participate in research.¹⁸ They assert that “to approach patients for recruitment into research based on information about them held by their treating physician infringes on their privacy because the information is used *outside the confined circumstances* for which it was given. . . . In other words, the principle of confidentiality should apply not only to prevent a patient’s records from being disclosed to others, including researchers, but also to constrain a doctor from making use of it himself if acting in a different capacity, such as that of a representative of a commercial health insurer *or* that of a clinical researcher.”

This is a novel and dubious construal of the concept of confidentiality. Breaches of confidentiality in professional contexts essentially involve an interpersonal communication by a professional who has a right to know private information about a client or patient and a duty not to disclose this to others who have no right to know this information without the consent of the client or patient. When the investigator who seeks to recruit his patient for research is the same person as the treating physician who is entitled to know the patient’s diagnosis, there is no disclosure of private information to another outside the therapeutic relationship. Hence, no breach of confidentiality is at stake in this invitation to participate in research. The shift from the therapeutic to the research role may be ethically problematic; however, it is not confidentiality that explains the ethical problem.

Instead of being seen as breach of confidentiality, this role shift might be viewed as an instance of exploitation. Alan Wertheimer analyzes exploitation as the situation of person A taking unfair advantage of person B.¹⁹ Treating physicians who endeavor to recruit their patients for research certainly take advantage of their therapeutic relationship in making the invitation to participate in research. In this situation, it is by virtue of the therapeutic relationship that the physician has access to an eligible patient who may consent to research participation. The ethical question is whether the use of one professional role to pursue a different professional role is unfair. When there is no ongoing therapeutic relationship, there is nothing wrongful or unfair in physician-investigators recruiting persons with a medical diagnosis for valuable clinical research. Indeed, clinical research is a socially valuable activity that requires the expertise of physicians and the participation of patients. It is unclear why a prior physician-patient relationship should make recruitment unfair provided that valid informed consent is obtained, which requires respecting the right of the patient to refuse without any penalty to the therapeutic relationship.

I conclude that that the issues of divided loyalty and potential pressure on patients to consent make research recruitment by treating physicians ethically problematic but not necessarily unethical. Other things being equal, it is better for recruitment and enrollment in research to be separated from a prior therapeutic physician-patient relationship. A strict separation should not be mandated, however, because it would unduly constrain the conduct of valuable clinical research. A vital safeguard against abuse in this situation is the professional integrity of the

physician-investigator.⁹ Concern with avoiding undue influence to participate by other members of the research team, such as nurses, may also contribute to participant protection.

Preserving Confidentiality and Privacy in Recruitment

Although U.S. federal regulations governing research with humans provide no explicit guidance about recruitment, they do address confidentiality and privacy. Among the “criteria for IRB approval of research” is the following stipulation: “When appropriate, there are adequate provisions to protect the privacy of subjects and to maintain the confidentiality of data” (§46.111(a)(7)).²⁰ Strictly speaking, this language does not clearly apply to the recruitment process, which involves contact with potential participants prior to enrollment in research. Yet the spirit of this requirement makes it applicable to IRB review of the recruitment process, in which genuine breaches of confidentiality may occur.

The following example illustrates the importance of IRB review of mechanisms of participant recruitment with an eye to protecting confidentiality. A protocol submitted to an IRB proposed to recruit patients hospitalized following motor vehicle accidents for the purpose of studying acute stress disorder, a psychiatric condition that often progresses to the chronic condition of posttraumatic stress disorder. Upon questioning by members of the IRB, it became clear that the investigators planned to station a member of the research team at a nearby community hospital who would receive from hospital staff the names of potentially eligible patients in order to approach them concerning their interest in participating in the research. Although this represented a convenient means of gaining access to patients for recruitment, the communication of the names of patients being treated for injuries after motor vehicle accidents was viewed by IRB members as violating the confidentiality of these patients. The recruitment plan of communication between hospital staff and the research team would have violated patient confidentiality because a researcher not connected with the care of these patients had no right to information about their presence in the hospital or their reason for being there.

Fortunately, in this situation a somewhat less convenient alternative recruitment plan was available. Clinicians involved in the care of potentially eligible patients could give them a flyer describing the research with a check-off box indicating willingness to be approached by a member of the research team. Under this approach, approved by the IRB, researchers would endeavor to recruit only those patients who previously consented to contact with the research team, thus preserving privacy and confidentiality. Because the details of recruitment plans may not be spelled out in protocols submitted to IRBs, it is incumbent on IRB members to raise questions about recruitment techniques so as to assure the protection of research participants.

Ethical concerns may arise about invading privacy in the recruitment process when no breach of confidentiality is involved. The issue of recruiting family members of participants enrolled in genetics research has recently received systematic attention by the Cancer Genetics Network Bioethics Committee.²¹ The authors note that a “central challenge in any approach is to provide appropriate protections while promoting sufficient recruitment to

achieve scientific goals.” A variety of recruitment approaches are considered ethical. As a general rule, this group recommends that initial contact with family members come from enrolled participants who are provided with written material concerning the research with a mechanism for the family members to either opt in or opt out of being contacted.

Advertising for Clinical Research

Advertising is an established method to recruit people for research. This practice, however, has received little ethical attention. The regulations of the U.S. Department of Health and Human Services concerning the protection of humans in research do not mention advertisements for clinical research as within the purview of IRBs; however, guidance issued by the U.S. Office for Human Research Protections directs IRBs to review recruitment materials as part of initial review of research protocols.²² For research under its jurisdiction, the U.S. Food and Drug Administration (FDA) requires that IRBs review and approve advertisements to recruit human participants.²³ The FDA “considers direct advertising for study subjects to be the start of the informed consent and subject selection process.”²³ Because advertisements may set the stage for interactions between patient volunteers and investigators and influence the quality of informed consent, they should be subject to IRB scrutiny and approval for all research with humans.

For many research participants, initial interest may be stimulated by advertisements. This first, anonymous communication between researchers and patient volunteers may tap motivations, foster beliefs, and create expectations that influence research participation in ethically significant ways. Commentators on the ethics of clinical research have noted the need to balance the traditional normative framework of protecting the rights and welfare of research participants with the more recent goal of promoting access to clinical trials.²⁴ Advertising to recruit research participants serves the latter goal; however, the accuracy of advertisements about clinical research and the nature of the inducements they offer raise ethical issues pertaining to participant protection.

Miller and Shorr examined weekly issues of the *Washington Post* “Health” section from December 1, 1998 through February 16, 1999.²⁵ They identified a total of 111 advertisements addressed to persons suffering from particular diseases or specific symptoms. Sponsors of the advertisements included institutes of the National Institutes of Health, academic medical centers, for-profit research firms, physician practice groups, and individual investigators. Nearly all the observed advertisements mentioned that volunteers were being recruited for a study or for research. More significant than the bare fact of disclosing that volunteers were being recruited for research was the overall tenor of the message of the advertisements and the motivations to which they were directed. In most cases, advertisements for patient volunteers began with bold type referring to a disease and/or symptoms. In the case of psychiatric research, these advertisements sometimes included pictures of people showing signs of psychic distress. The advertisements typically noted that study medications and medical examinations or evaluations would be provided free of charge. It appears that the predominant intent was to gain the attention of persons who were suffering (or their families) and to offer personal benefit. The appeal to suffering patients risks creating unrealistic expectations

Figure 37.1. Examples of Research Recruitment Advertisements in Newspapers

for medical benefit, because there is no guarantee that patients will benefit from research participation. On the other hand, none of the observed advertisements appealed to altruistic motivations—to contribute to scientific knowledge that might benefit future patients.

Even though advertisements almost always disclose that persons are being recruited for research, they typically appeal to prospective research participants as patients seeking needed treatment rather than as volunteers invited to join investigators as partners in research. A major difficulty in this appeal to personal suffering and benefit is that it fosters the expectation that clinical research has the same individualized, patient-centered orientation as clinical care, whereas clinical research is designed primarily to produce generalizable knowledge about a class of patients. Accordingly, the prevailing focus of advertisements may contribute to the therapeutic misconception, confusing clinical research and standard clinical care.¹⁶ Some commentators see the therapeutic

misconception as a pervasive characteristic of clinical research that compromises informed consent.¹⁷

In a large-scale survey of patients participating in clinical research, it was found that altruistic motivations were reported no less often than self-interested motivations. Of those patients in treatment studies, 76% indicated a “way to help others” and 69% “advance medical science” as major reasons for research participation; 69% indicated “gave hope” and 67% “chance to get better treatment.”²⁶ These data suggest that advertising appealing to altruistic motivations, such as to contribute to scientific research and to help future patients, might prove as effective as the prevailing appeal to individual benefit.

Advertisements for clinical research also should be evaluated with respect to what they fail to communicate. None of the observed advertisements mentioned any risks of study participation.²⁵ Detailed disclosure of risks is a matter for conversations between investigators and potential research participants and for

written consent documents. However, it is arguable that advertisements should at least mention that risks of study participation will be disclosed and discussed before enrollment begins. Indeed, the fact that advertisements mention potential benefits suggests that they should not omit any mention of risks. Such omission may skew the perception of what is involved in research participation.

Another significant omission in observed advertisements is reference to the use of placebos. There is no way of knowing the nature of the study design from most observed advertisements. It would be surprising, however, if none of them involved placebo controls, given the frequency of their use in randomized trials. Investigators may fear that the mention of placebos might dissuade some from inquiring about research participation. On the other hand, advertisements that create the expectation of benefit and offer free treatment might incline patients to decide in favor of research participation without careful thought about the meaning of enrolling in a placebo-controlled trial. Unrealistic initial expectations may be fostered that are not dispelled by the subsequent informed consent process, even when the use of placebos and how this makes a clinical trial different from standard clinical care are adequately disclosed.

Clinical trials sometimes require that patient volunteers stop prior treatment for a period of time before they receive medications under investigation. A few of the observed advertisements mentioned that patients must be free of medications as a condition of enrollment.²⁵ It is not clear, however, whether this requirement was disclosed for all studies involving a drug washout.

IRB oversight should aim at ensuring that advertisements strike a reasonable balance between the legitimate goal of recruitment and the adequacy of disclosure about the nature of clinical research. Accordingly, IRBs should review proposed advertisements in the light of the following questions:

- Does the advertisement make clear that participants are being recruited for research?
- Does the message of the advertisement have the potential to contribute to confusion between research participation and standard clinical care?
- Are the suggested benefits of research participation consistent with the scientific protocol and consent forms?
- Does the advertisement disclose important features of the study design that may influence enrollment: for example, the use of placebos or the requirement for prior medication withdrawal?
- Does the advertisement mention that risks will be disclosed prior to study enrollment?

Conclusion

Beginnings matter. Recruitment is the first stage of research participation, which can set the moral tone for the relationship between investigators and research participants. When physician-investigators enroll their own patients into clinical research the problem of divided loyalty between patient care and scientific investigation cannot be eliminated; however, it can be managed ethically by conscientious investigators. The process of recruitment deserves greater ethical attention in both conceptual and empirical research.

Research Involving Women

As of July 2005, the U.S. Census Bureau estimated that there were approximately 150,410,658 women living in the United States, a little less than 51% of the total population.¹ This percentage is not a new phenomenon; due to a greater death rate in men of a number of age groups, women have long been the majority sex in the United States.² Yet despite this majority, women have long found themselves excluded or at least underrepresented in many areas of society, including academia, the business sector, and the political arena.

What has recently come to be recognized, however, is that women have long been underserved in the context of modern medicine as well. Since the United States began seriously engaging in clinical research in the mid-20th century, views on women as participants and as a source of valuable research questions have changed enormously, fluctuating from a sort of indifference, to active exclusion, to today's state of deliberate inclusion. This oscillation is in large part attributable to the unique ethical dilemmas that surround the participation of female subjects in clinical research: Not only might women in general be subject to particular pressures and risks due to their status as a historically oppressed population, but their biological capacity to become pregnant and gestate may also put both them and future human beings at risk of dignitary and/or physical harm. Balancing these unspecified risks with the desire to enable research participation in hopes of more fairly distributing research's benefits has been a difficult and ongoing struggle.

Recent conceptual and empirical work has the potential to aid researchers and institutions grappling with these complex dilemmas. Data are still lacking on many important questions, yet existing information can enable clinical researchers to better analyze the conflicting obligations and grasp the practical nature of the problem at hand. Data and discussions also serve to illuminate the

creation of overarching policies and strategies for study design, bringing them more in line with contemporary thinking. To understand the maelstrom of ethics, empirical data, and policy questions that surround the issue of women's participation in clinical research, we start from the historical vantage point.

History

The history of women's involvement in modern medical research reflects a shift in society's priorities concerning sex differences. Whereas early researchers and research institutions sought to protect women and their potential unborn offspring from the hazards of research participation, more contemporary women's rights activists and research ethicists stress the importance of women's participation in order to fairly distribute both the direct and indirect benefits of medical research. The establishment and subsequent dismantling of the protectionist approach to women's research participation during the last quarter of the 20th century was marked by scandals, changing policies, reports, legislation, and a growing awareness in the health-care community of the important role research participation plays in overall health-care equity.

Protectionist Era of Women in Clinical Research

Scandals in Women's Health

Advocacy for women-specific health care, prominent in the modern debate over women's research participation, dates back to the

popular health movement of the 1800s. Early activists organized lectures and “conversations” designed to educate women about diverse topics such as hygiene, proper diet and exercise, and family planning.³ Indeed, women activists protesting the sale of addictive “tonics” for female health problems were the main impetus for the creation of the Food and Drug Administration’s (FDA) predecessor in 1906.⁴ However, little attention was specifically paid to the role of women in clinical research until the blossoming of research in the mid-20th century. As the number of new drugs and medical treatments available in the health-care market began to explode, a series of scandals related to women’s health, particularly maternal and fetal health, led to the institutionalization of a default exclusion of female research subjects in many types of clinical trials.

Perhaps the most infamous drug tragedy in the modern research age revolved around the discovery of the teratogenic effects of thalidomide, an anti-nausea drug being prescribed mainly for pregnant women with morning sickness. Though the drug was widely available in Europe throughout the late 1950s, the application for U.S. marketing approval was still pending at the FDA in 1961, when scientists publicly confirmed reports of thalidomide-induced birth defects such as stunted fetal limb development and damage to other organ systems.⁵ The visual impact of thousands of European thalidomide babies focused American attention on enhancing the FDA’s ability to protect consumers through more stringent requirements in the approval of new pharmaceuticals. This popular support for increased regulation of the pharmaceutical industry, in turn, proved to be the final boost Congress needed to pass the Kefauver-Harris Drug Control Act in 1962. Among other things, this legislation empowered the FDA to require drug manufacturers to prove the effectiveness of their products as well as their safety, to report adverse events to the FDA, and to ensure that advertisements to physicians disclosed the risks as well as the benefits of their products. Informed consent was also now required from participants in clinical studies. The FDA was given jurisdiction over prescription drug advertising and marketing techniques, the types of trials done on experimental drugs, and more.^{4,6} Although the new amendments did not specifically address the issue of women’s role as clinical research subjects, the tragedy of thalidomide boosted the FDA’s power significantly, paving the way for increased scrutiny of clinical research practices.

Though the thalidomide disaster occurred outside the realm of research and affected only pregnant women, another scandal in New Zealand illustrated how women generally could suffer unethical treatment in the context of clinical research. In 1966, the National Women’s Hospital of New Zealand began a study of cervical carcinoma *in situ* (CIS) in hopes of proving that a positive result on the newly developed Pap smear test should not be taken as a sign of imminent cervical cancer.⁷ Though common medical wisdom at the time held that positive Pap smears necessitated swift preventive measures (including hysterectomy) to ensure long-term health, the physician in charge of the National Women’s Hospital study allowed hundreds of women with positive test results to go untreated. The primary investigator, Herb Green, strongly agreed with the traditional view that hysterectomies for CIS needlessly compromised women’s core identities by depriving them of their reproductive capacity; he claimed that a sterilized woman had “thrown away a unique possession” and betrayed her “heritage” by having her uterus removed.⁷ Thus, Green and his researchers did not inform untreated women that they were being included in a research trial or that ignoring a positive Pap smear

was not the current standard of practice. Dozens of female patients died before the study was finally stopped in 1984. Although many details of the scandal emerged too late to significantly affect legislative changes in the United States, exposure of the trial in the popular media gave strength to the belief that female patients were at heightened risk of harm or exploitation in clinical research and required special protection.

Despite increased FDA supervision in the United States, several additional health-care scandals in the early 1970s resulted in significant harm for female patients and/or their offspring, further driving the campaign for greater protection of women research subjects. First, in 1971 the FDA announced that diethylstilbestrol (DES), a synthetic hormone often prescribed to pregnant women, had been found to be strongly associated with the risk of an extremely rare and aggressive reproductive cancer, clear cell adenocarcinoma (CCA), in female offspring.⁸ Despite a 1951 study that failed to demonstrate DES’s efficacy in preventing miscarriages, physicians had continued to administer the drug to women for another two decades, exposing an estimated 5 million to 10 million women and their unborn fetuses to DES and resulting in a spate of CCA diagnoses.

The uproar surrounding the Dalkon Shield, an intrauterine device first marketed nationwide in the United States in January 1971, was another medical product with unexpected dire consequences for female patients. Approximately 2.8 million Dalkon Shields were sold in the United States before 1974, when the manufacturer pulled the devices from the shelves after reports of increased infection and pregnancy complications. Subsequent reports revealed that users of the Dalkon Shield had a five-fold increased risk of pelvic inflammatory disease and a greater chance of medically complicated pregnancies.⁹ These two health-care tragedies contributed to the growing consensus among clinical and research institutions that women’s exposure to experimental or even relatively new approved procedures should be limited, both to avoid unforeseen health consequences for them and their potential offspring and to limit liability for drug manufacturers. By and large, women in the late 1960s and early 1970s reacted to these scandals by protesting the unethical inclusion of women in research.¹⁰

Beyond the specific realm of medicine, other social forces at work in the early 1970s contributed to the creation of a default exclusion of women from many types of research trials. The vocal pro-life community, galvanized in the wake of the U.S. Supreme Court’s 1973 *Roe v. Wade* decision, expressed concern for unborn fetuses by pushing for stringent limits on women’s research participation.¹⁰ Additionally, the revelation of the Tuskegee Syphilis Trial in the early 1970s and the subsequent convening of the National Commission for the Protection of Human Subjects in Biomedical and Behavioral Research attracted further attention to the potential of medical research to exploit populations of lower social status (see Chapters 8 and 14). Charged with identifying the core ethical principles that should govern the conduct of research with human subjects, the National Commission also proposed additional extra protections for populations it deemed to be historically vulnerable in light of past tragedies, including pregnant women and fetuses.¹⁰

Establishment of Protectionist Legislation

The series of particularly visible women’s health disasters, in conjunction with greater social and political focus on protecting his-

torically oppressed populations from unfair treatment, culminated in the adoption of several new guidelines designed to more strictly regulate women's participation in clinical research. First, in 1977 the FDA passed Guideline 77-3040, significantly proscribing research participation for "women of childbearing potential." According to these regulations, fertile women were not to participate at all in early clinical studies such as Phase I or Phase II trials, and should only be included in later clinical trials if animal studies had already been performed to investigate the reproductive effects of the investigational drug or device.⁴ The passage of this regulation effectively excluded a large majority of women from serving as research subjects in many types of clinical studies.

A second set of regulations, adopted by the U.S. Department of Health and Human Services (DHHS) in 1978 (revised in 2001), made official policy of many of the National Commission's proposals regarding research with populations previously designated as vulnerable.¹¹ In 45 CFR 46 Subpart B, the DHHS specifically delineated the types of research that were permissible with pregnant women and fetuses. Unless the proposed research had the potential to directly benefit a pregnant woman, she was not permitted to enroll in research that would pose greater than minimal risk to her fetus. Additionally, if research participation was thought to have the potential to directly benefit the fetus alone, informed consent was required from the biological father as well as the mother (unless "he is unable to consent because of unavailability, incompetence, or temporary incapacity or the pregnancy resulted from rape or incest").¹¹ Although these regulations applied only to research sponsored by the DHHS, they significantly curtailed the ability of pregnant women to enroll in clinical research.

The adoption of these two sets of regulations by government agencies marked the strongest moment of the protectionist approach to women's participation in clinical research. Faced with a series of public tragedies involving women as medical subjects, many officials felt that anything less than a stringent attitude toward women's participation in clinical research would only invite further disaster. Barred from almost all research if they were pregnant or of "childbearing potential," women found themselves generally excluded from research "for their own good" and the good of their potential offspring. Yet although women were now thought to be protected from future potentially harmful experimental products in the vein of thalidomide, DES, and the Dalkon Shield, a growing opposition movement began to point out and protest the dearth of information about women's health that resulted from their research exclusion.

Dismantling the Protectionist Approach

Changes in Public Opinion

One of the earliest signs of the sea change in public opinion regarding women's participation in potentially riskier endeavors was the 1978 passage of the Pregnancy Discrimination Act, an amendment to the Civil Rights Act of 1964. Passed just one year after the FDA instituted its policies excluding women from most forms of clinical research, the new legislation defined discrimination on the basis of pregnancy, childbirth, or related medical conditions as a form of unlawful sex discrimination prohibited under Title VII of the Civil Rights Act. Both married and unmarried women affected by pregnancy or related conditions were to be treated in the same

manner as other employees or applicants with similar abilities or limitations.¹² Pregnancy in itself could no longer be a legal reason for excluding women from the workplace.

Echoing the general reversal of public attitudes and policies toward fertile women's exclusion from the workplace, several political action groups in the early 1980s weighed in on the debate regarding the inclusion of women in clinical research. Regulations once thought to be protective were now increasingly deemed "paternalistic" and "discriminatory."¹⁰ As women of the baby boomer generation began to reach adulthood (and, in some cases, graduate from medical school), they became increasingly concerned with the significant lack of research with women and its impact on women's health.¹⁰ In response to data indicating that both pregnant and nonpregnant women were frequent users of pharmaceuticals that had never been tested in female research subjects, activists and ethicists pointed out that excluding women from research participation seemed actually to exacerbate the likelihood of harm; women would be taking the drugs either way, but were currently doing so without any evidence base or professional supervision.¹³⁻¹⁵ Furthermore, commentators observed that women's health, as a subspecialty, had long been conflated with women's reproductive health; little research attention had been paid to the ways in which the sexes varied outside the realm of obstetrics and gynecology.¹⁰

The widespread absence of women in studies of heart disease, for example, was one of the most glaring omissions in research on nonreproductive health issues: Large-scale studies such as the Coronary Drug Project (CDP), the Coronary Primary Prevention Trial (CPPT), the Multiple Risk Factor Intervention Trial (MRFIT), and the Physicians' Health Study (PHS) all recruited solely male subjects.¹⁶ Inspired by AIDS activists, who through the 1980s lobbied successfully for greater access to experimental drugs by stressing the fair distribution of the benefits of research participation, activists for women's rights began applying the same logic to encourage the greater inclusion of female clinical research subjects.¹⁰ Gathering pressure eventually led to the creation of a two-year public health task force, charged with investigating the effects of exclusionary policies on women's health.

New Mandates for Inclusion

The report of the Public Health Service Task Force on Women's Health Issues, published in 1985, was a watershed event in the debate regarding women's participation as clinical research subjects, marking the beginning of a 15-year flurry of government reports, policies, and legislative acts (see timeline, Figure 38.1). The task force report declared that "the historical lack of research focus on women's health concerns has compromised the quality of health information available to women as well as the health care they receive,"¹⁷ a perspective providing official credence to activists' claims. The National Institutes of Health (NIH), faced with pressure from both popular and government sources, enacted the first of its policies designed to dismantle the protectionist approach: the 1986 Policy Concerning the Inclusion of Women in Study Populations. This policy encouraged, but did not mandate, the inclusion of women in clinical trials.¹⁰ NIH administrators hoped that the lenient new guidelines would appease women's rights activists without creating animosity among those researchers who claimed that the addition of female subjects would beget greater costs and difficulties with study design.¹⁰

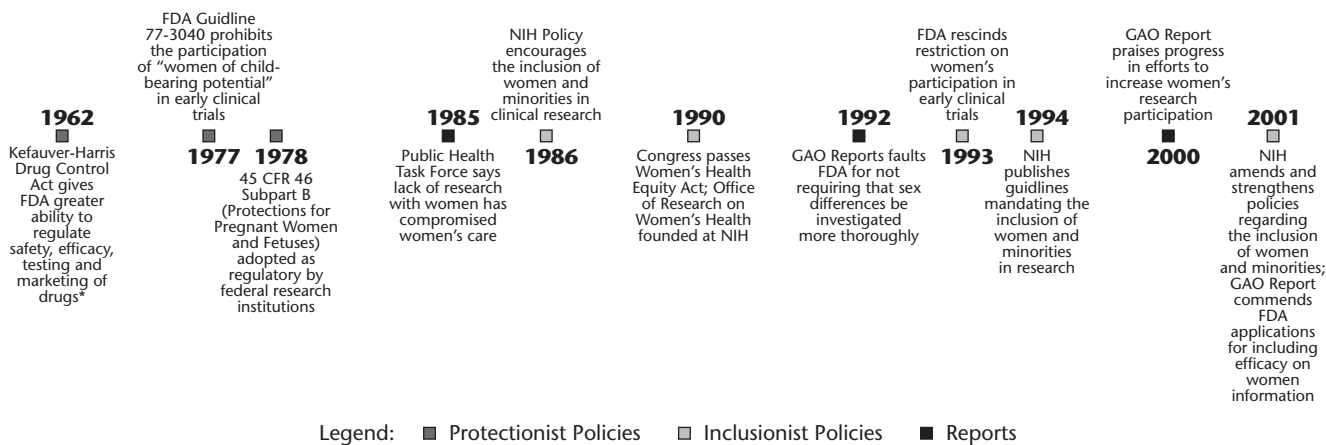

Figure 38.1. Timeline of Government Guidelines, Reports, and Policies

Despite this new policy, a General Accounting Office (GAO, now the Government Accountability Office) report issued four years later had the NIH scrambling to revise its policies toward female subjects yet again. After a thorough review of NIH policies and practices, the GAO concluded that, despite the 1986 policy change, NIH clinical studies were failing to include women at an appropriate rate.¹⁸ The report received a great deal more public attention than the earlier Public Health Service Task Force on Women's Health Issues, provoking a louder outcry from the general population and spurring reconsideration of many older policies regarding women's research participation.

Public reaction was so great as to prompt Congress to take action. Shortly after the official publication of the 1990 GAO report, the Congressional Caucus on Women's Issues, with Sen. Barbara Mikulski (D-Md.) as the primary sponsor, introduced the Women's Health Equity Act, calling for "greater equity in the delivery of health care services to women through expanded research on women's health issues, improved access to health care services, and the development of disease prevention activities responsive to the needs of women."¹⁹ The bill also mandated the creation of five contraceptive and fertility research centers as well as an Office of Research on Women's Health to serve as a "focal point for women's health research at the NIH."²⁰

The Supreme Court's 1991 decision in *United Autoworkers v. Johnson Controls* reflected the widespread growing resistance to the previous protectionist ideology even outside the research arena. In a unanimous decision, the justices wrote that the Johnson Controls manufacturing company's blanket prohibition banning fertile and/or pregnant women from working in positions potentially harmful to their reproductive capacities was in violation of Title VII of the Civil Rights Act.²¹ The decision held that the company's policy discriminated against women, as it did not prohibit fertile men from the same positions, despite the fact that lead exposure had also been proved hazardous to male reproductive systems; further, the potential for fetal harm due to lead exposure did not prevent women from doing any of the essential tasks required to perform their jobs. This ruling established that even well-intentioned employment policies meant to protect women and fetuses were forbidden if they resulted in the discriminatory exclusion of women.²¹

The NIH Revitalization Act of 1993 (P.L. 103-43) further encouraged the inclusion of women in research by including a provision requiring NIH to ensure that (1) women and minorities were to be included in all clinical research, (2) women and minorities were to be included in Phase III trials in numbers adequate to allow for analysis of gender and group differences, (3) cost was not an acceptable reason for excluding these groups, and (4) programs would be initiated to recruit and retain women and minorities for clinical research.²² In 1994, the NIH revised its policy to meet the legislative mandate, publishing "Guidelines on the Inclusion of Women and Minorities as Subjects in Clinical Research," and charged the NIH Office of Research on Women's Health with monitoring adherence to this policy.²³ A 1993 Institute of Medicine report offered numerous arguments regarding the need for women's inclusion, simultaneously tackling concerns about the resulting rising costs of studies by laying out strategies for designing efficient and scientifically appropriate research subject groups.²⁴

Having successfully spurred the NIH into action, the GAO turned its attention to the exclusionary policies of the FDA. In 1992, the GAO issued a second report, entitled "Women's Health: FDA Needs to Ensure More Study of Gender Differences in Prescription Drug Testing," strongly recommending that the agency revise its policy of excluding women from early trials in the pharmaceutical approval process so as to better serve the needs of women's health.²⁵ After a year's deliberation in July 1993, the FDA adopted many of these suggestions in its "Guideline for the Study and Evaluation of Gender Differences in the Clinical Evaluation of Drugs." This policy overrode the previous protectionist policy of 1977 and described the agency's new high expectations for pharmaceutical sponsors regarding the inclusion of both genders in clinical drug trials.²⁶ An FDA Office of Women's Health was established by congressional mandate in 1994.

With these dramatic changes at two major federal agencies, the protectionist approach to female research subjects quickly fell from favor. New GAO reports released at the end of the 1990s commended the NIH and FDA efforts to increase women's inclusion in clinical research, though the GAO warned that some newly approved pharmaceuticals still lacked sufficient safety data from women.²⁷ Some scientific journals even began publicly calling on

researchers to analyze their data for sex and ethnicity differences, though this trend has yet to become the norm at all biomedical publications.^{28,29}

By the beginning of 21st century, official and institutional policies toward women's research participation had undergone drastic changes in the space of a few decades, reversing and dismantling the protectionist approach popular in the 1970s. Although regulation 45 CFR 46 (Subpart B) still strictly limits the participation of pregnant women in federally funded clinical research, most barriers to the participation of nonpregnant women as research subjects have been removed. However, notwithstanding federal regulations, both researchers engaged in the daily work of clinical trials and ethicists attempting to parse the implications of women's participation still face a number of challenges. Despite a new official attitude regarding women's research participation, important ethical questions raised by the inclusion of women, particularly pregnant women, have not yet been laid to rest.

Ethical Issues

The fundamental ethical dilemma regarding women's participation in research centers on the question of balancing inclusion and protection. As women's rights activists point out, there are numerous reasons to include women in as much and the same types of research as men: The availability of research participation's benefits should not depend on sex alone, and women have many sex-specific health concerns that have received short shrift in past decades. On the other hand, as legislators faced with tragedies in the 1960s and 1970s realized, there are also reasonable arguments for excluding women from research. Most significantly, as illustrated by the fallout from thalidomide and DES, risks undertaken by women may be propagated to future or currently gestating fetuses. Additionally, women have long been a relatively powerless group in most societies, possibly making them more vulnerable than men to exploitation and other forms of unethical treatment. Greater inclusion of women has also been attacked from a resource allocation standpoint: Mandating inclusion may increase the costs of studies, jeopardizing other worthwhile research ventures. These conflicting concerns weigh on all those attempting to make participation policies as equitable as possible without unduly exposing women (and potential fetuses) to risk.

Ethical Issues With Women in General

Though the rhetoric about the ethical hazards of including women as research subjects often focuses primarily on the potential harm to gestating fetuses, there are also ways in which including women, regardless of their reproductive capabilities, brings up ethically difficult questions. Should women be considered vulnerable subjects who incur particular risks in the research setting? How should the possibility of increased costs because of inclusion be viewed? Should some research projects be discouraged for their potential social harm to an already oppressed group? And do women have claims to greater research participation?

"Vulnerability" and Resulting Risks

A discussion of the ethics of women's inclusion in clinical research necessarily requires consideration of the ethics of including or

excluding any population or group from research. Fundamental ethical principles of justice require that both the risks and benefits of research participation should be fairly distributed throughout the general population, an imperative that makes the exclusion of certain populations from research unethical without scientific or harm-based reasons.^{15,30} Faced with the prospect of exposing a possibly vulnerable population to unnecessary risk or harm in the context of clinical studies, many researchers and research institutions might be tempted to err on the side of caution by excluding members of that population from participation as a default option. However, such exclusion may be unfair when one takes into account the significant benefits that research participants may receive. These benefits can be both on a personal level, such as when participants receive early access to promising new drugs months before they are available on the general market, and on the population level, such as when new findings about subpopulations are reflected in better-tailored medical care and treatments. This general reasoning clearly applies to the exclusion of women from clinical research: If the reasons for their exclusion are not adequately justified by scientific validity concerns or particular risk of harm, barring their participation in research is not defensible.

The concession that women may be excluded from research for scientific validity reasons seems relatively straightforward; women might justifiably be excluded from studies of prostate cancer, for example. The principle that populations may be excluded if they are susceptible to a "particular risk of harm" not present in the wider population, however, leads to debate about what sort of harms women may be uniquely at risk for and/or vulnerable to. Are there good reasons to think that women should be considered a "vulnerable" population? Although many authors in the bioethics literature have tackled the question of how to deal with vulnerable populations in clinical research, the meaning and scope of *vulnerability* remains somewhat unclear.³¹ As the Council for International Organizations of Medical Sciences (CIOMS) argues in its commentary on Guideline 13, vulnerability is perhaps best conceived as the relative or absolute inability to protect one's own interests.³² This definition offers a starting point for discussion of whether women should be considered vulnerable in the context of clinical research, and, if so, in what particular situations.

What sort of factors, if any, might make women relatively or absolutely unable to protect their own interests in the research setting? Women as a group have historically been an oppressed and underprivileged population; as such, it has been argued, women's ability to protect their own best interests as research subjects may be compromised, creating vulnerability. This lack of power may be reflected in women's inferior social status, their socialization to defer to more powerful groups in society, and/or their lack of political and socioeconomic resources, all of which could make them vulnerable to particular risks and harms in the research setting. The nature of these risks may be manifested differently according to the nature of the research scenario.

For example, as a population that both holds less sociopolitical power and has been long socialized to defer to socially powerful groups such as physicians, women may be at greater risk for exploitation in the research setting. They also may be inclined to accept offers of unfair benefits in exchange for research participation.^{33,34}

Additionally, because of their lack of economic resources and power within relationships, women might be at risk of being "unduly induced." If women are offered particular goods or services

that they lack and need in exchange for enrollment, the worry is that they might disregard the risks of study participation or give the risks insufficient weight in their decision-making process. Concern about undue inducement often emerges in research with economically disadvantaged populations; authors have examined whether offers of access to medical treatment, money, free health care, and so forth, can beget irrational decision making in poorer communities.³⁵ Similarly, certain benefits offered in exchange for research participation might serve as undue inducements for female research subjects. The offer of free health care for female research subjects' children, for example, may be so attractive for new mothers who lack health insurance as to hinder their ability to objectively weigh the risks and benefits of research participation. In another example, women who otherwise lack the social power to demand monogamy or safe sexual practices from their partners may be unduly attracted to an experimental vaccine for a sexually transmitted disease.³⁶

Although these scenarios predicting heightened risk for women are theoretically possible, it is not clear that all or even most women actually feel powerless to protect their own interests in the research setting, even given their historical oppression and particular needs. Some research, for example, has noted the particular resilience and resourcefulness that populations lacking socioeconomic power often demonstrate in response to stressful situations.³⁷ Women as a population face many of the same hypothetical risks of exploitation and undue inducement in daily life that they might encounter in the research setting; research participation does not necessarily present more of a threat to them than their everyday experiences. Given the CIOMS definition of vulnerability as the relative or absolute inability to protect one's own interests against risks and harms,³² the application of the term *vulnerable* to women as a whole population remains contentious.

Further, not all members of a "vulnerable" or "historically oppressed" group are equally vulnerable or oppressed. For example, there are women who may be doubly or triply disadvantaged by virtue of age, race, ethnicity, education, and so forth. On the other hand, a white English-speaking woman of high socioeconomic status might be less vulnerable in research than a poorer Hispanic woman for whom English is difficult to understand. However, although it is overly simplistic to assume that all women have the same sets of needs and vulnerabilities in the research setting, it is also extremely difficult for researchers and policy makers to create written regulations that account for each individual's specific needs.

Increased Costs of Research

Mandatory inclusion of women as research subjects, some NIH spokespersons pointed out in the early 1990s, could significantly increase the overall costs of some studies. Requiring statistical power to detect differences based on sex would require a significantly greater number of research subjects, leading to greater budget requirements.¹⁰ The increased costs of including women could in turn become an ethical difficulty if money would therefore be unavailable to fund other valuable research studies. Given this tension, how should limited funding be spent? Is the inclusion of women as research subjects always more ethically important than enabling other avenues of research? Although opponents protest that full inclusion of all subpopulations (gender as well as

age, race, ethnicity, etc.) would produce astronomical research costs,³⁸ those in favor of women's inclusion argue that research recruitment ought to reflect the diversity of the wider population (whose tax dollars fund public research) and particularly the distribution in the general populace of the condition under study.^{24,39} For research involving specific diseases, advocates argue that the makeup of the research participant population logically ought to reflect the makeup of the disease population.²⁴ Empirical evidence on the costs of including women is lacking, a point that will be discussed further in the next section.

"Validating" Female Stereotypes

Some concerns about including women echo those raised with other minority or historically oppressed populations. For example, because minority groups are often saddled with negative public stereotypes, there may be special risk from research results that give leverage to harmful generalizations that minorities have long worked to overcome. In the particular case of women, researchers might reveal data that reinforce long-held beliefs that women are more emotional due to hormonal cycles, or that women have fewer neurons in sections of the brain thought to moderate math and science learning.¹⁵ These sorts of findings are far from hypothetical; recent data support a number of female stereotypes, such as that women are disinclined to adopt "warrior" mindsets⁴⁰ and that men are better able to understand and manipulate rule-based systems.⁴¹ If data such as these might contribute to the oppression of an already disempowered group, how should researchers proceed? Should such studies not be permitted for fear of giving leverage to historical oppression? Though complete suppression of research on sex differences and any resulting discoveries is inappropriate, the potential for such data to negatively affect oppressed groups inevitably influences decisions about dissemination of research findings.

Legal Rights and Entitlement Issues

Might women or any other population of research subjects have a constitutional right as U.S. citizens not to be unfairly denied research participation? Some authors have argued that because barring women from research participation has the effect of denying the known benefits of government-sponsored research to them as a class, this exclusion is unconstitutional without sufficient justification for such disparate treatment.^{42,43} The traditional justification for exclusion—that fertile women may potentially become pregnant during the course of research—is viewed as decidedly insufficient by proponents of this view. Although the exclusion of women on the basis of sex alone might not be unconstitutional in privately funded research, rational arguments exist for believing that sex-based exclusion from federally funded research violates constitutional entitlements, given that research participation can be thought of as a government-provided potential benefit.⁴²

Additionally, does the past exclusion of women from research entitle them to greater consideration than men in the current federal research agenda? In compensation for this history of unnecessary exclusion, several feminist authors have argued that women and other oppressed groups in society "should have a privileged place in studies that are likely to be of specific benefit to members of the group investigated" and have called for greater support for research on women's health concerns.³³ The U.S.

government has in some sense acquiesced to this demand, funding such projects as the Women's Health Initiative,⁴⁴ but there is some resistance to this policy. Critics claim that excessive attention and funding given to women's health issues works to the disadvantage of other groups in society, both privileged and underprivileged. Although women's rights proponents stress the importance of "catching women up" in terms of gender-specific research data, others emphasize the need to consider the lot of other groups in a research agenda with limited resources.

The range of ethical issues associated with the research participation of women in general is extensive, including ethical issues associated with all minority or historically oppressed groups as well as those specific to women. However, women's capacity to become pregnant and give birth adds a further set of ethical difficulties.

Ethical Issues Specifically With Pregnant Women

What aspects of pregnancy and bearing children might add greater ethical complexity to women's participation in research? First, the pregnant woman herself might have special needs and susceptibilities to risk by virtue of her pregnancy that are not shared by other minority or historically oppressed groups, including non-pregnant women. Second, fetuses and biological fathers have their own interests regarding pregnant women's research participation that may conflict with those of the woman herself. We now consider some of the main dilemmas researchers working with pregnant subjects may encounter; this is not meant to be an exhaustive list, but rather a collection of the concerns about pregnant research subjects that loom largest.

Pregnant Women as Vulnerable Subjects?

Although many oppose the classification of women in general as a "vulnerable population," regulations frequently label *pregnant* women as vulnerable and in need of special protections, including DHHS regulations governing federally funded research with human subjects.¹¹ This label, however, seems to confuse what entity is vulnerable and at risk. There does seem to be a widely held intuition among both researchers and the general public that pregnant women require greater protection than do nonpregnant human beings, but support for that intuition is often unclear, particularly in the research setting. Most regulations and guidelines offer no explanation for these special protective measures, and those that do usually refer to the risk of fetal rather than maternal harm during research participation.⁴⁵ Although teratogenicity constitutes an important ethical concern, many women's rights activists and ethicists have pointed out that the potential of a medical treatment to harm a gestating fetus should not be conflated with the potential for pregnant women themselves to become incapable of protecting their own interests.¹⁰ As one researcher writes, "Sometimes the obvious needs to be repeated: Being pregnant does not by itself result in diminished decision-making capacity."⁴⁶

Conflicts of Maternal and Fetal Interests

Yet whereas concern over pregnant women's particular vulnerability to coercion, exploitation, or undue influence in the research setting may be misguided, the ethical difficulties of potentially

conflicting interests of a woman and her fetus are less easily put aside. Although some authors have questioned whether the image of maternal-fetal conflict is the most useful way to portray this dilemma,⁴⁷ there is clear potential for contradictory needs on the part of the two entities.

Some regulations have attempted to tackle this potential conflict by establishing a hierarchy of dominant interests. DHHS regulations, for example, state that research on pregnant women may be permitted when

[t]he risk to the fetus is caused solely by interventions or procedures that hold out the prospect of direct benefit for the woman or the fetus; or, if there is no such prospect of benefit, the risk to the fetus is not greater than minimal and the purpose of the research is the development of important biomedical knowledge which cannot be obtained by any other means.¹¹

Although the guidelines establish a hierarchy of interests, difficulties remain in their implementation. First, even a guideline like this one, which attempts to cover all possible conflicts, cannot clear up all ambiguity, because it leaves to the researcher and the institutional review board (IRB) the determination of what constitutes a "direct benefit" or "minimal risk." Second, uncertainty about what these regulations require and fear of contravening them may result in fewer studies that include pregnant women. Exclusion of pregnant women in turn leaves important questions unanswered about how to treat a variety of illnesses and conditions in pregnant women and may unjustly skew the distribution of research's benefits.³⁰

Regulations and guidelines regarding the inclusion of pregnant women are often understandably influenced by the religious and political debate over the moral status of the fetus. Without overtly stating their justifications, regulations like the one quoted above often give weight to both fetal and maternal interests while granting ultimate precedence to the concerns of the mother; this is consistent with the widely held sentiment in public and legal opinion that an unborn fetus has inferior moral status to its living mother. Several authors in the bioethics literature have attempted to form a coherent rationale and conceptual framework to support giving more weight to maternal interests than to those of the fetus, with varying degrees of success. One intriguing framework suggests the unborn fetus has "dependent moral status"—that is, the fetus is only granted status as a person with legitimate interests by the personal preference of its mother, not out of her obligation to do so.⁴⁶ This granting of dependent moral status is closely correlated with the expectation that a given fetus will later achieve the moral status of a child with rights.

Research With Fetuses to Be Aborted

However, this raises another ethical dilemma: Should research involving pregnant women who are planning to abort be governed by different guidelines? The National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research concluded in the 1970s that the future of the fetus—that is, whether the pregnant woman planned to give birth or abort—was immaterial to the regulation of fetal research; it argued that if there were no potential of direct benefit for mother or fetus, only minimal-risk research should be permitted.⁴⁸ However, some authors have questioned the logic behind this statement. If the

regulations for research with pregnant women are justified to protect the interests of a future child who could suffer or be impaired as a result of teratogenic procedures, the regulations seem nonsensical when there will be no future child to protect.¹⁴

Fathers' Input

The role, influence, or veto power that a potential father should have in such research participation is another ethical concern specific to the situation of pregnant women. The National Commission occasionally referred to the need for consent from fathers without overtly detailing the nature and limits of their power, stating, for example, that "nontherapeutic research on the pregnant woman or on the fetus *in utero* may be conducted or supported, provided . . . the father has not objected."⁴⁸ DHHS regulations (45 CFR 46, subpart B) state that the consent of the father, in addition to the mother, is necessary for any research with the possibility of direct benefit solely for the fetus, unless the father cannot give consent for reasons of "unavailability, incompetence, or temporary incapacity or the pregnancy resulted from rape or incest."¹¹ The father's consent is not necessary, however, for research that holds out the prospect of direct benefit for the pregnant woman or for both the pregnant woman and the fetus, or when research involves only minimal risk but aims to develop important biomedical knowledge that cannot be otherwise obtained; the consent of the pregnant woman is still required in these situations (45 CFR 46.204). These variations partially reflect the public debate about men's say in abortion decisions, as demonstrated in the controversy over spousal notification laws.⁴⁹

Although relatively little has been written about men's role in the research participation decisions of their pregnant partners, some authors, particularly those more oriented toward feminist ideology, are reluctant to give fathers much say in the decision.¹⁴ They argue that although fathers might have a legitimate interest in preventing a pregnant woman who is not planning to abort from participating in a study potentially risky to the fetus, pregnant women would not be enrolled in these types of studies according to current regulations anyway.¹⁴ Alternatively, if the pregnant woman plans to terminate her pregnancy, these authors echo the general women's rights sentiment that denies men's veto power.¹⁴

Liability Concerns

One common concern in research with pregnant women is a particularly legal one: Sponsors worry about incurring liability for the possible injury of a fetus in the course of a research trial. Although data regarding the frequency and likelihood of legal action seem to indicate that suits on behalf of fetuses are unlikely (a point that will be discussed in the next section), the fear of liability remains significant among researchers and is probably one of the primary contributors to women's exclusion from clinical studies.^{15,45,46,50} However, even if fear of liability is justified by legal theories and practices, a number of scholars have pointed out that company sponsors and research institutions might also incur liability for *excluding* women from trials, given that drugs in the postmarketing phase will expose more women to the possibility of unexpected and adverse reactions to the treatment.^{43,51} Fear of liability among researchers must be scrutinized for its validity and directly addressed with clearly established regulations and policies so as to avoid unnecessary exclusion of pregnant and potentially pregnant female subjects.

Women as "Potentially Pregnant" Persons

Women with established pregnancies clearly present a host of difficult ethical problems unique to their biological condition, but an ethically grayer area involves the nature of fertile women as *potentially* pregnant entities. Although the FDA's 1977 regulations prohibiting all "potentially pregnant" women from early clinical research seemed to unjustly bar women from the personal and population-based benefits of research participation, the knowledge that fertile women may become pregnant in the course of research participation brings up difficult questions regarding how to anticipate and plan for this possibility. Specifically, should women's attitudes toward contraceptive use be factored into the decision about whether to enroll them in a given research trial?

To give an example, researchers studying a serious chronic disease want to evaluate the antiinflammatory effects of the known teratogen thalidomide. Should the use of birth control during the course of the study be mandatory? If there is a nonnegligible chance that women could become pregnant with severely deformed fetuses as a result of study participation, researchers might reasonably consider excluding women who would refuse to use contraception; on the other hand, this criterion would necessarily exclude particular subgroups of women who, for religious or other reasons, do not believe in artificial contraception.

At its core, the question over whether to make contraceptive use an inclusion criterion can be construed as balancing a woman's autonomy against beneficence-based and justice-based obligations to a hypothetical future child.⁵² Although researchers may sometimes be able to work with a woman to reduce the chances of pregnancy without violating her religious or moral beliefs, this will not always be a viable option. Rather, it has been suggested that requiring contraception use or abstinence as an inclusion criterion ought to be evaluated in light of the potential benefits of participation in a particular study. Although researchers may exclude a woman not using birth control from a trial that has little potential for her medical benefit and uses teratogenic substances, they might relax inclusion criteria if the woman could potentially greatly benefit from trial participation that involved experimental treatment unavailable outside of the research setting. Likewise, the greater the potential for teratogenicity in a trial, the more stringent the requirement for contraceptive use should be.

In the actual event of an unexpected pregnancy, women's rights advocates in the bioethics literature stress women's autonomy, contending that although fertile women should be explicitly informed during the consent process that an experimental drug/device has teratogenic potential, the choice to enroll and a possible subsequent choice regarding pregnancy termination should be left to the woman herself.^{46,53} Though some authors have also noted the ethical tensions that antiabortion researchers themselves might feel if faced with a pregnant participant in a study of teratogenic pharmaceuticals, they assert that researchers of both pro-choice and pro-life views should feel ethically comfortable with neutrally referring pregnant subjects to a obstetrician/gynecologist.⁴⁶

Although the gray area involving potentially pregnant women in possibly teratogenic studies has its own set of ethical difficulties, these dilemmas seem best managed on an individual study basis. Rigorous attention during the informed consent process to possible harms to the fetus from experimental agents or interventions, as well as counseling to help participants deal with unexpected pregnancies, may assist conscientious research planning.

Researchers ought to continue opening doors to female research participants, including those who are pregnant, but these ethical debates suggest that they should proceed with a certain amount of caution. Women's status both as a historically oppressed group and as the biological gestators of new human beings contributes to the ethical complexity inherent in involving them in an enterprise generally and necessarily fraught with risks for harm. The significant potential benefits from such involvement, however, strongly compel the research enterprise to seek ways of justly including female research subjects.

Empirical Data

Given the many ethical issues raised by the participation of pregnant and nonpregnant women in clinical studies, it is of the utmost importance to gather empirical evidence regarding the nature and effects of women's inclusion as research subjects. Data from many academic fields, including sociological, epidemiological, biological, and medical disciplines inform deliberations about the appropriate inclusion of female research subjects. Bioethics debates often benefit from population-based data that clarify the nature of disparities, opinions, and day-to-day realities that characterize the research environment.⁵⁴ In the particular case of women's research participation, existing empirical data can both buttress arguments for greater inclusion of women and help determine solutions to some of the problems created by their participation.

Evidence of Physiological Sex Differences

Empirical evidence establishes the need for female research subjects by illustrating the widespread and significant ways that male and female biology differ. In recent years, scientists have accrued a staggering list of conditions and general physiological characteristics that vary by sex (see Table 38.1). Though sex differences in physical and biological characteristics directly related to reproduction have long been acknowledged, researchers in recent decades have also begun to uncover sex differences that occur in other bodily systems or in the course of various illnesses.⁵⁵ Some conditions vary in prevalence by sex: Urinary incontinence, for example, is significantly more likely in women, as are type 2 diabetes, irritable bowel syndrome, chronic fatigue syndrome, musculoskeletal diseases such as osteoarthritis, and major depression; alternatively, autism, learning disabilities, and attention deficit hyperactivity disorder (ADHD) are significantly more common in men.

Sex differences are also seen in the presentation and natural history of some diseases. Women have a significantly lower initial HIV viral load than do men, for example, and they generally demonstrate lower pain tolerance. Men and women may also differ in their reactions to specific treatments and medications: Women react more positively to certain opioid analgesics for pain management than their male counterparts, for example, and pharmacologic agents used to treat cardiovascular disease induce different responses depending on sex. (See chart for citations.) This litany of physiological differences is not meant to be comprehensive, but rather to indicate the many and varied subfields of medicine in which sex differences exist, illustrating the vast extent of physio-

Table 38.1
Selected Studies Demonstrating Medical Differences Between the Sexes

<i>Condition</i>	<i>Details</i>	<i>Findings Published</i>
Urinary incontinence	2:1 more common in women than men ⁵⁶	2001
AIDS and HIV	Initial viral load in women is significantly lower than in men, though both sexes develop AIDS at the same rate ⁵⁷	2001
Pain management	Women appear to have lower pain thresholds and tolerances than men, ⁵⁸ certain opioids are much more effective analgesics in women ⁵⁹	2001, 1996
Type-2 diabetes	More prevalent in women than men, especially after age 65 ⁶⁰	2000
Irritable bowel syndrome	3:1 more common in women than in men ⁶¹	2001
Chronic fatigue syndrome	Nearly 2:1 more common in women than in men ⁶²	2001
Musculoskeletal diseases (osteoporosis, osteoarthritis, sports injuries)	More common in women than in men ⁶³	2000
Autoimmune diseases	More common (and deadly) in women than in men ⁶⁴	2000
Cardiovascular diseases	Differences in severity, incidence, importance of age, presentation, efficacy of treatment ⁴⁴	1999–2006
Depression	Twice as common in women as in men ⁶⁵	2000
Autism, learning disabilities, ADHD	More common in men ⁶⁶	2001

logical variation between men and women for which there is empirical evidence.

Extent and Effects of Research Exclusion

Given that women often differ from men in their presentation of disease and reaction to treatments, it is important to analyze how these sex differences interact with women's past exclusion from clinical research to affect them as a group. Data provided by numerous population-based studies strongly support the claim that less research has been done, and to a lesser degree continues to be done, with female populations than with male, particularly in studies of specific diseases.^{67–69} Though some authors question the actual size of the disparities in the current research agenda,¹⁶ several gaps appear to exist in the amount of research done with women in a number of medical fields.²⁴ Disparities exist not only in research on diseases unique to women, but also in areas unrelated to the reproductive system, such as chronic conditions like

Alzheimer's disease and obesity, genomic studies, musculoskeletal disorders, cancer, addictions, and more.⁷⁰

This lack of research data from female subjects, in turn, has been demonstrated to have a sizeable negative impact on women's health "downstream" because it impairs the quality of women's primary care. When new medications and procedures are tested only in one subgroup of the population, there is a heightened danger that other subgroups will experience unexpected and potentially adverse reactions to the same treatment.^{24,71} This is especially true given the documented physiological differences between women and men, who made up the bulk of study participants, particularly in older research studies. Historical examples abound: Male-only studies of heart disease and cholesterol led to widespread recommendations of a diet that could actually exacerbate the risk of heart disease for women;¹⁵ efficacy of certain approved psychological medications was later demonstrated to oscillate significantly over the course of the menstrual cycle;⁷² women with schizophrenia and bipolar disorder were found to exhibit different responses to treatment that had been found effective in studies using only men;⁶⁶ and so forth.

The impact of exclusion from research is also apparent with pregnant women. For a widespread example, little to no psychopharmaceutical research has been done with pregnant subjects.^{73,74} Consequently, physicians treating pregnant women suffering from psychosis and other mental disorders have little information about the teratogenicity of various psychopharmaceuticals. Prescribing such drugs anyway, without evidence of safety and teratogenicity, puts women and fetuses at unknown risk.⁷⁵ Fear of teratogenicity and unexpected side effects may make some physicians reluctant to prescribe untested drugs at all, potentially leading to the undertreatment of serious psychiatric disease during pregnancy. Empirical data thus lend objective credence to the claims that exclusion from research may impair the quality of women's clinical care for a number of medical conditions.

Prevalence of the "Male Norm/Bias"

If evidence indicates that sex differences do exist, even in many supposedly "gender neutral" diseases, and that women and men experience different symptoms and have different optimal treatment regimens, what sort of obstacles might prevent the embrace of more gender-tailored medicine and greater numbers of female research subjects? One such barrier might be physicians' conscious or unconscious adoption of a "male norm" of health and disease. One physician provided this comparison: "If a 50-year-old man goes to the doctor complaining of chest pains, the next day he will be on a treadmill taking a stress test. If a 50-year-old woman goes to the doctor and complains of chest pains, she will be told to go home and rest."⁷⁶ Although this statement could be written off as anecdotal or as one isolated physician's opinion, evidence indicates that many health care professionals operate with "a *male bias* (observer error caused by adopting a male perspective and habit of thought) and/or the *male norm* (the tendency to use males as the standard and to see females as deviant or problematic, even in studying diseases that affect both sexes)."⁷⁷ Proving that such norms and biases exist and are in practice is difficult; after all, many physicians and researchers may not realize they are employing them. It may sometimes be inferred, however, that biases or inappropriate norms are at work in health care pro-

professionals' opinions. For example, in reaction to the 1985 Public Health Service Task Force's report, some researchers publicly opposed new guidelines mandating the inclusion of female research subjects, claiming that women's menstrual cycles add an "extra variable" and thus extra work in their analyses. This argument, however, assumes that a nonmenstruating (male) body is the "normal" human body, exemplifying the thinking behind the "male norm." Determining what counts as "extra" depends on how the baseline is viewed.^{10,15,38} Though more empirical research on this topic is clearly needed, researchers' and physicians' beliefs about the sexes may influence their research designs and their treatment of patients.

Female Subject Recruitment

Empirical data may also prove useful in untangling ethical dilemmas related to women's inclusion in research. For example, how might recruitment and retention of female research subjects differ from that of male research subjects? Should recruiters utilize certain tactics to attract female subjects, or be particularly concerned about certain influences on a female subject's decision to continue or withdraw? Several studies suggest that the roles and responsibilities women commonly assume in U.S. society may influence their decision to enroll and continue to participate in research studies.

Often charged with the care of children, women may be less likely to enroll in research if there is no option for child care or if the study has an extremely inflexible research appointment schedule.⁷⁸ Similarly, elderly women in particular may be less likely to drive or to have sufficient income to absorb the cost of taxi fares.⁷⁸ Recruiters ought to be sensitive to any potential stigma that may be attached to certain studies for female participants. For women in rural Africa, for example, participating in an HIV vaccine trial could offer personal benefits; however, the social stigma associated with being mistakenly viewed as HIV-positive and/or engaging in extramarital relationships is sufficient to keep many women from enrolling.³⁶ In a less serious but similar situation, one research study discovered that using the word *menopause* on recruitment flyers had a deterrent effect on recruitment in a major metropolitan U.S. center, because menopause and aging have salient negative connotations in Western society.⁷⁸ In light of evidence demonstrating that women are faced with a different set of daily obligations, difficulties, and taboos than men, female subjects may warrant somewhat different recruitment strategies.

Recruiting and retaining women of color in clinical research might be even more challenging. African American, Hispanic, and other minority women contemplating research participation face not only the obstacles shared by ethnic minority men but also additional difficulties by virtue of their specific status as minority women. Much has been written about researchers' difficulties in recruiting participants of either gender from ethnic minority groups, including the widespread suspicion and distrust of research institutions among minorities, stronger spirituality that may make minorities unlikely to seek treatment for conditions that are "God's will," and the difficulty of committing to time-consuming studies for individuals of low socioeconomic status.^{38,79,80} Minority women may also have greater difficulties than white women due to child care responsibilities: Women of color are more likely both to be single parents and to adhere to traditional child caring roles in the home.⁷⁹ Armed with empirical information about the barriers

faced by women—and particularly minority women—researchers may be better able to increase recruitment and retention of female subjects, further patching the holes in knowledge about women's health.

Liability Concerns

As previously noted, a major concern in research with female participants is the fear of liability for any injuries that may occur during the course of trial participation. Though there is always a potential for the woman herself to be injured and sue in clinical research, this situation is no different from the potential liability researchers assume with male subjects. Rather, researchers and sponsors worry about assuming additional legal responsibility for a *fetus* harmed during the course of the trial. Although available information cannot completely assuage this fear, it can dampen the concern. Suits by patients injured in the course of research are rare,^{43,45} and suits on behalf of children injured in the course of their mother's research participation are even less common.⁴⁵ Although a few state courts have ruled in favor of prenatally injured children in lawsuits unrelated to research participation,⁴³ the extensive research consent process coupled with disagreement about the fetus's status as a rights-bearing human being lead some legal experts to doubt the success and even likelihood of any such lawsuit.^{15,50,52}

Effects of Increased Attention to Research on Women's Health

Despite difficulties with past exclusion as well as practical and psychological barriers to women's research participation, empirical data demonstrate the clear beneficial impact that greater inclusion of women in clinical research can have on the quality of clinical care. NIH's Women's Health Initiative (WHI), for example, a long-term, multimillion dollar research project, supported a large-scale study of hormone replacement therapy for post-menopausal women. Though previously believed to be harmless or even beneficial, WHI research demonstrated that estrogen-progesterone therapy was correlated with an increase in the risk of stroke, heart attack, and breast cancer, a discovery which led the U.S. Preventive Services Task Force of the U.S. Agency for Healthcare Research and Quality (AHRQ) to issue a recommendation against chronic estrogen and progestin therapy in post-menopausal women.^{44,70} Genomic studies of breast cancer, and the discovery of the *BRAC1* and *BRAC2* genes, have led to a number of new clinical preventive approaches for women found to be at genetic risk.^{81,82} Empirical data have revealed important sex differences in the symptoms and optimal treatment for cardiovascular disease, including the particular ways women present with myocardial infarction⁸³ and a sex-specific reduction in stroke for women taking aspirin regularly.⁸⁴ Despite the relative youth of the movement for greater inclusion of women in clinical research, large gains have already been achieved that may be translated into primary care.

Avenues for Future Empirical Research

Additional empirical data in yet uninvestigated areas could help administrators and researchers to create sensible policies regard-

ing female research subjects. For example, in response to the claim that the compulsory inclusion of women in research trials leads to extremely elevated costs,^{10,38} it would be helpful to know both the actual costs of adhering to the NIH inclusion guidelines and the estimated future costs of unnecessary or ineffective treatment of women—and lost productivity—because of the underrepresentation of women in clinical trials. Similarly, data on the primary care effects of women's research exclusion would be informative, such as the percentage of drugs taken by pregnant women that have been actively investigated for teratogenicity, or the extent to which female patients are still receiving the typical "male" treatment for diseases despite demonstrated sex differences in reaction to treatments. Information about the progress of recruiters in enrolling and retaining female subjects, particularly from racial minority groups or the elderly, would also benefit policy makers attempting to allocate resources appropriately. Finally, additional data revealing sex differences in responses to treatment or in disease manifestation are critical. Each upstream discovery in a specific field has the downstream potential to provide women with a higher quality of care and life. Further empirical evidence on these and a host of other questions will continue to enrich debates about the ethics of women's research participation.

Policy Implications

The historical record of women's exclusion and gradual inclusion in research studies, the ethical issues raised by their participation, and empirical evidence that supports or weakens the ethical debates all aim to influence public policy. Without a method of translating conceptual and empirical work into policy, however, academic studies will not affect the way women relate to and experience medical research. The success of this translation rests on how researchers and administrators use empirical findings and ethical clarification to shape both "big picture" policy decisions, such as issues of resource allocation and official research agendas, and more mundane policy questions such as how researchers design their studies and interpret existing ethical principles.

Major Policy Decisions

Establishing Priorities on the Research Agenda

One of the primary "big picture" policy concerns is how women's health needs should affect the ordering of research priorities, particularly for federally funded research. Several arguments support giving women's health problems at least some priority when competing for scarce funding resources. First, for conditions that affect both men and women, less research has focused on women—what treatments work for them, what symptoms they exhibit at the onset of the disease or condition, the usual clinical progression of the condition, and so forth.⁶⁷ Thus, compared to men, women with certain conditions are at a disadvantage in the doctor's office; they are more likely to receive inadequate treatment than their male counterparts for problems such as cardiovascular disease, for example.⁷⁰ Consequently, some argue, priority should be given to narrowing gender-based gaps in clinical care for diseases found in both sexes by investing greater resources in research on women's experiences with these conditions, with the aim of raising the quality of women's health care to equal status with that of men.¹⁵

However, other conditions that affect women—such as breast cancer, endometriosis, pregnancy, and so forth—simply do not occur in men, or occur predominantly in women. Thus, the call for greater research on these issues cannot be based on the imperative to equalize quality of care for men and women suffering the same illnesses. Rather, increased research on women-specific health issues might be justified as a means of improving the quality of women's health care overall, not just for specific conditions.⁴⁶

Some argue that resource allocation for research on specifically female issues is desirable in order to “make up” for past exclusionary practices.¹⁵ Critics liken such a policy to affirmative action in other sectors of society; research programs would be funded not for their merit alone, but in an attempt to make up for historical injustices. Though the affirmative action comparison does not exactly hold—men's health would not directly regress because of more research with women, in the way that men may actively lose jobs to women under employment-oriented affirmative action programs—these complaints stress the need for careful consideration of policies that put women's health issues at a premium, recognizing that other potentially worthy research projects may be unfunded as a consequence.

A tangential debate over research priorities springs from the widespread dearth of information on the teratogenicity of many widely prescribed treatments. Though some treatments are known to cause birth defects, many have never been studied for possible harmful effects on gametes and developing fetuses, leading women's research advocates to push for more funding for the investigation of drugs' and procedures' mutagenic potential.^{53,85} However, experimental pharmaceuticals and treatments may have mutagenic effects on the gametes of both sexes. If our research agenda stresses a closer examination of the teratogenic effects of new treatments, it seems logical to examine the effects on the reproductive systems of both women and men.^{14,15}

Eliminating Bias in Institutional Policy

Another important issue for policy change revolves around the idea of eliminating the male norm or male bias in official research regulations and guidelines.⁷⁷ Although it is hard to know precisely how often this bias is operative, advocates concerned with the persistence of views defining men as the “default” and women as “variations” urge policy makers to closely examine seemingly gender-neutral policies for the presence of these biases. Regulations that exclude women from research because of biological conditions found in most women—menstrual cycles, for example—are said to be operating under the assumption that women's differences from men are “extra” or “variations from the norm.”¹⁰ Though these policies may be based on a desire to keep costs and necessary analyses down, they represent a perspective on sex differences that many claim is unjust. Policy makers ought to carefully consider the reasoning behind regulations that seek to exclude women on the basis of a given biological difference.

Regulations Governing Research With Pregnant Women and Fetuses

Policy makers also ought to recognize the intentions and implications behind important barriers that exist in research with pregnant women and fetuses. For example, as previously noted, many current regulations and guidelines do not permit anything more than minimal risk for fetuses in clinical research if there is no

potential for benefit for mother and/or fetus, regardless of whether the woman plans to carry the pregnancy to term.^{11,48} Such limits on permissible risks in fetal research seem to be justified for protecting the interests of a future child, but is it logically consistent to extend these same limits to research on fetuses that will be aborted?^{14,86} At the very least, some clarification seems to be necessary regarding the reasoning behind the similar or differential treatment of fetuses based on whether the pregnancy is expected to be brought to term.

Similarly, policy makers might examine policies regarding pre-human animal studies that must occur in order to gauge the teratogenicity of new treatments. Although the federal regulations prohibit research with pregnant women and fetuses unless “appropriate” preclinical studies have been done with animals to assess risks, the text of the regulations offers little guidance on what studies are appropriate.¹¹ Different types of experimental treatments might necessitate different types of animal studies to best evaluate possible teratogenicity. In addition, inherent differences in biology and anatomy can make it difficult to predict how animal reactions to treatments will be reflected in human beings. Chemicals such as the rubella vaccine have been found to cross the placental membrane in humans but not in nonhuman primates.¹⁴ Animal data alone is insufficient to determine how a new pharmaceutical or treatment will affect a human fetus. Acknowledging that different types of animal studies might be necessary to properly assess the risks and benefits of study participation in a given research project, and that animal studies are not a sure indicator of teratogenicity in humans, policy makers ought to specify the types of information they actually hope to gain from animal studies and clarify existing regulations accordingly.

Daily Research Practices

Attitudes Toward Liability Concerns

Data regarding liability for research-related injuries might inform policy and practice at the day-to-day level of study design. We have already discussed empirical statistics that suggest legal action resulting from prenatal injuries is decidedly rare.⁴⁵ Furthermore, from a pragmatic viewpoint, there are the two previously discussed arguments claiming that excluding women could incur more liability than including them. First, because women have a constitutional right to equal protection under the law, they could bring lawsuits claiming unfair exclusion from studies.⁴³ Second, the liability that a drug sponsor assumes during the course of a research trial involving women is several orders of magnitude less than the liability a manufacturer could face if an unexpectedly teratogenic pharmaceutical enters widespread and unmonitored use.⁵⁰ Acknowledging the relevant data and logical arguments, research institutions ought to feel relatively confident about their current methods of reducing liability by disclosing information in the consent process and providing care for research-related injuries. Accordingly, potential liability from unexpected fetal defects should not be a reason for categorically excluding pregnant and potentially pregnant women from research trials.

Interpreting Ambiguous Regulations

IRBs and researchers might benefit from academic work, specifically in the ethics field, in their attempts to interpret policy regulations that use ambiguous or undefined terms. According to

U.S. federal regulations, for example, the permissibility of research depends to some extent on whether study participation “holds out the prospect of direct benefit to the pregnant woman,” but the phrase “direct benefit” is not defined.¹¹ Is there prospect of direct benefit even if the expected benefit is small or the chances of the woman actually responding to the treatment are slim?⁸⁶ Some ethicists have dealt with the question of what should be considered a “prospect of direct benefit” under the federal regulations by focusing instead on the sort of benefit that would be necessary to justify potential harm to a fetus; that is, although we might agree that a potentially teratogenic new acne medication technically has the prospect of providing a “direct benefit” to a woman, we still might conclude that this benefit is too minor to justify the significant risk to a developing fetus.⁸⁶ This approach calls for an individual calculation of the benefits and potential risks for the woman and the fetus with each research project.

A similar problem of definition exists with the federal regulations’ minimal risk standard. Research permissibility may depend on there being only “minimal risk” to the fetus; but what risks should be considered minimal? Although the federal regulations attempt to clarify *minimal risk* as “the risks of daily life,” this definition only raises the question of what “daily life” consists of.¹¹ IRBs have been found to vary enormously in their interpretation of the minimal risk standard, leading to further confusion among researchers.⁸⁷ Although the definition of minimal risk remains a live question, scientists trying to design and categorize their studies might gain some guidance from recent ethics work attempting to quantify the risks of *daily life* by using data on the risks of driving in a car or engaging in common sports.⁸⁸

Study Design

Conceptual and academic work on women’s participation in clinical research also has ramifications for research study design. These design strategies concern both the mechanisms by which women can be included fairly as participants in clinical research and the means of mitigating some of the more ethically difficult situations that can occur with female participants.

Creating Equitable Research Participant Populations

The first and most important consideration is how to ensure that women are not unnecessarily excluded from research participation at the level of study design. Women ought to be fairly included in clinical studies so as to fairly distribute the benefits of research—both the personal benefits of research participation and the general benefits that result from being able to tailor diagnoses and therapies to sex-specific differences.^{15,30} In addition, research designs that recruit sufficient female subjects to enable sex and gender comparisons are crucial to equalizing the “downstream” quality of health care between men and women.^{10,17,24,67}

Thought should be given to how to fairly include various subgroups of women as well, such as minority and elderly women, in acknowledgment of the possibility of relevant differences among different types of women. However, it is clear that at some point cost and complexity become limiting factors; if researchers were required to have equal numbers of every possible subgroup, research costs would become prohibitively expensive, and the an-

alyses might become so unwieldy as to be unworkable. To balance subgroup representation and finite resources, researchers should consider how the biological feature of interest expresses itself in the wider population, then aim for the research subject population to reflect this incidence appropriately.²⁴

Recruiting and Retaining Female Subjects

Researchers should also consider implementing different styles and methods of subject recruitment that may be more likely to attract women. Evidence suggests that women are more likely to enroll and stay with trials that cater to women’s particular needs, such as providing child-care options (particularly with ethnic minority women), maintaining a flexible appointment schedule, and providing transportation for subjects unable to arrange it themselves.⁷⁸ Additionally, recruiters ought to be alert to the potential stigma that can occur for women involved in certain cases of clinical research and should consider presenting the study in a different way to avoid negative reactions. For example, in the menopause studies mentioned earlier, recruitment materials were altered to focus on the positive need for more research on women’s heart disease. Often, by making relatively small changes, study recruiters faced with policies mandating greater inclusion of women in clinical research trials can make participation more appealing for female subjects.

Planning for unexpected developments during the course of women’s research participation should also be considered.⁵² In anticipation of the chance that fertile women may become pregnant during the investigation of a possibly teratogenic treatment, researchers involved in the consent process should take special care to (1) clearly communicate the risks a given study’s protocol would have for a potential fetus, (2) explain how women can successfully avoid pregnancy during the course of the trial, and (3) discuss what actions will be taken if the woman does unexpectedly become pregnant. Rather than excluding women opposed to birth control for fear of causing possible harm to a fetus, advocates for women’s clinical research participation urge researchers to provide sufficient information during the consent process so that women are sufficiently empowered to make their own choices about participation.⁵² This approach not only respects women’s ability to make autonomous choices, but makes it less likely that researchers will be found legally liable in the event of a research injury to the woman or fetus.⁵⁰

Conclusion

Women as a population hold a unique and thorny place in the arena of clinical research. Though women cannot technically be considered a minority, because they comprise more than half the total population, they have historically suffered discrimination and unfair treatment at the hands of many U.S. institutions, including the research enterprise. Despite the inclination to protect women, given their status as both a relatively disempowered population and the sex who share their bodies with future new human beings, society has come to realize the important role research participation has in improving the quality of health care and the general promotion of justice. The ethical difficulties that necessarily surround women’s research participation should not be underestimated and cannot be easily resolved. But in recent years both

conceptual and empirical work have driven significant improvements in both clarifying issues and delineating interests and concerns that should take priority in official policies and regulations.

The protective approach to women and pregnant women in clinical research has been difficult to debunk and is still reflected in many contemporary guidelines, but significant progress has been made in increasing women's opportunities to participate. These efforts have had an important impact on the creation of more equitable policies and study designs, which in turn has had and will continue to have a tangible influence on the quality of women's medical care. It is imperative to continue in this tradition to assure the fair distribution of research's benefits.

Research With Ethnic and Minority Populations

Historical Background

Egregious misconduct in clinical research has often centered on ethnic and minority populations. The Nazi “experiments” involved disregard for the lives of Jewish, Gypsy, and other subjects whom the Nazis considered racially inferior. The Tuskegee study was flagrantly unethical because of its lack of informed consent, its deception, and its exploitation of poor, often illiterate African Americans. The legacy of Tuskegee persists today among many African Americans, who are largely mistrustful of medical research and often unwilling to participate in clinical trials.¹ Specifically, a number of studies show that African Americans are more likely than people from other ethnic backgrounds to believe that researchers would lie to them about research and would expose them to unnecessary risks.^{1–3} In addition, African Americans tend to believe that to give informed consent for research is to sign away their rights.² Furthermore, African Americans view research in the context of broader concerns about racism and remain skeptical that research would provide any benefits to them as a group.^{1,4}

Some ethnic and minority communities also fear that research will support political and social policies that will be detrimental to them. For example, many genetics researchers in the late 19th and early 20th centuries supported eugenic public policies including immigration restrictions and forced sterilization.⁵ In retrospect, much of this research and the conclusions drawn from this research were flawed and biased. Because of this history, many ethnic and minority communities today remain concerned about the policy implications of research. This chapter will focus on racial groups such as African Americans, and religious groups such

as Ashkenazi Jews, but not minority populations of other kinds such as gay men or sex workers.

Current Interest in Research With Ethnic and Minority Populations

Certain diseases disproportionately affect minority groups. Worldwide, the vast majority of cases of HIV infection occur in sub-Saharan Africa and Asia, whereas in the United States, new cases of HIV, end-stage renal disease, lead poisoning, and other conditions are significantly more common in African Americans.⁶ Health disparities are another driving force for research on ethnic and minority populations; in the United States, racial and ethnic minorities tend to have poorer health-care outcomes, lower quality of care, and worse access to care than nonminority populations.⁶ These disparities are compounded because racial and ethnic minorities tend to have economic and social disadvantages that are also associated with worse health outcomes. However, studies find that health disparities persist even when minorities have similar access to care; thus, research is essential to clarify the reasons for these disparities. A recent Institute of Medicine report found evidence that bias and stereotyping by health-care providers and the health-care system contribute to unequal treatment.⁶

Researchers sometimes enroll members of ethnic and minority groups because it is necessary to include such individuals in order to adequately understand or ameliorate a serious condition that disproportionately affects them. For example, in the United States HIV infection in Caucasians most commonly results from men having sex with other men, whereas HIV infection in persons of

color results primarily from injection drug use or heterosexual intercourse with injection drug users. Hence prevention and clinical trials of HIV infection that enroll primarily Caucasian participants may not provide reliable data on HIV infection in minority communities because of differences in risk behaviors and adherence to therapy.

Studies targeting persons in ethnic and minority groups are justified when they are designed to improve the circumstances that lead to serious risks or illness in their lives.⁷ However, even when the disproportionate inclusion of persons from ethnic and minority groups is justified, such disproportionate enrollment can lead to concerns about or the perception of inequitable selection of subjects. For example, in the context of HIV research, the ethical concern is that minority persons in developing countries may be being used as research subjects to test vaccines or drugs that they may not have access to after research is completed.⁸ Indeed, the concern may be that if research shows the intervention to be effective and safe, people in industrialized countries will be the primary beneficiaries, because they will be able to afford it.

Populations from different geographical origins may differ in their physiological response to medications.^{9,10} Some groups have less favorable responses to standard medications for certain conditions. For example, some African Americans have a less favorable response to beta-blockers and ACE inhibitors in hypertension.¹¹ However, the effect is small, and the vast majority of African Americans have responses to these medications that are similar to those found in Caucasians. Similarly, African Americans may have less favorable responses to ACE inhibitors in congestive heart failure than Caucasians.¹¹ There are many potential explanations for this finding, including the selection of endpoints and the presence of comorbid conditions such as diabetes, as well as genetic differences between the groups. More research is needed to understand such differences.

Ethnic and racial minorities are underrepresented in research.¹² As a result, rigorous evidence is lacking regarding safety and efficacy of therapies in these populations. Hence clinical recommendations for such populations are based on weak scientific evidence. Such underrepresentation may be due to lack of access to clinical trials or unwillingness to talk to researchers about a clinical trial, rather than unwillingness to enroll in a trial once asked to do so.¹³

In the genomics era, there is a strong scientific rationale for conducting research on ethnic and minority populations. Genes for conditions of interest are more likely to be identified in populations that have a high prevalence of genetic disorders and/or low genetic diversity. Researchers who study human population genetics also need samples from diverse populations. In both instances, ethnic and minority populations may provide scientifically important data.

Research With Ashkenazi Jewish Populations

Over several decades, researchers have studied Tay-Sachs disease, the role of BRCA1 and BRCA2 genes in breast cancer, and the role of the APC gene in colon cancer in Ashkenazi Jewish populations. Researchers studying these diseases have worked closely with community and religious leaders and carried out extensive programs of community outreach and education. In addition to informed consent from individuals, researchers have obtained the support of rabbinic and community advisory committees for their studies.

Researchers have had to address concerns that individuals who are identified as carriers of a disease or at risk for an adult-onset disease would suffer stigmatization and discrimination. In the case of Tay-Sachs disease, individuals and community leaders feared that carriers would become unmarriageable.¹⁴ In the case of susceptibility to cancer, there were concerns about discrimination against at-risk individuals by health insurance companies and employers, particularly if confidentiality were breached.¹⁵ Researchers, in conjunction with community leaders, have addressed these concerns in innovative ways. With Tay-Sachs disease, researchers initiated extensive community education about the disease. After the ethical and social issues were widely discussed in the community, a nonprofit group called Dor Yeshorim was organized to carry out confidential and anonymous genetic testing for Orthodox Jewish couples considering marriage, and to inform them if either or both partners were carriers.¹⁴ In cancer genetics research, researchers offered participants the option of participating in research studies without learning the results of their own genetic tests.

Some Ashkenazi Jewish community leaders raised concerns about stigmatization of the group even if confidentiality of individual research participants were maintained. These leaders worried that the Jewish community might be labeled “bad gene carriers” because of news reports that perpetuated the idea that Jews are particularly susceptible to cancer and other conditions. Researchers found, however, that the Jewish community was not homogeneous regarding such concerns about group stigmatization. Although there was considerable concern in some cities, in others there was relatively little.¹⁶ Researchers therefore were able to successfully recruit participants in the communities that believed the potential benefits of the research outweighed the risks of group harm.

Research With Amish and Mennonite Communities

Amish and Mennonite communities have several characteristics that are advantageous in studying genetic diseases.^{17,18} They experience high rates of particular genetic diseases because of a founder effect (many members of the community can trace their ancestry to a single individual) and inbreeding. In addition, they are relatively small populations that remain geographically localized, have large families, and keep excellent genealogical records.

Research has been successfully carried out in these communities in large measure because the main researchers live within the communities and have made a commitment to public service.¹⁹ Physicians established the Clinic for Special Children in Pennsylvania to provide diagnostic services and therapy as well as to identify cases for research.¹⁷ The Amish and Mennonites do not buy medical insurance, nor do they accept public funding for medical care; therefore, the clinic carries out fundraising to help pay patients' medical bills. The researchers thus have made a long-term commitment to provide crucial health-care services to the community, rather than simply to collect research samples and data. Physicians also hold meetings to educate the community about the diseases under study, their research findings, and potential new therapies.

In order to study and treat this population, researchers must take into account the community's pervasive cultural values about science and technology. These groups traditionally shun modern

technology, including automobiles and electricity. Children with Crigler-Najjar syndrome, a congenital disorder that prevents the usual metabolism of bilirubin, which can then lead to kernicterus and brain damage, require extensive daily exposure to special blue lights. More advanced cases may require liver transplantation. In explaining the need for these therapies and for research on such high-tech interventions as gene transfer, researchers and physicians had to respect families' concerns about technology. Most families have accepted such research and therapies. They have accommodated these medical technologies, while continuing to reject most other technologies.¹⁹ Often the blue phototherapy lamps are the only electrical appliances in the home.²⁰

The Human Genome Diversity Project

The Human Genome Diversity Project (HGDP) proposes to study the variation within the human genome by collecting, storing, and analyzing samples from diverse populations.²¹ This project would be useful in identifying alleles that cause or predispose to disease and in ascertaining how genetic variation affects the response to drugs. The HGDP would also provide crucial information for human population genetics and about human migration and evolution.

The project has remained on hold, however, because of lack of funding, disagreements over what information should be collected about individuals, and opposition from activist organizations on behalf of native and aboriginal communities.

Critics attacked the HGDP as biocolonialism and biopiracy, because genes from indigenous peoples could be patented and developed into commercial products, yielding profits to corporations in the developed world.²¹ To address concerns about exploitation, HGDP investigators were urged to "seek ways in which participation in the HGDP can bring benefits to the sampled individual and their communities," for example through health screening, medical care, or education.²² Proponents of the project also declared that it would "work to ensure that the sampled population benefit from the financial return" from any commercial products that may be developed.²² Ironically, no medical or phenotypic information would be collected from donors, making the likelihood of developing commercial products actually very low.²²

One of the most contentious matters has been the issue of consent from groups as well as from individual participants who might donate samples for the HGDP. The North American investigators concluded that collective consent from groups was required through their "culturally appropriate authorities." The rationale was that the group itself was subject of the study and thus bore the risks of research.²³ In North America, the researchers were dealing with Native American tribes that have formal political authorities with the power to give or withhold such group consent. However, critics argued that group consent was generally impractical, particularly when there was no legitimized group government. Moreover, in their view, group consent reinforced the mistaken idea that there were significant genetic differences among populations with different cultures.²⁴⁻²⁶

Use of Racial and Ethnic Categories in Clinical Research

In the United States, racial and ethnic minorities tend to have worse health-care outcomes, lower quality of care, and worse

access to care than nonminority populations.⁶ These disparities, as well as the history of racial discrimination against African Americans, form the background for U.S. controversies over the use of ethnic and racial categories in research. The Institute of Medicine report called for ongoing collection of racial and ethnic data in outcomes research and clinical care in order to monitor these disparities and to evaluate measures intended to reduce them.

Going beyond outcomes research, some clinical trials are targeted specifically to certain ethnic populations. Historically, racial and ethnic minorities have been underrepresented in clinical trials, despite efforts by the National Institutes of Health (NIH) to increase their participation. As a result, the evidence base for the care of minority populations remains weak. In response to data suggesting that African Americans may respond differently to cardiac drugs, a randomized clinical trial that enrolled only African Americans showed in 2004 that a combination of hydralazine and isosorbide dinitrate added to standard therapy for congestive heart failure decreased mortality.⁹ This combination did not appear effective when added to standard therapy in a racially heterogeneous population. FDA approval was sought and given for use only in African Americans.^{27,28}

This study and its approach of using the participant's own categorization of his or her ethnicity in studies of race-based therapies have been sharply criticized. The sponsor of this trial obtained a patent to use two generic drugs in combination in African Americans. Hence the cost to patients and insurers of this patented combination drug, BiDil, is far greater than if the component drugs were sold as in generic formulations.²⁷ A more profound issue is the use of race as a proxy for the specific genetic variations, which have not yet been discovered, responsible for different responses to the drug being studied.¹⁰ More generally, testing for specific genetic polymorphisms would be a more reliable guide to therapeutic decisions for individual patients than is the use of race. These polymorphism markers are likely to be present in many but not all African Americans, and they will also be present in some persons who self-identify as Caucasian rather than as African American. Hence using racial categories to determine who should be prescribed a drug can lead to two errors: prescribing the drug to some patients who will not benefit, and not prescribing it to other patients who will benefit. However, the patent system offers the manufacturer of BiDil little incentive to carry out research to identify the specific genetic variations that cause patients to respond to the drug.

The BiDil example illustrates controversies over the use of racial and ethnic categories in clinical research. Some critics argue that ethnic and racial categories are outmoded in the genomics era and should no longer be used in research, because race and ethnicity are too imprecise to guide clinical decision making for individual patients.²⁹ Most genomic variation occurs within populations rather than across populations. A population may have a higher or lower probability of being at risk for a condition or of having a successful response to therapy; however, for an individual, the likelihood of being at risk or responding to therapy by virtue of being a member of the population is not sufficient to guide clinical decisions. Further testing or trials of therapies are generally needed to guide individual care. According to this line of reasoning, testing of individuals for specific alleles associated with disease susceptibility or response to therapy may be a better approach to genomics research and medical care than self-identified ethnic and racial categories. Such individualized testing will be

increasingly possible as genomic variations and their effects on disease and treatment are better understood and as microarrays for DNA testing become feasible. Moreover, the continued use of race in scientific publications reinforces the mistaken idea that race is a valid scientific category. In reality, its meaning is contested and overlaid with social and cultural values. Critics warn that race-based genomics research will be used or misused to reinforce existing racial stereotypes.

Others argue that racial and ethnic categories are useful in genomics research and clinical care.³⁰ For certain conditions, genetic variability accounts for medically important differences in disease frequency and outcome among racial and ethnic groups. In addition, some clinically important alleles occur almost exclusively in certain ethnic populations. Pharmacogenomics may be a fruitful area in which genetic variation is particularly likely to have clinically meaningful implications. Hence these scholars advocate using race and ethnicity as starting points for further research.

Special Considerations in Research With Minority Populations

The analytical framework of the Belmont Report—its focus on the assessment of the risks and potential benefits of research, respect for persons, and justice—provides a useful way to think about how minority populations raise special issues regarding research ethics.

Risks and Potential Benefits of Research

The risks of research participation may be greater for minority populations than for the general population. For example, in those minority populations that live within a small and tightly knit community, the participation of individuals in studies may not remain confidential. Mere participation in a research project may be stigmatizing; for example, others might infer that the participant has the condition under study. Thus, in a study of familial breast or colon cancer in an Ashkenazi Jewish community, some may conclude that an individual who participates in the study has a family history of cancer or is particularly susceptible to cancer.

Furthermore, even if individual confidentiality is maintained, the group as a whole may suffer psychosocial harms. A group that is perceived as vulnerable to disease may be viewed by others as inferior, or may cause individuals to suffer loss of self-esteem and self-image.¹⁶ From an ethical perspective, such harms would be particularly troubling if they occurred in groups that were already disadvantaged because of racial discrimination or because of co-existing low socioeconomic status.

Native American populations have raised specific concerns about group harms.^{31–33} Some tribes are concerned that findings from genetic research may undermine their beliefs about creation and tribal origins, the cultural history of their people, or their definition of membership within a group. Thus, some Native Americans oppose research that may result in these kinds of harms to the community, even though confidentiality of individual participants is maintained. Research may also violate cultural norms of some tribes. For example, some tribes have taboos against the handling of body specimens by persons of the opposite gender or against disclosing a name and location of a particular community to

outsiders, even in a research publication. But these problems, once identified, can be addressed by changes in the research protocol; for example, only the general geographical location, rather than the name of the community, need be mentioned in publications.

Some writers have rejected such intangible group risks as speculative or unimportant.²⁵ However, from the point of view of the ethnic or minority group, these harms may be considered serious because they disrupt long-standing traditions and core beliefs of the group. Generally, the perspective of the person who would suffer the harm should guide the protocol; in research trials, it is the participant's evaluation of the degree of risk, not the researcher's, that is determinative. Moreover, all risks are matters of probability and thus in some sense speculative rather than certain. Even a small risk of a very serious harm deserves attention.

The risks of research participation may also be different in kind, not just in magnitude, for minority populations. If there is a history of perceived exploitation, groups may be skeptical that the prospective benefits of research will actually occur. They may fear that minority and ethnic groups will disproportionately bear the risks of research but not gain from the fruits of that research.⁴ For example, members of an economically disadvantaged group may doubt that they will have access to new treatments developed from the research. In the case of genomics research with blood samples, they may believe that their participation in research will primarily benefit drug and biotech companies, which will reap profits from their biological materials and information. In addition, Native American and other groups may object to patenting natural materials, which may be perceived as tribal property or as beyond the control of human beings.³³

Respect for Persons

Research with minority and ethnic populations that have a distinctive culture may also raise special concerns about respect for persons and about the informed consent process. When U.S. researchers carry out studies in other countries, it is not sufficient to simply translate consent forms into the language used in the community. In the culture of the community, the biomedical model of health and illness may not be accepted.⁸ For example, some hold the view that disease is caused by spirits or by an individual's failure to observe prescribed rituals. In this case, it would be difficult to articulate the rationale for research to potential participants. It may also be a challenge to reconcile the concepts of genomics with the community's cultural views of ancestry and family. Furthermore, if the authority of healers typically is not questioned, it may be difficult for potential research participants to accept that healers do not know the best course of treatment, which is an ethical prerequisite for a randomized clinical trial. Moreover, in cultures in which the patients do not give consent for therapy, the idea of explaining what the research involves and asking for consent may seem bizarre. Furthermore, key concepts in clinical trials, such as blinding and randomization, are difficult to explain to highly educated persons, let alone to individuals with low health literacy. Investigators have found that community groups and representatives often can suggest how to explain these concepts to participants in the particular study in a clear and comprehensible manner.^{4,34}

The concept of individual informed consent may also be alien to a community's culture.⁸ Participants may feel obligated to

consult with others, rather than making independent decisions about participating in research. In some cultures, individuals regard themselves primarily as members of a family, community, or culture, in contrast to the view that individuals mold their own autonomous identities. Thus, asking participants to give individual consent effectively asks them to disregard their primary affiliation and sense of self. In such cultures, it may be important to give participants the option of consulting with others about the decision to participate in research.

When participants consult with others about their participation, researchers need to distinguish two situations regarding consent. First, an individual may not want to participate in research, but someone else in a controlling social role—such as a husband, father, or group leader—may want them to participate. This situation is often gender-specific; women in some cultures traditionally defer to their husbands, fathers, or group elders. The individual herself may decide to consult with others and believe that she cannot contravene their wishes, but ultimately the individual must be permitted to refuse to participate in research. That is, others in the community may not give permission to enroll her in the study over her objections. Researchers must observe the ethical guideline of respect for individual autonomy.⁸ It would be desirable for researchers to devise a consent process that would provide the refusing individual some protection against reprisal. For example, in a study of home-based HIV counseling and testing in sub-Saharan Africa, researchers were careful to have the home interview take the same amount of time, whether or not the prospective subjects agreed to testing.

Second, an individual may want to participate in research although group leaders object to the project. Group leaders or advocacy groups may not have legal veto power unless they have political authority. However, it may not be feasible for researchers to pursue the project in the face of widespread and determined opposition. HIV prevention trials of preexposure prophylaxis with the drug tenofovir were halted in Cambodia and in several sub-Saharan African countries because of strong opposition from advocacy groups.³⁵ Similarly, an individual may want to participate but her spouse may object. Researchers need to ascertain that the participant understands the psychosocial risks she may face in this situation. Researchers should also take steps in the protocol to minimize those risks, for example, by implementing additional measures to protect confidentiality. However, researchers should allow informed persons to enroll themselves in the study.

Justice

Justice is pertinent to research with minority and ethnic populations in several senses. First, the selection of research participants should be equitable. On the one hand, recruitment targeted to specific ethnic/minority groups requires justification. Mere convenience or access to subjects is not an adequate rationale for targeting minority and ethnic communities. An increased burden of disease or a heightened importance of the research topic for the group is a necessary condition, but not a sufficient one. Beyond the burden of disease, it must be plausible that the research will lead to benefits for the group itself, as opposed to benefits that accrue primarily to others or throughout the population as a whole. Minority and ethnic populations may also have concurrent conditions that make them vulnerable as research subjects, such as low literacy, poor education, poverty, low social status, and so

forth. On the other hand, including minority and ethnic groups in research is essential to obtain reliable evidence on which to base clinical care. When minority and ethnic communities are disproportionately likely to suffer from a disease, they need to be included in research so that scientists can learn how to provide them with better care. Researchers will need to devise outreach, recruitment, and educational procedures that overcome barriers to the participation of minority and ethnic communities and individuals in clinical research. Community and advocacy groups can be invaluable in planning such activities.⁴

Second, justice as reciprocity requires researchers and sponsors of research to give participating individuals and communities their due. Researchers need to address concerns that minority and ethnic communities may raise about the history of exploitative research projects. To be sure, researchers cannot predict what they will find, nor can they be responsible for how others use their findings. However, the process of conducting research in minority and ethnic communities can address these concerns. The project can try to hire members of the community as research staff and provide them opportunities for training and advancement. Moreover, in conjunction with the project, researchers can carry out community service, such as outreach, educational initiatives, and screening programs. Finally, ethnic or minority communities that are economically disadvantaged may not be able to afford drugs that are proven effective in clinical trials. Although the issue of access has been raised primarily in terms of access to HIV drugs that are studied in resource-poor countries, it is an issue in all countries, including the United States.^{6,36} Researchers should take reasonable steps to help the groups that participate in clinical trials obtain access to the intervention after the trial.⁸

Recommendations for Research With Minority and Ethnic Populations

Community Involvement in Research

The primary goals of community involvement in research are to show respect for the community, to identify and minimize risks to participants and to the community, and to strengthen informed consent.⁴ Community involvement can also benefit researchers, for example, by enhancing the enrollment in studies. Alternatively, strong opposition from respected community leaders may make a research study impractical to carry out.

A community may be involved in research in a variety of ways.^{4,37} On the most basic level, researchers should provide information about the topic and purpose of research and the specific project to the communities targeted for participation. Furthermore, after the study is completed, researchers should communicate their findings to the community. These activities should be required of all research, and especially that which targets ethnic and minority populations.

On the next level, researchers can discuss the study design and protocol with community representatives, who can give feedback on the risks and burdens of research in the particular setting, ways to minimize those risks, and ways to enhance informed consent. This interaction is most appropriate when an ongoing series of research projects is envisaged. A similar process commonly occurs with disease-specific research where researchers have learned to work with advocacy groups, such as those who advocate for

research on HIV, breast cancer, and rare genetic conditions. Such interactions provide benefits to researchers as well as project participants and the community. The discussions often strengthen the protocol scientifically by focusing on the research questions that will make a difference in clinical decision making, and by balancing the potential benefits and risks more favorably. Suggestions for changes in the protocol from community members often enhance recruitment and follow-up. Community support may also help researchers obtain funding and recruit subjects.⁴

Problems may arise from the range of views within a community. There may be a disconnect between the views of community leaders and those who are affected with the condition under study or who are providing services to them. In addition, there is the potential for co-option if researchers pick community representatives who are likely to agree with them. These problems are not specific to this situation but also occur with any process of selecting community members, as in the selection of lay and community members for institutional review boards (IRBs), as required under the Common Rule. Difficulties and potential pitfalls in implementing a policy in good faith should not be viewed as a justification for rejecting the policy completely.

Even greater involvement occurs in community-based participatory research using community-based organizations. Studies of cancer screening and prevention have been organized among African Americans through churches, which are important and respected institutions in those communities.³⁸ Researchers have involved church leaders and members in the design of research and writing of grant applications, as well as in recruitment. This kind of involvement often necessitates changes in protocol. One such study involved a nutritional intervention. Although a usual-care control group was originally planned, researchers decided to give the control group a delayed intervention in response to community objections. At a follow-up visit, researchers found that over 90% of individuals in the intervention group and over 85% of those in the control group expressed high levels of support for the research project.³⁸ The researchers ascribed the high levels of trust, satisfaction, and perceived personal benefit to active community participation in the design of the study.

The highest level of community involvement is formal approval from the community. Some ethnic or minority communities have authorized political leadership, are localized geographically, or have clear rules for group membership. Native American tribes, for example, are like sovereign nations. In this situation, formal approval from the tribal government may be required to carry out research. Community involvement is more controversial and more complex, however, if the community has no political authority, is geographically dispersed, and has cultural heterogeneity and ambiguous criteria for group membership.³⁷ In the latter situation, it is difficult to determine who has legitimacy to speak on the community's behalf. In the absence of such formal authority, critics object to a requirement for community consultation and to allowing a community to have veto power over individual members' decisions to participate in research.^{24,39,40}

Several practical issues regarding community involvement need to be addressed. Researchers have considerable latitude in determining who speaks for a community. They should not choose community representatives based on the likelihood that the representatives will agree with researchers and approve the projects. Rather, researchers should appreciate the need to elicit different perspectives and moreover should be sensitive to patterns of social

interaction that may make it difficult for individuals to speak up in a public forum. Communities may have customs about deferring to elders or to persons in certain social roles. Thus, individuals who have conflicting points of view may not speak up in a meeting when first asked to do so.⁴¹

Heightened Review by IRBs and Funding Agencies

Recruitment targeted to specific ethnic/minority groups should trigger special IRB review because of the possibility that the protocol represents research with a vulnerable population. The targeting may be intentional or may result from a recruitment strategy that appears, but is not, neutral regarding recruitment of ethnic and minority groups. Some questions that the IRB should ask are the following:

- Is the targeting of these groups as research participants justified?
- Are these groups at particular risk in this study?
- Are there special informed consent issues in these groups regarding the study?
- Are there additional issues that are salient in the ethnic or minority group? For example, a study to collect and store samples for DNA testing and use in future research studies in an African American population would need to address issues of trust in research and researchers.⁴

Federal regulations require IRBs to take into account local considerations in assessing risks and potential benefits and approving consent procedures. However, IRBs may not have sufficient expertise among their members regarding the perspectives of ethnic and minority groups. Thus IRBs may need to add ad hoc reviewers who are from the communities being studied.⁴ For example, someone both fluent in the language and knowledgeable about the culture must review recruitment advertisements and consent forms in a foreign language. This additional review would be similar to ad hoc scientific reviewers with particular technical expertise, or reviewers from a disease advocacy group for a rare condition with which an IRB is not familiar.

Peer review by funding agencies should also include reviewers who are knowledgeable about conducting the particular type of research in the targeted populations.⁴¹ Such review would help assure that the proposed project is feasible and is likely to have an ultimate impact on clinical care.

Responsibilities of Researchers

Researchers who carry out research with minority and ethnic communities have special obligations to vulnerable populations to assure that the balance of risks and potential benefits in the study is acceptable. One reason is that communities may fear that such research might be misinterpreted or misused in ways that adversely impact the groups. Moreover, such communities may believe that in the past, their participation in research has not led to improvements in their health or social conditions; that is, they have not derived any long-term benefits from participating in research.⁴ Furthermore, because of the suspicion that some minority and ethnic communities have about research, researchers need to overcome mistrust in order to carry out the study. Researchers can fulfill these obligations in several ways as we discuss below.

Investigators should involve the affected minority and disadvantaged community in the planning of the research project.⁴ Researchers should elicit community concerns about the project and respond to them. Scientists need not make all changes in the study requested by community stakeholders, but they need to listen to the concerns and explain why they do not agree with the requests.⁴ This process shows respect for community members and groups and helps to build trust.

As previously discussed, researchers should provide community education about the project and the topic of research. In addition, researchers ought to make some effort to use their expertise for the well-being of the subjects and communities. This can involve providing scientific information to help communities pursue changes in public policy and helping community groups write grant applications to obtain funding for needed social services.⁴

Researchers need to use due care in presenting and publishing their findings, particularly in light of the history of misinterpretations and abuses of research with ethnic and minority communities. Researchers need to point out the limitations of their findings, making clear that their results apply only to the condition and population that they studied. They should distinguish their empirical findings from hypotheses for future research, implications for theories and models, and policy recommendations.

Researchers also should take some responsibility for helping to disseminate their study findings in the lay media. Scientists are sometimes reluctant to give media interviews about their work, believing that peer-reviewed publications speak for themselves. However, by helping to write press releases and by providing reporters with clear explanations of their work in lay terms, scientists can increase the likelihood of accurate coverage in the press. Scientists also have some responsibility to speak out when others misinterpret their data in ways are likely to harm the community or participants in the study. Although researchers cannot be responsible for the social and political uses to which findings are put, they are responsible for using their expertise and authority to try to correct misunderstandings and distortions of their work. This responsibility may involve giving interviews to the press and testifying before government committees. Although all researchers have such responsibilities, they are particularly important in the context of long-standing health disparities that in part result from widespread public misunderstanding, unfounded group stereotypes, and bias and stereotyping by health-care professionals.

Conclusion

In summary, ethnic and minority communities may mistrust researchers because of a history of unfavorable experiences with research projects. However, there may be cogent reasons to target such communities for research and research may also benefit these communities. Researchers must be sensitive to the particular ethical issues that arise in research with such communities and must take steps to ensure that their projects meet high ethical standards.

Research Involving Economically Disadvantaged Participants

A hypothetical institutional review board (IRB) meets to discuss three hypothetical protocols. In the first, investigators propose to study the effectiveness of a new antianxiety drug that has been shown to be safe in Phase I trials. Participants will be eligible if they demonstrate high levels of stress on a validated screening instrument, are not currently taking another antianxiety drug, and have no significant medical problems. The procedures include several blood draws, physical exams, and hour-long interviews over the course of six months. The participants will be paid \$500 on completion of the study. The IRB approves the study with only a few minor changes to the consent form.

The second protocol involves a comparison of a long-lasting formulation of an antihypertensive drug and the standard shorter-lasting version to see if the new version improves adherence. The participants are already taking the standard formulation and there are no additional risks. They will be paid \$25 each visit for a blood pressure check and other basic tests. The IRB has many questions about the protocol and with some reluctance approves it.

In the third protocol investigators are studying a new and expensive drug for vascular complications of diabetes. No payment will be offered to participants. There are some known risks as well as unforeseeable ones. The IRB decides that the risk-benefit ratio is acceptable and that the consent form is clear and accurate. Yet it sends the protocol back to the investigator for further revisions.

What accounts for this hypothetical IRB's seemingly inconsistent decisions? Economic disadvantage played a different role in each protocol. In the first, the antianxiety drug for highly stressed people, the participants were medical students. Their low income and burgeoning debt were not seen as problems in obtaining

consent, nor was \$500 seen as an "undue inducement." In the second protocol, a study of an antihypertensive drug, most of the participants would be unemployed drug users recruited from a public hospital clinic. Some IRB members worried that the payment, modest though it was, would be spent on alcohol or drugs. Investigators in the third protocol, studying the expensive diabetes medication, planned to recruit participants from private physicians' offices. In this case the IRB felt that this plan did not provide for equitable selection of participants, especially because it would not reach many men and women with diabetes who come from poor, ethnic minority communities.

Poverty Matters, but How Much and in What Ways?

What does *economically disadvantaged* mean in the context of the ethics of clinical research? From the relatively sparse literature, one can conclude that there is a consensus that poverty matters. However, it is not as clear to what extent economic disadvantage is a significant factor to be weighed on its own or is rather an indicator of other factors such as low educational level or language barriers, which might impede full understanding and voluntariness. In the United States, where poor people often have limited access to health care because they lack insurance, there is a particular concern that uninsured people will be induced to enter research studies to obtain basic health care.¹ Internationally, the concern goes beyond the potential for exploitation of poor people as individuals or as members of minority groups to include entire populations in resource-poor countries and regions.²⁻⁴

On the other hand, some advocates who speak for economically disadvantaged groups in the United States are concerned that poor people are being deprived of the opportunities to benefit from clinical trial participation and that information gathered from other groups will not be applicable to them. For example, Stephen Sodeke, interim director of Tuskegee University's National Center for Bioethics in Research and Health Care, acknowledges that historical abuses have led to mistrust of the health-care system among African Americans and other economically disadvantaged populations. Yet, he believes, "We have a responsibility to assist the community to understand why research is done and how it can help individual members of the community. . . . The only way to get the best information is to involve more of the various populations of people that make up a community in the research process. This means we must involve them as research subjects in clinical trials as well as in community groups and as community representatives."⁵

Economic disadvantage has come to be seen as a marker of *vulnerability*, a signal that an IRB needs to take special care in the selection of research participants and in the approval of the protocol. It is helpful to review how this linkage came about, and how it has been interpreted.

Vulnerability and Economic Disadvantage in Clinical Research

A fundamental assumption underlies the modern history of research ethics: Certain categories of people are more likely than others to be misled, mistreated, or otherwise taken advantage of as participants in clinical research. These populations are deemed *vulnerable*, a status that imposes a duty on researchers, review committees, and regulators to provide special protections for them. Although other basic tenets of research ethics—*informed consent* and *risk-benefit analysis*, for example—have been the subject of extensive discussion and debate, until recently the concept of *vulnerability* has been relatively unexamined. The only significant questions raised have been whether or not to include a particular group in the *vulnerability* category, and to a lesser degree, what kinds of protections are needed.

Vulnerability is typically explained in terms of examples, rather than being explicitly defined. Although used freely in the *IRB Guidebook* produced by the U.S. Department of Health and Human Services' Office for Human Research Protections, *vulnerability* is not defined in the Guidebook's extensive glossary.⁶ However, other "special classes of subjects" are highlighted for special consideration. These include cognitively impaired persons; traumatized and comatose patients; terminally ill patients; elderly/aged persons; minorities; students, employees, and normal volunteers; and participants in international research.

The U.S. federal regulations (45 CFR 46) provide special protections for what they call "particularly vulnerable populations": children; prisoners; pregnant women, fetuses, and neonates.⁷ "Economically disadvantaged" persons as such are not included in these designated categories, although they are listed in the regulations as "vulnerable" (CFR 46.111(a)(3)).⁷ They are "vulnerable" but not "particularly vulnerable," whatever that distinction may mean in practice. In what would be a broad expansion of the regulations, Howard Stone suggests that economically and educationally disadvantaged people—the "invisible vulnerable"—

should be given additional protections under a new subpart of the U.S. regulations. These protections, he says, should limit their participation to studies that present minimal risk to participants or to research that holds out the potential of directly benefiting the individual participants.⁸

In the international arena, the most recent revision of the World Medical Association's Declaration of Helsinki simply states, "Some research populations are vulnerable and need special protection" (see Chapter 13). The Declaration advises that the "particular needs of the economically and medically disadvantaged must be recognized. Special attention is also required for those who cannot give or refuse consent for themselves, for those who may be subject to giving consent under duress, for those who will not benefit personally from the research and for those for whom the research is combined with care."⁹ Inclusion of this latter group suggests to me a similar concern as in the United States: Poor people will agree to participate in research in order to obtain basic care.

With an even more specific list, the 2002 guidelines of the Council for International Organizations of Medical Sciences (CIOMS) include as vulnerable "junior or subordinate members of a hierarchical group," such as "medical and nursing students, subordinate hospital and laboratory personnel, employees of pharmaceutical companies, and members of the armed forces or police"¹⁰ (see Chapter 16). Furthermore, the guidelines describe elderly people as "likely to acquire attributes that define them as vulnerable." The commentary on Guideline 13 also includes other categories such as "residents of nursing homes, people receiving welfare benefits or social assistance and other poor people and the unemployed, people in emergency rooms, some ethnic and racial minority groups, homeless persons, nomads, refugees or displaced persons, prisoners, patients with incurable disease, individuals who are politically powerless, and members of communities unfamiliar with modern medical concepts."¹⁰ Some of these groups are by definition poor; others are probably also in that category.

The concept of *vulnerability* that has become so firmly fixed in the ethics vocabulary was established in the 1979 Belmont Report, a product of the U.S. National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, which formed the basis for the U.S. regulations¹¹ (see Chapters 14 and 15). The Belmont Report addressed *vulnerability* in the context of the principle of justice as applied to the selection of research participants. *Vulnerable* groups, the report stated, should not bear unequal burdens in research. The report explained that its examples of vulnerable populations—"racial minorities, the economically disadvantaged, the very sick, and the institutionalized"—may continually be sought as research participants because of their "ready availability in settings where research is conducted." These groups require special protections because of their "dependent status and frequently compromised capacity for free consent."¹¹

Concern about "economic disadvantage" creating *vulnerability* is thus directly tied to the venerable Belmont Report, although it was never codified in regulation. However, the Belmont Report, written at a time when most research was conducted in clinics or academic medical centers, focused on the "ready availability" of poor people in these settings and their "dependent status." It did not anticipate the situation today: A much broader sponsorship and dispersion of research, as well as a strong belief (primarily but not exclusively among the economically well-off) that research

participation is not a burden but rather that it offers benefits such as early access to promising investigational drugs and additional monitoring. In the early years of the HIV/AIDS epidemic, early access to promising drugs was not just a slogan but a war cry. Those who led the charge were primarily gay, white, middle- and upper-class men and their advocates. They accelerated the pendulum swing in research ethics from protection to inclusion.¹²

From the available data it appears that economically disadvantaged people are not overrepresented in U.S. clinical trials today, although they undoubtedly were in the 1970s, when the National Commission wrote the Belmont Report. A few studies do show that people without health insurance enter trials when free medical care is an incentive.¹³ However, this does not seem to be typical. Because many trials at best pay only for the care associated with the research itself, besides providing the study drug, the participant's health insurance, the institution, or the participant must directly pay for much of the additional care.¹ (Consent forms are supposed to point this out.) Studies that require high investments from participants arguably discriminate against those without resources. On the whole, those who are male, white, insured, middle-class, and well-educated are more likely to participate in research studies than are women and men from lower socioeconomic groups. Wendy Rogers points out that as a result of the general observation that people in trials fare better than those outside of them, "lack of participation in trials effectively removes this benefit from disadvantaged groups." More important, however, is the paucity of research evidence about which interventions are effective in these groups.¹⁴

The concept's prominence in the Belmont Report and its staying power in clinical research ethics undoubtedly derive from post-World War II history. Revulsion against the abuses of research on captive populations in World War II by the Nazis (and, as later revealed, by the Japanese as well) profoundly affected the development of international codes of research ethics.¹⁵ However, the impetus for the creation of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research in 1974 was a series of domestic scandals, first revealed by Henry Beecher in his 1966 *New England Journal of Medicine* article.¹⁶ These scandals included the Jewish Chronic Disease Hospital study, in which elderly patients were injected with live cancer cells without their consent, and the Willowbrook hepatitis vaccine studies, in which some institutionalized children were accepted as patients only if their parents consented to the studies. The U.S. Public Health Service syphilis studies of poor black men in Tuskegee, Alabama, which had numerous ethical violations, played a major role in supporting a regulatory climate in which protection was paramount¹⁷ (see Chapters 6–8). Research came to be seen as a risky enterprise, from which institutionalized or cognitively impaired individuals in particular needed protections that they were not able to provide for themselves.

Although the early guideline and regulation drafters were reacting to a series of specific historical events, the more recent history of vulnerability in biomedical research seems based more on general concerns about political, economic, and social inequality. Here economic disadvantage comes much more to the fore. In the international context, the 2002 CIOMS guidelines for biomedical research define, if not vulnerability, then at least vulnerable persons: "those who are relatively or (absolutely) incapable of protecting their own interests" because they may have "insufficient power, intelligence, education, resources, strength,

or other needed attributes."¹⁰ Commenting on an earlier draft of the CIOMS guidelines from 2000, Deborah Zion and her colleagues define vulnerable people in political terms: "those who lack basic rights and liberties that make them particularly open to exploitation."¹⁸

Beyond individuals or groups, Ruth Macklin suggests that whole communities or countries may be vulnerable to exploitation, particularly if "investigators or sponsors are from a powerful industrialized country or a giant pharmaceutical company and the research is conducted in a developing country."² A Pakistani researcher points to widespread poverty in South Asia as one potential cause of tension between the aims of the researchers and the needs of the community; the others are illiteracy, male dominance, a hierarchical society, lack of health care, and corruption.¹⁹

In arguing against double standards in research in multinational studies—permitting research in destitute countries that would not be approved in wealthy ones—Michael Kottow distinguishes between vulnerability and susceptibility. Vulnerability, he says, applies to everyone; what really matters in research ethics is susceptibility, which means being poor, undernourished, and lacking in medical care and therefore predisposed to additional harm.³

These definitions and comments reflect concerns that poor people in developing countries will be used, as they have been in the past, to test drugs that are destined for developed country markets, without compensating benefit to the participants or their communities in terms of improved access to health care. International research protocols, on this view, should be evaluated not just with regard to the impact on the individuals who enroll but also on the health-care needs and power imbalances in the country. Research thus becomes not just a scientific effort, but a tool for social and economic reforms as well.

Social Science Research and Economic Disadvantage

It is instructive to look at social science research, which also addresses economic disadvantage in the selection of research participants, because economic disadvantage plays an even more significant role in many of these studies. Although there does not seem to be a single definition of vulnerability in social science research, there is some overlap with definitions in biomedical research. The characteristics of a vulnerable population in social science research are typically described in terms of a group's social status, powerlessness, and potential for exploitation. Social status and powerlessness are also described as sources of vulnerability by the CIOMS guidelines for biomedical research. Similarly, Jacquelyn Flaskerud and Betty Winslow define vulnerable populations in health services research as "social groups who experience limited resources and consequent high relative risk of morbidity and premature mortality."²⁰ Among the groups "recognized as vulnerable" are "the poor; persons subject to discrimination, intolerance, subordination and stigma; and those who are politically marginalized, disenfranchised, and denied human rights."²⁰

Recognizing both the individual and social aspects of vulnerability, Robert Chambers notes that "vulnerability has two sides: an external side of risks, shocks and stress to which an individual or household is subject; and an individual side which is

defenselessness, meaning a lack of means to cope without damaging loss.²¹ Martin Watts and Hans-Georg Bolhe offer three coordinates of vulnerability: “The risk of being exposed to crisis situations (exposure), the risk of not having the necessary resources to cope with these situations (capacity), and the risk of being subjected to serious consequences as a result of the crises (potentiality).”²²

In reviewing the ethical implications of vulnerability for participants in research conducted by the Substance Abuse and Mental Health Services Administration (SAMHSA), Thomas McGovern claims, “Vulnerability is a universal and ongoing human experience. The awareness of being wounded and the potential for same gnaws at our sense of security. We are capable of being hurt at many levels: physical, mental, emotional, and spiritual. . . . Our greatest vulnerability centers on assaults from within and without that threaten our integrity and dignity as persons.”²³ In bioethics terminology, vulnerability in this sense involves not just the risk of being harmed physically, socially, or psychologically but also the risk of being wronged—of being treated in ways that assault one’s dignity or one’s personhood. Poor people may or may not be at heightened risk of harm in particular protocols; but given the unjust conditions in which they live and are treated in society, they are surely at heightened risk of being wronged.

The mental health literature often links vulnerability with its opposite or antidote—resiliency. In 1996, the Basic Behavioral Science Task Force of the U.S. National Advisory Mental Health Council posed the question, “Why do some people collapse under life stresses while others seem unscathed by traumatic circumstances, such as severe illness, the death of loved ones, and extreme poverty, or even by major catastrophes such as natural disasters and war?”²⁴ In seeking to answer this question, the Task Force developed, if not a definition, a good description of vulnerability: “Studies to date suggest that there is no single source of resilience or vulnerability. Rather, many interacting factors come into play. They include not only individual genetic predispositions, which express themselves in enduring aspects of temperament, personality, and intelligence, but also qualities such as social skills and self-esteem. These, in turn, are shaped by a variety of environmental influences.”²⁴ Taking this holistic view, economic disadvantage can lead to vulnerability, but also to inner strength and resolve.

In brief, then, the concept of vulnerability as it is used in clinical research emphasizes limitations to an individual’s or a group’s decision-making capacity and the potential for coercion among populations that are literally or figuratively “captive.”²⁵ In social science research, by contrast, *vulnerable* most often describes people who may have decision-making capacity but who lack the power and resources to make truly voluntary choices. Economic disadvantage is but one factor among many to consider.

Economic Disadvantage as a Group Characteristic

As a matter of justice, the concept of vulnerability stereotypes whole categories of individuals without distinguishing between individuals in the group who indeed might have special characteristics that need to be taken into account and those who do not. Particular concerns have been raised about considering all poor people, all pregnant women, all members of ethnic or racial mi-

norities, and all people with terminal illness as inherently unable to know their own best interests and to make appropriate choices for themselves.

Debra DeBruin makes this argument from a philosophical perspective. She claims that “vulnerability ought not to be conceived of as a characteristic of groups. Rather, certain traits may render certain persons vulnerable in certain situations.”²⁶ On this view, putting poor people or poorly educated people in the class of vulnerable participants treats them as less capable of asserting their autonomy than those who are better off. The argument that people with life-threatening illnesses can still make their own health-care and research decisions has been made most forcefully by people with HIV/AIDS, but it is by no means limited to them.

Furthermore, some people may be vulnerable in certain ways or circumstances but not in others. After all, the mythic archetype of the vulnerable person is Achilles, immortal except for that one little spot on his heel that his goddess mother failed to dip in the sacred waters of the River Styx. Just as “decision-making capacity” for health-care decisions is now generally understood to depend on the question being asked and the consequences of the decision, an individual’s need for special protections in the research context depends on the kind of study, the implications of participating or not participating, and the alternatives available. An economically disadvantaged person may have become extraordinarily adept at “gaming” the system to obtain medical care and other benefits, whereas a person with far greater resources may be naïve and overly sanguine about the goals of research and the demands of the protocol. Having had to look out for their own interests, poor people may well be more astute at judging whether to enter a particular research protocol than people who have come to believe that the system always works or can be made to work in their favor. Some skepticism about the research enterprise is often a rational response.

Weighing Economic Disadvantage

In their ethical analysis of enrolling uninsured people in clinical trials, Christine Pace and her colleagues weigh the competing issues of susceptibility to undue inducements and the right of the uninsured to “fair consideration for research participation.” They conclude that enrolling uninsured research participants “is not inherently exploitative and that, in fact, excluding such participants without scientific reason is unfair.” The risks that the participants will lack access to effective treatment after the trial and of undue inducement, they assert, do not justify a categorical exclusion of those without health insurance.¹

Using an economic model, Laura Dunn and Nora Gordon point out that “rational potential research participants make decisions based on expected costs and benefits of participation.”²⁷ These include the opportunity cost of forgoing another way of spending one’s time, transaction costs such as transportation and child care, and potential discomfort of adverse responses. Although most concern about payment has focused on the idea that higher payment will disproportionately encourage poor people to participate, these authors argue that “relatively low compensation levels would do the same because wealthier research participants have higher opportunity costs and value their last dollar earned less than poorer participants.”²⁷ They conclude that trust and perceived fairness, not economic status per se, are central to ethical recruitment.

In considering the weight that ought to be given to economic disadvantage in terms of the protections afforded research participants, several aspects should be considered. For example, what is the purpose of the protocol? If it is a study that is designed to test a drug for a disease that affects the potential participant, or that is prevalent in that person's community, the socioeconomic status of the participants might not be a particular cause for worry. If, on the other hand, it is a physiologic study in which the investigators are looking for normal healthy volunteers, and in which the participants are drawn from a pool of unemployed people who consistently volunteer for the money alone, some more thought about the relevance of socioeconomic status to the selection process is warranted.

As with all studies, the level of risk to which research participants will be subject is another important consideration. As noted earlier, Stone suggests limiting research recruitment among poor people to studies with minimal risk,⁸ but this proposal draws the line too narrowly and may deprive individuals of potential benefit and the opportunity to contribute to research of benefit to future patients. Nevertheless, when moderate or significant risk is known or can be anticipated, it is essential that potential participants fully understand and accept the risks. For example, in some cases in which the risks may be unknown or unknowable, some form of "special scrutiny"—a specially-focused review—may be warranted.²⁸

In many but not all instances, economic disadvantage is accompanied by lower educational status; in such cases, informed consent processes must be carefully developed and monitored. The setting of the research, including factors such as the availability of transportation and child care, are critical factors that must be considered. Any features of the research setting that might make participants feel that they have limited options to decline, such as in emergency rooms or drug abuse clinics, bear further consideration. Other factors might include whether the participant has a regular physician with whom he or she can discuss the protocol and to whom he or she can be referred for follow-up; whether there is adequate provision for care in case of adverse effects; and what possibilities exist after the research ends for obtaining the study drug if it proves beneficial.

In studies in which it is important for scientific or ethical reasons to increase the participation of economically disadvantaged people, some concrete actions can be taken. Research studies can be discussed in community settings, such as churches and social service agencies, in which community leaders and potential participants can ask questions and raise concerns. Research opportunities can be widely disseminated, so that poor people are not being singled out for enrollment. Subsidies can be built into the funding so that participants do not incur additional financial burdens on account of their participation.

Logistical barriers to participating—lack of child care, transportation, and so on—can be reduced. Flexible plans can be instituted for contacting study participants who may not have telephones or be able to receive calls at work. Using experienced patient-education staff to provide health information as well as information about study requirements may build trust. In a cervical cancer prevention trial, for example, Joanne Bailey and her colleagues found that multiple strategies were needed to recruit and retain economically disadvantaged women. These included "expansion to five geographically distinct clinical sites, the use of nurse practitioners focused primarily on patient issues, extremely

flexible study hours and location, honorariums, support for transportation and child care, and creativity in maintaining contact with study participants."²⁹ Using these strategies, 90% of eligible patients consented to participate in the study.

In international studies, the rationale for the study and its design should be subjected to particular scrutiny because of the potential for exploitation that is noted in all statements of U.S. and international bodies and individual advocates (see Chapters 64–67). Only when a protocol has been deemed acceptable on these grounds should the methods of recruitment, consent, and other aspects come under consideration. Although in my view it is unrealistic and unfair to hold the research enterprise responsible for reforming the health-care system and repairing underlying inequities in a country, it is nevertheless important to create something of value for the communities from which the participants are drawn.

Conclusion

Economic disadvantage is a deceptively simple criterion on which to make an ethical judgment about the selection of research participants. Poor people can indeed be vulnerable to exploitation and undue inducements; yet to consider them, on the basis of poverty alone, incapable of making decisions about their own best interests, fails to recognize their autonomy and treats them with condescension. Researchers, sponsors, and IRBs have to weigh all the factors in a protocol judiciously, and when economic disadvantage plays an inordinate role, work to minimize its impact.

Research Involving Those at Risk for Impaired Decision-Making Capacity

Medical conditions that impair a person's ability to make decisions (e.g., dementia, stroke, schizophrenia) are devastating for affected individuals and their families. Too often, modern medicine provides only modest symptomatic improvement for patients with these disorders. Much-needed progress in the diagnosis, treatment, and prevention of these illnesses depends on clinical advances through research. However, the conduct of research exposes these individuals to the possibility of exploitation precisely because they may not be able to make informed decisions about participation.

This chapter employs a process-oriented and practical approach to the ethics of research with adults who may not be able to provide informed consent because of impaired decision-making capacity (DMC). Neither emergency research nor research with children will be addressed. The chapter is organized into the following sections: a brief history of ethical aspects of research with those who are decisionally impaired; our conceptualization of DMC as it relates to the ethics of clinical research; a review of empirical data on research subjects who have, or are at risk for, impaired DMC; policy and study design implications; and unresolved empirical issues regarding the ethics of DMC and clinical research. Throughout the chapter, we emphasize the integral relationship between research methodology (i.e., subject selection, the nature of the proposed research interventions, and specific protocol details) and the ethical analysis of a given research proposal.

History

Concerns about clinical research with decisionally impaired subjects received serious consideration following revelations of Nazi

experimentation with mentally disabled individuals during World War II (see Chapter 2). Although they are more infamous for participating in the extermination of hundreds of thousands of mentally ill patients, Nazi physicians also conducted unauthorized experiments (e.g., infection with malaria, sterilization) on mentally disabled prisoners.¹⁻³ Indeed, the Nuremberg Code begins with the following two sentences:

The voluntary consent of the human subject is absolutely essential. This means that the person involved should have legal capacity to give consent; should be so situated as to be able to exercise free power of choice, without the intervention of any element of force, fraud, deceit, duress, overreaching, or other ulterior form of constraint or coercion; and should have sufficient knowledge and comprehension of the subject matter involved so as to enable him to make an understanding and enlightened decision.⁴

A literal interpretation of the Nuremberg Code would preclude all research involving incompetent persons, including children and incapacitated adults. As noted by other commentators,⁵⁻⁷ it is not clear whether this was the intent of the judges of the Nuremberg tribunal. Subsequent research codes and guidelines (e.g., more recent versions of the Declaration of Helsinki; the Council for International Organizations of Medical Sciences' *International Ethical Guidelines for Biomedical Research Involving Human Subjects*; and the U.S. Code of Federal Regulations)⁸⁻¹⁰ explicitly allow the enrollment of those who are unable to provide informed consent provided that other conditions are met (e.g., permission by a legally authorized representative).

In the years following World War II, several cases of research abuse in the United States were revealed, including the exploitation of decisionally impaired subjects. Henry Beecher's classic 1966 article in the *New England Journal of Medicine* detailed 22 cases of research ethics violations, several of which involved subjects with, or at risk for, impaired DMC.¹¹ These examples of exploitation of the mentally disabled provided the backdrop for a 1978 report by the U.S. National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research entitled "Research Involving Those Institutionalized as Mentally Infirm."¹² In this report, the Commissioners called for the adoption of specific federal regulations governing research with the "mentally disabled," as they later did for children in 1983. However, their proposed framework was never incorporated into the U.S. regulations governing federally funded research.

Current U.S. regulations make minimal specific references to the mentally disabled, including the following: "When some or all of the subjects are likely to be vulnerable to coercion or undue influence, such as children, prisoners, pregnant women, mentally disabled persons, or economically or educationally disadvantaged persons, additional safeguards have been included in the study to protect the rights and welfare of these subjects."¹⁰

The regulations do not provide a definition of what constitutes a mental disability. As a result, variable practice exists within the research community regarding who is considered decisionally impaired due to a mental disability. Furthermore, the only specific guidance regarding "additional protections" included in the regulations is the requirement that a legally authorized representative provide permission for research participation if the subject is unable to do so.

In the early 1990s, allegations were made against schizophrenia researchers at the University of California, Los Angeles following the death of a former research subject. The investigators were accused of conducting "high-risk" research with "vulnerable" subjects and without adequate informed consent. This case, and its subsequently well-publicized federal investigation, ushered in a period of intense ethical scrutiny and criticism of research involving mentally ill subjects. In 1995, the National Bioethics Advisory Commission (NBAC) was established and charged with providing recommendations on bioethics (including research with the mentally disabled), to the National Science and Technology Council. Following extensive public testimony and investigation, NBAC released its 1998 report, "Research Involving Individuals With Mental Disorders That May Affect Decisionmaking Capacity."¹³ Although these recommendations have not been incorporated into U.S. research regulations or adopted by the research community in any coherent fashion, they have stimulated much debate and research relevant to those at risk for impaired DMC.

Core Conception and Methodological Rationale

The principal ethical concern raised by research involving subjects with impaired DMC is the potential exploitation of such individuals. An inherent tension exists between the danger of exploitation and the compelling need for improvements in the clinical care of patients who suffer from medical, neurological, and psychiatric illnesses that impair DMC. Because progress through research requires the participation of subjects at greatest risk of exploita-

tion, an ethical assessment of these studies depends critically on how they are conducted.

Clearly, some medical conditions are associated with predictable impairment of DMC (e.g., advanced dementia, massive head trauma, delirium). However, we contend that a diagnosis-based approach to the ethics of research with subjects at risk for impaired DMC is not supported by existing data and, further, that such an approach stigmatizes the millions of people who suffer from mental illness. Data summarized below demonstrate that many, if not most, of these individuals are quite capable of providing informed consent for research participation. Furthermore, impaired DMC represents just one of several ways in which research subjects can be "vulnerable." There exists no consensus about what constitutes adequate informed consent for any research, let alone research with those thought to be vulnerable. Consequently, we advocate a process-oriented and protocol-driven approach as described below.

Our approach to the ethical analysis of research with decisionally impaired subjects is based on four core concepts. First, DMC is a complex and modifiable clinical phenomenon. As such, the domains of competency, DMC, and the ability to provide informed consent must be understood as closely related yet distinct. Despite the complexity of DMC, the clinical research review and approval processes require the rendering of categorical determinations about inherently continuous phenomena. Although individuals vary in their decisional capacity and their actual understanding of a given research protocol, they must be judged to be capable or incapable of giving informed consent and as having or lacking sufficient understanding to qualify as providing valid consent. Ultimately, these decisions require some measure of "clinical judgment," but our approach mandates that DMC is viewed as a continuous variable. Second, those judged to be at substantial risk for impaired DMC are appropriately considered vulnerable in the research context and deserving of additional safeguards. Consequently, the default position of investigators and institutional review boards (IRBs) should be to conduct studies with volunteers who clearly are able to provide informed consent. If an IRB concludes that important research requires the enrollment of subjects who may not be able to make capacitated decisions, then additional safeguards must be incorporated into the design and conduct of the study to protect those subjects. Third, distinctions between the provision of standard medical care and clinical research participation have important implications for decisionally impaired subjects. Fourth, as a practical matter, the ethical analysis of research with decisionally impaired subjects should be anchored to the IRB oversight process and considered on a protocol-by-protocol basis.

Throughout most of the developed world, adults are presumed competent to make autonomous decisions. A judgment that someone is incompetent is made by formal judicial ruling and rendered in the context of the person's ability to make specific decisions (e.g., choices concerning medical care, management of finances, designation of a substitute decision maker, execution of a will). From a legal perspective, persons are either competent to make decisions for themselves or incompetent, in which case someone else makes decisions on their behalf. Furthermore, the threshold for incompetence varies depending upon the task an individual is called upon to perform. Unfortunately, limited empirical data are available to help determine appropriate thresholds. Therefore, competency determinations are made on a case-by-case basis.

The evidence upon which a judicial determination of competence relies includes the formal assessment of decision-making abilities by professionals with appropriate expertise. This clinical evaluation is generally referred to as the assessment of DMC. Few human activities are as complex and individually determined as how we make decisions. Core components of DMC include intellectual ability, emotional state, memory, attention, concentration, conceptual organization, and aspects of executive function such as the ability to plan, solve problems, and make probability determinations. Most of the literature on DMC in the clinical research setting focuses on cognitive functions and uses psychometric approaches to the study of individuals with neuropsychiatric illnesses such as dementia, psychosis, major depression, and bipolar disorder.¹⁴ Psychologists, cognitive neuroscientists, and economists have contributed to an extensive parallel literature through studies of healthy volunteers in which various experimental manipulations are used to probe the dynamics of decision making (e.g., the effects of time pressure on risk-taking and information-processing strategies).^{15,16} Despite this rapidly expanding body of evidence, the manner in which individuals assign relative importance to a particular cognitive strategy when making decisions remains poorly characterized.

The contributions of mood, motivation, and other mental processes on risk assessment and decision making have direct implications for the process and quality of informed consent for research. However, the extent to which these factors, and less discrete concepts like intuition, trust, duty, or altruism, influence someone’s choice to enroll in a study is not known. Cutting across all of these determinants is the fact that decisions about participating in research typically take place within the context of relationships between research subjects and investigators. How characteristics of these relationships impact DMC and the informed consent process are also unknown. Although much work remains to better understand decision making and informed consent, it is clear that focusing exclusively on measures of cognitive impairment is insufficient.

In the medical setting, it is common for patients to manifest diminished DMC in some domains but retain the ability to make

autonomous decisions in others. For example, a patient with schizophrenia may suffer from delusions or hallucinations yet still adequately attend to activities of daily living and manage her financial affairs. However, even in cases of patently impaired DMC, it is unusual for such patients to undergo formal competency evaluations and judicial proceedings. Informal judgments about competence based on these capacity assessments are generally accepted as reasonable proxies for judicial review. In this chapter, we use the terms *capacity* and *impaired capacity* to refer to findings from a clinical evaluation and *competence* and *incompetence* to refer to the status of individuals to make their own legally binding decisions. In the clinical research setting, a judgment that a person is capacitated means that he or she is able to provide informed consent for the specific research protocol under consideration.

In contrast to the dichotomous nature of competency determinations, DMC is more accurately conceptualized as a skill set that varies along a continuum from incapacitated to fully capacitated (see Figure 41.1). For example, individuals in the early stages of dementia may be unable to provide informed consent for a complicated clinical trial but retain the ability to appoint a trusted family member or friend to serve as the holder of a durable power of attorney (DPA) for medical and research decisions. Despite this spectrum of DMC, clinical researchers routinely make yes or no determinations as to whether a subject understands the risks and benefits of a study “well enough” to provide informed consent. Indeed, there are several examples relevant to clinical research in which categorical decisions are made with respect to continuous phenomena. Research regulations typically require that a sharp line of demarcation be drawn between childhood and adulthood despite the wide variability and uneven maturation among adolescents and young adults in their cognitive and emotional development. Similarly, IRBs make categorical risk determinations (i.e., minimal risk and more than minimal risk) for research-related harms and discomforts that actually reflect continuously distributed probabilities. IRBs face multiple challenges when reviewing protocols designed to enroll subjects with variable DMC into research that poses a range of risks and offers an uncertain prospect of direct medical benefit.

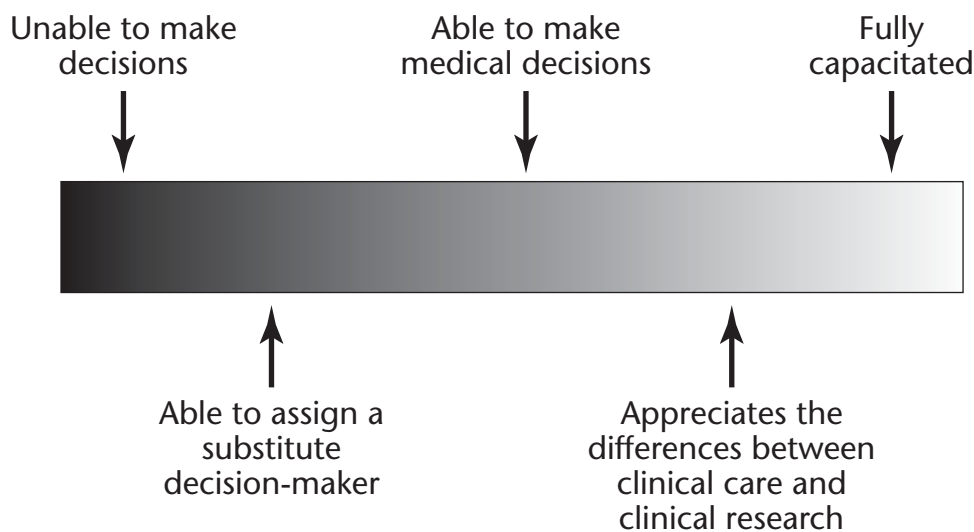

Figure 41.1. Decision-Making Capacity as a Continuous Phenomenon

One straightforward approach to protecting vulnerable research subjects is to require that incapacitated adults be enrolled in research only when their participation is necessary to answer the scientific question posed. This requirement has been termed the *necessity clause* and has been articulated best by Wendler and colleagues.¹⁷ In our experience, this fundamental question of whether it is scientifically necessary to enroll subjects who are unable to provide informed consent is often inadequately addressed in the IRB review process. Investigators may argue that excluding subjects who are unable to provide informed consent will result in a selection bias (i.e., enrolling healthier subjects) that compromises the scientific validity of the study. Another objection to the necessity clause is that it will result in unacceptably long recruitment time and/or make the study impracticable. Our position is that the investigator is responsible for explicitly justifying the enrollment of subjects who are unable to provide informed consent. The IRB must then make an independent judgment regarding whether this justification is acceptable.

An IRB determination about the acceptability of a research project likely to enroll individuals at risk for impaired DMC raises several further questions. How will the subjects be recruited? What is the probability that subjects will be unable to provide informed consent? Who will evaluate DMC? What methods will be employed in this assessment? How will questionable cases of DMC be resolved? Will research authorization be permitted by surrogates if the subject is unable to provide informed consent? If so, is there a need to assess the capacity or appropriateness of the surrogate for this task? Because individual research subjects can manifest impaired DMC at any time during a study, whether or not this was anticipated by the IRB, is there a mechanism in place for the evaluation and protection of subjects with unanticipated incapacity?

The answers to these questions vary widely among individual investigators and research institutions. In contrast to the research setting, a clinical and legal framework for the assessment of DMC in the medical setting is well-established. Within this framework, several important points of consensus have emerged for determining decisional capacity in the treatment context and making medical decisions for incompetent adults.¹⁸

First, competence is understood as relative to the type and complexity of the treatment decision at stake. Some decisionally impaired patients are competent to make simple treatment decisions but incompetent to make complex ones that require weighing and balancing the risks and benefits of alternative treatments and factoring in uncertainty about outcomes. The assessment of capacity, which informs decisions about competence, includes assessing the abilities: (1) to make and express a choice; (2) to understand information relevant to the treatment decision; (3) to appreciate the significance of this information for the individual's own situation; and (4) to reason with the relevant information in weighing options.¹⁹

Second, thresholds for competence to make treatment decisions should adopt a "sliding scale."²⁰ The thresholds for competence should become more demanding as the risks of a treatment intervention, the uncertainty of its benefits, and/or the complexity of the research increase.

Third, assessing DMC is the responsibility of the treating physician. In cases in which capacity is called into question, a psychiatric or neurological consultation to more formally assess DMC may be indicated and helpful.

Fourth, when patients are judged incapable of making treatment decisions, surrogate decision makers must be engaged. Two legal and ethical standards govern surrogate decision making.²¹ If the prior preferences of the patient are known, then the surrogate should make a "substituted judgment" that he or she believes the patient would have made if able; if not known, the surrogate together with the physician chooses the option believed to promote the patient's best interests. Exceptions include emergency interventions or when surrogate decision makers cannot be found, in which case physicians make treatment decisions for the patient. Surrogate decision makers may be designated by patients through a DPA. Additionally, written guidance about the patient's treatment preferences may be available in the form of an advance directive or living will. The vast majority of patients have not engaged in such formal advance planning, although many may have informally communicated their preferences to others. If no surrogate has been designated in advance, next of kin are generally considered appropriate surrogate decision makers and recognized as such by law. It is presumed that they know best the preferences and values of the patient that should determine or inform treatment decisions and that they will be concerned to promote the patient's best interest.

Differences between clinical care and clinical research affect the applicability of the framework developed for clinical care of incapacitated adults to the research setting. Four specific issues deserve attention: (1) DMC must include the ability to appreciate key differences between clinical care and clinical research—clinical research is designed to develop scientific knowledge concerning diseases and their treatment, not to promote optimal medical care for particular patients; (2) levels of risk that are justified in medical care may not be justifiable in clinical research; (3) a formal plan for capacity assessment may be necessary in some research protocols; and (4) surrogate decision making should take into account the differences between clinical care and clinical research.

Although the same types of abilities that constitute capacity to consent to treatment are relevant to capacity to consent to research,²² capacity assessment in research is complicated because patient-volunteers may have a "therapeutic misconception" in which they see various research interventions as directed to individualized diagnostic or therapeutic benefit.^{23–25} No agreement exists on how realistic it is to expect sick patients deciding to enroll in clinical research to be able to fully appreciate the differences between personal care and research participation. Nonetheless, the ability to appreciate these differences may be so impaired that some individuals, who may be capable of making treatment decisions, should be judged incapable of making research decisions.

Individuals who lack capacity to give informed consent may be capable of assent—a less demanding standard of research authorization.²⁶ Along with the requirement for parental permission, the U.S. federal regulations on research with children allow children to give assent for research in accordance with their capacities for understanding, appreciation, and reasoning.¹⁰ Adults who are incapable of giving informed consent may similarly have sufficient ability to assent to research participation. Soliciting assent shows respect for the capacities that they retain as well as for their former autonomy.

Just as incapacitated individuals are often unable to provide valid consent to research, they are similarly unable to decide to withdraw from research. Dissent is widely accepted as sufficient

grounds for withdrawing from research. However, it is also generally assumed that valid dissent is a result of a rational decision-making process. It is much harder to know how to respond to behavior suggesting dissent that is not the result of a rational decisional process, for example, dissent that might be voiced by an individual in an acute paranoid psychosis or postconcussive state. Behaviors suggesting objection in these types of cases may represent anxiety, confusion, or ambivalence rather than a rational decision to decline participation. Although there is no consensus on what to do when faced with these situations, withdrawing the individual from the research may not always be the most ethically appropriate course of action. Halting the particular procedure and considering reapproaching at a different time may be an appropriate alternative. A surrogate decision maker can sometimes be helpful in making these types of determinations. However, persistent objection should be respected by withdrawing the individual from research.²⁷

Given the ethical and procedural complexity of research with decisionally impaired subjects, it is not surprising that efforts to craft definitive policy and legislation have been largely unsuccessful. Nonetheless, one tangible outcome from extensive public deliberations over the past decade has been a significant increase in the number and quality of studies of DMC in the research setting.

Empirical Data

Potential research subjects may be considered at risk for impaired DMC for several reasons. The most common cause for concern is the nature of the underlying medical, neurological, or psychiatric disorder under study.^{13,14,23,28–37} Frequently cited conditions include dementia, delirium, psychotic disorders, depression, mania, and intoxication with alcohol or illicit substances. The nature of the research protocol, rather than the disorder being studied, might also render research subjects at risk for impaired DMC. For example, an oncology trial for malignant melanoma in which individuals receive high dose interleukin-2, a cytokine associated with central nervous system toxicity, places otherwise capacitated subjects at risk of losing DMC. In this case, the concern is less about adequate informed consent on the “front end” of the study than it is about subjects losing their ability to provide adequate ongoing informed consent after receiving interleukin-2.

Although investigators and IRBs are charged with making their best judgments about “high-risk” study populations and protocols, intuitions about DMC are not always confirmed by research findings. Several methodologically sound studies of DMC suggest the following three important findings:

1. *DMC is variable within and between diagnoses.* A wide range of patient groups (e.g., those with dementia, schizophrenia, depression, Parkinsonism, HIV/AIDS, delirium, and diabetes mellitus) have been studied with respect to their ability to provide informed consent for either an actual clinical trial or a hypothetical investigation. Several studies have confirmed that some patient groups are at higher risk for impaired DMC than samples of healthy controls or other medically ill comparison groups.^{29,38–41} However, each of these studies reported substantial overlap in measures of DMC between comparison groups and suggested that diagnosis alone was inadequate for differentiating between subjects who were and were not able to give informed consent for the study. More importantly, despite predictable cognitive and deci-

sional deficits, only a minority of subjects from these “high-risk” samples (e.g., those with schizophrenia, dementia, or depression) were determined to be incapable of providing informed consent for clinical care or a research study.^{29,32,38,40,42–49} Interestingly, certain aspects of neurocognitive deficits (e.g., working memory, “negative” symptoms of apathy, avolition, and inappropriate affect) are more predictive of impaired DMC than psychotic symptoms (e.g., hallucinations and delusions).^{29,39,43,44}

2. *DMC can be improved through educational interventions.* An important finding replicated by several independent research groups is that educational interventions for at-risk patients designed to improve informed consent are effective. Typically, the most robust improvements in DMC, as they relate to the informed consent process, are observed in the domains of *understanding* and *reasoning*. Some investigators reported that following an educational intervention, subjects with impaired baseline DMC performed as well as healthy comparison subjects on tests of DMC. Several different educational approaches were used in these studies, and it remains uncertain whether specialized educational programs provide additional improvement in decisional capacity beyond standard subject education.^{29,39,46,50–52}

3. *Surrogate consent is acceptable for some research.* Not surprisingly, proxy decision makers report ambiguity in their role and experience this activity as psychologically burdensome.⁵³ Still, the majority of “at-risk” subjects and caregivers are supportive of this mechanism of research authorization for low-risk research that offers a prospect of direct medical benefit to subjects.^{54–56} Fewer data exist regarding the willingness of proxy decision makers to enroll decisionally impaired subjects in higher risk research. However, in a related study, Wendler et al. queried healthy individuals who had a close relative with Alzheimer’s disease about their attitudes toward research advance directives.⁵⁴ They found that of the 39 healthy respondents who filled out a research advance directive, 20 were willing to participate in research with greater than minimal risk and no potential benefit.

Policy and Study Design Implications

Several policy and study design implications stem from the conceptual considerations and empirical data relevant to DMC. First, it is unlikely that one simple policy will address the scope and complexity of this aspect of research. Although some studies propose the enrollment of subjects known to be incapacitated, others will enroll only capacitated subjects onto a trial of a medication that will lead to loss of capacity in susceptible individuals. A single approach to such different studies is inappropriate. Policies on DMC in research will need to be flexible enough to allow for both a wide range of studies and individual cases of protocol-emergent loss of capacity. Second, current research guidelines provide insufficient detail as to appropriate additional safeguards and how they should be implemented.^{57–60} Third, investigators should build specific educational interventions into their protocols. Fourth, the greater use of advance directives and a DPA for research participation should be encouraged by IRBs (or mandated for high-risk studies). Fifth, the protection of decisionally impaired subjects may be strengthened by more specific research regulations similar to those for children.

Although there are no regulations governing risk-benefit assessment for research with incompetent adults, the federal policy

framework for research involving children offers valuable guidance (see Chapter 42). Under this framework, research that provides a prospect of benefit to the child-subject and/or poses minimal risk to subjects is allowed.¹⁰ (The regulations define *minimal risk* as “the probability and magnitude of harm or discomfort anticipated in the research are not greater in and of themselves than those ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests.”¹⁰)

Research that presents a minor increase over minimal risk and does not hold the prospect of benefit for the child-subject may also be justifiable if it fulfills the following conditions: (a) “the intervention or procedure presents experiences to subjects that are reasonably commensurate with those inherent in their actual or expected medical, dental, psychological, social, or educational situations”; (b) “the intervention or procedure is likely to yield generalizable knowledge about the subjects’ disorder or condition which is of vital importance for the understanding or amelioration of the subjects’ disorder or condition”; and (c) “adequate provisions are made for soliciting assent of the children and permission of their parents or guardians.”¹⁰ Proposed research that has greater than a minor increase over minimal risk and no prospect of benefit for the subjects must be approved by the Secretary of Health and Human Services. We believe that these risk-benefit categories are also reasonable to apply to research with incompetent adults, even though there debate continues about how best to interpret the definitions for the various risk levels.^{61,62}

Because the presence of a diagnosis is neither necessary nor sufficient to identify an individual in need of protections above and beyond those in place for all research subjects, we suggest that additional safeguards should be considered for any subject or class of subjects who are either unable to provide informed consent or who are at risk of being unable to do so for a particular study. With this approach, investigators, IRBs and others charged with monitoring research can make determinations of vulnerability and the need for additional safeguards on a protocol-by-protocol basis or for individually identified subjects.

Protocol Review and Determination of Appropriate Safeguards

Despite a substantial literature on the subject of research with decisionally impaired subjects, there exists little practical guidance for IRBs with respect to the kinds of safeguards that can be employed to protect decisionally impaired subjects.^{13,28–30,33,38,63–66} Protocols must include a description of how informed consent will be obtained and are expected to include additional procedural details when subjects are likely to have impaired DMC. The IRB, in turn, makes its own determination as to the adequacy of these plans.

Many commentators on this issue have called for the assessments of DMC to be performed by someone independent of the research team. This was a key recommendation in NBAC’s report which stipulated that this assessment of capacity to consent should be made by an “independent, qualified professional” when studies pose more than minimal risks.¹³ The commissioners did not specify how investigators and IRBs were to decide who that professional should be, their requisite degree of independence, what

methods of evaluation should be used, and how this process would be administered within a research setting.

For protocols enrolling subjects who might have decisional impairment but who are not at particularly high risk in this regard, the IRB can require that the informed consent discussion between the subjects and the investigators be observed by someone who is not part of the research team (i.e., consent monitor). If the consent monitor has concerns about the subject’s ability to provide informed consent, then a more formal capacity evaluation of that subject would be indicated.

Obtaining informed consent from a research participant is an early, ongoing and integral component of what should be a trusting relationship between investigator and subject. As such, it should not be interfered with without cause. The presence of a consent monitor is, no doubt, an intrusion and could influence the informed consent process in both positive and negative ways. However, if all parties (i.e., investigator, IRB, consent monitor, and subject) are clear about the purpose and function of consent monitoring, this intrusion can ultimately serve to improve this fundamental research contract with minimal disruption to what has been historically a private and highly variable conversation.

In contrast to consent monitoring, independent capacity assessment should occur after the initiation of discussions about a study but prior to signing the informed consent document. It is essential that the person or team that performs these evaluations has clear authority and administrative backing to prevent the enrollment of subjects who are unable to provide informed consent.

Safeguards other than consent monitoring and assessment of DMC can be employed by the IRB. For research institutions that provide a bioethics consultation service, review of a research protocol or a specific subject’s participation by an individual or group independent of the research team can provide meaningful protection for subjects. The use of an independent clinician to manage clinical care separately from the research care of subjects has also been proposed as a safeguard for high-risk studies with vulnerable subjects. An infrequently employed safeguard is the enforcement of a specific hospital policy on research with decisionally impaired or potentially impaired research subjects. Despite the obvious guidance such policies can provide to investigators and IRBs, only a few exist.^{67,68}

Which safeguards are chosen for which protocols should depend on the level of risk posed by the research and the nature of the anticipated decisional impairment of subjects. For example, although it is reasonable for the IRB to require independent assessment of DMC for potential subjects in a more than minimal risk schizophrenia clinical trial, this same requirement would make little sense for a minimal risk MRI study in advanced Alzheimer disease. A more appropriate safeguard in this latter case would be for the IRB to stipulate the assignment and active involvement of a legally authorized representative in providing surrogate permission.

Some researchers have instituted a procedure by which individuals likely to have declining capacity prepare an advance directive at the time of enrollment that includes assigning a surrogate decision maker to take an increasingly active role in decision making as the subject’s own abilities decline.⁶⁹ Although this model will not work in all protocols, it may be a useful way to incorporate surrogate decision makers into a system of safeguards for at-risk subjects.

Areas in Need of Further Research

One of the more pressing needs for empirical data is to examine methods and tools with which to identify individuals who are decisionally impaired and who are thus unable to provide adequate informed consent. In our view, the MacArthur Competence Assessment Tool for Clinical Research (McCAT-CR) employs the most meaningful framework currently available for the assessment of DMC for research participation. The McCAT-CR is a modification of the DMC model described earlier and addresses the domains of understanding, appreciation, reasoning, and the ability to express a choice. To date, the McCAT-CR has been used predominantly as a research tool^{29,31,32,34,38,43–45,47–50} and is limited by the need to customize it each time it is used for a new protocol. Some research programs have piloted the use of the McCAT-CR modified in such a fashion that a short version can be rapidly adapted for a new protocol. One facet of the McCAT-CR model, the concept of appreciation, has not been well explicated. In this context, appreciation is generally understood as the extent to which subjects understand the relevance of the research activity to their particular circumstances. For example, knowledge that a clinical trial includes both a placebo and an active medication arm demonstrates “understanding.” In contrast, a full awareness that one may actually receive placebo and as a result forgo other available treatments is an example of “appreciation.” What constitutes appreciation and how it should be assessed remain key unanswered questions.

A related issue in need of empirical research is a framework for assessing the adequacy of surrogate permission to enroll incapacitated individuals in research. Just as we need more systematic studies of the motivations and experiences of research participants, we need the companion data relevant to surrogate decision makers. Only then will we be in a position to know what constitutes adequate or appropriate understanding by a proxy decision maker. Current policy at the National Institutes of Health’s Clinical Center requires an ethics consultant to assist in the selection of surrogates for incapacitated adult prospective research subjects.⁶⁶ Like patient-volunteers, surrogates may be subject to the therapeutic misconception that confuses clinical research with individualized medical care. Education for surrogates as well as consultation with a neutral professional or lay advocate may help prepare them for their responsibility to make informed choices on the behalf of incapacitated subjects.⁷⁰ Clearly, there is much to be learned about the factors involved in deciding for others in the research setting.

Several other important questions related to the protection of vulnerable subjects remain unanswered. With so much attention and effort being directed at decisional capacity determinations at the “front end” of research participation, there has been little discussion of optimal ways to protect those subjects who are able to provide informed consent at the start of the study but who then lose that capacity during the study. The use of a research advance directive or prospective authorization for research is a logical strategy in this regard but one that has yet to be widely implemented. As research programs move toward the systematic implementation of additional safeguards for vulnerable research subjects, there will be a growing need for data on how to construct the most efficient and effective programs to protect research subjects. Finally, research into novel and effective methods of training clinical investigators holds out the promise of improving the ethical conduct of

virtually every aspect of human subjects research, including specific protections for decisionally impaired subjects.^{71,72}

Conclusion

One of the major conclusions to emerge from a decade of debate on research involving individuals with compromised DMC is that it is both inaccurate and stigmatizing to conclude that all or most individuals with a psychiatric diagnosis are unable to make decisions for themselves. Nonetheless, for certain types of studies involving subjects judged to be at risk for impaired DMC, there are compelling reasons to consider them vulnerable and therefore in need of additional safeguards. As is true for any clinical study, when a member of the research team encounters any subject, at any time during the conduct of the study, who presents with questionable DMC, that subject should be carefully evaluated and either managed according to the dictates of the protocol or removed from the study.

The ethical framework applicable to enrolling incapacitated adults in clinical research deserves more systematic exploration and articulation. Although the framework for treatment decision making for incompetent adults and the framework for research with children are helpful, they fail in several ethically important ways as described above. More systematic empirical data are needed to better understand the extent to which adults in a variety of conditions have impaired ability to give informed consent to research participation. In addition, too little is known about surrogate decision making, for example, the motivations of surrogates for enrolling incapacitated persons in research, their understanding and appreciation of what research participation involves, their knowledge about the research-relevant preferences and values of the incapacitated individuals whose research participation they authorize, and the extent to which they are involved in monitoring research participation. Programmatic experimentation and evaluative research are needed in the areas of enhancing the capabilities of decisionally impaired individuals to give informed consent, formal methods of capacity assessment, independent capacity assessment, consent monitoring, advance directives for research participation, evaluation and education of surrogates, and the use of lay advocates. Funding sources for clinical research involving decisionally impaired individuals should support initiatives to improve the protection of these vulnerable research subjects and to conduct well-designed, ethics-related empirical research.

Research With Children

In the developed world, biomedical and public health research during the 20th century resulted in dramatic changes in maternal and infant mortality rates, the near eradication of infectious causes of death in childhood, and the conquering of many serious diseases affecting children. The development of vaccines to prevent diphtheria, polio, and measles; pharmacologic treatment regimens to change leukemia, other cancers, and human acquired immunodeficiency disease from uniformly fatal to chronic or even curable diseases; and the application of technology and molecular biology to the treatment of the consequences of profound prematurity are a few examples of the successes of scientific progress combined with clinical research involving children.

The great benefits of research involving children are tempered by concerns that children require added protection from the risks of research. Unlike adults, children cannot consent to place themselves at some level of risk with uncertain benefit in a research setting for the purpose of generating new knowledge that will likely help future children. Some commentators have questioned whether it is ever ethical to use children in research.^{1,2} Most agree that we should be willing to place some children at risk for the sake of all children, but we must develop the necessary methods to protect those children who are enrolled in research so as not to place them at undue risk without compensating direct benefit. Research with animals, and research with adults and older children who can participate in the decision-making process should, when feasible, precede research with young children and infants. Yet the distinct aspects of childhood diseases, the need to consider the broad range of childhood growth and development, children's unique metabolism, and unexpected drug toxicities require that research be conducted with children in order to create the scientific and

medical advances expected by society to enhance the health and well-being of children.

The history of research involving children reveals that the interests of child participants were not always protected and some children were exploited by researchers.^{3,4} Since the 1970s, a system of regulation and supervision of research involving children has developed in the United States that allows advances in the understanding of the physical, psychological, and social growth and development of children and the pathophysiology and treatment of diseases and disorders that affect them, while protecting children from unnecessary and uncompensated risks and discomfort. The benefits to children of research advances and the need to study proposed and standard interventions and therapies in order to identify unanticipated harms make it imperative to have a system of research regulation that enables research involving children to go forward.

History of Research With Children

Medical research with children is not well documented prior to the 18th century and the development of pediatrics as a medical specialty. Although the history of medicine with children begins with references to specific childhood conditions in texts from ancient Egyptian, Greek, and Roman physicians, most of these references are observational in nature and do not explore the unique physiological status of children and adolescents.³ Discussion of children and their medical conditions continued into medieval times, and some writing on the subject emerged, particularly after the introduction of printing in the 1400s. However, most of the

pediatric writing until the late 1600s centered on observations, folklore, and suggestions based on informal trial and error. Infant mortality during these times was extremely high and considered unalterable.

The 17th century saw a rebirth of medicine, and physicians began to take a greater interest in children. Entire texts devoted to the treatment of childhood conditions began to appear, and European medical schools began to include instruction in pediatrics. The 17th century also saw the beginning of modern medical research, “the study of disease by the recording and correlating of clinical phenomena.”³ This type of formal clinical observation led to advances in medicine, including the introduction of inoculation for smallpox in the 18th century. Children, who were highly susceptible to smallpox, were among the first to be inoculated in England when members of the British royal family began having the procedure performed on their offspring. In 1796, Edward Jenner conducted his famous smallpox vaccination experiment using cowpox on an 8-year-old patient and other children in his village.⁵ Jenner saw his work as highly beneficial, particularly to families, and although he discussed the risks with his subjects and attempted to minimize them, he did not seem troubled by the use of children in experimentation. Jenner’s trials, as other early research with children, had its roots in a sincere desire to benefit society and help a group that had historically been ignored by medical practitioners.

Pediatric medicine became a recognized medical specialty in the 19th century, and medical societies in the United States and Europe began to form pediatric sections in the 1880s.⁶ A growing interest in child health led to the creation of pediatric hospitals, which, along with orphanages, provided investigators with a ready population of children on whom to experiment.⁷ These types of institutions often had rapid outbreaks of various communicable diseases, and their readily available populations made useful subjects for a growing number of investigations.⁴ There was little concern about securing informed consent from children or their parents, and few objections within the medical community to research involving institutionalized children. Most saw the societal benefits of the research as outweighing the potential risks to subjects, particularly for institutionalized children whose risk of contracting a communicable disease was very high.

Research with children continued into the 20th century. As with earlier research, many of these U.S. studies focused on highly communicable diseases that spread rapidly in institutions, such as smallpox, molluscum contagiosum, tuberculosis, pertussis, measles, and polio.^{8–13} Other studies examined new diagnostic techniques such as spinal taps or looked at child physiology such as stomach emptying in an attempt to understand differences between children and adults.^{14,15} However, in contrast to Jenner, investigators during the early 1900s rarely discussed the risks or discomfort associated with the research, and rarely mentioned any ethical concerns about using children in research. Furthermore, the subjects in these studies were often poor or abandoned children who were provided to researchers by doctors working in orphanages and asylums, and these studies contain no mention of obtaining consent.

Although most medical professionals did not voice objection to the use of children in research, the antivivisectionist movement, which had long protested the use of animals in medical research, objected to the use of children in research beginning in the late 19th century. Antivivisectionists opposed the “research imperative” and “experiments on live animals” or on children.¹⁶ These protests included journals devoted to citing research cruelties and

pamphlets arguing against research involving children. The protests prompted some lawmakers to propose antivivisection bills that attempted to formally regulate or ban research with live animals and with children.

As the 20th century progressed, protests against research with children remained confined to antivivisectionists, and research continued mostly unobserved and unhindered. Some investigators were concerned with safety and attempted to obtain prior consent from subjects, but investigators were rarely criticized for experiments that put children at undue risk.¹⁷ The advent of World War II and concern over injury and illness among soldiers overseas created an urgent need for medical research, and the number of research studies in the United States dramatically increased.

Moving Toward Research Regulation

Numerous medical experiments were conducted on humans by Nazi doctors in concentration camps during World War II (see Chapter 2). Many of these experiments had dubious, if any, scientific bases, and experimenters made no attempt to solicit consent or to explain the purpose of the studies. Many of these experiments resulted in tremendous suffering, disability, and death. Children were not exempt from experimentation; indeed, some Nazi physicians specifically sought children for studies. Josef Mengele, a Nazi doctor and scientist, tortured and murdered numerous children in the name of science.¹⁸ For example, in “germ warfare” experiments, one child, a twin, would be injected with bacteria, become deathly ill and be allowed to die, and the healthy twin would be killed in order to examine differences between organs of the two children. These children, like all of the prisoners who were experimented upon, had no way of knowing that they were being used as guinea pigs, nor could they refuse participation.

Nuremberg Code

After the liberation of the concentration camps and the end of the war, 23 of the physicians and Nazi officials who had performed experiments were brought to trial at Nuremberg. The U.S. judges at the trial issued the Nuremberg Code, a list of 10 governing principles to guide medical experimentation with humans (see Chapter 12). The Code was intended to be a universal statement to ensure the ethical conduct of research and was adopted by the judges due to a lack of commonly accepted practices in this area. In addition to mandating sound scientific experimental methods and appropriate risk-to-benefit ratios, the Code required the voluntary consent of every person who participated in research. It insisted that the “voluntary consent of the human subject is absolutely essential” and that consent was valid only if the person giving it had the legal capacity to do so.¹⁹ This requirement would have effectively prohibited any research with children, as well as with other incapacitated individuals, such as those with mental illness or physical ailments that affect capacity to consent, and it was largely ignored in the United States. Not only did Americans view Nazi doctors and the situation of the Holocaust as removed from the reality of medicine and experimentation in the United States, but to adhere to the Code would have meant ending all ongoing research with children.²⁰ Accordingly, research with children continued in the United States without any real attempts at regulation for the next 20 years.

Declaration of Helsinki

In the early 1960s, the World Medical Association (WMA) set about to create and promulgate a universal set of professional guidelines to aid investigators in conducting ethically sound research. Given the largely indifferent response to the Nuremberg Code and its prohibition of research with children, these guidelines were created by physicians for physicians and would help the progress of research as it sought to standardize its practices. The result of the WMA's work was the Declaration of Helsinki, which first appeared in 1964 and has since undergone many revisions, most recently in 2000 (see Chapter 13). Key in the Declaration was the distinction between therapeutic research (research combined with medical care) and nontherapeutic research (research performed on healthy individuals to gain generalizable knowledge).²¹ Furthermore, the final, adopted version of the Declaration allowed for both types of research to be performed using minors, provided that consent was obtained from the minor's representative and assent was obtained from the minor him- or herself whenever appropriate. Thus, the Declaration was far more tolerant of research with children than the Nuremberg Code, and was widely supported, particularly by researchers in the United States. However, though the Declaration was an influential document, particularly in that it was internationally recognized, there were still no regulations to govern research with humans in the United States.

Evolution of U.S. Federal Regulations on Research With Children

Although research involving children continued without formal regulation in the United States even after the adoption of the Declaration of Helsinki, there was a growing awareness among professionals, government agencies, and members of the public that some form of research oversight was needed. After it was discovered that the use of the experimental drug thalidomide by pregnant women caused severe birth defects, the Food and Drug Administration (FDA) mandated in 1962 that experimental drugs be tested in standardized trials using formal consent procedures.²² In 1963, the director of the National Institutes of Health (NIH) created a committee to examine research under the auspices of the NIH to study problems of consent and unethical practices in research protocols. This committee developed several proposals for consideration by the U.S. Public Health Service (PHS) that resulted, in 1966, in a memorandum from the U.S. Surgeon General, William H. Stewart, to all institutions receiving federal funds. The memorandum stated that no research involving humans would be funded by the PHS unless the grantee had indicated that the grantee institution had provided prior review by a committee of "institutional associates" to assure an independent determination of the rights and welfare of the research participants, the appropriateness of the methods used to secure informed consent, and the risks and potential benefits of the investigation.²³

Willowbrook and Tuskegee

Two studies exposed in the early 1970s made the public aware of questionable research practices and instigated the creation of government research regulations. Studies on the transmission of hep-

atitis in institutionalized children were conducted over a number of years at the Willowbrook State School, a large hospital for mentally disabled children in Staten Island, New York. Hepatitis was endemic at Willowbrook, and investigators were working to find a way to prevent its spread, much as scientists had done for centuries in other institutions.²⁴ This research program was criticized when published studies indicated that children at the institution had been deliberately infected with hepatitis virus as a means of studying the potential to develop a vaccine for the disease.²⁵ The investigators defended their work and argued that exposing children to hepatitis while following a protocol and keeping them in a special hepatitis unit entailed "less risk than the type of institutional exposure where multiple infections could occur."²⁶ Although permission of the children's parents had been solicited, critics argued that deliberately infecting healthy children was mere exploitation of an institutionalized population²⁷ (see Chapter 7).

The Tuskegee Syphilis Study was funded in 1932 by the U.S. PHS as a natural history study of the progression of syphilis in 400 black men in Alabama. Although the Tuskegee study did not include children, its exposure focused attention on the potential for exploitation of vulnerable populations in the context of research. The study was not a secret in the medical community or to the government sponsors; over the years, several papers were published with updated results and observations.^{28–30} However, in 1972, when a reporter for the Associated Press wrote an exposé documenting the study, there was a great deal of public criticism^{31,32} (see Chapter 8).

These two studies and the resultant public outcry prompted an examination of the problem of research abuses and creation of standards for the protection of research participants. The Department of Health, Education and Welfare (DHEW)—now the Department of Health and Human Services, DHHS—implemented the *Institutional Guide to DHEW Policy*, which was more detailed than previous NIH/PHS policies and highlighted "at-risk" research populations, including children. The FDA applied the new DHEW policy to research protocols for new drugs, and in 1974, Congress strengthened the DHEW policy and required institutional review of any protocol under DHEW purview.³³

Paul Ramsey and Richard McCormick

In addition to the general public's concern about research practices, there was a vigorous debate in the 1970s among health-care providers, researchers, and ethicists about the morality of involving children in research. Paul Ramsey, a Protestant theologian, wrote that research involving children was only justified if it furthered the medical interests of that child.³⁴ He argued that research without the potential for benefit should never be performed without the informed consent of the subject. Richard McCormick, a Catholic theologian, argued on the other hand that research with children was necessary to improve the health and well-being of children and that parental consent was sufficient to protect the interests of individual children exposed to research risks even without compensating benefits.³⁵

McCormick argued further that individuals, even infants, ought to value human life and the health of others. If they were able to make informed decisions, he asserted, children would most likely choose to participate in experiments that held the potential of contributing to knowledge, provided that the risks to themselves were not too great. Thus, he maintained that parents and guard-

ians, in the interest of serving what would be the choices of their children, should be able to consent to the participation of their children in research. McCormick and others, including William Bartholome—a leading figure in the development of pediatric research ethics, for whom the American Academy of Pediatrics has named an annual award—believed that parents not only should be allowed to consent to research involving their children because of the future benefits to children in general, but should contribute to their children’s moral development by consenting to their participation in research without the prospect of benefit, as an altruistic gesture to society.³⁶

Ramsey vehemently disagreed with McCormick’s arguments and maintained that to enroll children in research because they “ought” to help others was to impose adult morality on a population that lacked the capacity to make such decisions.³⁷ He maintained that being involved in research could not contribute to the moral growth of children because their participation was unconscious and unwilling. He argued that any nontherapeutic research participation by those persons unable to provide consent, no matter how small the potential risk, was ethically untenable.

The U.S. National Commission

As a result of substantial public concern about the research enterprise, Congress passed legislation in 1974 to create the National Commission for the Protection of Subjects of Biomedical and Behavioral Research (hereafter, the National Commission) to make recommendations about how research should be regulated in the United States. Research involving children was among the most pressing concerns of the National Commission.

The Belmont Report—perhaps the most respected explication of the principles of research ethics ever published in the United States—was published by the National Commission in 1979 and laid out a broad justification of research involving children (see Chapter 14). The report states the following: “Effective ways of treating childhood diseases and fostering healthy development are benefits that serve to justify research involving children—even when individual research subjects are not beneficiaries.”³⁸ The report goes on to mention another justification for research involving children: “Research also makes it possible to avoid the harm that may result from the application of previously accepted routine practices that on closer investigation turn out to be dangerous.” However, the report is quite clear in describing children as potentially vulnerable and in need of protection from undue influence and coercion. Concerning this issue, in defining the principle of respect for persons, the report incorporates two ethical convictions: first, that individuals should be treated as autonomous agents, and second, that persons with diminished autonomy are entitled to protection. Children, unable to consent for their own participation in research, are entitled to protection. Invoking the authority of parents as surrogate decision makers is seen as only one aspect of that protection. Careful scrutiny of the level of risk to which child participants might be exposed in the research context, and minimizing risks in research whenever possible, were two additional protective approaches described in the report.

The National Commission released *Research Involving Children*, its report that examined the ethical aspects of research with children, in 1977. The commissioners noted that the most pressing concern about involving children in research is their “reduced

autonomy” and “incompetency to give informed consent,” leaving them vulnerable and unable to protect themselves against unscrupulous research practices.³⁹ The National Commission’s support of research involving children was based on the fact that in many instances, there is no suitable alternative population of research participants. Additionally, the prohibition of such research would impede innovative efforts to develop new treatments for diseases that affect children, decrease knowledge of the antecedents of adult disease, and result in the introduction of practices in the treatment of childhood diseases without the benefit of research or evaluation.

The report defines children as “persons who have not attained the legal age of consent to general medical care as determined under the applicable law of the jurisdiction in which the research will be conducted.” Such a definition recognizes the local implementation of federal guidelines or regulations and implies that the recommendations made in the report would vary in their applicability, depending on local and state laws. The definition also focuses on ability to consent as a distinguishing factor between children and adults, one that is not dependent on chronological age. The definition exempts individuals who might be younger than a designated “age of majority” from the recommended protective restrictions, depending on applicable local statutes regarding consent for medical treatment.

The National Commission directly addressed Ramsey’s arguments against allowing research with children that has no therapeutic intent and rejected his views as overly restrictive and unnecessary to protect the rights and interests of children. The Commission did, however, recommend specific limitations on research with children, requiring that a local institutional review board (IRB) determine that:

- A. The research is scientifically sound and significant.
- B. Where appropriate, studies have been conducted first on animals and adult humans, then on older children, prior to involving infants.
- C. Risks are minimized by using the safest procedures consistent with sound research design and by using procedures performed for diagnostic or treatment purposes whenever feasible.
- D. Adequate provisions are made to protect the privacy of children and their parents, and to maintain confidentiality of the data
- E. Subjects will be selected in an equitable manner, and
- F. The conditions of all applicable subsequent recommendations are met.³⁹

Subsequent recommendations include discussions of permissible levels of risk, the balancing of risks and potential benefits, the role of parental permission and child assent, and the involvement in research of children who are institutionalized or wards of the state.

U.S. Federal Regulations Regarding Research With Children

In 1981 Congress adopted the DHHS Policy for Protection of Human Research Subjects, regulations that were revised in 1991 and now referred to as the Common Rule and codified at 45 CFR 46.⁴⁰ The regulations require institutional review of all research with humans as well as voluntary informed consent from research

participants or their guardians. This chapter will focus on the special protections afforded to children that were adopted in 1983 as subpart D of the regulations, titled Additional Protections for Children Involved as Subjects in Research (codified at 45 CFR 46.401–409),⁴⁰ and those adopted as subpart B, titled Additional Protections for Pregnant Women, Human Fetuses and Neonates Involved in Research, revised in 2001 (codified at 45 CFR 46.201–207).⁴⁰

The regulations in subpart D have also been adopted (with one notable exception concerning waiver of parental permission) by the FDA for application to clinical drug trials.^{41,42} The National Commission's report, *Research Involving Children*, had a significant impact on the creation of this part of the regulations. Much like the National Commission's Belmont Report, subpart D, at 45 CFR 46.402(a), defines children as "persons who have not attained the legal age for consent to treatments or procedures involved in the research, under the applicable law of the jurisdiction in which the research will be conducted."⁴⁰ This definition has significance particularly for adolescents, who in many jurisdictions may consent for clinical care and treatment for sexually transmitted diseases, pregnancy and its prevention, and mental health services. Although permitting adolescents to give such consent is somewhat controversial and not universally applied, when local statutes permit, IRBs may consider research on these issues involving adolescents to be reviewed as if the prospective participants were not children but rather autonomous adults who may consent for participation in research without parental involvement. Forgoing parental permission is not permitted in research regulated by the FDA. The general issue of consent in adolescents will be discussed later in the chapter.

Over the past several years, there has been increased recognition of the need for more pediatric research. Health-care decisions for children are often based on extrapolation from adult data because limited evidence exists regarding treatment of children.⁴³ Recent policy and regulatory changes have encouraged the involvement of children in research. The Food and Drug Administration Modernization Act of 1997 created pediatric exclusivity incentives, allowing the FDA and the NIH to encourage companies to perform more pediatric clinical trials of drugs that may provide health benefits to children.⁴⁴ In 1998, the NIH published guidelines requiring the inclusion of children in clinical research unless there were scientific or ethical reasons to exclude them.⁴⁵ In 2002, the U.S. Best Pharmaceuticals for Children Act reauthorized the pediatric studies provisions of the Food and Drug Modernization Act, and directed the National Cancer Institute to expand and intensify research on treatments for pediatric cancers.⁴⁶ The Pediatric Research Equity Act of 2003 requires research on pediatric uses of new drugs and biological products.⁴⁷ In 2006, the European Union Parliament and Council adopted a regulation on medicines for children that creates a pediatric committee, extends patent protection for pharmaceutical companies, and requires companies to present a "pediatric investigation plan," among other things.^{48,49} All of these initiatives have resulted in an expanding number of pediatric studies and in studies that include children. None of these initiatives to increase research involving children include any provisions to decrease the strong protections that exist for children participating in research. Nevertheless, with the expansion of pediatric research comes a greater need to ensure that programs and activities that protect the rights and safety of children enrolled in research are performing well.

The federal regulations create four categories of permissible research involving children. First, research is permitted if the level of risk is no greater than minimal, regardless of whether there is the prospect of direct benefit to the child. Second, research that holds out the prospect of direct benefit to individual subjects is permitted as long as the risks are minimized and justified by the level of anticipated benefit. Third, research is permitted even if it involves greater than minimal risk and no prospect of direct benefit to individual children, provided that the level of risk is a minor increase over minimal, the intervention or procedure presents experiences to subjects that are commensurate with actual or expected medical, dental, psychological, social, or educational situations, and the research is likely to yield generalizable information of vital importance about the subjects' disorder or condition. Fourth, research that is not otherwise approvable under the first three categories but presents an opportunity to understand, prevent, or alleviate a serious problem affecting the health or welfare of children may be permitted by the secretary of the DHHS after expert consultation and opportunity for public review. This regulatory framework imposes a significant limit on the discretion of investigators and parents to permit the participation of children in research that entails more than minimal risk, but at the same time it allows much research of importance to the health and well-being of children. Each of these categories requires interpretation of various terms and requirements. Figure 42.1 depicts Robert Nelson's algorithm that is useful in applying the regulations and understanding the components of each category.⁵⁰

Research Not Involving Greater Than Minimal Risk (45 CFR 46.404)

According to 45 CFR 46.102 of the regulations, a risk is considered *minimal* if "the probability and magnitude of harm or discomfort anticipated in the research are not greater in and of themselves than those ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests."⁴⁰ This definition has been controversial and open to differing interpretations since its adoption over 20 years ago. A study of pediatric researchers and department chairs in 1981 revealed broad disagreement on the level of risk represented by common procedures performed in pediatric practice.⁵¹ A more recent survey of IRB chairs confirmed the continued lack of agreement on this fundamental definition and revealed wide variation in perceived risk levels of such research procedures as confidential surveys and simple blood draws.⁵²

Several commentators have criticized the definition for its use of comparisons to the risks encountered in daily life.^{53,54} Clearly, there is a wide range of socially acceptable behaviors that normal, healthy children encounter in their daily lives that are quite risky. These include traveling in cars and buses, bicycle and horseback riding, and playing sports. Few researchers or IRBs have been confused by the intention of the regulations even if the words allow for misinterpretation. For a procedure to be considered minimal risk, it must have an exceedingly low likelihood of significant or sustained discomfort, irreversible harm, or substantial embarrassment.

Recent reports by two federal advisory committees to the secretary of the DHHS^{55,56} and the Institute of Medicine (IOM)⁵⁷ have attempted to clarify the definition of minimal risk. These reports concur that minimal risk should be an objective standard,

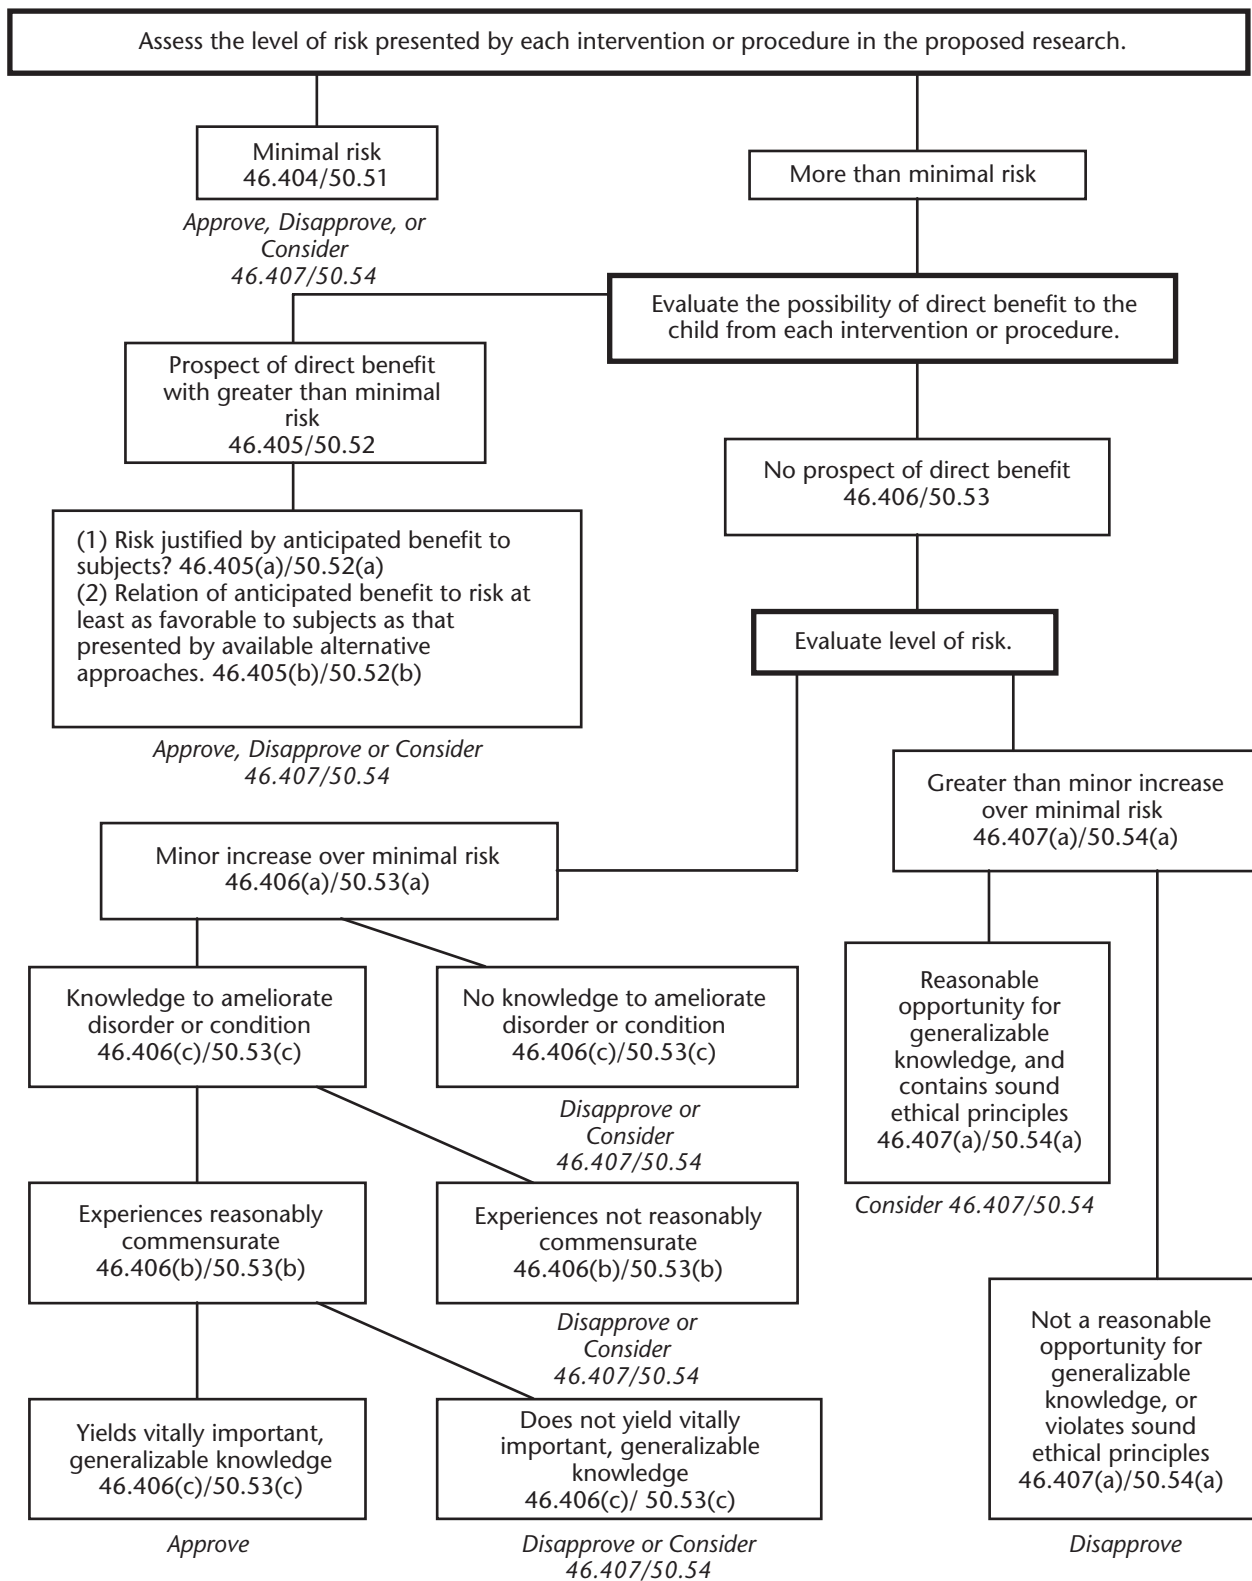

Figure 42.1. Algorithm for Making Assessments of Research Protocols as Required by 45 CFR 46.404–407 and 21 CFR 50.51–54.⁵⁰

that is, related neither to the level of illness of the child nor to the social circumstances in which the child finds him- or herself. Risks should include all harms, discomforts, indignities, embarrassments, and potential breaches of privacy and confidentiality associated with the research, and minimal risk should be that level of risk associated with the daily activities of a normal, healthy, average child. Indexing the definition of minimal risk to the lives of healthy, average children eliminates considering those higher risks that are routinely experienced by sick children or children exposed on a daily basis to greater risks because of social circumstances.

This definition does, however, allow the concept of minimal risk to take into account the changing risks normally experienced by children of different ages. The daily risks encountered in the life of an infant or toddler who is rarely, if ever, left unattended by an adult differ dramatically from the risks encountered by an adolescent who attends school, might drive, plays sports, and engages in many independent activities. Thus, research that might be considered to pose greater than minimal risk for a younger child might be consistent with the risks ordinarily encountered in the daily lives of an older child and thus might be considered minimal risk for that population.

The definition of minimal risk also includes those experiences encountered by normal, healthy, average children in routine physical and psychological examinations such as during routine visits to the doctor or dentist, or routine psychological testing and observations in school. This allows research procedures such as simple blood draws, noninvasive urine collections, questionnaires, and interviews with healthy children to be permissible as minimal risk under this section of the regulations. However, when procedures performed once are deemed to be consistent with the definition of minimal risk, the same procedure performed serially or repetitively over a short period may or may not still constitute minimal risk.

The definition of minimal risk need not be interpreted literally as only those risks encountered in the actual daily lives of children or during their visits to a doctor's office, but may include risks thought to be *equivalent* to those routinely encountered in the daily lives and experiences of normal, healthy, average children. What research procedures fit into this interpretation of the definition is left to individual IRBs.

Prospect of Direct Benefit to Individual Subjects (45 CFR 46.405)

IRBs may approve research that entails more than minimal risk to a child if the intervention or procedure holds out the prospect of direct benefit for the child or may contribute to that child's well-being. Any risks must be justified by the anticipated benefits, and the relation of the anticipated benefit to the risk must be at least as favorable to the child as that presented by alternative available approaches.⁴⁰ Most clinical trials fall under this category of research. Many such research studies are targeted to benefit participants afflicted with serious diseases while exposing the participants to a substantial level of risk. This is the crucial balancing required of IRBs. When determining whether a research proposal offers the prospect of direct benefit to individual participants, IRBs should ensure that the benefits accrued are from the research interventions themselves and not from the collateral benefits often associated with participation in research. Furthermore, the provision of standard clinical care not otherwise available to individ-

uals, or monetary compensation for research participation, should, in and of itself, not be considered benefits that warrant exposing participants to risks greater than minimal.

Each procedure in a study, if greater than minimal risk, must be evaluated independently to assure that there is a prospect of direct benefit to the participant from that procedure. If a specific risky procedure (e.g., bone marrow aspirate, spinal tap, imaging with sedation) has no potential to benefit the participant and is performed only to collect data that is not of clinical relevance, the IRB may not approve that portion of the research based on the regulatory standards of 45 CFR 46.405—the category of “prospect of direct benefit” research. Such a procedure might be considered and possibly approved under the standards of 45 CFR 46.406—the category of “minor increase over minimal risk” research.

When assessing the risks imposed by research participation, it is also important to distinguish between those risks associated with research interventions or procedures and risks inherent in standard diagnostic approaches and treatments of disease.⁵⁸ To assist in defining the incremental risks of the research itself and determining whether the risks to children of research participation are reasonable in relation to anticipated benefits, IRBs can do a component analysis. Through component analysis, the IRB examines each procedure and intervention to determine the prospect of benefit, level of risk and whether the risks have been sufficiently minimized. This approach can help define incremental risk and assist IRBs to fulfill their obligations to protect children who are the participants in research.⁵⁹

Research Involving Greater Than Minimal Risk and No Prospect of Direct Benefit to Individual Subjects (45 CFR 46.406)

Research that involves greater than minimal risk to children with no prospect of direct benefit is permissible only under certain conditions. The research must involve risk that is only a minor increase over minimal risk; the intervention or procedure must present experiences to the children that are reasonably commensurate with those inherent in their actual or expected medical, dental, psychological, social, or educational situations; and the research must be likely to yield generalizable knowledge about the child's disorder or condition that is of vital importance for the understanding or amelioration of that disorder or condition.

The concept of a *minor increase over minimal risk* is contingent upon the interpretation of the definition of minimal risk. The level of risk contemplated by the regulations as a minor increase over minimal risk is a small increment over that level of risk experienced by normal, healthy, average children in their daily lives and experiences. It is not intended that a minor increase over minimal risk be defined as the level of risk generally experienced by children who are ill or in socially compromised circumstances. In addition, it is the role of the investigator to make the case and the role of the IRB to review the evidence that research proposed under this category meets the standard of providing generalizable information of vital importance and that the procedures are reasonably commensurate with the prior or expected experiences of the potential research participants.

The definition of *disorder or condition* also requires interpretation, and there is some disagreement. In our view, a condition affecting children should be understood more broadly than a specific disease or diagnostic category; it refers to a specific set of

physical, psychological, neurodevelopmental, or social characteristics that have been shown to affect children's health and well-being or their risk of developing a health problem in the future. This definition of *condition* can include a genetic or familial predisposition to future illness or even a social circumstance that has been linked to a potential deficit in future health and well-being, as long as the investigator can substantiate that there is an established body of scientific evidence or clinical knowledge to support that association.

Research Not Otherwise Approvable That Presents an Opportunity to Understand, Prevent, or Alleviate a Serious Problem Affecting the Health and Welfare of Children (45 CFR 46.407)

The regulations are intended to limit research that involves significant risks without compensating benefit to individual children. However, the regulations create a process for review of credible research that may not be approved at the local level under the three categories outlined above but has the potential to significantly affect child health and welfare. An IRB may determine that a proposed study may not be approved under the minimal risk (45 CFR 46.404), prospect of direct benefit (45 CFR 46.405), or minor increase over minimal risk (45 CFR 46.406) categories, yet find that the research has a reasonable opportunity to further the understanding, prevention, or alleviation of a serious problem affecting the health or welfare of children. The IRB may then send the proposal to the DHHS Office for Human Research Protections (OHRP) and request review and approval by the secretary of the DHHS. The secretary must consult with a panel of experts and assure public review and comment before determining whether the research should be permitted to proceed. This procedure has been used sparingly in the past and more frequently in recent years; an efficient process has been developed to facilitate timely review.⁶⁰

Minimizing Risk

According to 45 CFR 46.111(a)(1), it is the duty of the investigator and the IRB to ensure that risks are minimized in all research.⁴⁰ This is particularly relevant to research involving children. Even in research studies that involve minimal risk or a minor increase over minimal risk, every attempt should be made to minimize risk. Research procedures should be integrated with clinical care and diagnostic procedures whenever feasible in order not to duplicate uncomfortable procedures and interventions. Procedures should only be performed by professionals skilled with children. Protocols should include specific rules setting limits on the number of unsuccessful attempts at a procedure or the length of time for completion of a questionnaire. And appropriate methods should be used to accustom children to the research environment and to decrease potential anxiety and discomfort whenever possible.

In determining whether a proposed procedure has minimized risks, the IRB should take into consideration the context in which the research will be performed. The population under study, the experience of the investigator and the professionals performing the procedures, as well as the research environment, may influence the level of risk of each proposed procedure. Some groups

of children may perceive certain interventions or procedures as involving more risk, anxiety, or discomfort as compared to other groups. For example, children who are mentally challenged, emotionally disturbed, or mentally ill may experience a simple procedure, such as a blood draw, as extraordinarily disconcerting. Because of their likely reaction, a blood test with such children might be considered more than minimal risk research, unless efforts could be made to ameliorate their distress.

Examples of Risk Levels Associated With Common Research Procedures

Table 42.1, reproduced from the final report of the National Human Research Protections Advisory Committee, aims to clarify specific portions of subpart D of the federal regulations and provide some examples of the level of risk of common research procedures.⁵⁵

The National Human Research Protections Advisory Committee report also highlights the importance of several factors that go into interpreting the level of risk in common procedures. For example, the level of risk of the insertion of an intravenous catheter or an injection may be considered minimal, but the risk level may increase based on the length of time the needle will remain in place, the substance being injected or infused, the age and cognitive capacity of the child, and the experience of the investigator performing the procedure. Another common research procedure, an MRI imaging test, may be minimal risk if no sedation is required for the procedure, but the level of risk increases if procedural sedation or general anesthesia is required in order to perform the test.

Parental Permission and Child Assent (45 CFR 46.408)

Informed consent remains the cornerstone of protection for humans in research, even when the research participant is a child. However, because children are generally not capable of providing informed consent, the process of obtaining consent for children is best thought of as parental permission with child assent sought as appropriate.⁶¹ Parental permission is required, except in specific circumstances, for all research involving children. An IRB may determine that permission of one parent is sufficient for research approvable under 46.404, involving minimal risk, or under 46.405, providing the prospect of direct benefit to the individual child. However, the permission of both parents is required when research is approved under 46.406, involving a minor increase over minimal risk and no prospect of direct benefit, or when the research requires the approval of the DHHS secretary under 46.407. Exceptions include when one parent is deceased, unknown, incompetent, or not readily available, or when only one parent has legal responsibility for the care and custody of the child.

Waiver of parental permission may be approved in circumstances similar to the waiver of informed consent for adult participants in research found at 45 CFR 46.116(c)-(d).⁴⁰ These circumstances include research conducted by local governments to evaluate public benefit or service programs, or research that involves no more than minimal risk and that could not practically be carried out without the waiver. In this circumstance, the waiver must not adversely affect the rights and welfare of the children, and whenever appropriate, the children or their parents

Table 42.1
Common Research Procedures by Category of Risk⁵⁵

Procedure	Category of Risk		
	Minimal	Minor Increase Over Minimal	More Than a Minor Increase Over Minimal
Routine history taking	X		
Venipuncture/fingerstick/heelstick	X		
Urine collection via bag	X		
Urine collection via catheter		X	
Urine collection via suprapubic tap			X
Chest X-ray	X		
Bone density test	X		
Wrist X-ray for bone age	X		
Lumbar puncture		X	
Collection of saliva	X		
Collection of small sample of hair	X		
Vision test	X		
Hearing test	X		
Complete neurological exam	X

Note: The category of risk is for a single procedure. Multiple or repetitive procedures are likely to affect the level of risk.

should be provided with additional pertinent information after participation.

There are additional circumstances that may permit waiver of parental permission. Although it is generally beneficial to include parents in decisions about the care of their children, there are situations in which involving parents in the medical care of their child may be detrimental to the child's best interest.³⁹ This has been recognized by laws in virtually every state that permit medical treatment for specific conditions in adolescents (such as sexually transmitted disease, mental illness, and pregnancy) with the consent of the young person and without informing parents.⁶² Waiving parental involvement in consent can be appropriate in the research context as well. Federal regulations, at 45 CFR 46.408(c), permit IRBs to waive parental involvement in research when "parental or guardian permission is not a reasonable requirement to protect the subjects."⁴⁰ This could permit waiver of parental permission in research involving child abuse or neglect or when adolescents might be hurt by revealing certain behaviors or illnesses to their parents. In each case the IRB must ensure that the investigator will both assess the capacity of the adolescent to understand the research and his or her research rights and has created appropriate procedural safeguards (such as the availability of a counselor independent of the research) to protect the interests of the adolescent participants. At present, parental permission may not be waived in any research regulated by the FDA.

In addition to obtaining parental permission, researchers working with children must also solicit the child's assent when appropriate. Assent is defined at 45 CFR 46.402(b) as "a child's

affirmative agreement to participate in research."⁴⁰ IRBs must take into account the age, maturity, and psychological state of the children involved in the research when determining whether assent will be required or can be waived. IRB practices vary widely in the interpretation of the regulations concerning assent.⁶³ If a child does not provide affirmative agreement or fails to respond, assent cannot be assumed. Not all children, especially those who are very young, are able to provide assent. IRBs may determine that all children in a particular protocol must assent to participate; that children above a certain age (such as 7) must assent; or that each child must be assessed individually for the capacity to provide assent. Such individualized decisions are left to the IRB. Assent is not required if the research intervention or procedure involved holds out the prospect of direct benefit that is important to the health or well-being of the participants and is available only in the context of the research. Assent from children may be waived by IRBs just as informed consent may be waived for adults.

The assent process must be age- and developmentally appropriate and should be an empowering and respectful experience. It does not directly parallel the informed consent process for adults, and there is no need to duplicate all the essential elements required in adult informed consent during the assent process.⁵⁷ Obtaining assent from children includes making them aware of their condition (when appropriate), informing them about what will happen and what to expect, assessing their ability to understand their situation, and asking them whether or not they are willing to take part in the research.⁶⁴ Assent need not include

a written form or a signature. The assent process should describe what will happen from the perspective of the child and what discomforts might be involved in the research. Of course, as children become older, assent information should become more substantive and specific and should begin to resemble an adult informed consent.

In the case of research that provides the prospect of direct benefit available only in the context of the research, assent is not a requirement. In such cases, children should still be informed about the research but they should not be asked for their assent if lack of affirmative agreement to participate will not be respected. It is disrespectful of children to ignore their preferences after they have been solicited. This can result in lack of trust in the research enterprise and significant tension among the parents, children, and investigators.

Wards (45 CFR 46.409)

The final section of subpart D concerns research with children who are wards. There is no definition of wards in the regulations, but it is taken to mean children who do not have a parent or legal guardian from whom to obtain permission for enrollment in the research. Such children may be institutionalized or in foster care. The regulations permit wards to be enrolled in research that involves no greater than minimal risk or has the prospect of direct benefit without additional protections. However, according to 45 CFR 46.409(a), research that involves a minor increase over minimal risk with no prospect of direct benefit, or research approved by the secretary of DHHS, may be conducted with wards only if the research is related to the child's status as a ward or is to be "conducted in schools, camps, hospitals, institutions, or similar settings in which the majority of children involved as subjects are not wards."⁴⁰ Such research also requires the appointment of an advocate to act in the child's best interests during the child's participation in the research. The advocate may not be associated with the research, the investigators, or the institution legally responsible for the child.

Incentives, Compensation, and Payment

Compensation of pediatric research participants and their families has long been a controversial issue.⁶⁵ Federal regulations regarding the protection of humans in research do not explicitly mention compensation and payments related to participation in research studies. However, investigators often believe that financial inducements are essential to enhance recruitment and retention, particularly in studies that provide no benefit to participants. Some commentators believe that children should never be paid for research participation because this may be an undue inducement that affects the voluntariness of their participation.⁶⁶ Similarly, some commentators argue that parents ought not to be paid to enroll their children in research, for fear that children will be used as commodities and placed at undue risk for the sake of parental financial gain. A survey of factors that influenced parental views on enrollment of their children in clinical studies in one U.S. city found that financial factors had some influence on parental judgment about participation, even if it was not one of the most important factors in the decision.⁶⁷

The basic concern is to balance the need to make participation in studies attractive to children and their parents, particularly when there is no prospect of individual benefit, with the desire to protect children from the potential risks of research and to ensure that parents remain free of inappropriate influences on their decisions about the interests of their children.⁵⁷ Compensation of participants and their parents may be considered in two general categories: reimbursement of incremental costs of participation in the research, and inducements to participate.

It seems unfair to ask parents and children to bear additional costs that result from participation in research. Reimbursement for expenses directly related to research participation such as travel, parking, meals, and child care seem warranted and can be calculated based on real out-of-pocket costs to the families or based on a reasonable estimate of average costs. Payment of lost wages for the older child and parent as a result of participation in the research is sometimes considered a reasonable reimbursement, because lost wages will undoubtedly be a substantial disincentive to participation. However, determining a fair level of reimbursement in this area can be difficult and should not exceed the actual lost income due to participation.

There are three types of inducements to participate: compensation for time spent in participation; enticements for recruitment and retention; and gifts of appreciation at the completion of the study. It is generally agreed that individuals who participate in research with the major motivation of benefiting others with no prospect of direct benefit to themselves may receive some additional incentive for participation. A small token gift to the child as a "thank you" for participation in research is common in such settings. Because larger gifts to the parent or child may unduly influence participation, it seems acceptable only to vary the value of the gift based on the length of time required by the research, not based on the level of risk. A modest incentive for each activity in a study is a common practice but may become an undue inducement if the cumulative amount is excessive and able to influence voluntary participation.

The OHRP's *IRB Guidebook* discusses IRB responsibilities in assuring that consent is truly voluntary, uncoerced, and not unduly influenced by external factors, including payment.⁶⁸ In some of its review and criticism of institutional compliance with federal regulations, OHRP has argued that enrollment procedures should minimize the possibility of undue influence and that IRBs must recognize the provision of free care as a potential undue influence on voluntary participation. However, there is little specific guidance about providing payment or free care in research involving children.

The FDA has specific guidelines for review of compensation in the case of clinical drug trials.⁶⁹ The FDA requires that IRBs review and approve all amounts, methods, and timing of payments to research participants to assure that there is no coercion or undue influence on participation. Additionally, any credit for payment should accrue as the study progresses and not be contingent upon the person completing the entire study. However, a reasonable bonus for the completion of the study is acceptable as long as the IRB determines that the amount is not so large as to unduly induce people to stay in the study when they would otherwise have withdrawn. The American Academy of Pediatrics suggests that if remuneration is to be given directly to the child in the research, it is best if it is not discussed until after the study so as not to affect voluntary participation.⁶⁴ The Academy also states that medical

costs associated with treatment under a research protocol may be permitted in certain circumstances. Because health-care insurance is not available to all children, this practice may be coercive and an undue influence on participation for children living in poverty. But in some circumstances, when the research requires the provision of specific care, provision of medical costs may be warranted. The potential of this type of compensation to unduly influence poor and uninsured families to be part of research studies must be considered by the IRB in its deliberations.

Compensation for Injury

Section 45 CFR 46.116(a)(6) of the U.S. federal regulations require that for research involving more than minimal risk, informed consent include a statement concerning whether any compensation or medical treatment will be available if injury occurs as part of the research, and stating where further information about such compensation may be obtained.⁴⁰ No federal law or regulation requires or provides compensation for research-related injury. Most research involving children does not offer compensation for nonnegligent injury that might occur during a research study. Although this issue is not unique to child participants in research, it seems unfair that children who are enrolled in research without their autonomous consent might be subject to long-term disability due to the research without any compensation from the investigators or sponsors. A 2004 IOM report concerning research with children recommended that research organizations and sponsors pay the medical and rehabilitation costs for children injured as a direct result of research participation, without regard to fault.⁵⁷ This practice is unlikely to become commonplace unless there is federal regulation requiring it and a no-fault insurance pool is developed for such purposes.

Special Populations

Adolescents

Although the federal regulations regarding research with children apply to all individuals under the legal age of consent to medical treatment for the procedures involved in the research (18 years old for most medical treatment in the United States), there has been a growing concern about how these protections ought to pertain to adolescents. Adolescents are individuals between 10 and 21 years of age, and their constant state of physiological and psychological development sets them apart from younger children and adults.^{70,71} This population has a number of unique health-related needs and behavioral risks that deserve the attention of the research community.⁷² Many adolescents are also unwilling to take part in research if disclosing their illness, condition, or behaviors to their parents or guardians is required.^{73,74} As a result, studies that involve substance abuse, mental health, sexual activity, and pregnancy often lack sufficient adolescent participation, and development of interventions in these areas to address adolescent concerns may be lacking.

Some adolescents do not require the involvement of parents in decision making about their medical care or research participation because they are legally emancipated. Emancipated minors are individuals below the age of majority who have the legal status of

adults.^{70,75} Historically, minors became emancipated when they married, enrolled in the military, or were financially independent and living apart from their parents. The emancipation process used to be conducted in the courts, but many states now have laws describing specific conditions warranting emancipation. Because of their legal status as adults, emancipated minors may consent to medical treatment and presumably participation in research, although not all states explicitly include this right in their emancipation statutes.

Another potential exception to parental permission in research comes through the mature minor doctrine. This doctrine has evolved in the courts in the context of medical treatment so that minors who possess the decisional capacity necessary to provide informed consent may do so in certain circumstances and receive treatment without parental permission; and doctors who treat them cannot be held liable for providing care without consent.⁶² This generally includes minors who are not emancipated from their families. Some states have passed laws explicitly defining a mature minor and cite certain characteristics such as age, educational level, marriage status, living situation, financial independence, being a parent, and whether or not an individual is incarcerated or has previously been emancipated. However, beyond these explicit standards, the courts have also invoked the doctrine to allow treatment without parental permission in cases in which the minor patient seemed capable of providing informed consent.⁶²

In addition to the mature minor doctrine, all states have statutes that allow minors to consent to treatment based on certain specific types of treatment they are seeking. The conditions for which minors are allowed to seek medical and mental health treatment without parental permission vary from state to state, but states often permit adolescents to consent to treatment for conditions about which they might be reluctant to inform their parents. These conditions generally include sexually transmitted diseases, mental illness, substance abuse, pregnancy, and birth control.⁶² Because the definition of *children* in the federal regulations includes those not legally allowed to consent to treatment involved in the research, an IRB may waive the requirement for parental permission and accept the consent of a mature minor for enrollment in certain research studies that wish to enroll adolescents who may legally consent for the type of treatment being studied.

For most adolescents, parental permission is required ostensibly to protect those who do not have adequate capacity to provide informed consent; but there is evidence to suggest that many adolescents under the age of 18 (the nearly universal age of legal consent to treatment) have the decisional capacity necessary to consent to medical treatment and research participation.^{76–78} Most minors under the age of 14 lack the developmental and emotional maturity required to provide informed consent.^{76,79} Adolescents older than 14 may lack life experience and may be more easily influenced than adults (particularly regarding physical appearance and social concerns), but there is evidence that they can provide meaningful informed consent for treatment and research participation in the proper environment.⁸⁰ As a result, a number of health-care providers, researchers, educators, and other professionals, including the Society for Adolescent Medicine, have advocated allowing older adolescents to provide full informed consent for participation in research by increasing the use of waivers of parental permission.^{57,72,81}

The IOM report on research involving children recommends that IRBs consider waivers of parental permission in informed consent for research when (1) the research is important to the health and well-being of adolescents and cannot be reasonably or practically carried out without the waiver, or (2) the research involves treatments or procedures that state laws permit adolescents to receive without parental permission. In addition, the investigator is required to present evidence that the adolescents are capable of understanding the research and their rights as research participants, and that the research protocol includes appropriate safeguards to protect the interests of the adolescent consistent with the risk presented by the research. This approach, consistent with the Common Rule,⁴⁰ has been controversial but has received widespread support.

Neonates

In November 2001, a revised section of subpart B of the federal regulations was published and codified at 45 CFR 46.201–207 concerning nonviable neonates or neonates of uncertain viability involved in research.⁴⁰ These additional regulations have the potential to be confusing because of some overlap with subpart D that specifically addresses regulations for all children (including neonates) involved in research. The primary purpose of subpart B is to regulate research involving pregnant women and fetuses and, in addition, regulate research pertinent to nonviable fetuses after delivery. However, definitions in this subpart create some new challenges for pediatric research.

A *nonviable neonate* is defined at 45 CFR 46.202(e) of the regulations as “a neonate after delivery that, although living, is not viable.”⁴⁰ And at 45 CFR 46.202(h), *viable* is defined as “being able, after delivery, to survive (given the benefit of available medical therapy) to the point of independently maintaining heartbeat and respiration.”⁴⁰ The difficulty for pediatric investigators and IRBs is that much neonatal research involves extremely premature neonates at gestational ages of 23 to 26 weeks whose long-term viability is considered very uncertain. The regulations in subpart D (Additional Protections for Children Involved as Subjects in Research) have adequately protected the interests of these babies who participate in research, but now provisions of subpart B (Additional Protections for Pregnant Women, Human Fetuses and Neonates Involved in Research) must also be applied to this population.

For research involving these neonates of uncertain viability, subpart B requires that the research hold out the prospect of enhancing the probability of survival of the neonate to the point of viability, or that the purpose of the research is the development of important biomedical knowledge that cannot be obtained by other means and there will be no added risk to the neonate resulting from the research. This provision of subpart B could be interpreted to be in direct conflict with the minimal risk and minor increase over minimal risk standards of subpart D. Thus, for research that does not offer the prospect of direct benefit to neonates at the threshold of viability, IRBs must utilize the “no added risk” standard of subpart B rather than the “minimal risk” standard of subpart D. This may result in an IRB being unwilling to approve important research involving premature neonates that could have been approved under the 46.406 provision in subpart D, which permits research that has a level of risk just a minor increase over minimal.

Economically or Educationally Disadvantaged Children

Federal regulations, at 45 CFR 46.111, admonish investigators and IRBs to provide additional safeguards when subjects are likely to be vulnerable to coercion or undue influence because of being economically or educationally disadvantaged.⁴⁰ Many of the most important illnesses and conditions affecting children are disproportionately represented in those who are economically or educationally disadvantaged, and much important research is focused on preventing and ameliorating these conditions. Children who are economically disadvantaged have multiple vulnerabilities, including living in poor neighborhoods in substandard housing, lacking access to health care, and being educated in lower quality schools. Their families are more likely to be immigrants or members of minority groups who may have suffered and continue to experience racism and discrimination. These factors make research with disadvantaged children fraught with potential ethical problems. The relative lack of social, economic, and political power of low-income families can affect the voluntariness of informed consent. The educational disadvantage of such families may affect understanding of the nature of the research and may increase the likelihood that participant families will suffer from a therapeutic misconception, conflating research studies with clinical care.⁸²

One approach might be to exclude socioeconomically vulnerable children from research in order to protect them from the potential for exploitation and harm. This approach may protect some children but would result in depriving the children who need help the most from the knowledge gained and the potential benefits of research. Research can be viewed as a burdensome enterprise with substantial risk, but it also can be seen as an activity that provides potential benefits to individuals and affected populations. Vulnerable populations should be permitted to participate in research when appropriate, but additional scrutiny and procedural safeguards may be required to assure their protection from harm.⁸³ Fairness requires that all children who are affected by a condition, whether rich or poor, be offered the opportunity to be potential participants in research. The burdens of the research and the benefits of the findings should be distributed among all those who may benefit. It is important, however, to involve disadvantaged children in studies that have the potential to improve the circumstances in which they live and provide knowledge about the social determinants of their health.

IRBs responsible for review of research involving multiply vulnerable poor and minority children must give special scrutiny to these proposals to ensure that the balance of risks to benefits in the research are acceptable and that parents are well informed and assisted in making a truly voluntary choice about the participation of their children in the research.⁸²

Conclusion

Over the past few years, several regulatory and legislative initiatives have increased funding for research involving children in the United States and have created incentives for the pharmaceutical industry to study drugs in children.^{45–47,84,85} The pediatric research community and many advocates for children have applauded these changes as long overdue programs to enhance the

health of children. Pediatricians note that clinical research is required because many medications used in children have never been studied in appropriate populations, and because translating knowledge gained from recent advances in developmental biology, genetics, and neuroscience into improved diagnostic tests and treatments for children is possible only through research.

Others have voiced concern about increasing research in children because they believe the present system for protecting human research participants is generally inadequate to protect the interests of all participants.¹ Children, particularly vulnerable because of their limited capacity for informed consent, require additional special protections. These concerns are reinforced by a Maryland court decision that questioned the authority of parents to consent for children to be enrolled in studies that include any level of risk without “therapeutic” benefit,² and by reports of healthy children exposed to “risky” medications solely for research purposes.⁸⁶

Those who criticize the system for protection of children involved in research claim that increased federal funding and incentives to pharmaceutical companies result in healthy children being subjected to undue risks and sick children being enrolled in trials that provide more benefit to the pharmaceutical industry sponsor than to the child participants. They argue that IRBs are not properly evaluating the level of risk in protocols and are approving studies not in the interests of participants. However, none of the recent initiatives to increase research in children has weakened the federal regulations that have governed research involving children since 1983. Clearly there are aspects of the system to protect child participants in research that would benefit from modification, as has been suggested in recent reports from the National Bioethics Advisory Commission⁸³ and the IOM,⁸⁷ but the fundamental structure of the system to protect children as participants in research is sound and appears to work pretty well.^{88,89}

The quality of IRB review of individual protocols varies greatly, and there is general agreement about a need for accreditation of IRBs and better education of IRB members to increase uniformity and accountability, as well as for development of performance measures to evaluate the system.⁹⁰ Few IRBs provide the kind of detailed guidance on their web sites that might help pediatric investigators to ensure ethically designed and implemented protocols.⁹¹ Specifically, for children in research, there is a need for clarification of the present regulations and assurance of qualified pediatric expertise on IRBs. There is also a need for federally promulgated guidance about several controversial issues, such as waiver of parental permission in research involving adolescents and compensation for children who are research participants and their families.

Well-designed and well-executed research involving children is essential to improve children's health. Investigators, IRBs, research institutions, and government policy makers and regulators all play critical roles in facilitating excellence in research while assuring the protection of children who are participants.

Research With Captive Populations

Prisoners, Students, and Soldiers

Today, respect for persons is a bedrock principle governing research with humans. But although Americans have long held the belief, as Justice Cardozo declared in 1914, that “every human being of adult years and sound mind has a right to determine what shall be done with his own body,”¹ they have not always applied this notion equally or scrutinized its significance without prejudice. Following World War II, for example, Americans condemned the Nazi experiments on concentration camp prisoners but asked strikingly few questions about the status of participants in their own research activities. Into the 1960s, the popular understanding of captive populations in research often overlooked the influence of captivity, or inequality of physical, financial, educational, or social status, in making many captive populations seem more willing to participate in research than other groups in society.

This complacency ended in the late 1960s and 1970s. At that time, widespread challenges to the ethics of the medical profession dovetailed with public reports of abuses in U.S. prisons. Consequently, public policy toward captive human research participants, particularly those who were imprisoned, ricocheted from an unquestioning presumption that they were “volunteers” to the restrictive conclusion that, for most research participants, captivity itself precluded voluntarily consent. Society also became more sensitive to the ways in which other groups may in effect be “captive,” and therefore in need of special protection to ensure that they have free choice to participate in research, if possible. For example, the exercise of free choice is often in direct conflict with the command structure of military duty. Despite numerous longstanding regulations and policies mandating soldiers’ voluntary participation in research, national interests may sometimes supersede individual interests. Students too may be denied free

choice, if, for example, they are required to participate in research as a condition of completing their coursework, or if their choice to participate in research is unduly driven by their financial needs.

The tacit and uncritical assumptions that governed medical research with captive populations before the 1970s, and the challenges that continue to appear, reflect a tension between competing interests. The interests of the group—including the interests of future patients and the scientific community—compete with the interests of an individual in exercising autonomous choice over the use of his or her body. Without doubt, most researchers respect and seek to advance the rights and welfare of those who participate in their experiments, including the right to free choice. Less clear, however, is what level of scrutiny is given to appreciating the effects of captivity on a person’s ability to function as a true volunteer. Even today, when informed and voluntary individual consent is a central tenet of the research enterprise, group interests may supplant (or override) individual interests.

I. Captivity and Research

The Meanings of Captivity

What does it mean to be a “captive” population? Perhaps the most essential common element is that captive populations in some critical sense lack the ability to exercise free choice. For one reason or another, their individual autonomy is limited. The most obvious of these limits, frequently, is physical. Captive populations are separated, often physically or through other means, from the general population. They often live, with little or no choice, in

institutions. Prisoners are kept in locked cells established by the state to prevent them from interacting with society at large. They sleep, eat, dress, and work together in groups with no freedom to leave. Soldiers are often housed in barracks or on bases where uniforms, room, and board are provided, and they are free to leave only after their commander consents. Students, although relatively free to move amidst the general population, often live together in dorms or other student housing. They are separated by their location, their dress, and often their resources from the rest of society. The physical isolation that each of these captive populations faces suggests that they may be more easily manipulated and coerced into research participation.

Less obvious than physical restraints, but often more influential, is that captive populations have limited choices and are to some degree under the control of others. Restrained behind locked prison gates, prisoners must do what their guards and wardens instruct. They cannot seek outside employment or otherwise exercise independence. Soldiers are subject to the military command structure and obligated, sometimes upon threat of grave physical consequences, to follow orders issued from above. Students are often limited in their ability to exercise free choice because of financial needs or academic and professional goals that keep them beholden to their teachers. Each of these groups is dependent upon and subject to the commands of others. They are unequal players.

In the medical research arena, the effect of this power differential is compounded by the traditional, and often closely guarded, authority that medical professionals routinely exert. Since the time of Hippocrates, physicians have vowed, as a condition of sharing in the knowledge of medical science, “to help, or at least to do no harm” and to “abstain from all intentional wrong-doing and harm.”² This oath leads many patients to assume that their physicians, first and foremost, will protect them, an assumption that is a key reason for the trust that patients put in their doctors. Patient trust is grounded also in the mystery that surrounds the practice of medicine. Compared with the general population, medical professionals undergo extensive training and licensing that separates them from laypeople and requires the uninitiated to defer to them. For prisoners, soldiers, and students, this deference can be magnified by their limited opportunities to select among physicians (or teachers) and the other indicia of captivity that often make them especially attractive candidates for research.

The Advantages Captive Populations Offer in Research

Captive populations offer special advantages for medical research. Typically, health information about these groups is centrally maintained, and investigators may be able to access it more easily than information about the general population. Certainly recruitment can be more efficient. Advertisements seeking males and females aged 18 and over are commonplace on university campuses for just this reason. Moreover, research participants who are physically confined are less likely to be lost for follow-up examination. Soldiers and their medical records are readily located. Students can be expected to complete their role in a study, especially if they are enrolled in the investigator’s course. For similar reasons, participants from captive groups may also be especially cooperative and compliant with protocol requirements. They are accustomed to being monitored or graded and they are used to completing duties or tasks that others assign.

In addition to being efficiently recruited and retained, captive populations may be more motivated to participate in research than the general population. For example, research may offer greater or more immediate access to income than other options. Students can fit participation in a trial into irregular school schedules and may be paid a higher hourly wage than is offered by more typical work-study opportunities. Prisoners, and to some extent soldiers, may find research to be one of only a few feasible ways to supplement their existing income. But financial rewards are not the only, nor necessarily the primary, reason for participation in research.

Captive populations also may be motivated to participate in research to respond to many other needs in their lives. Prisoners have reported joining a study as a way to repay some of their debt to society, or to obtain other nonmonetary benefits.³ They may also receive better medical care and attention when they participate in research. Soldiers may see research as a necessary component of supporting their fellow troops and establishing and maintaining an effective and safe fighting force. Students may want a favorable grade, or if they are planning to enter the research field or training to practice medicine, they may believe that participating in research will enable them to better understand the research process, be more successful in their later careers, or impress those who may support their applications. As captive populations, each of these groups has reasons for participating in research that are separate from financial rewards or other factors that may ordinarily motivate the general public.

The Moral Hazards of Research With Captive Populations

For the very reasons that captive populations can offer special advantages for researchers, they also present particular moral hazards. Isolated and under the direction of others, captive groups are limited in their ability to exercise choice. Absent free choice, it cannot be said that a participant is a “volunteer” in any meaningful sense of that term, and thus, a researcher’s use of that person is morally suspect. This idea is widely recognized, at least in theory. For example, writing in a 1916 edition of the *Journal of the American Medical Association* in language nearly identical to that of Justice Cardozo, pioneering experimental physiologist Walter Cannon stated that “there is no more primitive and fundamental right, which any individual possess than that of controlling the use to which his own body is put.”⁴

In medical ethics discourse over the past 50 years, many thoughtful commentators have examined and expanded upon the basis for Cannon’s conclusion. In its seminal report on the ethical principles for research with humans, commonly called the Belmont Report, the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (National Commission) explained the idea as “respect for persons,” which, in the research context, “demands that subjects enter into the research voluntarily and with adequate information”⁵ (see Chapter 14). The challenge when captive populations become research participants is that they are unequal players and may thereby have a diminished ability to exercise free choice, which may lead them to be coerced or manipulated into participation. Soldiers or students required by superior officers or professors to participate in research, for example, cannot be said to be choosing freely. Pris-

oners facing few or nonexistent alternatives to participation face similar illusory choices.

An additional moral concern that may arise with captive populations is that expediency may diminish scrutiny of a participant's capacity to volunteer. In some cases, the needs of others and a social consensus that certain subgroups are unequal can seem to justify experimentation that otherwise might not occur. Unequal bargaining power, legal philosopher H.L.A. Hart observed, is morally problematic not only because it may limit an individual's free choice but also because it defies accepted social ideals of equality. Hart explained that "most modern societies" assume that all people are "entitled to be treated alike and that differences of treatment require more to justify them than just an appeal to the interests of others."⁶ But, Hart noted, society often falls short of this paradigm. It is "plain," Hart wrote, "that neither the law nor the accepted morality of societies need extend their minimal protections, and benefits, to all within their scope, and often have not."⁶

The history of research with captive populations confirms that at times, and often unreflectively, society views and treats certain subgroups differently from others. For example, a 1962 study addressing prisoners' participation in research identified this disparity: "When the public hears that inmates are [participating in a seemingly very hazardous study], they rationalize 'Well, I wouldn't do it, but it's all right with prisoners.'"⁷ More recently, researchers at the University of Rochester exposed a healthy student to four times the maximum anticipated dose of an anesthetic drug in order to obtain tissue samples in a cancer study. In the military, special pressures relating to protecting and arming troops can affect judgments about voluntariness. For example, during and after World War II, uncertainty about the effects of radiation, combined with the increasing demands for knowledge about its risks, led the military to sponsor experiments in which soldier-participants, among others, were not informed about or given the choice to decline participation.⁷ Military exigencies—the need to protect fighting forces and civilians—continue to put strains on policies to protect individual autonomy, as we describe below.

Despite a general presumption that the interests of others should not justify treating subgroups differently, the interests of others have frequently provided a significant rationale for research with captive populations, if only implicitly or in part. Among these others are fellow soldiers, future patients, the public, investigators, and research institutions. Policy efforts to protect captive populations have aimed, in part, to mediate the risk that the capacity for voluntary consent may be compromised when captive populations participate in research.

Policy Efforts to Protect Captive Populations

To ensure that individuals truly choose to participate, and to combat the risks of coercion, manipulation, and exploitation that fueled many tragedies in clinical research over the last century, policy makers have crafted various rules requiring that research participants be "volunteers" who make informed choices to participate. Among the best known of these rules is the Nuremberg Code, promulgated in 1947 by the judges presiding over the trial of Nazi physicians charged with human rights abuses perpetrated on concentration camp inmates during World War II. The code's famous first sentence reads: "The voluntary consent of the human subject is absolutely essential."⁸ To ensure that consent is volun-

tary, the code requires that subjects "should be so situated as to be able to exercise free power of choice."⁸ Absent from this guidance, however, are specific standards for evaluating whether particular populations are so situated (see Chapter 12).

Later codes proposed more concrete guidance, sometimes specifically targeted to captive populations. For example, the 1961 draft Code of Ethics of the World Medical Association, which later became the Declaration of Helsinki, proposed that research intended solely to advance science, but offering no prospect of medical benefit for the participant, should not be conducted with those who are (a) "in a dependent relationship to the investigator, such as a medical student to a teacher . . .," (b) "prisoners of war, military or civilian . . .," or (c) "in prisons, penitentiaries, or reformatories."⁹ These specifics were deleted from the final draft, although the document retained a general admonition that an investigator should be cautious "if the subject is in a dependent relationship to the investigator."¹⁰

Current U.S. regulations—codified at 45 CFR 46, and generally referred to as the Common Rule—expand upon the framework established in these earlier codes. Human testing is generally prohibited absent the person's informed consent or the consent of a legally authorized representative, which must be obtained in "circumstances that provide the prospective subject or the representative sufficient opportunity to consider whether or not to participate and that minimize the possibility of coercion or undue influence."¹¹ In setting forth the elements of a valid informed consent (at 45 CFR 46.116(a)(1)-(8)), the federal rules expressly require prospective participants to be informed that their participation is voluntary and that they cannot be denied any benefit to which they are legally entitled if they decline to participate.¹¹ They also limit research with certain captive populations, namely, prisoners because, as the regulations explain at 45 CFR 46.302, "prisoners may be under constraints because of their incarceration which could affect their ability to make a truly voluntary and uncoerced decision" to participate in research.¹¹ As discussed below, international standards are equally, and sometimes even more, stringent.

II. Prisoners

Prisoners, perhaps the paradigm of a captive population, have long been a desirable group for medical research. From ancient history through the 20th century, societies have used prisoners to experiment on human health. Often prisoners were used because their welfare and interests were unilaterally and routinely subordinated to those of society as a whole. However, even in societies in which prisoners were not viewed as mere means to advance the interests of others, they have been sought for research because of their captive status. Describing the benefits of working in prisons, researchers writing in the *Journal of the American Medical Association* in 1967 explained:

One of the chief advantages of [working in prisons] is that it permits selection of men of any given age, height, and weight. By screening, the investigator can select persons who have a specific disorder. . . . He can select subjects with any characteristic that might commonly be found within a prison population. These subjects can then be hospitalized in the metabolic ward under combined prison and research discipline or in the clinical research center under

similar supervision for the time necessary to complete an experiment.¹²

Prisoners are an especially attractive population because their captive status means that, generally, they eat the same food, sleep in the same conditions, undertake the same amount of exercise, and are readily observable. In addition to the opportunity for close monitoring and a controlled environment, the authors of the 1967 article found that prisoners were willing research participants: “The level of compliance by prisoners with research rules and regulations has been surprisingly high. They have eaten strange diets, swallowed tubes, submitted to repeated venipunctures, and participated in a wide variety of physiological tests with a commendable degree of good humor and cheerfulness.”¹²

In justifying their use of prisoners for research, these researchers, like many before them, relied on expediency. They explained that they needed participants “urgently” and that the “ideal circumstances” of the prison made their activities appropriate.¹² As was common when referring to prisoner participants, they added that participation in research “enables the participants to feel they are serving a useful function.”¹² Thus, the history and still evolving public policy of prisoners in research provides useful insight into the ways captive populations are used in research.

Twentieth-Century Experience

Before World War II, prisoners were used in research in relatively small numbers and with little controversy.¹³ In the early 1900s, Harvard professor Richard Strong tested experimental vaccines for cholera and plague in prisoners awaiting death in the Philippines. In one of these experiments, 13 of 26 participants died. The U.S. Public Health Office induced pellagra in 12 Mississippi prisoners in 1915 and used 500 prisoners in San Quentin in testicular transplant experiments from 1919 to 1922.

During and after World War II, however, revelations about horrific exploitation and torture of prisoners in Nazi concentration camps, ostensibly in the name of advancing science and fortifying the war effort, brought the use of prisoners into new light. Telford Taylor, the lead prosecutor during the Nuremberg Doctors’ Trial, argued that the Nazi researchers were “not ignorant men,” but that they were instead “callous to the suffering of people regarded as inferior.”¹⁴ At Dachau concentration camp, for example, they conscripted prisoners for high altitude or low pressure experiments that involved locking the victims in chambers, reducing air pressure to simulate high altitude and depriving them of oxygen until they died, a half hour later. Other prisoners received oxygen, but were pummeled by severe atmospheric changes designed to replicate falls from over 47,000 feet. Dachau prisoners were also used in freezing experiments, in which they were stripped and left standing in below-freezing temperatures for nine to 14 hours, or immersed in freezing water for up to three hours at a time. Many died¹⁴ (see Chapters 2 and 12).

These examples are only a few of the numerous ways in which the Nazis used human beings as a means to advance their scientific, military, and medical goals. In other cases, prisoners were infected with malaria, typhus, yellow fever, smallpox, cholera, epidemic jaundice, and other contagious diseases. These, along with thousands of sterilization experiments, phosphorous burn studies, and others, shocked the Allies’ consciousness when they came to light following the war. (Although not widely known at the time,

Japanese researchers also made ready use of prisoners. From 1938 to 1945, Japanese immunologist Ishii Shiro tested anthrax and cholera as a means for biological weapons on thousands of Chinese prisoners in Harbin and Ping Fan Prison in Manchuria, known as Unit 731.)¹⁵

Ironically, given the prominent role that Americans played in prosecuting the Nazi doctors and formulating the standards that would be used to convict them, Americans, too, used prisoners for research during and after World War II. However, the prisoners used in the U.S. experiments were in the regular domestic prison system, not in concentration camps or prisoner-of-war camps. Moreover, U.S. experimenters often paid little attention to whether the prisoners were—in the words of the Nuremberg Code—“so situated as to be able to exercise free power of choice.” Much of the interest in prisoner research came from the military, which needed to identify and protect troops from health risks, especially infectious diseases to which they were exposed in fighting overseas. For example, malaria presented a serious threat to forces fighting in the Pacific, and the United States sponsored numerous treatment and prevention studies in prisons in the 1940s. Prisons in Illinois, Georgia, and New Jersey provided many hundreds of humans for this research, which continued into the 1950s. The prisoners participated without compensation or promise of pardon or sentence reduction, and they were celebrated for their patriotism.⁷

Recognizing the risks these prisoner-participants faced, and perhaps sensitive to public opinion, Illinois Governor Dwight H. Green in 1946 appointed a committee to consider whether to pardon or reduce these prisoners’ sentences “as a reward for service in addition to that ordinarily allowed because of good conduct.”¹⁶ The committee was chaired by Andrew Ivy, a physician who served as Taylor’s chief medical ethics expert in the Nazi doctors’ trial and drafted the standards that formed the basis for the Nuremberg Code. Ivy’s committee anticipated the Nuremberg Code’s mandate for voluntariness and characterized it this way: “when a person is able to say ‘yes’ or ‘no’ without fear of being punished or of being deprived of privileges due him in the ordinary course of events.”¹⁶ Although the committee acknowledged that reduction of sentences might be an inducement for prisoners, it did not reject the idea altogether. Instead, because prisoners who participated in research showed “a social consciousness of high order,” the committee objected only to any “excessive reduction in sentence which would exercise undue influence in obtaining the consent of prisoners.”¹⁶

But even though the Nuremberg Code, the Illinois committee, and occasional published literature insisted that prospective research participants must be true volunteers, the prison experiments increased after World War II—with little attention to the circumstances motivating prisoners’ participation. In 1956, Albert Sabin tested experimental polio vaccine on 133 prisoners in Ohio.¹⁷ From the 1950s into the 1970s, hundreds of Pennsylvania prisoners participated in experiments for viral hepatitis, psychopharmacological testing, skin research, and various diseases¹⁸ (see Figure 43.1). As with the wartime experiments, these experiments offered the prisoners no prospect of medical benefit and the popular press continued to support the “volunteer” prisoners and celebrate their generosity.¹⁹

In 1962, the demand for prison research rose sharply after federal legislation required manufacturers applying for drug approval to give the U.S. Food and Drug Administration (FDA) data

Figure 43.1. Solomon McBride, medical administrator of Holmesburg Prison's human research, questions an unidentified prisoner/research subject in H block in Feb. 1966. Source: Urban Archives, Temple University. Reproduced with permission.

from at least two “adequate and well controlled” clinical studies.^{20,21} To meet this new demand, pharmaceutical companies began performing early (Phase I) safety testing of drugs almost exclusively on prisoners.²² The research involved exposing prisoners to new compounds to determine the level at which they might harm human health. The testing offered no prospect of clinical benefit, though prisoners generally received small cash payments to participate. Prisons were in a unique position to supply the large number of humans needed for this testing, and throughout the country, many thousands of prisoners participated. By 1976, roughly 85% of Phase I testing was being conducted in prisons.¹³

The risk of coercion, abuse, and conflict of interest in these studies was high. For example, in one program involving three state prison systems, the company running the studies paid the prisoners, the prison systems, and the prison physicians for participation. One doctor received supplemental income that exceeded his annual salary by more than 250%—\$20,000 versus \$8,000—and others were shown later to own the company conducting the research. As a result of these activities, between 500 and 1,000 prisoners in these systems contracted hepatitis and 4 died.²³

Government agencies also continued experimenting on prisoners, again with no promise of direct benefit to them. For example, from 1963 through 1973, Carl G. Heller and C. Alvin Paulsen conducted government-sponsored testicular irradiation experiments on prisoners in Oregon and Washington to better understand the health effects of exposure to radiation in space

flight, in weapon and nuclear plants, and during battle.⁷ These experiments included multiple testicular biopsies and required a vasectomy at the close of the research (to prevent the prisoners from fathering children with possible chromosomal anomalies). Payments of \$25 per biopsy and for the vasectomy meant that many prisoners received payments of \$100 or more when their prison salary for, say, laundry work, was about 25 cents a day.⁷ Reviewing these studies in 1995, the President’s Advisory Committee on Human Radiation Experiments found “little doubt that the financial incentives offered for participation” in the studies were “the main reason most inmates volunteered.”⁷

Americans’ social acquiescence to prisoner research began crumbling in the late 1960s and early 1970s. As various reports of abuse and tragedy surfaced,^{24,25} researchers began expressing a more specific appreciation for the effects of incarceration on prisoner “choices” than had earlier investigators. One writer in the *Journal of the American Medical Association* in 1974, explained: “Judgment about an acceptable degree of risk requires contact with the free world as opposed to the prison environment. What may be perceived as an acceptable risk for a person inside prison may be totally unacceptable for the same person outside.”²⁶

Politics and the courts also came into play. As publicity concerning abuses in the prison system emerged, many prisoners filed lawsuits alleging lack of informed consent and poor oversight.⁷ In January 1973, the Oregon Corrections Division shut down all prison research programs in the state after the chief prison administrator found that prisoners could not freely consent.⁷ In late 1973, Massachusetts Senator Edward M. Kennedy convened

hearings to examine research with prisoners and other groups.²⁷ In 1976 the Federal Bureau of Prisons announced plans to suspend all prisoner research by the end of that year.¹³ Today, the Federal Bureau of Prisons allows research to occur, under tight conditions.²⁸

The National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research also reviewed the ethics of prisoner research in 1976. The members failed to reach consensus about banning prison research, but they proposed that it should proceed rarely and only under strict conditions to ensure that the prisoners volunteered freely. The U.S. Department of Health, Education, and Welfare (now the Department of Health and Human Services, DHHS) was statutorily required to respond to the Commission's recommendations. Finding that "most testimony before the Commission opposed the use of prisoners in any form of medical research not intended to benefit the individual prisoner,"²⁹ the agency promulgated regulations in 1978 that significantly limited prisoner involvement in federally funded research.²⁹

The 1978 regulations, which today remain largely unchanged (and are found at 45 CFR 46, Subpart C),¹¹ brought research with prisoners to a virtual standstill in the United States. But they were controversial and arguments for and against prisoner research persisted. For example, in 1980 the FDA prepared to issue regulations to prohibit using prisoners in clinical trials, including Phase I research, but some prisoners objected, based on a perceived "right" to participate. These objections led FDA to stay the final rule, which by early 2006 had yet to appear.³⁰

Ethical Assessment and Current Policies

Respect for persons requires that individual autonomy be promoted and protected. One interpretation of respect for persons requires society to permit prisoners to participate in whatever kind of research they want. This is the view advanced by those who objected to the FDA's proposed regulations to ban clinical research with prisoners. It generally discounts suggestions of "undue" influence arising from prisoners' living conditions or financial resources, especially when prisoners are "free" to decline participation through some form of consent process. It objects to perceived paternalism in regulations aimed at reducing such influences. But, in so doing, this interpretation largely ignores the historical record of abuse in research with prisoners and ignores the reality of many prisoners' everyday lives.

The National Commission favored a different view. Because "prisoners are, as a consequence of being prisoners, more subject to coerced choice and more readily available for the imposition of burdens which others will not willingly bear,"¹³ the National Commission concluded that "the appropriate expression of respect [for persons] consists in protection from exploitation."¹³ In other words, in the National Commission's view, respect for persons recognizes that external conditions may motivate people "to engage in activities which, were they stronger or in better circumstances, they would avoid," and demands "that they be protected against those forces that appear to compel their choices."¹³ This view, the basis for current federal law governing prisoner research, seeks to balance the risks of exploitation with the necessity for free choice.

Undoubtedly, the prospect of higher income and better living conditions for people who have few, if any, other choices can lead them to make choices and accept risks that they would not or-

dinarily accept. Various studies in the late 1960s and 1970s confirmed that prisoners' decisions to participate in research often arose squarely from the circumstance of their prison life. At the same time, however, prisoner-participants reported a sense of importance and higher self-esteem among their peers, and many participated out of a sense of patriotism or desire to make amends for their crimes.³¹ These interests cannot be ignored.

In weighing the need to protect prisoners from exploitation versus the need to enable them freely to determine the uses to which their bodies will be put, U.S. federal rules, adopted in 1978 and applicable today, strongly favor reducing the risk of coercion and exploitation. These regulations, which apply to all entities receiving federal funding for research from DHHS, presume that prisoners "because of their incarceration" may be unable "to make a truly voluntary and uncoerced decision whether or not to participate" in research. Therefore, the regulations—at 45 CFR 46.306(a)(2)—generally limit research to the following four areas: (1) the possible causes, effects, or processes of incarceration and criminal behavior; (2) the prison as an institution or prisoners as incarcerated persons; (3) conditions particularly affecting prisoners as a class—for example, hepatitis vaccine trials or alcoholism research; and (4) practices that intend and have a reasonable probability to improve the health or well-being of the prisoner-participant.¹¹ Procedural limitations for findings of "minimal risk" or DHHS approval further protect prisoner interests. Following complaints from public health researchers that these categories unduly limited low-risk epidemiological research, the U.S. Office for Human Research Protections (OHRP), which administers and oversees the DHHS regulations, announced a waiver that essentially added a fifth category in 2003.³² Through the waiver, DHHS funds can be used to conduct or support epidemiological research with prisoners so long as prisoners are one of many populations studied and not an exclusive target group.³² The waiver permits research related to chronic diseases, injuries, and environmental health—for example, surveys involving all HIV-infected persons in a state—so long as the research involves no more than minimal risk and no more than inconvenience to the prisoner participants.³²

These regulations reflect a heightened sensitivity to the ways in which individual circumstances can affect the choice to participate in research that was absent from public debate before the 1970s. Defending the policy, one commentator explained: "Correctional institutions, with their stated aims of confinement, are inherently coercive . . . and the introduction of research [adds] one more element to benefit the strong, punish the weak, encourage the extortionist, and further undermine fairness and evenhandedness in administration."³³ Still, as the 2003 waiver shows, public policy in this area is evolving.

In 2006 the Institute of Medicine (IOM) of the National Academies of Science completed a report on the rules that currently apply to federally supported prison research, with recommendations for reform.³⁴ The report, "Ethical Considerations for Research Involving Prisoners," was developed at the request of OHRP. The current regulations had not been revised since their creation 25 years before and the OHRP found them difficult to interpret and apply to modern prison conditions. Among the IOM recommendations were that the current definition of prisoner be expanded to include all those whose liberty has been restricted, that the same rules should apply to all prisoners regardless of which jurisdiction they may fall under (federal, state or local), that

assessments of research proposals be based on risks and benefits, that a concept of collaborative responsibility be added to the framework of research protections, and that systematic oversight of research involving prisoners be enhanced. These recommendations could result in a modification of the current federal regulations concerning prison research.³⁴

In Europe the Nuremberg Code's requirement for "free choice" seems to have precluded most prison experiments and bright line standards continue.^{13,35} The 1993 recommendations of the Council of Europe state with regard to prisoners that "persons deprived of their liberty may not undergo medical research unless it is expected to produce direct and significant benefit to them." Like U.S. regulations, this standard reflects the notion that prisoners are generally limited in their capacity to give informed consent. Other international bodies have adopted similar standards, but sometimes with different ethical underpinnings. For example, the Council for International Organizations of Medical Sciences, an organization formed by the World Health Organization and the United Nations Educational, Scientific and Cultural Organization, claims in its International Ethical Guidelines for Biomedical Research Involving Human Subjects that prisoners generally should not be used in research because historically they participated in experimentation disproportionately: "The central problem . . . is that such plans [to use prisoners and other "vulnerable" populations in research] may entail an inequitable distribution of the burdens and benefits of research participation."³⁶

In the United States, individual state laws can be even more restrictive. For example, §3505 of the California Penal Code prohibits most biomedical research with prisoners and permits behavioral research only when it concerns the "causes, effects and processes of incarceration," "prisons as institutional structures," or "prisoners as incarcerated persons."³⁷ And other regulatory provisions in California permit biomedical research only when a physician determines that it is in the "best medical interest" of the prisoner, the prisoner gives informed consent according to specific standards, and the state Department of Corrections approves the research.^{38,39}

III. Students

Although the use of prisoners in research is a fairly well documented and closely examined practice, with concern about coercion and exploitation rigorously debated during the past 30 years, the use of students is less studied. Little attention is paid to students as research participants because the vast majority of studies that recruit students are low-risk, survey research studies. In a historic practice that continues, many introductory courses in the behavioral sciences seem to require students to serve as research subjects in order to receive a grade. Students seem generally to be offered the option of writing a paper instead of participating in a study, but many students may find this option singularly unattractive. This required participation is in minimal risk research but when participation in research is a condition of completing a course and, therefore, successful completion of the student's major, one may argue that the participation is less than fully voluntary.

Students make a desirable research population for some of the same reasons that prisoners are attractive. Most students are within a defined age group. At universities there are often thousands of possible participants from whom to choose, and students usually have time to participate during the day. They are often highly

motivated. Some students are compelled to participate, but many studies recruit students outside of class, through flyers and advertisements in student papers. Considering that students' finances are often strained, they generally respond favorably to financial compensation offers, which helps ensure that students will return to complete the study.

Science students, in particular, are often highly educated, schooled in scientific methods, and interested in the professional advancement that may result from working with the researchers who experiment upon them. Describing medical students' traditional involvement in research, historian Susan Lederer explains that "students were readily available for experiments and they did not require elaborate explanations of the goals, needs, and risks of the research."⁴⁰ This ready supply of students for research, however, in rare cases has led to tragic consequences.

From Routine to Tragic

It is not surprising that many scientists are willing to expose themselves to potentially great health risks to accomplish their goals. Whether they are, or only strive to be, a part of "the research team," many students share these risks and goals with their mentors. Other students participate in research for more mundane, though no less manipulable, reasons. They need money or a grade; participating in research solves these problems.

Historically, college health departments have been a locus of research involving students as subjects.⁴¹ According to historian Heather Munro Prescott, Harold S. Dielh, then director of student health at the University of Minnesota, explained in 1927 that research by health center staff served to "stimulate scholarship" and "prevent the day's work from becoming routine and monotonous."⁴¹ Frequently, this research examined diseases and conditions commonly found in student populations, including childhood infectious diseases and alcohol abuse.⁴¹ Other studies used student populations to identify "standards of normality" for various health characteristics, including body type, blood pressure, metabolism, and psychology.⁴¹ Many researchers saw students as a uniquely useful pool of potential research participants. As Prescott notes, Oberlin College's R.W. Bradshaw opined in 1929 that "[t]here is no other large group of people who can be so well molded into an experiment as the average college student body."⁴¹

Students also are a convenient population. Large numbers of students can be assembled quickly and efficiently. To be sure, research on students has nearly always occurred without harm and with little popular attention or concern.⁴¹ But several well-publicized incidents illustrate how students may be selected as participants *because* they are young, perhaps impressionable, and more willing than their elders to undertake certain activities and risks.

In the early 1960s, Harvard professors Timothy Leary and Robert Alpert conducted research involving hallucinogenic psilocybin, a mushroom derivative, with numerous undergraduate and graduate students in Boston. In response to university concern about the health effects of the drug, the researchers at first agreed to suspend experiments with undergraduates, but, later, they were dismissed for continuing the experiments. Another example of research perhaps especially suited to a student population is the "prison life experiments" in which students role-played as inmates and guards in a "prison" in a Stanford University basement. The student-guards' actions were so severe and brutal,

for example, in meting out punishment to the student-inmates, that the researchers stopped the study after only six days.⁴² A third study that was little noticed at the time it was performed in 1962 gained notoriety in 2000 when it was revealed that Ted Kaczynski, popularly known as the “Unabomber,” participated in it as an undergraduate. The study sought to test how the students would respond when their self-described personal beliefs were systematically attacked by an authority figure who aimed to undermine them. Recalling their experiences over 25 years later, some participants described shock, anger, and “unabating rage.”⁴³

Although some of the most shocking stories of student research involve studies that would not likely be approved by an institutional review board (IRB) today, tragic stories of students injured while participating in research can still be heard. In 1996, a 19-year-old undergraduate at the University of Rochester, Nicole Wan, died two days after participating as a “normal,” or healthy, volunteer in a study examining bronchial cell defense mechanisms. The investigators recruited participants from local colleges and offered Wan \$150 for her participation in the study, which involved bronchoscopy and brush biopsies to obtain cell samples. To prevent pain, the researchers administered lidocaine, a topical anesthesia. However, before finishing the protocol, which called for ten bronchial brushings, the researchers had undertaken 28 brushings and given Wan what was later found to be more than four times the maximum dosage for lidocaine. The medical examiner concluded that she died from lidocaine poisoning.⁴⁴

After Wan died, critics charged, among other things, that the protocol failed to state whether participants would receive the promised compensation, an apparent incentive to participate, if they withdrew or failed to complete the study. Although the injuries resulted from failure to follow the study protocol, and may theoretically have occurred with any subject, Ms. Wan’s death illuminated how students, more than some other groups in society, may face such risks. State officials later directed the university to develop guidelines to protect “vulnerable populations,” which in the state’s view included “college students [who] may be especially vulnerable to the inducement of a substantial honorarium for participating in a professor’s research project.”⁴⁴

Ethical Assessment and Current Practices

As public doubts about the ethics of medical research in prison populations evolved during the last half of the 20th century, discourse about students in research also increased, though on a much smaller scale. This discussion regularly focused on the students’ educational “opportunities” and generally downplayed the risk that financial or academic inducements could unduly influence students’ choices. However, even as many denied these risks, the mere recognition of these confounding variables in students’ motivations constituted an important shift in thinking that opened the door to the development of policies to limit students’ risks. Nicole Wan’s death vividly illustrates that students who “choose” to participate in research may face tragic consequences. Today, although there are no federal rules expressly prohibiting or limiting the use of students as research participants, many academic centers have policies aimed at reducing the risk that students, by virtue of their status as students, can be exploited or manipulated into participating in research.

The key ethical issues arising from the use of students as research participants concern financial inducements, academic in-

ducements such as grades or extra credit, and academic pressures such as professors asking or otherwise communicating a desire to have students volunteer. The issue of financial inducements was the first and perhaps the easiest to be recognized. In 1956, Harvard Medical School adopted a policy for student participation that framed the issue as one of preserving students’ ability to succeed academically. “Motivation should stem from an opportunity to learn and to contribute,” Harvard stated, “rather than from a financial inducement per se.”^{45–47} Thus, “payment should not ordinarily be made to the student for participating as a subject in an experiment,” but payment could proceed for students “collaborating” in a project, participating as a subject “during vacation periods,” or “under special circumstances at other times during the research year” and to student research fellows.⁴⁶ Despite this laudable design, the reality, acknowledged by some researchers and the school even then, was that financial interests clearly influenced students’ choices to participate.⁴⁸

Defending the role of financial incentives, some have argued that students would not be willing to participate without compensation.⁴⁵ Proponents of paying students have argued that “[e]arning money from participation in research is at least as reputable a way as a variety of others available to students, such as selling their blood, tending bar, or babysitting for a faculty member’s children.”⁴⁹ Moreover, critics of special protections to limit or deny payments to students have argued that disparate treatment of students, as compared with the rest of the general population, is elitist.^{49,50} According to Angoff they ask, “Why is it acceptable to ask the masses to accept risk in the name of science but not the very people [e.g., medical students] whose futures are linked to the successful perpetuation of biomedical research?”⁴⁹ They also contend that students, like the rest of the population, ought to be free to participate in research as an expression of their own autonomy.

Generally missing from these criticisms, however, is acknowledgment that students like Nicole Wan may be and frequently are situated differently from the “masses.” As Shannon writes, because many students “need the stipends offered for their participation” they may be induced to do things they would not otherwise do.⁵¹ They are not necessarily “free” choosers.

Academic interests and pressures also create circumstances that may undermine students’ ability to exercise free choice. In the 1960s and 1970s, researchers began expressing conflicting views as to how students’ academic requirements could undermine, if not preclude, voluntary consent. One researcher concluded that so long as participation in experiments “was not a requirement” of a course, the students “had volunteered” even if they did “receive two points credit towards their final grade for having taken part.”⁵² But, another researcher opined, “if a student in a classroom is asked to volunteer by his instructor, there is at least the implied threat of loss of affection (and decreased academic grade) if the student fails to volunteer.”⁵³ A medical student writing about this phenomenon in 1979 explained that “[m]edical students are vulnerable to undue pressure from an investigator whose dual role as instructor makes it difficult for the student to refuse [a request to participate].”⁵⁰ When these requests are attached to course requirements or offers of extra credit, the pressure to accept may be overwhelming.

Today, some universities have promulgated policies to ameliorate some of these inequities. For example, one institution explains that the “relationship of teacher and student is inherently of

unequal power” and, consequently, if the researcher is “a professor of the student or is in another position of authority” he or she is to proceed cautiously.⁵⁴ Another university, which expressly aims to “reduce the element of coercion or influence in any use of students as subjects” in research, requires professors to inform students before course enrollment if they may be asked to serve as research participants and give “alternative ways” to satisfy participation requirements.⁵⁵

Other institutions apply more scrutiny to academic “alternatives,” including extra papers, book reports, or quizzes, because these may not mitigate coercion when they require additional study and they involve greater uncertainty because the teachers will still grade them.⁵⁶ One university requires preapproval for all alternatives and will likely reject, for example, “the choice of either volunteering for a 30-minute experiment involving filling out a questionnaire or writing a 5-page paper.” The university views this choice “as coercive, since writing a 5-page paper involves considerably more time, effort, and stress.”⁵⁷

Although modest compared with the procedures for prisoners and soldiers used in research, these university policies represent a significant step toward understanding a little-discussed problem. The ethical issues for this research are mainly of inequity and coercion, not death or serious injury. But historical examples like Leary’s Harvard experiments and the Stanford “prison” experiments show that students can sometimes face unusually high health risks. Moreover, tragedies like Nicole Wan’s death highlight the more dramatic risks that students, like other research participants, may face. Researchers may not always fully appreciate these risks, perhaps because they depend heavily on student populations, and also because they view participation as valuable for the student, at least for medical students or others in research training. But justifying a research intervention on the ground that it benefits the subject, the researcher, or other interests can obfuscate risks to individual autonomy. Key examples of this hazard are provided in the history of soldier-participant experiments.

IV. Soldiers

Problems of Research Consent in the Military

Today, the U.S. Department of Defense (DOD) requires that potential research participants give informed consent, except in certain “minimal-risk” research studies. Carefully drawn parameters, aimed to ensure voluntariness, govern when and how consent is obtained. But these policies have evolved from many years of contentious debate and even today, military planners face unusual and often unique challenges. These challenges stem largely from the circumstances of soldiers’ lives and the role they play in society. The command and control framework of military operations means that soldier-participants can be ordered to participate in activities like research or find themselves the recipients of an experimental product administered without their knowledge when their supervisors determine that the action is necessary to protect the safety of the force or accomplish military goals.

As has been well documented elsewhere,⁷ the military leadership wrestled with how and whether to obtain consent from soldiers throughout the middle part of the last century when it faced unknown health threats from new atomic, biological, and chemical weapons. Having convened the Nuremberg trial in 1946,

the military had every reason to know of the Nuremberg Code and its principles for research. In 1953 then-Defense Secretary Charles Wilson issued a memorandum that effectively adopted the Nuremberg Code and set written, voluntary consent as the Pentagon’s policy for research in atomic, biological, and chemical warfare. The “voluntary consent of the human subject is absolutely essential,” the document stated, and voluntary consent required “that the person involved should have the legal capacity to give consent; should be so situated as to be able to exercise free power of choice, without the intervention of any element of force . . . duress . . . or other ulterior form of constraint or coercion.”⁷ Wilson’s directive would seem to eliminate any questions about the need to obtain voluntary consent before testing a new product or treatment modality, but the history is much more complicated.

Evidence shows that the DOD did not implement the Wilson policy or communicate it effectively down the chain of command. Part of the reason for the disparity between the military’s written policy and its field activities arises from questions about what is a “medical experiment” versus, for example, necessary treatment in the face of uncertain risks or a required training exercise. Another reason is that imminent attack or health threats may change the calculus in balancing the needs of the group and the interests of any individual.

Landmark Cases

The military has a long tradition of experimenting with soldiers and other populations. Faced with soldiers dying from yellow fever in Cuba in 1900, the U.S. Army ordered Walter Reed to identify the vector of the virus. Reed’s team asked American soldiers and local workers to agree to be exposed to mosquitoes that had just feasted on yellow fever blood.⁵⁸ Reed was apparently the first researcher to require participants to sign a contract memorializing their status as volunteers, though the agreement bears little resemblance to the detailed informed consent forms used in research today⁵⁸ (see Chapter 1).

Early military requirements for “voluntary” participation appeared to reflect the view that when an activity posed an especially high and often unknown or hard to calculate risk, soldiers should have freer choice whether to participate. In 1925 the Army established a policy requiring that “volunteers” be used in “experimental research” involving infectious diseases.⁷ In 1932, the Navy established a policy permitting early diving experiments with “informed volunteers.”⁷ However, the fear of punishment for insubordination and the desire to serve may have undermined servicemen’s ability to make truly free and uncoerced decisions.

The onset of World War II created new demands for human testing from many sources. Recognizing that many of these experiments would be dangerous, and that some might fall outside soldiers’ ordinary duties, military planners articulated a requirement for voluntariness, though liability concerns also appeared. In one early letter, the head of the military’s research coordinating group, the Committee on Medical Research, explained, “When any risks are involved, volunteers only should be utilized as subjects . . . and these only after the risks have been fully explained and after signed statements have been obtained which shall prove that the volunteer offered his services with full knowledge and that claims for damages will be waived.”⁷ Despite this clear statement, the military undertook substantial research without following these principles.⁷

For example, in 1942, the military began a series of gas experiments to test protective gear against chemical weapons, including, for example, mustard gas, one of the deadliest chemicals used during World War I. Mustard gas, also called sulfur mustard, causes severe skin blistering, vomiting, eye swelling, blindness, and internal and external bleeding, and in many cases during World War I, threatened slow and painful death. Then, as today, no known antidote existed. To combat mustard gas, the military developed masks and protective clothing and tested this equipment and troops' abilities when wearing it.

In its 1993 report on military gas experiments during World War II, the National Academy of Sciences concluded that "although the human subjects were called 'volunteers,' it is clear from the official reports that recruitment of the WW II human subjects, as well as many of those in later experiments, was accomplished through lies and half-truths."⁵⁹ Some of these experiments, which the soldiers swore to keep secret, occurred in gas chambers. Soldiers were outfitted with the protective clothing and locked in the gas chambers for one to four hours while gas was pumped in around them.⁵⁸ Afterward, they were required to wear the clothing and masks for up to 24 hours, and then the experiments were repeated until the soldiers developed skin reactions.⁵⁸ A contemporaneous Navy report of these tests explained how dissenters were managed: "Occasionally there have been reports of individuals or groups who did not cooperate fully. A short explanatory talk, and if necessary, a slight verbal 'dressing down,' has always proven successful. There has not been a single instance in which a man has refused to enter the gas chamber."⁵⁸

Field tests also were conducted. To test protective gear in tropical battlefield conditions in 1944, 150 soldiers marched into a jungle area near Panama shortly after two U.S. bombers dropped 200 gas-filled bombs on the region. Describing the test, military reports later explained that the soldiers "had only to look about them to see the shining mustard on the foliage, to see the pools of mustard in bomb craters around their position."⁵⁸ Some of the soldiers reacted poorly, and "there were moments when panic or mass hysteria seemed close to the surface" among the troops.⁵⁸ But, as in the chamber tests, declining to participate was not an option.

After the war, the U.S. military continued using soldiers in an array of tests designed to better understand new atomic, biological, and chemical weapons. Experiments were often conducted without the person's knowledge or opportunity to make an informed decision about whether to participate. In part, this deception arose from a sense of expediency and a failure to distinguish among soldiers used as research participants and others exposed to similar conditions during mandatory service activities. For example, in 1946, the Navy and the Army Air Force jointly conducted the first underwater explosion of an atomic bomb during Operation Crossroads in the Marshall Islands.⁶⁰ As part of the test series, which aimed to test the survivability of ships and equipment, medical personnel also monitored the health risks to servicemen who were exposed to radiation during the tests and posttest surveillance of the area.

Servicemen did not "volunteer" for this duty. It was assigned in the normal course of business. Indeed, throughout the 1940s and 1950s, as the military developed its nuclear arsenal, medical researchers mined soldiers' training experiences to evaluate protective clothing designs and understand "how much radiation penetrated the human system" during, for example, mushroom cloud fly-throughs.⁵⁸ These activities were not considered "human ex-

periments," and soldiers were not asked to consent or given a choice not to participate.

At the same time, however, other soldiers participating in human research—for example, flash blindness studies to test visual impairment after exposure to a nuclear blast—were asked for consent and informed of the experiment's risks.⁵⁸ One research participant later explained that "[w]hen the time came for ophthalmologists to describe what they thought could or could not happen, and we were asked to sign a consent form, just as you do in the hospital for surgery, I signed one."⁵⁸ Thus, it is clear that in some cases the military, even in the middle of the last century, undertook serious efforts to obtain informed consent before soldiers participated in research.

But tempting though it is to look for patterns in the military's consent practices during this time, they are hard to find. The line between military operations and medical research was often muddy and military planners, although generally affirming the principle of voluntary consent for experimentation, did not apply it consistently or across activities.

In the early 1960s, military regulations for human research became somewhat clearer, though the tension between operations and research continued. For example, the U.S. Army's 1962 regulation, AR 70-25: Use of Volunteers as Subjects of Research, required "voluntary consent" for research when "human beings are deliberately exposed to unusual or potentially hazardous conditions"—defined as conditions "which may be reasonably expected to involve the risk, beyond the normal call of duty, of privation, discomfort, distress, pain, damage to health, bodily harm, physical injury, or death."⁶¹ Exempted from this policy were activities "encountered as part of training or other normal duties," experiments "wherein disclosure of experimental conditions to participating personnel would reveal the artificial nature of such conditions and defeat the purpose of the investigation," and "investigations involving the basic disease process or new treatment procedures conducted by the Army Medical Service for the benefit of patients." In some respects, these exceptions swallowed the rule and experiments sometimes occurred without regard to obtaining voluntary consent and often without telling the individual.⁷

Among the most famous, or infamous, government-sponsored research activities during this time were the Army and Central Intelligence Agency (CIA) experiments involving the hallucinogen lysergic acid diethylamide, or LSD. Code named "MKULTRA" in the CIA, the studies exposed military personnel and others to LSD without their knowledge or consent. Among other victims, CIA scientist Frank Olsen received the drug during a staff retreat in 1953. After his death was tied to the LSD experiments more than 20 years later, Olsen was said to have suffered a severe psychiatric reaction to the experiment and shortly thereafter fell to his death from the 10th floor of the Statler Hilton in New York City.⁵⁸ The precise circumstances of Olson's death are still a matter of disagreement.

Thousands of military personnel were used in the LSD experiments. Master Sergeant James Stanley volunteered in 1958 to participate in a study to combat chemical weapons but instead the Army gave him LSD. Stanley suffered years of unexplained personal turmoil thereafter. Only after congressional investigations in 1975 revealed the LSD testing, mustard gas studies, and other secret experiments involving soldiers did Stanley learn the truth about the drugs he ingested. Stanley sued the government to compensate him for his injuries.⁵⁸ Ultimately, the Supreme Court,

in a 5–4 ruling, dismissed the case as barred by the long-standing doctrine that prohibits military personnel from suing for damages incurred incident to service.⁶² But, in dissent, Justice O'Connor rejected the majority's conclusion in prose that echoes Justice Cardozo's clear affirmation 70 years earlier. Calling the research "so far beyond the bounds of human decency that as a matter of law it simply cannot be considered a part of the military mission," Justice O'Connor concluded that "[n]o judicially crafted rule should insulate from liability the involuntary and unknowing human experimentation alleged to have occurred in this case."⁶² Although Stanley and other soldiers were unable to redress their grievances in the courts, the revelations of MKULTRA and other hidden experiments involving military personnel fueled debate about human experimentation that, as with prisoners and students, led to greater public sensitivity about what it means for a research participant to volunteer.

Gulf War Illness and Post-Desert Storm Controversy

Military policies, by the time of the *Stanley* decision in 1987 and today, support the notion that human participants should be informed volunteers.⁷ But the sense of necessity and urgency that motivated many of the military's human experiments with unconsenting and uninformed soldiers has not disappeared. Instead, these tensions continue to arise as the United States faces new security threats.

In planning for Operation Desert Storm in 1990, for example, the military faced serious questions and concerns about the effects of Iraq's chemical and biological weapons on soldiers' safety and effectiveness. To combat these risks, new vaccines and drugs were tested. The military wanted to use them, but given concerns about the feasibility of obtaining informed consent from the hundreds of thousands of troops to be stationed in the Gulf, and about the possibility that some soldiers might decline to participate, the military asked the FDA for a waiver of the consent requirements for investigational products.²⁰ The military argued that it needed the waiver because of the imminent battlefield risks: "[M]ilitary combat is different. If a soldier's life will be endangered by nerve gas, for example, it is not acceptable from a military standpoint to defer to whatever might be the soldier's personal preference concerning a preventive or therapeutic treatment that might save his life, avoid endangerment of other personnel in his unit and accomplish the combat mission."⁶³

After lengthy internal and interagency discussions, the FDA agreed and in December 1990 issued a new, interim regulation to permit the military to administer investigational drugs and biologics to military personnel without obtaining informed consent.^{63,64} Under the regulation, the FDA could issue waivers, on a case-by-case basis, when a military physician, the investigational product's sponsor, and an IRB find a waiver to be "ethically justified" in a particular combat-related situation. Each must also find that informed consent is "not feasible" and that "withholding treatment would be contrary to the best interests of the military personnel."⁶³ This policy was premised on the conclusion that the exigencies of war could justify forced participation: "Military combat (actual or threatened) circumstances in which the health of the individual or the safety of other military personnel may require that a particular drug or biologic for prevention or treat-

ment be provided to a specified group of military personnel, without regard to any individual's personal preference for no treatment or for some alternative treatment."⁶³ Subsequently, the FDA approved the military's proposed use of two investigational products: (1) pyridostigmine bromide to be administered in tablet form every eight hours to protect against the effects of nerve gas, and (2) injected botulinum toxoid to vaccinate against botulism.⁶⁵

The FDA's policy choice angered many critics. Many found the military's rationale for the waiver—battlefield exigencies—to be insufficient to justify jettisoning the fundamental respect for persons embodied in the requirement for informed consent.⁶⁶ Others felt that the military did not need the waiver to accomplish many of its goals. For example, one of the drugs, pyridostigmine bromide, was approved for other uses and therefore (technically) available for any treatment use, and the vaccine for botulism was ultimately administered on a voluntary basis, demonstrating that consent was obtainable.⁶⁶ Within several weeks after the FDA issued the interim rule, a soldier stationed in Saudi Arabia and his wife filed suit to enjoin the military from using unapproved products without obtaining consent.⁶⁵ The U.S. District Court for the District of Columbia dismissed the case, *Doe v. Sullivan*, in favor of the government in January 1991, 16 days after the Gulf War began. The court concluded that "judicial interference" in the military's "strategic decision would not be proper," once the military had explained that using the unapproved products would "improve the survival rate of troops that may encounter chemical and biological weapons," which, in turn, would "increase the safety of servicemen in the field and . . . decrease the medical burden of treating victims."⁶⁵

Reflecting the long-standing tension of distinguishing *research* and *operations*, the court found that the planned action was not *research*, subject to separate DOD statutory prohibitions on using humans in experiments without prior informed consent, because the "primary purpose of administering the drugs is military, not scientific" and because "the DOD has responded to very real circumstances and chosen what it views as the best alternative given current knowledge."⁶⁵ Moreover, the court concluded that the military's interest in "successfully accomplishing the military goals of Operation Desert Storm" as well as its desire to protect the troops "constitute legitimate government interests that may counterbalance an individual's interest in being free from experimental treatment without giving consent."⁶⁵ The U.S. Court of Appeals for the District of Columbia affirmed the lower court's analysis.⁶⁷

Ethical Assessment and Current Practices

As the *Doe v. Sullivan* case illustrates, in some respects, the concept of informed consent that today is an accepted prerequisite for voluntary participation in medical research is unsuited to the military context. Military regulations intentionally deny individual soldiers' autonomy in order to preserve and advance the fighting force. Thus, it is no surprise that U.S. history includes not only groundbreaking policies to ensure that soldiers participate in research only if they volunteer but also examples showing that the concept of voluntariness has not been well understood or executed.

The question of waiving informed consent for military use of experimental agents during wartime remains a live issue. In 1997, the FDA sought public comment on its Gulf War waiver

provisions.⁶⁸ The following year, in 1998, Congress passed a law prohibiting the administration of experimental drugs and drugs unapproved for their intended use to service members without their informed consent.⁶⁹ The only exception to this policy was through presidential waiver based on a finding that consent is not feasible, is contrary to the soldier's best interests, or is contrary to national security.⁶⁹ President Bill Clinton issued an executive order in 1999 reiterating these standards.⁷⁰

Shortly thereafter, the FDA repealed its Gulf War waiver provisions and issued a new interim rule to establish criteria for the president to apply when considering a waiver in accord with the law.⁷¹ But, after the terrorist attacks of Sept. 11, 2001, and the onset of operations in Afghanistan and Iraq, Congress went further. In 2004 Congress authorized use of unapproved medical products, or products unapproved for particular uses, pursuant to an "emergency use authorization" (EUA) issued by the FDA after an emergency or potential for emergency involving heightened risk of attack with a specific biological, radiological, nuclear, or chemical agent is identified.⁷² At the same time, however, Congress required that all individuals to whom products are to be administered under an EUA be given information about risks and benefits and have the option to refuse administration.⁷²

The DOD's Anthrax Vaccination Immunization Program (AVIP), which provides anthrax vaccine to service members, became a test case for these provisions. In a suit brought by six active duty military personnel, the U.S. District Court for the District of Columbia in 2004 enjoined the military from requiring personnel to receive anthrax vaccines in the absence of "informed consent or a Presidential waiver."⁷³ But, in April 2005, following passage of the 2004 law and declaration of an EUA, the court allowed the military to resume anthrax vaccinations under certain conditions. The court specified, consistent with the law, that members of the armed forces receive education on the program and be given the option to refuse the vaccination without penalty.⁷⁴ The following year, after the FDA designated the vaccine as "safe and effective" to combat anthrax inhalation exposure, the need for the EUA and the court's injunction dissolved.⁷⁵

As the challenges to the AVIP program illustrate, when the circumstances of military life require a soldier to participate in an experiment or accept an unproven therapy against his or her will, it cannot be said that the soldier is "volunteering." More than any other of the captive populations we have discussed, soldiers live in circumstances in which the command structure may force them to participate and the needs of the whole may override the interests of the few. As the military stated during the Gulf War, ingestion of an experimental vaccine may be necessary to ensure that the entire force will be protected. This paternalistic usurpation of an individual's expressed, and presumably informed, judgment can only be justified in rare circumstances, if at all. The history of involuntary research with uninformed soldiers, especially in dual-purpose activities in which research and training occur together, demonstrates how military expediency may be used, albeit subconsciously, to authorize research in soldiers that would not be permitted in the general population.

Excepting situations in which competing group interests may outweigh respect for individual choices to decline participation, the military setting does not per se preclude the possibility of free choice. For soldiers to truly "volunteer" they must feel that they can decline without suffering adverse consequences. When soldiers are informed about the risks of participation and are given genuine

options to decline, the risk that a soldier will misunderstand the research or feel pressured to participate is reduced. In these circumstances, soldiers are like their nonmilitary counterparts who volunteer for research. So long as the soldiers do not face or perceive career limits for opting not to participate, voluntary consent is feasible. Today's military has many provisions in place to ensure that soldiers who volunteer truly are "volunteers."

Conclusion

Captive populations are different from the general society. Often they are physically separated, sometimes locked behind prison walls or concentrated on military bases. At other times they are separated by their dress, lifestyle, or financial opportunities. Together, they live in circumstances and share interests that may make them especially vulnerable to coercion and exploitation. Moreover, and perhaps most important, society generally has looked at captive populations through colored lenses that failed to scrutinize, or even recognize, how these differences could affect captive populations' ability to "volunteer" for research. Ironically, having condemned the Nazi crimes, the United States in the mid-20th century at least by its silence condoned extensive prisoner research at home without considering whether the terms of the Nuremberg Code—the concept of genuinely free choice—held any relevance to the lives of prisoners who were not in the extreme circumstances of concentration camp inmates.

During the last half of the 20th century, the United States examined the effects of captivity with more precision. For some captive groups, like prisoners, policy makers judged that the conditions of their captivity effectively precluded voluntary consent in most cases and found that often the risks of research far outweighed its potential benefits. In other cases, like the military's consent exception during the Gulf War, the benefits for the group may outweigh individual choices. What is essential in examining research with captive populations is to recognize how the conditions of captivity can influence whether a participant truly "volunteers" for research, and how the interests of others, including investigators, fellow soldiers, or the scientific enterprise, may influence what sorts of risks participants are allowed to accept.

Research With Identifiable and Targeted Communities

Most research studies that involve human participants target specific categories of people through inclusion/exclusion criteria. Some of those targeted categories are defined by scientific criteria, such as people with a diagnosis of a particular disease or people without the disease who can serve as “healthy” controls. Other targeted categories are defined by demographic criteria, used either as proxies for specific life experiences, exposures, or incidence rates or as measures of inclusiveness. As an example of the latter, even studies that recruit members of the “general public” often use social identities such as gender, race, or ethnicity to ensure that a sample resembles the makeup of that larger general population.

Some of the categories of people targeted for study recruitment may be more vulnerable than others to harms associated with taking part in research, requiring special considerations in the evaluation of and protection against potential research risks. Prisoners, for example, are more vulnerable to coercion because of their incarcerated status, whereas children and the mentally incapacitated may not be able to fully understand what they are giving consent to do. Other categories of people, such as pregnant women and the elderly, may have health risks greater than other participants. Ethical review committees and institutional review boards have historically provided higher levels of protection for such vulnerable persons, including greater scrutiny of studies that target them, additional protections from potential risks, and the inclusion of advocates for them on such committees and boards.

These examples of populations typically considered more vulnerable to research risks are designated as such because of functional attributes that may affect their ability to consent or that may pose special physical risks; that is, prisoners have less individual autonomy than others, children and the mentally impaired tend to

have less well developed abilities to make autonomous decisions, and pregnant women and the elderly tend to have greater health risks than other healthy adults.

Other groups, though, such as Native American tribes and other indigenous groups around the world, have also been proposed for special consideration as targeted populations.^{1–3} Two primary arguments have been made for extending a special status to them: (1) that their members are readily identifiable as such, so that research findings associated with a named group or community can have consequences for all identifiable members of the group or community, and (2) that their shared identities indicate collective moral, cultural, and/or legal authorities that are recognized by most persons whom those identities label as having some license to regulate or sanction individual claims to group membership and appropriate behaviors in group contexts, and so should be consulted and respected when targeted by a research study.^{4,5} Because of these collective implications and qualities, some ethicists and group members have proposed higher levels of scrutiny and special protections for populations targeted because of shared social identities.^{6,7}

Studies that target such populations often present risks to individuals outside the researcher/research participant relationship, and so can introduce a number of distinctive ethical challenges.

First, studies in which targeted communities are identified in research reports may inadvertently reinforce existing stereotypes about the community and its members. For example, studies of existing health disparities—such as studies of a particular locale or workplace—may reinforce local perceptions of a community as unsafe or unhealthy. These negative images of a community or its members may be associated with forms of social devaluing such as

decreased property values, individual discrimination such as decreased access to employment opportunities, and stigma, leading to decreased opportunities for social interaction with individuals outside the community. These considerations are particularly noteworthy in contexts in which there are histories of social disadvantage or pervasive social divisions that are the result of existing stereotypes regarding a targeted community.

Second, studies of targeted communities may cause a range of disruptions within a targeted community. For example, intracommunity discussions about taking part in a study of a condition that has the potential to be publicly prejudicial, such as alcoholism or HIV, or in a study that uses a methodology about which some segments of the public are suspicious, such as genetics, can become polarizing issues that divide community members. Despite a sincere intention to improve the health of community members, these disruptions to existing social relationships may be considered by those persons affected to be a significant harm resulting from the research.

Third, studies of targeted communities may suggest an inappropriate image of the community as static or one-dimensional. Most targeted communities are heterogeneous and diverse with regard to a range of variables that may be associated with increased health risks. When studies of targeted communities present data suggesting an association between one aspect of the community and a particular health risk, this may be understood by some as suggesting that *all members* of the community are at increased risk. Such studies may thus undermine efforts to increase sensitivity to important variability within communities with a common collective label such as “Italian American” or “elementary school teachers.”

These and other risks to people indirectly affected by studies of targeted communities may be difficult to anticipate in advance. As a result, researchers may fail to disclose all salient risks to prospective participants or to community leaders during the informed consent process. When histories of profound mistrust of medical researchers exist, researchers may find that it is difficult to communicate the full range of potential benefits and risks associated with a study to community members whose past experiences condition them to anticipate the worst possible harms. In addition, researchers may inadvertently present research findings in a manner that is insensitive to potential harms to affected third parties or otherwise fail to establish adequate protections for individuals placed at risk. When the risks at issue are closely tied to the unique social histories of the community under investigation, and the investigators conducting the study are not intimately familiar with those histories, it may be especially difficult to identify the potential harms at stake without substantial community participation in the design and development of a research protocol.

Indeed, to a considerable extent, most discussions of the ethical significance of collective risks and interests have been linked with discussions about processes for involving communities and their members in evaluating these risks and interests. The involvement of communities recognizes that researchers and ethics committees cannot evaluate the risks and interests unilaterally because they often lack information about how members of other communities perceive those risks and interests.^{8,9} Thus, taking account of the collective implications that a research study may have (that is, the implications for all those who share a targeted identity whether they take part in the study or not) is necessarily a combination of conceptual and empirical approaches. In partic-

ular, various forms of group or community consultation have been proposed as supplements to individual informed consent to manage the additional level of risks that may be associated with collective identities as well as to recognize the importance of engaging those collective entities in studies that specifically target their members. These include community consultations, in which some community members are engaged in discussions about a proposed study before it is undertaken, and in some cases community consent, in which some formal approval is obtained from a community in which formal decision-making processes exist, such as in Native American tribes.^{10–12}

In some instances, requirements for community consultation and/or consent have been adopted by local ethics committees, government agencies, and international organizations.^{13,14} However, there is a continuing debate about the kinds of existing social groups and communities that merit such special protections and the extent to which collective concerns should be weighed alongside individual concerns about taking part in research.^{15–17} In this chapter, we review approaches and guidelines that have been proposed, outline the issues that have arisen in this developing area of research ethics, and anticipate future directions in which those might lead.

Current Standards and Guidelines

For some time, communitarian frameworks have been available within research ethics as alternatives to the dominant focus on individual autonomy. Innovations in the ethics of the collective implications of research, however, have grown out of more practical concerns about research that focuses on tribes and indigenous groups rather than from philosophical critiques of individualism. Many aboriginal groups have or assert unique legal statuses within larger nation-states in addition to having experienced long histories of discrimination and stigmatization that often include having been subjected to medical studies that would today be considered unethical.¹⁸ That combination of assertions of collective authority and experiences of past abuses contributed to a series of guidelines for research from indigenous peoples in Canada,¹⁹ Australia,²⁰ and the United States.²¹ Some of these guidelines were motivated by heightened concerns about the implications of genetic research for group identity, particularly the use of genetic information to rewrite population history. Other concerns included the ownership of intellectual property arising from the development of gene-based diagnostics and therapeutics that might be commercialized.²²

Many of the principles articulated in those guidelines are common to what has become community-based, participatory research (CBPR). CBPR brings targeted communities into the planning of a study, focusing on a community's research priorities rather than the researcher's, structuring a study to build capacity within the community, making provisions to share any benefits from the study with community members and presenting research findings back to the community.²³ Other provisions deal with the collective authority or jurisdiction of the group and include such issues as whether the group has the right to approve or veto proposed studies, whether manuscripts must be approved by the group before publication, and whether data generated by the study are owned by the group rather than by researchers, their institutions, or the agency that funded the study.^{24,25}

These latter claims are best understood in the context of similar legal and political negotiations, in which many indigenous peoples also have been engaged, about land claims, treaty rights, ownership of natural resources, self-determination, control of cultural symbols and heritage, and sovereignty, as well as the health disparities and limited access to care that such groups continue to experience. Some indigenous groups have succeeded in establishing their own ethics committees that review proposed studies and also have begun to build their own research infrastructure, often in collaboration with outside institutions.²⁶ Some local ethics committees now require separate tribal approval for studies that target members of specific native communities. In addition, increasing numbers of researchers negotiate conditions of data ownership and publication with indigenous groups prior to beginning a study with their members.²⁷ Although some controversies continue to arise, often based on older studies,²⁸ research practices increasingly recognize that indigenous groups have some legitimate claim to collective authority when a study specifically targets group members for participation.

This growing recognition, however, has not been codified into a single set of consensus standards or best practices that can be applied generally, despite various efforts to do so. A primary reason for this failure is that the unique cultural and historical positions of different native groups are more conducive to situational negotiations than to a single policy. At the same time, notions of collective authority and collective implications have been extended beyond indigenous groups to include a broader range of social entities. These extensions include localities in which emergency medical studies are subjected to local community approval,²⁹ the common interests of groups of people defined by a shared disease status such as HIV/AIDS,³⁰ and local community consultation for genetic samples that are used as proxies for larger ethnic and continental populations.³¹ Different levels of collective interests and authority are also routinely recognized in international research, ranging from national governments to ethnic, cultural, and religious subgroups to localities.³²

These extensions raise a number of questions about the organizational capacity and moral authority of social groups and categories that, unlike most indigenous communities, lack a long-standing tradition and process of collective decision making. Both Weijer and Emanuel¹¹ and Sharp and Foster¹⁰ have proposed systematic frameworks for evaluating whether different social entities have appropriate capacities and authorities for the consideration of collective ethical implications. Weijer and Emanuel emphasize the importance of social cohesion within a group for establishing the moral authority considered necessary for true communal consent or approval of a study. They consider this kind of social cohesion rare in examples outside aboriginal communities or localized geographical communities that have legitimate mechanisms for political representation and decision making. Community consultation—stopping short of formal consent—is treated as a lesser level of protection, but one that also requires some degree of cohesion, as might exist in the case of religious communities that share a common cultural framework and communication network but lack centralized decision-making processes.¹¹

Sharp and Foster also note the importance of social cohesion to establishing moral authority, but they explore the ways in which social science methods can be used to sample the range of views that exist within more dispersed, less centralized commu-

nities or populations.¹⁰ A strong case can be made for considering the collective implications of studies that target certain larger geographically dispersed populations such as African Americans, for example, because of their history of discrimination as well as specific examples of abuse in clinical research^{33,34} (see Chapter 8). However, such populations are socially and culturally diverse, at least more so than localized, centrally organized entities, and have multiple levels of organization and leadership, none of which can speak definitively for the whole.

Empirical examples of community consultation are primarily situated at local levels and emphasize repeated face-to-face interactions between researchers and community members, arguably a necessary dynamic to encourage interaction and build trust.³⁵ For studies that involve implications that are generalized beyond the immediate communities from which participants are recruited, however, the localized dynamics of consultation may limit the extent to which the range of views of the immediate community can be considered to represent the larger population views, depending on how representative the local community is of the larger group.

Perhaps the highest-profile example of community consultation has been the engagement with three local communities—in Tokyo, Beijing, and Ibadan, Nigeria—leading up to DNA sample collection for the International HapMap Project.³¹ In a series of individual interviews, focus groups, surveys, and public meetings, these communities were consulted about their preferences for how donors would be recruited, how their communities were to be named in labeling the samples and in subsequent publications that identified them, and how community advisory groups were to be set up to monitor future uses. A primary focus of these consultations was the collective implications of findings from the HapMap. Those implications included both the immediate communities in which samples were obtained and the larger ethnic and continental populations for which the samples served as proxies in seeking common patterns of human genetic variation. At best, though, consulting with members of local communities enabled researchers only to tailor their recruitment procedures, social labels, and framing of study findings to the ways in which some Japanese, Han Chinese, and Yoruba understood those collective implications, given the practical difficulties of sampling larger populations with millions of members each.

The HapMap experience suggests that collective implications and interests of populations targeted for research might be divided into two categories: (1) those of the larger population to which findings are generalized and (2) those of the local community or communities from which participants are recruited. Protections for the latter category will necessarily provide some benefit for the former as well, but may not fully address all concerns about implications for the larger population. Nonetheless, the advantage of focusing ethical protections for collective interests on local communities from which participants are to be recruited is that these are the settings within which collective and individual considerations will intersect in actual decisions to take part in research studies. That local intersection supports the goals of community consultation that Dickert and Sugarman have delineated: protection of participants' welfare and interests, enhancement of benefits for participants and their communities, ethical and political legitimacy for the study, and shared responsibility for the research through establishing a truly collaborative partnership between researchers and the communities they study.³⁶ Still, a number of conceptual and methodological issues remain in incorporating the

evaluation and protection of collective interests of targeted populations and communities into clinical research ethics.

Issues to Be Resolved

How can we satisfy both individual autonomy and collective interests? This is perhaps the central conceptual challenge in incorporating the collective interests of targeted populations into research ethics. When community consent is appropriate, as in the case of politically organized tribes, a collective decision to disapprove a research project in effect denies individual tribal members the opportunity to take part in a study that some might consider valuable. Moreover, some group members may not subscribe to the authority of leaders to approve manuscripts that describe study findings or to have oversight over future uses of biological samples or other data. Even in cases in which consultation is undertaken without the possibility of community consent, some individual members may strongly disagree with the political or moral authority of those whose views were solicited to speak on their behalf.

This moral conflict becomes particularly acute in the case of members who live outside the territorial jurisdiction or homeland of the population or community in question. Should the authority of the parent population be respected, or should emigrants who may not recognize that authority be given the opportunity to make individual choices about studies that target those who share a particular identity? That problem arises not only with respect to members of indigenous groups who move to urban areas, but also to members of a variety of national, cultural, ethnic, and other populations who emigrate outside their ancestral homeland, often to other countries, and are approached by researchers as proxies for those ancestral populations. Despite their geographical and social separation, their shared social identity can subject both emigrant and ancestral populations to the same implications of research findings.

How can we weigh differing views of a population's collective interests? Different local communities can have very different views about the collective implications of a proposed study, particularly in the case of large, geographically dispersed populations.¹⁰ Moreover, organizations that claim to represent the interests of larger populations across localities, and that may do so in some part, also can have different views either with one another or with some local communities. For example, several national and international Native American organizations have called for prohibitions on genetic research with tribal members, whereas some sovereign tribal governments have approved genetic studies and even themselves invested in genetic projects.³⁷ A similar situation, of course, can arise in the case of targeted populations or communities that lack the political organization of tribes. In either instance, researchers and ethics committees are left to weigh those differing views in deciding whether and how to protect the varying representations of collective interests at issue.

Does a consultative focus on local communities constitute forum shopping? Given the possibility that some local communities or organizations within a targeted population may have few concerns about a specific study whereas others may have considerable concerns, researchers might be accused of forum shopping in collaborating with the former rather than dealing with the stronger objections of the latter. So long as choosing to consult with a particular local community does not violate the political or

moral authority of some other entity within which that locality is encapsulated, however, it is difficult ethically to fault researchers and communities for collaborating based on greater shared interests. The test of encapsulation is also useful in defining a community to approach for consultation. Preexisting communities should evidence some degree of shared, and therefore bounded, social and moral regulation among their members, even if that regulation is only informal and relatively weak and is focused primarily on claims to and symbols of a common identity.³⁸ Although *community* is a concept that can be defined at many different scales, any claim to consult members at a particular level should include some rationale for involving or sampling those who can be said to speak for whatever diversity of views exists within that social universe.

Are collective risks more a matter of perception than reality? Although many concerns have been raised about the collective risks of genetic research, for instance, there are in fact few documented examples of collective harms based on shared social identities.¹⁵ Nonetheless, three responses can be made to this question. First, ethical evaluation and protection are premised on anticipating the reasonable potential for harm, not as responses after harm has been shown to occur. Second, history is replete with examples of people who have been harmed or killed due solely to their social identities. Third, perceptions of risk often are culturally constructed, so that what may be perceived as a minor matter to an outside researcher or ethics committee may be a much more significant risk to members of a particular cultural community. For this reason, involving members of populations or communities targeted for research in evaluating proposed studies often is a necessary empirical exercise in weighing the ethical significance of collective interests.^{39–41}

What is the threshold for requiring community consultation beyond those communities that have centralized political processes capable of community consent? For the most part, consultations tend to be undertaken in populations or communities that have experienced histories of discrimination and health disparities—and/or that have cultural frameworks different from those of researchers—are more likely both to be vulnerable to collective harms and to have perceptions of collective implications or interests that may not be anticipated by outsiders.⁴ Community consultation also may be appropriate for those groups that have strong collective interests in the risks and benefits of the study being conducted because they themselves may be affected by its conduct and/or outcome. Examples include people with HIV/AIDS, who have shared interests in studies focused on that disease, or those who reside in localities in which emergency medical studies may be conducted without individual consent and who could themselves end up as unconsenting participants.

Who is an appropriate representative for a community that does not have centralized political processes capable of community consent? Researchers most often try to identify leaders of local organizations such as churches or educational institutions when approaching a community for collaboration. Relying on local leaders alone, though, may not provide a sufficient perspective on community members' views, because leaders often have a self-interest in augmenting their positions by acting as intermediaries between members and outsiders. Sampling methods developed by social scientists offer more reliable means for consulting a cross section of local community members, but may require greater time and effort to complete than simply dealing with local leaders.

What kinds of community concerns are sufficient to force abandonment of a proposed study? As with risks to individuals, risks that may significantly harm collective interests, and for which protections cannot be devised, should be considered reasons to abandon targeting a particular population or community. However, before that question reaches an ethics committee, it is likely that consultation with community members will make evident the nature of the collective risks and the difficulty that those collective considerations will impose in recruiting participants, an early indication to researchers that a proposed design may be inappropriate for that community.⁴ Similarly, consultations that provoke strong arguments among community members, leading to disruptions in their interactions with one another, provide evidence that carrying out the proposed study could cause further disruptions.³⁹ The consultation process should enable researchers and community members to collaboratively work out modifications in a study protocol that will reduce both collective and individual risks.

Does community consultation mistakenly define social identities as biological categories? An influential criticism of community consultation in genetics research has been that using social identities to evaluate studies that investigate biological categories contributes to the conflation of the social with the biological.⁴² Indeed, using social identities for such purposes may tend to support the idea that racial, ethnic, and other categories are biologically defined. There are two difficulties with this critique. First, social categories can have biological relevance, as when socially labeled populations have differing frequencies of particular alleles. Second, most clinical studies recruit and label participants, and report findings, using social identities—and especially racial and ethnic identities—due both to a history of using those identities to document population-based health disparities and, in the United States, to legal mandates for inclusion of specific racial and ethnic minorities in federally funded studies.⁴³ So long as those practices continue, the collective interests of the social groups involved are appropriate subjects for ethical analysis.

Future Directions

The focus on collective interests of populations and communities targeted by clinical research has benefited from the convergence of several coincident trends: an emerging focus on population-specific patterns of genetic variation, coupled with special funding opportunities for research on ethics in genetics; the increasing involvement of disease-specific advocacy groups in scientific policy and planning; and heightened interest in and funding for community-based, participatory research. This convergence will continue to provide a growing number of opportunities for researchers, ethicists, funders, and community members to innovate standards and processes for community involvement in the planning and oversight of clinical research studies, with special attention to the collective interests of populations targeted for those studies. In addition, the ongoing debate over the relevance of racial and ethnic identities in clinical research and practice will ensure that collective interests continue to be at issue in interactions between researchers and study participants.^{44,45}

It is unlikely, however, that a single standard or process will be established for all populations or all kinds of studies, due mainly to differences in forms of social organization and moral

authority by which different populations construct communities to regulate their shared identities (with greater and lesser degrees of social cohesion). Differences in the cultural frameworks by which collective implications are perceived also make standardization difficult. What is likely, though, is that communities will increasingly expect researchers to demonstrate respect for the moral authority of community-specific social practices and cultural beliefs and to consult members about studies that target them as those protocols are planned and carried out. That expectation will require researchers and ethicists to develop a flexible set of best practices for involving communities in research as well as for evaluating and weighing information about collective interests produced through that involvement.

At the same time, technological advances and emerging health issues may contribute to new kinds of communities based on shared disease status, as happened in the emergence of a community focused on HIV/AIDS, or on shared genetic characteristics, as may happen in the case of those who have lower response rates to specific drugs because of polymorphic variation, and so have shared interests in the development and availability of alternative therapies to which they will respond. Populations defined in these ways have specific collective interests in research that targets their members, but few have social and cultural frameworks for constituting communities with sufficient social cohesion and moral authority to engage with researchers in pursuing those interests. Nonetheless, a variety of disease-based advocacy groups have had a growing influence on research policy and also have been involved in the planning of specific clinical studies and trials. That increasing level of involvement may support the development of greater social cohesion and authority among persons affected by a common disorder.

Future developments in the ethics of collective implications and interests of populations targeted for research will continue to require a combination of conceptual innovation and empirical investigation to better understand and involve the diverse, dynamic social and cultural entities that researchers engage in clinical research studies. It is difficult to imagine an approach to the ethics of research with communities that does not maintain that necessary link between empirical and conceptual activities.

Research With Healthy Volunteers

In the winter of 2005, at a time when fear of a global influenza pandemic galvanized public concern, healthy young people were volunteering to test the safety and efficacy of an experimental vaccine derived from an avian influenza virus.¹ Scientific research with the potential to have a great public health impact thus depends on the willingness of healthy individuals to volunteer the use of their bodies. In addition to testing experimental vaccines, healthy volunteers are needed for early-phase safety testing of pharmaceutical agents, to evaluate the efficacy of various agents to prevent common diseases that cause substantial mortality and morbidity, for a wide range of studies aimed at understanding normal human biology, and as a comparison group for research aimed at understanding the nature of diseases and better ways to treat them.

A healthy volunteer, sometimes historically referred to as a *normal volunteer*, may be a person who appears to be free of any disease or health-compromising condition, or one who may have some health-compromising condition but not the condition under study in the protocol. Healthy volunteer is not synonymous with *control* because in some research, controls are chosen who are not healthy; they may have a disease that is relevant to the study but is not its direct object, for example, a diabetic without heart disease who serves as a control in a study of the cardiac complications of diabetes.

The research ethics literature has little to say about *normal subjects* or *healthy volunteers*. Although the ethics literature and regulations pay attention to special classes of vulnerable subjects, the healthy subject merits little notice, often not even appearing in the indices of books on research ethics. The use of the word *healthy* may suggest that these subjects can take care of themselves and

need little attention or protection. This is an unfortunate misunderstanding. *Healthy* or *normal* may not mean healthy and normal in all respects. Indeed, one institution's research policy statement declares that "[t]here are no federal regulations that address the participation of normal volunteers in research protocols. However, this class of subjects could be considered vulnerable, and special precautions must be taken to ensure that their rights and welfare are adequately protected."² Although healthy subjects should not immediately be considered vulnerable and in need of special precautions, some healthy volunteers may be vulnerable for particular reasons.

The promise of research involving healthy volunteers must be assessed against the perils of such human experimentation, including abusive experiments of the past and the rare but disturbing fatal outcomes of some contemporary research. In a high-profile case that occurred in 2001 at Johns Hopkins University, a healthy volunteer died as the result of receiving a pharmacologic agent administered in a study of the pathophysiology of asthma.³ From an ethical perspective, clinical research with healthy volunteers underscores the fundamental moral concern of human experimentation, namely, that some are exposed to risks and burdens for the sake of benefits to future patients and society. Although this concern applies to all clinical research, it is apt to be obscured in research involving subjects who are also patients, especially clinical trials that evaluate treatments and thus offer participants a prospect of direct medical benefit.⁴ Subjects are prone to confuse clinical trials aimed at developing generalizable knowledge about the treatment of disease with personalized medical care—a phenomenon known as *the therapeutic misconception* (see Chapter 58).

Moreover, the ethics of clinical research may be confused, or conflated, with the ethics of medical care because of failure to recognize the ways in which clinical research necessarily departs from the physician-patient relationship. In medical practice, risks to patients can be justified only by anticipated medical benefits. In clinical research with healthy volunteers, however, research participants are exposed to risks and burdens solely for the benefit of others. Recognizing this fact helps to focus attention on the fundamental challenge posed by the ethics of human investigation. It also helps to reinforce the insight that the relationship between investigators and research participants throughout clinical research is not equivalent to or completely continuous with the doctor-patient relationship in medical care. Finally, despite such terms as *beneficence* and *risk-benefit ratios* that apply appropriately to both medical care and clinical research, research with healthy volunteers demonstrates that this central ethical terminology does not have exactly the same meaning in clinical research as in medical care. Healthy volunteers receive no direct medical benefits from their research participation, and there is comparatively little chance that their participation will have indirect or ancillary health benefits for them.

Historical Background

There is a long history of biomedical and behavioral research in healthy people, some of whom were vulnerable in other respects. In one of the earliest historical references to medical research, the Roman medical writer Celsus reported in the 2nd century that two prominent Egyptian physicians were allowed to perform vivisection on condemned criminals in order to study normal anatomy and observe physical processes in vivo.⁵ In the early 19th century, the American military physician William Beaumont took advantage of a fistula in the stomach of his indentured servant, Alexis St. Martin, to perform experiments to test the acidity of gastric juices.⁶

A major milestone for research with healthy volunteers was the famous yellow fever research led by Walter Reed.^{7,8} At the turn of the 20th century yellow fever was an untreatable, often fatal disease. In order to demonstrate the mode of transmission of yellow fever, healthy volunteers were exposed to mosquitoes in Cuba, where yellow fever was rampant. Most of the recruited volunteers got yellow fever but none died; however, one of Reed's coinvestigators who participated in the experiments died as a result. An ethically important innovation associated with this research was the use of written "contracts" to designate voluntary consent for a potentially life-threatening experiment. This research has been considered heroic, although it is doubtful that research of comparable risk to healthy volunteers would be considered ethically approvable according to current standards (see Chapter 1).

Certain forms of research by their nature require healthy subjects. Inoculation and vaccination must be tested on healthy subjects, for example, because vaccines are intended to prevent the onset of an infectious disease by stimulating a protective immune response. Thus, a vaccine's first use amounts to an experiment to determine whether it is safe and immunity can be achieved. In the early 18th century, Zabdiel Boylston in Boston inoculated his own son and some slaves against smallpox;⁹ and in 1796, Edward Jenner vaccinated an eight-year-old healthy boy, James Phipps, and finally a group of orphan children in preparation for vaccination of the royal children.¹⁰ Children dwelling in

orphanages and asylums were common subjects of vaccine research in the 19th and early 20th centuries. The development of polio vaccines in the 1940s and 1950s required experimental use in thousands of healthy children, and a few children died in these experiments⁸ (see Chapter 5). In this sort of research, the subjects are physiologically healthy but often vulnerable because they are children or institutional residents.

The Nazi medical experiments are important for the ethics of research with healthy participants for two major reasons (see Chapter 2). First, they represent the extreme of human experimentation for the sake of developing biomedical knowledge. Second, the Nuremberg Code was promulgated at the war crime trials of Nazi physician-researchers (see Chapter 12). The Nazi experiments were performed in concentration camps, of course, and did not involve volunteers. But many involved prisoners who were selected as biologically normal humans, rather than as subjects with a disease. These experiments illustrate the potential for the objectifying gaze of science to treat humans as laboratory material—guinea pigs—to be manipulated without concern for their suffering and deliberately killed for the sake of developing biomedical knowledge.

In one of the most brutal experiments, prisoners at Dachau were immersed in a tank of ice water for up to three hours to investigate the body's reactions to hypothermia, with the aim of learning how to save the lives of German pilots forced to parachute into the North Sea. The opening statement of the prosecution at the 1946 Nuremberg Trial quoted a 1942 report of Dr. Sigmund Rascher, who supervised hypothermia experiments:

Electrical measurements gave low temperature readings of 26.4° in the stomach and 26.5° in the rectum. Fatalities occurred only when the brain stem and the back of the head were also chilled. Autopsies of such fatal cases always revealed large amounts of free blood, up to ½ liter, in the cranial cavity. The heart invariably showed extreme dilation of the right chamber. As soon as the temperature reached 28°, the experimental subjects died invariably, despite all attempts at resuscitation.¹¹

Noteworthy is the detached, objective language describing torture and murder in the context of scientific investigation. Hubert Markl, president of the Max Planck Society for the Advancement of Science, aptly observed in a remarkable 2001 address concerning the Nazi experiments: "The guilt for utilizing human beings as laboratory animals can be specifically placed on biomedical science that was robbed of every moral boundary."¹²

The Clinical Center of the National Institutes of Health (NIH), which opened in 1953, admitted patients suffering from particular diseases to serve as subjects in NIH research projects, and also recruited "normal volunteers" to serve as control subjects and subjects of physiological and pharmacological research on their healthy bodies. In the beginning, these normal, healthy volunteers were often employees of the Clinical Center, and during the 1960s also convicts from local prisons. The major pool of healthy volunteers, however, were conscientious objectors from the traditional "peace churches," such as the Mennonites and the Church of the Brethren, who were allowed to fulfill their Selective Service obligations by participating in research. In 1957, an NIH report stated that 173 volunteers had provided 18,329 days of research service: 59% were under 21 years of age and 12% were female. The volunteers received living accommodations and a small sti-

pend (about \$10/month). Soon the need for volunteers outgrew this source and NIH sought recruits from among college students, particularly those in the health sciences.

The NIH program continues to recruit “residents of the local community who respond to advertisements in the media or visit the Clinical Research Volunteer Program office and review information about protocols that need healthy volunteers. A small cadre of healthy clinical research volunteers is available through selected colleges, which permit their students to participate in long-term inpatient studies.”¹³ During 2004, the NIH Clinical Center healthy volunteer program registered 9,926 participants who received a total compensation of \$2 million. Compensation averages \$40 per day for inpatient studies and about \$7 per hour for outpatient studies; allowances for travel and inconvenience are also provided. Some participants are college science students who also were enrolled in preceptorships.¹⁴

The earliest NIH Clinical Center policies distinguished between patients admitted for the study and treatment of their diseases and healthy volunteers. Patients were considered protected by the physicians who cared for them, bound by the traditional duty to seek the benefit of their patients (the fact that these physicians were also investigators and thus susceptible to possible conflict with regard to that duty was not considered problematic). Healthy volunteers, on the other hand, were recognized as unprotected by this traditional medical duty. An explicit policy of requesting them to sign a written consent as research subjects was adopted in the 1950s. This distinction prevailed until the revisions of NIH policy in the mid-1960s made written consent universal.¹⁵

One of the largest groups of healthy subjects participating in U.S. clinical research was inmates in U.S. prisons who were, for many years, recruited into research projects. For example, in the 1950s, the testicles of prison inmates were irradiated to study the effect of X-rays on sperm production. These prisoners were “normal” in that they were healthy adults; they were also volunteers. However, they were also vulnerable subjects because they were susceptible to coercion due to their incarceration. The practice of using prisoners for research greatly expanded in the United States during World War II when prisoners were asked to participate in studies of infectious diseases affecting American troops. These incarcerated volunteers were given public praise but were not granted pardons or shortened sentences as enticement, as often believed. After the war, many pharmaceutical companies set up prison programs for Phase I drug testing. In 1975, a survey reported that 16 of 51 reporting drug companies used incarcerated persons: 3,600 prisoners participated in 100 protocols studying 71 substances.¹⁶ Since the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research’s investigation of research with prisoners in the mid-1970s, federal regulations have limited permissible research involving prisoners.

An example of healthy subjects who appear less vulnerable occurred in the venerable practice of scientists serving as experimental subjects in their own research, as did the yellow fever researchers.¹⁷ From the earliest days of pharmacological research, investigators ingested or injected new drug formulations in their own bodies before inviting others to take them. Cardiac catheterization began in 1929 when Walter Forssmann, then a medical student in Germany, inserted a catheter into his own heart. This practice of “auto-experimentation” was considered ethically proper and recognized in the first major formulation of research ethics.

Provision 5 of the Nuremberg Code states that “No experiment should be conducted where there is an *a priori* reason to believe that death or disabling injury will occur; except, perhaps, in those experiments where the experimental physicians also serve as subjects.”¹⁸ Hans Jonas, in a pioneering essay on the ethics of research, took the position that researchers, who most fully identified with the goal of the research and understood its risks, should be the first to volunteer.¹⁹

In some historical cases, normal, healthy persons have been subjected to research without being volunteers. In the 1950s, offshore Navy ships sprayed *Serratia marcescens* bacteria over San Francisco and thousands of residents unknowingly inhaled it. The purpose was to study the efficacy of such a mode of delivery of biological weapons. Although the bacterium was then thought to be harmless, 11 persons became ill and 1 died. Similar experiments were performed in Florida, Minnesota, and in the New York subways.²⁰ Such research is unquestionably a violation of current standards of research ethics. Nonetheless, this experiment starkly poses a current ethical question: In an era when biological warfare and pandemic infection are real threats, how should large-scale studies be carried out? Ethical problems associated with research on communities of subjects have not been well delineated. Community consent has been proposed but methods of gaining such consent have yet to be perfected, and the validity of community consent may be questioned when risks fall upon individuals. The ethics of research, however, has focused almost exclusively on the autonomy and protection of the individual; the principle of justice, although confirmed as one of the basic principles of research ethics in the Belmont Report, has not been seriously explored as a basis for evaluating such forms of research.

Ethical Guidance

The Nuremberg Code remains a central source of ethical guidance for human investigation, especially for research with healthy participants.¹⁸ The first principle declares that “The voluntary consent of the human subject is absolutely essential.” Few, if any, commentators subscribe to this principle without qualification, as it would rule out all research with children or incapacitated adults, as well as valuable minimal-risk research for which informed consent is impossible to obtain. Yet informed, voluntary research participation in the case of competent adults is the moral norm, and the burden of proof rests on investigators who propose to deviate from this standard.

In addition, the Nuremberg Code requires that proposed research must have potential social value, that “the anticipated results will justify the performance of the experiment,” that appropriate animal experimentation should precede human investigation, that scientifically unnecessary physical and mental suffering and injury should be avoided, that due care should be taken in experimental design and conduct so as “to protect the experimental subject against even remote possibilities of injury, disability, or death,” that subjects should be free to withdraw from research, and that the responsible investigator must stop the experiment if there is reason to believe that a participant is likely to experience injury, disability, or death. Accordingly, the Nuremberg Code is the source of much of the basic ethical guidance for subsequent codes and regulations, such as the requirements to minimize risks, justify risks by the social value of the anticipated

knowledge from research, obtain informed consent, and protect subjects from undue risks of harm during the course of research. The Nuremberg Code differs from some other prominent ethical guidance, such as the Declaration of Helsinki and the U.S. federal regulations, by placing an upper limit on allowable risks: “No experiment should be conducted where there is an *a priori* reason to believe that death or disabling injury will occur.”¹⁸ This principle will be examined below. An important omission in the Nuremberg Code, in view of subsequent developments, is the absence of any requirement for prior review and approval by an independent ethics committee.

Although the Declaration of Helsinki is primarily concerned with research conducted by physician-investigators with patient-subjects, it contains a few provisions specifically concerning research with healthy participants.²¹ It stipulates that special attention is required “for those who will not benefit personally from the research,” but explicitly states that medical research involving healthy volunteers should not be precluded. After declaring that “Medical research involving human subjects should only be conducted if the importance of the objective outweighs the inherent risks and burdens to the subjects,” the Declaration of Helsinki observes that “This is especially important when the human subjects are healthy volunteers.”²¹ Presumably, this derives from the fact that healthy volunteers, unlike many patient-subjects enrolled in clinical trials, have no prospect of direct benefit to their health from participation in medical research. These various statements in the Declaration of Helsinki suggest that research with healthy volunteers is inherently a matter of ethical concern, though vital to the progress of biomedical knowledge. The Declaration relaxes the highly restrictive first principle of the Nuremberg Code by allowing research on children, including healthy children (and incompetent adults), provided that there is informed consent for these subjects from “the legally authorized representative.” It also stipulates prior review and approval by an independent committee, which also should have the authority to monitor ongoing research to protect subjects.

The U.S. federal regulations refer throughout to human subjects, without stipulating any requirements for healthy volunteers as distinct from patient-subjects.²² There are, however, special provisions for research involving prisoners and for children, among whom are included healthy participants. The regulations governing research with children allow institutional review boards (IRBs) to approve research involving healthy children only if it poses minimal risks. In contrast, children who are patient-subjects can be enrolled in greater than minimal risk research if it holds out a prospect of direct benefit to them (subject to additional constraints). Furthermore, children with a medical disorder or condition can be exposed to research interventions that pose “a minor increase over minimal risk.” Whether this differential risk-benefit standard for healthy children and those who are patient-subjects is ethically defensible is open to question. As mentioned above, the federal regulations do not stipulate any limitations for allowable risk for adult subjects. Rather, they state that IRBs must determine that “Risks to subjects are reasonable in relation to anticipated benefits, if any, to subjects, and the importance of the knowledge that may reasonably be expected to result.”²² As there are no anticipated benefits for healthy participants, in principle, any level of risk might be justified so long as risks are minimized “consistent with sound research design”—that is, they are no greater than necessary to provide a scientifically valid answer to the

research question—and they are judged by an IRB to be reasonable with respect to the knowledge to be gained from the research.

A risk threshold for research with healthy participants was adopted in a 1986 report of the Royal College of Physicians of London, which stated that “a risk greater than minimal is not acceptable in a healthy volunteer study.”²³ The report defined *minimal risk* as including the following two types of situations: “The first is where there is a small chance of a recognized reaction which is itself trivial, e.g., a headache or feeling of lethargy. The second is where there is a very remote chance of a serious disability or death.”²³ The first situation relating to discomfort produced by research procedures is unduly restrictive, as it would appear to prohibit a considerable range of valuable research with healthy volunteers such as Phase I toxicity studies and challenge experiments.

Ethical Issues in Research With Healthy Volunteers

Research with healthy volunteers is subject to the same ethical requirements as all clinical research. However, the nature of and history of research with healthy volunteers suggest that particular emphasis should be given to risk-benefit assessment, especially the evaluation of acceptable risks, and to fair selection of subjects.

Risk-Benefit Assessment

Satisfying the key ethical requirement for a favorable risk-benefit ratio in a study enrolling healthy participants involves the sequential steps of identifying the risks posed by research interventions, minimizing these risks, and judging that the potential benefits of the research to society justify the risks. The identification of risks involves three domains of assessment: probability, magnitude, and duration of harm. Accordingly, three questions must be addressed in assessing the level of risk posed by a study. First, what is the chance or probability that the research interventions will produce various harms to the health or well-being of participants? Second, how serious is the potential harm from study interventions? Third, how long is the potential harm expected to last if it occurs, and is it treatable or reversible? Risk assessment includes consideration of temporary discomfort or distress associated with research interventions as well as lasting physical harm.

Data on Adverse Events

Little systematic data are available concerning the extent of adverse events in research with healthy volunteers. A 1998 study of adverse events in Phase I drug studies of healthy volunteers in a single center in France over a 10-year period reported data on 1,015 healthy volunteers.²⁴ The incidence of adverse events, defined as the ratio between the number of adverse events and the number of days of follow-up, was 12.8% (1,558/12,143). Ninety-seven percent of these adverse events were rated as “of minor intensity,” and 3% as “severe.” Out of the 43 severe adverse events, nine were rated as “worrying,” requiring hospitalization in two cases. A recent similar single-center study of Phase I drug testing in Germany, involving 1,559 healthy participants over 29,664 follow-up days, found an incidence of adverse events (defined in the same way as the previous study) of 8.8%.²⁵ Nearly all of these

(99.2%) were rated as of mild or moderate intensity, and only six were rated as severe.

Given that Phase I studies aim to determine the maximum tolerated dose of new pharmacologic agents, adverse events are expected. However, these data suggest that, on the whole, this common method of research with healthy volunteers is safe. Nevertheless, serious adverse events do occasionally occur, and the authors of the French report noted that a review of the extant literature revealed case reports of four deaths of healthy volunteers in Phase I research and five life-threatening events.²³

Minimizing Risks

The requirement to minimize the risks of research involving healthy volunteers does not mean that these risks must be “minimal.” Risks must be minimized within the context of designing and conducting valuable and rigorous clinical research. Accordingly, minimizing risks requires an inherently comparative assessment. A proposed research plan should be evaluated in the light of alternative ways to provide a rigorous answer to the scientific question that pose less risk to subjects. If the question can be answered by an alternative study design with lower risk to subjects or without including a procedure that carries significant risks to subjects, then this alternative should be adopted and/or the unnecessary procedure omitted.

Multiple dimensions of the design and conduct of clinical research are relevant to the requirement to minimize risk. Exclusion criteria for eligible participants should rule out those who can be predicted to be at increased risk from research interventions. Experimental procedures posing higher risks of physical harm or serious discomfort need to be carefully scrutinized to judge whether they are necessary to produce valuable data. Investigators must thoroughly review the literature to determine if drugs or procedures proposed for use in research have been associated with serious adverse events and take steps to obviate or minimize such risks. Failure of due diligence in reviewing the literature on the safety of research interventions was a major factor contributing to the death of a healthy volunteer in the Johns Hopkins asthma experiment.³ Alternative, less risky ways to test study hypotheses should be explored. For example, imaging studies without the use of ionizing radiation, such as MRI, are preferable to those that use radiation, such as PET scans, provided that data of adequate quality can be obtained. When radiation use is scientifically necessary, the lowest dose needed to test research hypotheses should be administered. Finally, to minimize risks, careful procedures must be in place to monitor the condition of research participants and to intervene to counteract adverse events. Investigators should be prepared to end the study participation for particular subjects or terminate the study to protect subject safety.

Screening of Volunteers

Medical screening of prospective healthy participants is important both to assure the scientific validity of research and to protect subjects. Healthy volunteers are often recruited for studies as a comparison group to patients diagnosed with a given disease or condition. If prospective healthy subjects are not normal with respect to the medical conditions under investigation, then the data derived from studying these subjects may be invalid or biased. However, it is not necessary, or feasible, for healthy volunteers to be free of any medical condition. The point of screening for sci-

entific validity is to assure that volunteers do not have conditions that would confound the research.

Screening is also essential to minimize the risks of harm to participants. Volunteers who present themselves as healthy may upon medical examination turn out to have evidence of a condition that would put them at excessive risk of harm from the research procedures used in a given study. Many studies recruiting healthy participants may enroll repeat volunteers, who participate in research as a source of income.²⁶ Whereas the risk of harm from participating in a single study may be minor, risks might be of greater concern for individuals who have repeatedly volunteered for research. For example, when studies include procedures involving radiation, the cumulative exposure of prospective subjects to radiation in previous research participation needs to be assessed.

Does the Importance of the Knowledge Justify the Risks?

After identifying the risks posed by a proposed study and taking care to minimize risks, the final step of risk-benefit assessment is to determine whether the potential benefits of the knowledge to be gained justify the risks to subjects. A difficult and unsettled issue of risk-benefit assessment is whether there exists an upper threshold on allowable risk for research involving healthy volunteers.²⁷ As the risks from proposed studies increase, the value of the potential knowledge needed to justify these risks certainly must also increase. Are some studies too risky to conduct no matter how much potential benefit in clinically relevant knowledge they offer? Neither the U.S. federal regulations nor the Declaration of Helsinki place any definite limits on the risks to which research participants can be exposed. In contrast, the Nuremberg Code stipulates, “No experiment should be conducted where there is an *a priori* reason to believe that death or disabling injury will occur; except, perhaps, in those experiments where the experimental physicians also serve as subjects.”¹⁸ The Nuremberg Code does not make clear what antecedent probability of death or disabling injury from a research intervention should rule out a study enrolling healthy volunteers. For some research procedures, such as an exercise stress test, there is a known but very remote risk of death.

In view of the risks that people routinely take in daily life, including activities aimed to help others, it seems unreasonable to exclude research procedures with an extremely low risk of death, especially when adequate precautions are taken to minimize risks. On the other hand, it is not clear that higher risk research that would not otherwise be justifiable might be approvable on the condition that investigators also participate as subjects. (This possible exception for research involving self-experimentation was included in the Nuremberg Code with an eye to Walter Reed’s famous yellow fever research.²⁸)

The inherent uncertainty of research deserves attention in considering the issue of stipulating limits to research risks in the case of healthy participants. The social value of a research protocol depends crucially on the ability of the proposed investigation to provide a compelling answer to the research question, and also on the actual answer provided. Both “positive” findings confirming study hypotheses and “negative” findings that affirm the null hypothesis are scientifically and socially valuable. However, a positive finding that demonstrates a breakthrough in the understanding, treatment, or prevention of disease will obviously have

greater social value than a negative finding that runs contrary to the study hypotheses. Because the answer is unknowable in advance of research, the value of the knowledge that will be generated by a study is uncertain. Moreover, on the whole, any given research study is likely to provide at best an incremental increase in biomedical knowledge. When research procedures pose risks of death, serious injury, or disability that are known to have more than a remote or very small chance of occurring, it is difficult to see how they can be justified by the uncertain prospects of benefit from the knowledge to be gained.

It might be objected that it is unjustifiably paternalistic to preclude informed, altruistic, healthy volunteers from knowingly risking their health or life for the sake of highly important medical research. The justifiability of paternalism is a complex issue in moral philosophy. Yet it is not clear that affirming an upper limit on allowable risk is necessarily taking a paternalistic stance. At stake ethically in this issue are both the professional integrity of conscientious scientific investigators, who must take responsibility for the anticipated consequences of their research, and the integrity of biomedical research. Public trust, necessary for the conduct of biomedical research, may erode if healthy volunteers are sacrificed, even with their informed consent, for the sake of science. All things considered, placing a heavy burden of proof on the conduct of high-risk research involving healthy volunteers seems reasonable.

How, then, in the final analysis, can it be determined whether the potential value of knowledge to be gained from a given study can justify the risk posed to research subjects? There are no formulas available. The assessment calls for carefully considered and deliberated judgments by research sponsors, investigators, and IRBs.

Fair Subject Selection

Healthy subjects selected for research participation may also be members of a vulnerable population or perceived as particularly vulnerable to undue influence or exploitation. These include the economically disadvantaged, prisoners, employees of research institutions, and students. Ethical concerns about recruiting members of such groups generally center on the voluntariness of their participation and fair distribution of the burdens and benefits of research. But there is controversy over the propriety of designating any particular population as vulnerable. For example, employees and students may be quite intelligent and competent, and they may have a wide range of choices. At the same time, they may be subject to certain sorts of discrimination, influences, and sanctions arising from a dependent relationship. The extent to which these considerations actually relocate a subject from normal to vulnerable is often a matter of discretion rather than generalization.

People volunteer as research subjects for many reasons. Some may be highly altruistic individuals who are motivated only to help unknown others. Some may be interested in particular diseases because they have a family member or friend who is afflicted. Some may be motivated by fascination with research or by offers of compensation. Although a few studies have examined volunteer motivations, relatively little is known about who healthy volunteers are, how many there are, or why they volunteer. Advertisements inviting health professional students to participate can be found on the bulletin boards of medical, dental, and nursing

schools, and many research projects post notices on web sites. Increasingly, attractive invitations appear in newspaper, magazine, radio, and television ads. IRBs customarily scan such advertisements but many may escape scrutiny. Large research institutions may have a pool of persons who show up regularly as volunteers, and in some places there are small cadres of “professional” research volunteers who make their living by participating in research studies.

Beauchamp and colleagues have presented a detailed ethical analysis of research involving one of the most vulnerable groups of healthy volunteers, namely, homeless individuals recruited for Phase I pharmaceutical research.²⁹ They argue that categorical exclusion of the homeless would be unjust discrimination and would unfairly deny them an opportunity to earn appropriate monetary compensation from participation. However, to avoid exploitation, according to these authors, the homeless should not be targeted for such research; nor should they be disproportionately represented among research participants. With respect to payment, Beauchamp and colleagues contend that “The key is to strike a balance between a rate of payment high enough that it does not exploit subjects by underpayment and low enough that it does not create an irresistible inducement.”²⁹

Whether scientists and others invested in the research should be allowed to take risks in auto-experimentation that affect only themselves is another relevant question. First, although it can be supposed that these subjects are, as Jonas says, the most informed and the most committed, they may also be the most indiscreet. Their enthusiasm for their project may entice them to take risks that are beyond what is reasonable. Rash decisions leading to disastrous results for the investigator might constitute harm to others because the event could cast research in a bad light or lead to compromise or even abandonment of a promising line of research. An IRB might, on these grounds, prohibit the researcher from taking highly risky steps. Walter Reed’s scientific colleagues and Werner Forssmann might object that taking these risky steps in a free, informed manner is precisely what has advanced science and benefited health. A corollary of this problem is the possibility that auto-experimentation, particularly when highly risky, may entice the investigator to biased interpretation of the data and thus taint the experiment. Auto-experimentation, although noble in intent, deserves careful scrutiny by prudent consultants and review bodies.

Community volunteers do not have the same investment and understanding of the research as do investigators. Their generosity in offering themselves should be matched by particularly careful protection from risks as discussed above, and by informed consent.

Informed Consent

On the whole, there is less ethical concern about the quality of informed consent in the case of healthy volunteers than with patient-subjects, who may harbor therapeutic misconceptions that lead them to confuse research participation with standard medical care. Additionally, healthy volunteers do not suffer from potential impairments in cognition and judgment associated with being ill, which can complicate or make impossible informed consent. However, in higher-risk research, it may be desirable to institute formal measures to test the comprehension of healthy volunteers

with respect to the risks and discomforts associated with research interventions.

One issue related to informed consent of healthy participants, which is widely considered to raise ethical concern, is payment for participation. When, if ever, does the level of payment for research participation constitute “undue inducement,” particularly for those who are economically disadvantaged? The major concern is that participants may discount the risks and discomforts of study participation because of their need for money (see Chapter 36).

Conclusion

Research with healthy volunteers is a necessary component of biomedical research. It evokes ethical concern especially because healthy volunteers face risks of discomfort and physical harm but have no prospect of benefiting directly from research participation. Accordingly, as in all clinical research, careful attention to risk-benefit assessment is ethically required to conduct research with healthy volunteers. Members of the public owe a debt of gratitude to healthy volunteers, and to patient-subjects, for contributing to medical progress.

Research With Fetuses, Embryos, and Stem Cells

Biomedical research involving the human embryo or fetus raises a host of ethical questions. Because the embryo or fetus cannot consent to be a research subject, who is morally entitled to authorize research involving it? The fetus has a unique relationship to the mother, and their interests can sometimes conflict. How should these different claims be balanced? Intensifying all these questions are sharp disagreements over the moral status of the embryo and the fetus, raising the question of whether either really has any claims on us. All these questions make embryo and fetal research one of the most controversial topics in biomedicine today.

Following a definitional preface, this chapter begins by examining the array of issues surrounding fetal research. For a variety of reasons, there is greater consensus about the norms governing this area of research than any other. Next, the chapter turns to human embryo research, which has been a topic of controversy for 25 years. More recently, controversy about embryo research has been intensified by the progress of human embryonic stem cell and therapeutic cloning research. This will be treated as a separate arena of moral and legal debate. As each issue is discussed, the leading moral debates will be placed against a background of existing laws and regulations both in the United States and elsewhere.

Definitions

For scientific purposes, *embryo* is usually defined as the product of conception until eight weeks gestation. From that point onward, the term *fetus* is used. However, these definitions are not pertinent to the major legal and ethical debates about research. For example,

the U.S. regulations governing fetal research define *fetus*, at 45 CFR 46.203(c), as “the product of conception from the time of implantation . . . until a determination is made, following expulsion or extraction of the fetus, that it is viable.”¹ Because implantation occurs in vivo at about five to six days of gestational age, this identifies as a fetus what science describes as an embryo. In ethical terms, there is an important distinction between entities produced by in vitro fertilization (or flushed from a uterus following natural fertilization) and which exist in vitro, and those that have implanted in a womb, in which research necessarily implicates the gestational mother. For this reason, following Tauer and others,^{2,3} this chapter will define the *embryo* as “the product of conception (whether produced in vitro or flushed from a uterus) as it exists in the laboratory and that has not undergone transfer to a woman” (see Figure 46.1). The *fetus*, accordingly, is “the product of conception existing in a womb” and comprises both in vivo embryos and fetuses. These definitions bypass the question of the organism’s developmental stage. However, because it is not possible to culture an embryo in vitro for more than five or six days, a limit not likely to be exceeded soon, the term *embryo* as used here describes the early product of conception—that is, a mass of largely undifferentiated cells with no body form or organs—whereas the term *fetus* usually refers to a more developed entity undergoing organogenesis and possessing an incipient nervous system. In debates about embryo research, the terms *preembryo* or *preimplantation embryo* have been used for the ex utero embryo. This chapter will use the more general term *embryo* for this entity.

These definitions leave some issues unresolved. What are we to make of the phrase *product of conception* in an era when it is possible, by means of somatic cell nuclear transfer (cloning)

Figure 46.1. Human Embryo. Colored scanning electron micrograph (SEM) of a human embryo at the 10-cell stage on the tip of a pin. The ball of cells of the embryo is known as a *morula*, a cluster of almost identical, rounded cells each containing a central nucleus. This 10-cell embryo is about three days old. It is at the early stage of transformation from a single cell to a human composed of millions of cells. The cells multiply by repeated cleavage divisions (mitosis) and will form a hollow ball of cells (the blastocyst). Development of the blastocyst occurs before the embryo implants into the wall of the uterus (womb). Magnification: $\times 130$ at 6×7 cm size. Magnification: $\times 450$ at 8×10 inch size. technology, to produce organisms that are capable of developing to birth and adulthood without fertilization having occurred? Although no human being has yet been produced in this way, the possibility cannot be ruled out. Are the human cell clusters that result from cloning *embryos*?⁴ Should they be accorded the same moral protections given to sexually produced embryos? Another question is how we should regard parthenotes, human eggs that have been induced by electrical or chemical means to cleave and develop *in vitro*. Because human parthenotes lack the paternal imprinting needed for the proper development of placental tissues, it is unlikely that they could ever develop to birth even if transferred to a womb. Nevertheless, both primate and human parthenotes have been cultured *in vitro* up to the blastocyst stage.^{5,6} Should we regard parthenotes as merely sex cells, like sperm or eggs that do not merit protection as research subjects, or should they be accorded the same ethical consideration as embryos or fetuses? The Dickey-Wicker amendment to the Balanced Budget Downpayment Act of 1996, an annual appropriation measure repassed each year since 1996 by the U.S. Congress, forbids

federal funding for any research that destroys an embryo. It further defines *embryo* as “any organism . . . that is derived by fertilization, parthenogenesis, cloning, or any other means from one or more human gametes.”⁷ Adopting this expansive definition for moral and legal analysis would have the effect of blocking many research and clinical directions.

At what point should an embryo be regarded as coming into being? Although many people speak of the *moment of conception*, it is now well known that conception/fertilization is not a discrete event but a process that takes places over many hours or days.⁸ Beginning with the transmission and reception of chemical signals between egg and sperm while they are still apart, it progresses to sperm penetration of the outer layers of the egg; the migration of male and female pronuclei to the egg’s center; syngamy (the lining up of the pronuclei in their complementary configuration at about 22 hours after sperm penetration); cleavage (which does not occur until at least 24 hours after sperm penetration); and, finally, the appearance at the two-cell stage of the first cells with a normal envelope around their nuclear material. Further complicating matters is the fact that continued development is entirely governed by oocyte genes until the six- to eight-cell stage, approximately two days after penetration of the egg by sperm. Only then does the paternal genetic component begin to influence development.

Thus, there are at least several candidate *events* that might be used to mark conception/fertilization. The choice among them determines whether the organism is an embryo or a sex cell and can significantly alter our moral and legal conclusions with regard to specific research protocols. For example, regulations in the State of Victoria in Australia define fertilization as occurring at syngamy,⁹ whereas British regulations hold that fertilization is complete at the appearance of “a two cell zygote.”³ Although slightly different, both of these definitions open the door to significant studies on the development of the early embryo as well as the efficacy of some contraceptive measures. A definition of *fertilization* that stressed “sperm penetration of the egg” would be even more limiting.

This chapter will not try to resolve these issues, other than to say that, for definitional purposes, we should probably be guided by reasonable intuitions. Thus, entities having approximately the same viability and developmental potential as sexually produced embryos should be regarded as embryos for ethical and legal purposes. This would bring cloned human organisms under the rubric of human embryo research, whereas it would exclude both parthenotes and pluripotent stem cells from the definition of *embryo*. As far as the commencement of the embryo is concerned, jurisdictions that have looked closely at the issue tend to regard syngamy as the earliest point at which a novel organism can be said to exist.

Research on the Human Fetus

Although our abortion debates reveal that there are sharp disagreements in our society about the moral status of the fetus, several considerations have muted these disagreements when fetal research is concerned and have tended to produce more consensus about ethical and regulatory matters than is true for embryo research. One is the more advanced developmental stage of the fetus, including the presence of bodily form, a heartbeat, and early neural development (with the possibility of sentience). Another

is the possibility that the fetus might go on to term. This brings it under similar protections afforded to children who are born. Finally, the presence of the fetus in the mother's body accentuates the willingness to extend protections to it because research-related harms can implicate the mother's life, health, and decisional freedom.

Three distinct research areas come under the heading of fetal research: (1) direct research on the fetus itself; (2) research directed toward pregnant women or the condition of pregnancy, for which the fetus is an indirect subject of research; and (3) fetal tissue transplantation research. For each of these research areas, existing U.S. regulations identify the major moral issues involved and, with one or two exceptions, also reflect the international moral consensus on these issues.¹⁰

Direct Research on the Fetus

When research on the fetus itself is concerned, current U.S. federal regulations, at 45 CFR 46.208, governing federally funded or conducted research and FDA-regulated drug research distinguish between research directed at the health needs of a particular fetus and research not directed to the health needs of the fetus.¹ In the former case, institutional review boards (IRBs) may approve a protocol if the fetus will be placed at risk only to the minimum extent necessary to meet such needs. An example is research on a new technique for fetal transfusion for Rh incompatibility. When the health needs of the fetus are not at issue, however, research is permitted if the risk to the fetus imposed by the research is minimal and the purpose of the activity is the development of important biomedical knowledge that cannot be obtained by other means.¹ As in pediatric and other research with humans, the U.S. federal regulations define *minimal risk* at 45 CFR 46.102 to mean that "the probability and magnitude of harm or discomfort anticipated in the research are not greater in and of themselves than those ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests."¹ Examples of minimal risk research might include studies of minor changes in maternal diet (daily life) or the use of ultrasonography (routine tests).

The U.S. standard for research on the fetus in utero is somewhat stricter than that which applies to research on children. Regulations permit research on children that represents no prospect of direct benefit to individuals and a minor increase over minimal risk if, according to 45 CFR 46.406(c), the intervention or procedure is likely to yield "generalizable knowledge about the subjects' disorder or condition which is of vital importance for the understanding or amelioration of the subjects' disorder or condition."¹ However, when research on the fetus is concerned, there is no such permission for a minor increase over minimal risk unless the mother's health is at issue. Not all nations hold to this strict standard, which partially reflects heated U.S. debates over abortion and the moral status of the fetus. Finland, for example, broadly permits research on the fetus not directly to its benefit if the research "is likely to benefit the health of people related to the woman or the foetus" (Finnish legislation does not clarify the meaning of the word *related* here).³ Because the Dickey-Wicker amendment extends the same protections to embryos, as defined by that legislation, as it does to fetuses, this very high level of protection also applies to federally funded in vitro research on embryos, parthenotes, and cloned organisms.

United States regulations, and those of most other nations, do not distinguish between a fetus destined for abortion and one intended to be carried to term. At first sight, it might seem reasonable to permit some degree of increased risk when the termination of the pregnancy is in prospect and when useful research can be done. An example is an experiment to see whether a teratogenic agent passes through the placenta. However, endangering the fetus in such cases will either limit a woman's freedom to change her mind about abortion or result in harm to the child if she should choose to continue the pregnancy to term. The unacceptability of either of these alternatives commends a standard of similar treatment of all fetuses. It is important to note, however, that once this standard has been met, nothing prevents preferential use of fetuses intended for abortion when minimal risk research is concerned.

Direct research can also take place on the fetus ex utero following a spontaneous or induced abortion. A viable fetus is treated by existing U.S. regulations as a premature infant and comes under the protections of regulations governing research on children. The fetus is judged to be viable, according to 45 CFR 46.203(d), if it is able to survive (given the benefit of available medical therapy) to the point of independently maintaining heartbeat and respiration.¹ In general, a fetus that has not attained a gestational age of 20 weeks and does not exceed 500g in weight is judged to be nonviable.¹¹ Independent medical assessment of nonviability is required when these limits are exceeded. A nonviable fetus may be involved in research only when (1) its vital functions are not artificially maintained; (2) experimental activities that of themselves would terminate its heartbeat or respiration are not employed; and (3) the purpose of the activity is the development of important biomedical knowledge that cannot be obtained by other means. According to 45 CFR 46.209, until it is ascertained whether or not a fetus ex utero is viable, it may not be involved in research unless (1) there will be no added risk to the fetus resulting from the activity, and the purpose of the activity is the development of important biomedical knowledge that cannot be obtained by other means; or (2) the purpose of the activity is to enhance the possibility of survival of the particular fetus to the point of viability.¹

Because fetuses normally have male and female progenitors, the question arises as to whose consent is required for such research. The need for the mother's consent is evident and is recognized in all jurisdictions. Perhaps reflecting our debates on maternal-paternal consent for abortion, in the United States the father, as coprogenitor, is also required to consent. However, U.S. federal regulations at 45 CFR 46.208(b) and 209(d) permit exceptions to this rule if the father's identity or whereabouts cannot reasonably be ascertained, if he is not reasonably available, or if the pregnancy resulted from rape.¹

The Fetus as an Indirect Subject of Research

Research directed at women who are pregnant necessarily implicates the fetus. At 45 CFR 46.207, the U.S. federal regulations specify that no pregnant woman may be involved in research unless either (1) the purpose of the activity is to meet the health needs of the mother, and the fetus will be placed at risk only to the minimum extent necessary to meet such needs, or (2) the risk to the fetus is minimal.¹ In such cases, research may proceed only if the mother and father are legally competent and have given their

informed consent. The father's consent is not required, however, if the purpose of the research is to meet the health needs of the mother or if the three exceptions to paternal consent mentioned in connection with research directed at the fetus apply.

Regulatory protections also apply to nonpregnant women of childbearing age. The regulations codified at 45 CFR 116(b)(1) require that, when appropriate as part of the informed consent process, women be provided "a statement that the particular treatment or procedure may involve risks to the subject (or to the embryo or fetus, if the subject is or may become pregnant) which are currently unforeseeable."¹¹

These regulations raise several ethical questions. Research whose primary purpose is to meet "the health needs of the mother" requires a determination of whether a procedure, drug, or dosage level imposes risk on the fetus "only to the minimum extent necessary." Because some procedures, drugs, or dosage levels may enhance maternal outcomes while increasing fetal risk, this can create a dilemma for investigators and IRBs, putting them in a situation of having to weigh the mother's welfare against that of the fetus. The very existence of this requirement raises a larger question of whether investigators or IRBs are the appropriate makers of this decision. Some would ask why the mother should not have sole authority to determine the degree of risk to which both she and her fetus may be exposed. Once again, U.S. abortion debates may have shaped the outlines of current laws.

Some have also asked whether the fetal-protective nature of current regulations does not evidence inherent discrimination and injustice toward women. It has been pointed out that some substances have the potential to affect the genetic components of sperm and, through this, the health of any resulting child. Yet current regulations do not require investigators and IRBs to balance the health needs of fertile men involved in research against possible risks to their offspring.¹² It is also pointed out that current regulations have had the broad effect of reducing the amount of research done on women of childbearing age, preventing this group as a whole from benefiting from that research.¹³

Fetal Tissue Transplantation Research

The curative potential of fetal tissue was recognized as early as 1928 when fetal tissue was first transplanted into patients suffering from diabetes. More recently, fetal neural tissue has been used, with mixed results, in the treatment of Parkinson's disease and other neurological disorders as well as other conditions.¹⁴ During the 1980s there was substantial controversy about the ethical permissibility of fetal tissue transplantation (FTT) research. Concerns focused on a possible linkage between this research and abortion. Abortion opponents feared that the prospect of FTT might serve as inducement for women to terminate pregnancies. This could occur if women were able to designate donors of the tissue or if women or abortion providers benefited financially or otherwise from donation. Debate centered on whether it is possible to remove these incentives and render consent to FTT research independent of the abortion decision. It should be noted that fetal tissue donation for research purposes, when no prospect of transplantation is involved, remains uncontroversial. Under most existing regulatory regimes, once a fetus is dead, its cells, tissues, organs or placental material may normally be used in research with the consent of the mother.

In the United States, the first Bush administration established the Human Fetal Tissue Transplantation Research Panel in 1988 to examine this issue. A majority of the panel concluded that federal funding of FTT research under strict guidelines is "acceptable public policy."¹⁵ However, the Bush administration did not accept this recommendation, and federal funding of FTT was prohibited until 1993, when President Bill Clinton, in one of his first acts of office, issued an executive order permitting it. Congress later passed this order into law in the provisions of the National Institutes of Health (NIH) Revitalization Act of 1993.¹⁶

Over the past decade, a strong international consensus has emerged about some of the central conditions for good clinical practice regarding FTT. These include the following: (1) The decision to abort should not be influenced by the prospect of tissue transplantation; among other things, this means fetal tissue donors should not be permitted to designate tissue recipients. (2) Commercialization is not acceptable; neither donors nor clinicians should profit from the provision of fetal tissue. (3) Tissue may only be obtained from dead embryos or fetuses. (4) Informed consent should be obtained. (5) The decision to terminate the pregnancy must be made before consent for donating fetal tissue is solicited. And (6) experimental studies should be approved by a qualified ethics committee.¹⁷

Within this broad consensus, some important debates continue over details of implementation. One question is whether it is either necessary or desirable for there to be an intermediary organization between the woman donor and the clinical research team utilizing fetal tissue.¹⁸ The worry here is that if clinical researchers become involved in the woman's care, they can experience a conflict of interest between their responsibilities to her and their research goals. Another question concerns the timing of the donation decision. After a woman has decided to terminate a pregnancy, should she be asked to consent to tissue donation before undergoing the abortion, or should this request be postponed until after the abortion has been completed? Postponing the request until after an abortion helps ensure that the prospect of donating fetal tissue doesn't make the decision to abort more likely, but it presents the decision to the woman at a time when her reflective capacity may be impaired by the recent medical procedure or the use of anesthesia. A third question is whether FTT—if proved effective—should be exceptional, used only in the rarest of cases when alternatives are demonstrably unacceptable, or whether it should be developed for widespread use, including the possible creation of an extensive network of fetal tissue providers. This question is complicated by the fact that some alternatives to FTT, such as stem cell technologies, are only in the beginning phases of research, whereas other more developed alternatives, such as xenotransplants, pose considerable risks of their own, including the introduction of animal pathogens into the human population.

There are voices that entirely reject this international consensus. The Roman Catholic Church continues to oppose FTT research. In August 2000, Pope John Paul II told an International Congress of the Transplantation Society that the manipulation and destruction of nascent human life with a view to obtaining tissues or organs for transplantation is morally unacceptable.¹⁷ In the Netherlands, the Lindeboom Institute, a conservative Protestant biomedical ethics organization, has argued that the *separation principle*, the idea that the decision to abort and the decision to donate fetal tissue can be compartmentalized, is a fiction. The institute argues that the mere knowledge that fetal material can be

used for transplantation purposes could influence the decision of a woman who is trying to determine whether she will or will not continue a pregnancy.¹⁷ Nevertheless, in the United States it appears that the restrictions put into effect by the NIH Revitalization Act of 1993 have eased fears even among many abortion opponents. One sign of this is the fact that although President George W. Bush questioned any use of tissues from aborted fetuses in transplantation research shortly after coming to office,¹⁹ his administration has taken no further action to change the law permitting federal funding of this research.

Relevant provisions of the NIH Revitalization Act of 1993 evidence the struggle between the opposing sides of the U.S. abortion debate.¹⁶ On the one hand, the provisions reflect many features of the international consensus permitting FTT research. A woman donating human fetal tissue must sign a statement declaring that the tissue is being donated for therapeutic transplantation research, the donation is being made without any restriction regarding the identity of individuals who may be the recipients of transplanted tissue, and without her having been informed of the identity of those individuals who may be the recipients. The attending physician must sign a statement declaring that the tissue has been obtained in accord with the donor's signed statement and that full disclosure has been made to her of the attending physician's interest, if any, in the research to be conducted with the tissue. Other provisions of the act declare it unlawful for anyone to solicit, acquire, receive or transfer human fetal tissue for "valuable consideration" or as the result of a promise to the donating individual that the tissue will be transplanted into a recipient specified by such individual or a relative of the donating individual.

On the other hand, some provisions of the act represent concessions to antiabortion sentiment in the United States. The attending physician's statement must declare that no alteration of the timing, method, or procedures used to terminate the pregnancy was made solely for the purposes of obtaining the tissue. This provision is not present in some other national regulations governing fetal tissue transplantation. Another provision requires the disclosure to all downstream researchers or tissue recipients that the tissue is from an aborted fetus. The assumption here is that such individuals have the right to learn about the source of the tissue and to decline its use. If we consider that fetal tissue obtained from abortions has been used without comment in biomedical research for decades, as in the development of vaccines for rubella, rabies, and polio,²⁰ we can see that the increasing polarization around the abortion issue has shaped U.S. law and policy on FTT research.

Human Embryo Research

Despite the heated nature of current debates about the use of human embryos in biomedical research and therapy, the ex utero human embryo did not emerge as a subject of research until the late 1970s. Some preliminary work on fertilizing human eggs ex utero had been done in the mid-1940s by Rock and Menkin,²¹ but public debate about embryo research began in earnest in 1978 with the birth in Oldham and General District Hospital in the north of England of Louise Brown, the world's first "test tube" baby. For the first time in history, human embryos could be created outside the womb, cultured, studied during their earliest

phases of growth, and then returned to the womb for gestation and birth. Not only did the development of in vitro fertilization (IVF) make the early ex utero embryo a possible research "subject," but the rapid growth of infertility medicine created a demand for more successful and less risky infertility treatments. This intensified the demand for embryo research.²²

In 1975, the U.S. Congress created an ethics advisory board (EAB) in the Department of Health, Education, and Welfare (now the Department of Health and Human Services) to recommend and apply guidelines for federally funded research in this area. The EAB took up its work in 1978 and after months of study, discussions, and public hearings, issued a report in May 1979 recommending support for a broad range of research using human embryos.²³ The report made no distinction between embryos created for research purposes and embryos remaining from infertility treatments. In endorsing the deliberate fertilization of eggs for research purposes, the EAB acknowledged a practice that had been employed by Edwards and Steptoe and others in the early development of IVF.²⁴ These pioneering researchers believed that in creating artificial reproductive technologies, it is scientifically and morally imperative to create and study embryos for research before transferring them to a womb.

The EAB's deliberations and its report stirred enormous controversy, including letter writing campaigns by conservative religious groups, and no action was ever taken on the report. When the EAB's charter expired in 1980, its membership was not renewed and no funding was provided. Because U.S. law required that any research in this area supported by the NIH or other federal agencies be reviewed by the EAB, the result was a de facto moratorium on federal support for embryo research during the administrations of Presidents Ronald Reagan and George H. W. Bush. Research continued, however, in the private sector.

In the United Kingdom, events took a different turn. A commission chaired by Dame Mary Warnock issued a report in 1984 recommending government permission and support for IVF and embryo research.²⁵ This resulted in the creation of a voluntary licensing authority that oversaw infertility clinics and IVF research projects in the United Kingdom. In 1990, Parliament passed the Human Fertilisation and Embryology Act.²⁶ This led the following year to the establishment of the Human Fertilisation and Embryology Authority (HFEA), an official government agency brought into being to provide oversight and guidance for clinical and research programs in infertility medicine. In its current activities, the HFEA oversees and licenses all clinical infertility programs in the United Kingdom as well as research on human embryos. British regulations are the most comprehensive concerning embryo research and among the most permissive in the world. Embryo research is permitted for a wide variety of reasons, including the following: to promote advances in the treatment of infertility; to increase knowledge about the causes of congenital disease and miscarriages; to develop more effective techniques of contraception and methods for detecting the presence of gene or chromosome abnormalities in embryos before implantation; to increase knowledge about the development of embryos; and to increase knowledge about serious disease or to enable such knowledge to be applied in the development of treatments to combat serious disease.²⁷ In the pursuit of these goals, British regulations permit the creation of embryos for research purposes and, more recently, cloned embryos for therapeutic cloning research. During this same period, Australian researchers were also able to conduct some

embryo research using a feature of Australian regulations that permitted research before the occurrence of syngamy.²

In June 1993, the NIH Revitalization Act nullified the requirement for EAB approval of federal funding for infertility and embryo research projects. The NIH was free to respond to the backlog of research proposals it had received. Before approving any of them, however, NIH administrators felt they needed guidelines to instruct members of IRBs. These developments led to formation of the Human Embryo Research Panel, a 19-member multidisciplinary group that issued a report in late 1994 recommending a substantial program of federal support for human embryo research and establishing guidelines for the conduct of that research.²⁸ The most controversial of these was a recommendation for the deliberate creation of embryos for research purposes under specified circumstances.

Within hours of the acceptance of the Human Embryo Research Panel's report by the advisory committee to the director of the NIH, President Clinton issued an executive order rejecting this recommendation. Events soon prevented implementation of any of the other recommendations. Over the next two years, a newly elected conservative Congress sought to reverse most Clinton administration reproductive health initiatives. In this vein, Congress passed the Dickey-Wicker Amendment, raising to the level of law what had been a de facto ban on federal funding for human embryo research before the onset of the Clinton administration and extending the ban to research on parthenotes and embryos produced by cloning. Thus, although extensive manipulations of human embryos and the introduction of new clinical therapies have gone on in hundreds of private clinics in the United States over the last quarter of a century, human embryo research has not been funded by federal research agencies. Nor have there been federal regulations or ethical oversight of such research. This is in contrast to Great Britain, where the HFEA code of practice applies to both public and private research. In 2004, the President's Council on Bioethics, an entity created by the administration of George W. Bush, considered recommending increased federal regulation of infertility medicine generally. However, because Bush himself was on record as opposing embryo research, patient-advocate groups and clinicians who believe that federal regulations could lead to increased restrictions on clinical activities did not greet this idea favorably, and in its final report the Council backed away from recommending significant legal restrictions.²⁹

The prolonged absence of federal support for human embryo research in the United States, a country with approximately 400 infertility programs, the largest of any nation, has had many unfortunate consequences. It has slowed progress in our understanding of the causes of birth defects and miscarriages. The relegation of research to privately funded clinics lacking sufficient resources for large or multicenter studies has contributed to the inefficiency and high cost of IVF.³⁰ Because of the reliance on stimulatory drugs for ovulation induction, thousands of women are exposed to medications whose long-term impacts on health remain uncertain.^{31,32} The absence of research and federal oversight has also led to the introduction of new procedures, such as intracytoplasmic sperm injection (ICSI), without sufficient preliminary studies of their long-term safety for the children brought into being by them.^{33,34} Inefficient procedures already play a large role in the epidemic of premature births associated with current infertility treatments.³⁵

Behind the heated political debates that have stalled federal involvement in this area are major moral disagreements. The prin-

cipal matter of controversy concerns the moral status of the early human embryo. Unlike fetal research, in which the welfare of women and the children to which they might give birth complicates matters, embryo research unavoidably poses the question of how much protection we should give to nascent human life. In these debates, two main positions have emerged. The first, strongly associated with the views of conservative religious groups, holds that human life deserves full moral protection from conception onward. This places the earliest embryo on a plane of equality with children and adults and rules out embryo research that is not medically to the benefit of the embryo under study. It forbids the deliberate creation and destruction of embryos for research purposes, and it also tends to oppose the creation of supernumerary embryos in infertility medicine to increase the chances of a pregnancy.^{36,37}

Some who hold this view maintain that the genome represents a defining feature of the human being, the possession of which justifies according an entity the strictest protections.³⁶ Others draw less on the matter of genetic identity and stress the potential of human life even at the earliest stage of development as a sufficient reason to extend full moral protection.³⁸ Still others argue that there is no better "marker point" for human protections than conception. To choose later developmental events, they say, opens the way to making subjective judgments that put all human beings at risk.³⁹ Discussions by Roman Catholic moral theorists and statements by Roman Catholic leaders, which have been influential in shaping U.S. and European policy, incorporate elements of all of these views. Although the Catholic Church has not yet taken a formal position on when an individual human life begins, it insists that because of the possibility that an individual human soul may be present from conception, the embryo must be treated from that time as a human being meriting all protections.⁴⁰

Opposing this position is a range of views that can be termed *gradualist* or *developmental*. These take various forms. Some stress the moral importance of qualities like sentience, brain activity, the presence of substantial bodily form, or the ability to survive independently of the mother (viability). Still others emphasize not one but a plurality of considerations that, taken together, compel us to extend protections.^{28,41} What all of these views have in common is the conclusion that the moral weight of the embryo or fetus is not established once and for all, but increases over the course of a pregnancy as additional morally significant features make their appearance. Those holding these views may disagree about the precise protections that should be afforded at each stage, but they tend to agree that the early embryo has reduced moral status. Lacking differentiated cells and organs, bodily form, sentience, or cerebral activity, it has few of the features that elicit moral regard. Most who hold this view are willing to permit significant embryo research, including research that destroys the embryo, up to 14 days of development. At about this time, the "primitive streak" appears amidst the undifferentiated cells of the embryo's inner cell mass. This establishes the cranial-caudal (head-to-tail) and left-right body axes. In the following week gastrulation occurs, with the emergence of three discreet germ layers or tissue types, and formation of the neural tube begins. Because morally significant developmental events cannot be ruled out beyond the 14-day point, this has become the focus of an international consensus among those who support embryo research as the point beyond which research should not be allowed.

For those holding this position, other qualities of the embryo call into question any characterization of it as a protectable human individual. One is the early embryo's very high natural mortality. Although estimates differ, it is likely that at least 50% of all conceptuses stop growing within the first few days of development and pass, often unnoticed, out of the woman's body.^{42,43} This high rate of natural mortality limits the force of claims about the embryo's developmental potential. Also noteworthy is the early embryo's unusual genetic character. Each of the blastomeres, or cells that compose the embryo, is totipotent (capable of giving rise to an entire organism). In some experiments this characteristic has been exploited to produce multiple embryos by dividing a single embryo and providing an artificial protective coating to replace the natural zona pellucida.⁴⁴ When this phenomenon occurs naturally in vivo it leads to the birth of monozygotic (identical) twins or triplets. This raises the question of whether the early embryo is not better described as a *community* of organisms rather than as a single individual. It sometimes also happens that two genetically distinct early embryos fuse. Because intracellular signaling drives body formation, the result is a single individual possessing cell populations from two distinct genetic lineages. Recent clinical reports describe such chimeric individuals.^{45,46} All these possibilities run counter to the claims of those who maintain that personal identity overlaps with genomic identity and that the human individual begins at conception. They also pose significant metaphysical difficulties for religious views that assert the presence of a "human soul" at conception.⁴⁷⁻⁴⁹ For if the start of spiritual individuality (ensoulment) occurs at this time, how can we explain the later appearance of souls in twinning or the disappearance of souls in embryo fusion? The uncertainty of the embryo's genetic uniqueness strengthens the view of those who emphasize the moral importance of the formation of the primitive streak at about 14 days development. Only then, with cellular differentiation rendering twinning or embryo fusion no longer possible, can we speak of the presence of a discrete individual organism.

These two opposing views on the status of the early embryo account for much, but not all, of the disagreement over the permissibility of human embryo research. In addition, some commentators believe that although the early embryo may not have features that render it an object of moral concern, abusing or destroying it can nevertheless threaten our respect for more mature forms of human life. Those holding this view stress the importance of the embryo as a symbol of human vulnerability and worth. This position has played a role in debates about the moral appropriateness of creating embryos for research purposes only.⁵⁰ Some opponents of such research have asked whether the deliberate creation of an embryo for use in research, followed by its destruction before the 14-day limit, violates at least the spirit of the Kantian maxim that individuals are not to be used as a "means only" for the betterment of others. Others fear the development of a vast commercial market in which human embryos are created, distributed, and used for morally trivial purposes, such as the testing of cosmetic products.^{51,52} Such uses, they maintain, would reduce our respect for human life. Still others are prepared to allow the deliberate creation of supernumerary embryos for the purposes of establishing a pregnancy, but oppose doing so for research purposes. In the former case, they argue, the parents' reproductive intent sufficiently outweighs any negative symbolic implications.⁵³

Many who share the view that the embryo has little intrinsic weight are not persuaded by these arguments. The NIH Human Embryo Research Panel took the view that "although the preimplantation human embryo warrants serious moral consideration as a developing form of human life, it does not have the same moral status as an infant or child."²⁸ On this basis, the panel endorsed the creation of embryos for research when two conditions were met: (1) "when the research by its very nature cannot otherwise be validly conducted"; and (2) "when a compelling case can be made that this is necessary for the validity of a study that is potentially of outstanding scientific and therapeutic value."²⁸ An example of the former is research whose endpoint is fertilization, such as studies of in vitro oocyte maturation followed by fertilization. Such research could lead to far safer fertility procedures and would greatly expand the supply of human eggs for clinical and research purposes. Examples of the latter are studies of the effects of powerful ovulation-inducing drugs on eggs and embryos in order to better establish the risks for the women exposed to, or the children produced by, the administration of these drugs. Although one member of the panel dissented from this recommendation, the others did not agree that symbolic concerns outweighed the possibility of clear therapeutic benefit. It has been noted that many couples using infertility procedures routinely create more embryos than can be transferred to a womb. As a result, approximately 400,000 frozen embryos now exist in the United States.⁵⁴ To those who remain unpersuaded by the symbolic arguments, it is not clear why such activities for reproductive purposes are acceptable, whereas life- and health-preserving biomedical research is not.⁵⁵

The creation of embryos for research purposes remains one of the most controversial issues in human embryo research. The Human Embryo Research Panel's recommendation for federal funding of such research was never implemented. In Europe in 1996, following a lengthy process of deliberation, the Council of Europe approved a "Convention for the Protection of Human Rights and the Dignity of the Human Being" (see Chapter 17). Article 18.2 of this convention prohibits the creation of embryos for research purposes.⁵⁶ However, Britain has not ratified this convention and provisions of the Human Fertilisation and Embryology Act, as noted, permit the creation of embryos in vitro for research purposes.²³

Whenever human embryo research is permitted or contemplated, questions arise regarding its conduct. These include questions about the norms governing gamete and embryo donation. In general, there is a consensus that all progenitors of reproductive materials used in embryo research must consent to its use and be informed of the specific purposes of a research program. This creates difficulties in the use of some embryos created by anonymous sperm donation and has occasioned debate about whether such embryos may ever be used.²⁴ It also raises the question of whether it is permissible to use in research oocytes harvested from aborted fetuses or oocytes that are procured from women after their death and that have been donated (without the woman's explicit consent) by family members. Although such donations of other bodily tissues are routine in many research areas, the sensitive nature of reproductive materials, and the fact that they can involve a new human life, justify adhering to the strictest standards of informed consent by donors. The selling of gametes or embryos is also normally prohibited, although compensation of women for the time and inconvenience involved in egg donation is sometimes allowed.⁵⁷ Finally, there is a strong

presumption against the creation of human-animal chimeras or the transfer of human embryos to animal wombs for incubation.

New technological developments can sometimes challenge these guidelines. For example, how are we to assess the use of nuclear transfer with animal oocytes and human nuclear DNA to produce embryonic stem cells?⁵⁸ Although this runs counter to the view that it is wrong to create animal-human chimeras, the possible efficiency of this procedure and the promise that it may reduce the need for human eggs makes it scientifically and ethically attractive.

Stem Cells and Therapeutic Cloning

In its 1994 report, the Human Embryo Research Panel took note of the fact that it might be possible in the future to develop human embryonic stem cell (hESC) lines. These cells are undifferentiated, pluripotent (able to produce any cell or tissue type in the body), and theoretically capable of proliferating indefinitely in culture (self-renewing). Once techniques for growing and redifferentiating such cells are developed, stem cell lines may be used to replace damaged cardiac tissue following a heart attack, or repair now irreversible spinal cord injuries. Parkinson's disease and diabetes are on the long list of conditions that might be cured by the ability to produce new bodily tissues. Basing its discussion on information available from over a decade of mouse stem cell research, the Human Embryo Research Panel supported permitting the use of embryos remaining from infertility procedures ("spare" embryos) for the purpose of creating hESC lines. However, because of the remoteness of this prospect in 1994, it did not recommend the deliberate creation of embryos for this purpose.

Just four years later, in 1998, hESC research became a reality when James Thomson of the University of Wisconsin published a report documenting the creation of several hESC lines from donated spare embryos.⁵⁹ At almost the same time, a Johns Hopkins team headed by John Gearhart reported development of a human embryonic germ cell (hEG) line derived from the gonadal tissues of aborted fetuses.⁶⁰ Neither Thomson nor Gearhart relied on federal funding for the research. Concerned that he might run afoul of the prohibition of federal funding for embryo research, Thomson set up a separate laboratory to keep his work apart from other, federally funded activities at the university. Although Gearhart's work was legally eligible for federal funding under provisions of the NIH Revitalization Act that permit fetal tissue transplantation research, his team chose to use private funding rather than dealing with sensitive NIH administrators.

These developments once again moved human embryo research to the forefront of ethical and political debate. Supporters of human embryonic stem cell research maintain that it holds out enormous medical promise.^{61,62} Opponents argue that it is morally offensive and that "adult" stem cells, the somewhat differentiated progenitor cells that reside in all our bodies and that furnish replacement blood, bone, skin or other tissues, might be able to accomplish these purposes without requiring the use of human embryos.⁶³ In reply, defenders of hESC research point to the biological limitations of adult stem cells, including their absence in many tissues and their uncertain plasticity or proliferative ability.⁶⁴ These limitations, defenders of hESC research maintain, justify keeping both lines of inquiry open and providing generous federal support for continued research on both cell types. Ongoing studies

support the claim that adult stem cells may have therapeutic potential but also show that many questions regarding their plasticity and proliferative ability remain unanswered.^{65,66}

In December 1999, the NIH issued draft guidelines specifying the conditions and restrictions under which it would support research using hESCs. These guidelines rested on an NIH-solicited legal opinion that hESCs are not themselves "embryos" within the meaning of the Dickey-Wicker amendment, and that research "utilizing" but not deriving them from human embryos did not constitute research violating Dickey-Wicker's ban on "research in which a human embryo or embryos are destroyed." This use-versus-derivation distinction was subject to criticism by both friends and opponents of federally funded stem cell research. In September 1999, the Clinton-era National Bioethics Advisory Commission (NBAC) issued a report, "Ethical Issues in Human Stem Cell Research," that chose not to rely on the NIH's use-versus-derivation distinction. Instead, the NBAC recommended that Congress pass an exception to existing legislation that would allow both the derivation and use of stem cells from embryos remaining after infertility treatments.⁶¹

Following a period of public comment, the NIH proposed roughly similar guidelines on August 25, 2000.⁶⁷ These guidelines embodied the prohibition in Clinton's December 1994 intervention against any research using embryos that are deliberately created for research purposes. They specified that research on stem cells derived from embryos could be conducted "only if the cells were derived (without federal funds) from human embryos that were created for the purposes of fertility treatment and were in excess of the clinical need of the individuals seeking such treatment." In addition they adapted to this issue the logic of existing fetal tissue transplantation regulations. They specified that "no inducements, monetary or otherwise, [may be] offered for the donation of human embryos for research purposes." Research had to maintain "a clear separation between the decision to create embryos for fertility treatment and the decision to donate human embryos in excess of clinical need for research purposes to derive pluripotent stem cells." To ensure this separation, and to provide time for decision, only frozen embryos could be used as a stem cell source. Researchers or investigators proposing to derive or utilize human embryonic stem cells in research were to have no role in securing spare embryos for the research, and the attending physician for fertility treatment and the researcher were not to be one and the same person. The NIH guidelines would have permitted payment for cell lines using federal funding so long as payment did "not exceed the reasonable costs associated with the transportation, processing, preservation, quality control and storage of the stem cells." As is true for fetal tissue for transplantation, the NIH guidelines would have required that donation of human embryos be made "without any restriction or direction regarding the individual(s) who may be the recipients of transplantation of the cells derived from the embryo." Consent for such research would have to include statements acknowledging these restrictions and informing donors that donated embryos would not survive the human stem cell derivation process and would in no case be transferred to a woman's uterus.

Despite the considerable thought that went into the NIH guidelines, they never went into effect (although features of the donor consent portions of the guidelines have been incorporated in recent regulations).⁶⁸ During the 2000 election campaign, candidate George W. Bush spoke out against human embryo and

hESC research. Following his election, it was widely anticipated that he would bar federal support for this research and perhaps try to extend this ban to research in the private sector. However, following months of lobbying by patient advocacy and biotechnology groups, on August 9, 2001, the president announced a more moderate position in a prime time televised statement. Federal funds would be made available for research using hESC lines that had been brought into being before that date. Justifying his decision, the president described these lines as those on which “the life and death decision has already been made.”⁶⁹

In the period since this announcement, NIH support for embryo research has moved at a slow pace. Although the NIH initially stated that there were at least 60 lines in existence that would qualify for funding, nearly five years later, in the winter of 2006, only 22 lines had been sufficiently characterized and freed of ownership restrictions to be made available for use by federally funded researchers.⁶⁸ Recent studies have also confirmed that all the lines authorized for NIH-funded research were contaminated with mouse molecules that were likely to cause rejection or disease if the cells were used in human transplantation.⁷⁰ Outside the United States, in countries like Sweden, Israel, and Great Britain, in which embryo research is less restricted, the development and banking of hESC lines have proceeded more rapidly.⁷¹

Further intensifying these U.S. debates is the emergence of private sector and overseas research on therapeutic cloning.^{72,73} This employs somatic cell nuclear transfer technology to produce an embryo for stem cell purposes. In this procedure, a body cell (somatic cell) is taken from one individual and is inserted into an egg from which the nucleus has been removed. Following electrical or chemical stimulation, this reconstructed *nuclear transfer unit* begins to divide and develop as would a fertilized egg. Instead of being transferred to a womb, as in the case of reproductive cloning, the resulting embryo is disaggregated to make a pluripotent and immortalized hESC line.⁷⁴ The donor of the somatic cell used in this process can then receive a transplant of these tissues. Because most of the DNA in these tissues is from the somatic cell donor, they would presumably be genetically compatible, avoiding the problem of tissue rejection that is present in the use of immunologically unrelated hESC tissues. Because this research involves the creation and destruction of what Dickey-Wicker defines as an *embryo*, it is ineligible for federal funding. However, following a favorable report by Britain’s Chief Medical Officer’s Expert Group⁷⁵ and the intervention of Parliament, such research is now permitted in Great Britain. In 2004 and 2005, Korean researchers, led by veterinarian Woo Suk Hwang, reported dramatic advances in therapeutic cloning research, but these reports were later attributed to fraudulent data. This episode caused considerable distress in the stem cell and therapeutic cloning research communities.^{76,77}

Those who defend this research emphasize not only possible medical benefits but also its contribution to our understanding of the process of the genetic reprogramming of cells. In the words of the British Expert Group report, therapeutic cloning may prove to be “transitional research” that will be replaced, as knowledge grows, by the reprogramming of adult cells and the direct production of replacement tissues from an individual’s own cells.⁷⁵

Opponents of this research raise many objections. They see it as involving the same issues as the deliberate creation and destruction of human embryos. They believe that the application of

nuclear transfer technologies to human cells will hasten the day when someone will attempt reproductive cloning, which they regard as inherently offensive. Based on these objections, bills were introduced in the U.S. Congress and Senate to ban all forms of cloning research in both the private and public sectors. Although the House of Representatives passed such legislation twice, by 2006 the Senate had not followed suit. One consequence of this was that bills that would ban only reproductive cloning, and for which there was much wider support, were sidelined. The same has happened at the international level. Despite opposition by Great Britain and some other traditional European supporters, the Bush administration repeatedly sought to have the U.N. General Assembly ban all types of cloning research.⁷⁸ In March 2005, the U.N. approved a “Declaration on Human Cloning” that urged member states to ban all forms of cloning, including therapeutic cloning.⁷⁹

If we ask why U.S. conservatives invested so much energy and political capital in this issue, we are returned to the issue of human embryo research. Although opposition to cloning plays some role here, a review of the wording of bills to ban therapeutic cloning supports the conclusion that they very much represent an effort to embody in legislation the view that human life is sacred from conception onward. For example, a bill introduced in the New Hampshire legislature to ban all forms of cloning contains the statement, “all human embryos are simultaneously human beings.”⁸⁰

Benefiting From Evil

The preceding discussion reveals the sharp moral debates and political controversies that have been provoked by research involving the human embryo and fetus. It is unlikely that these debates will end anytime soon. It is also unlikely that fetal and embryo research, including stem cell and therapeutic cloning research, will be stopped. By 2006, California and several other U.S. states authorized and, in some cases, provided funding for both stem cell and therapeutic cloning research.⁸¹ Even if opponents of this research prevail in some political jurisdictions, research will go on elsewhere, as it has already begun to do.^{82,83} If that research is successful in producing stem cell lines or similar materials derived from human embryos or fetuses, clinical researchers and patients who oppose embryo research will have to answer a difficult moral question: When, if ever, is it permissible to derive benefit from the fruits of morally objectionable activities? Can a devout Roman Catholic neurologist, who believes that abortion is morally evil, participate in research that uses fetal tissues to alleviate symptoms in Parkinson’s patients? Can the parents of a diabetic child who believe that life begins at conception ethically consent to the use of pancreatic cells developed from embryonic stem cells?

In the past, the question of benefiting from evil has been addressed somewhat indirectly in Roman Catholic moral theology under the heading “cooperation with evil.”⁸⁴ It has also arisen previously in bioethics in connection with the utilization of the findings of Nazi biomedical research^{85,86} (see Chapter 2). But it is likely to grow more common if fetal and embryo research yield valuable tissues and medical therapies. That we sometimes regard it as permissible to benefit from deeds we morally oppose is il-

lustrated by the stem cell debate. Although President Bush was criticized by some of his conservative supporters for authorizing the use of existing stem cell lines, many others defended his decision as a legitimate effort to derive some good from a bad situation. Germany's Law for the Protection of Embryos makes it a criminal offense to injure or destroy embryos in research. Nevertheless, on January 1, 2002, the German Bundestag passed a law permitting the use of stem cell lines created outside Germany before that date.⁸⁷ These recommendations show that even those holding very conservative positions on the issue of embryo destruction are sometimes prepared to accept benefit from practices they oppose. Throughout the course of the stem cell debate, many individuals otherwise uncomfortable with the destruction of embryos for research purposes were prepared to go beyond President Bush's position and permit the creation of some new hESC lines from spare embryos. They reasoned that because these embryos were unquestionably slated for destruction, it would be better if they could be used to treat disease rather than merely being discarded.⁸⁸

Benefiting from evil normally strikes us as wrong for at least several important reasons. One is an emotional aversion to being associated with evil deeds. This aversion is highly subjective. What repels one individual—for example, the use of data from unethical research—may not bother another. A second consideration is more objective and amenable to reasoned assessment. This is the concern that profiting from wrongful deeds will encourage their repetition in the future. This can occur when wrongdoers are rewarded (through payments or other valuable concessions) by those they benefit. This consideration partly explains laws that criminalize the receipt of stolen property. Or it can occur, even if the wrongdoer is not rewarded, when the acceptance of benefit somehow legitimizes the kind of conduct at issue. This may explain our discomfort about the use of Nazi research data. In doing so, we send to all researchers the unfortunate message that even heinous research can be partly redeemed through its value.⁸⁹

If this brief analysis is correct, researchers, clinicians, and patients who oppose fetal tissue and stem cell research will not necessarily have to forswear use of tissues derived from that research. However, to conscientiously use these materials, they will have to provide convincing negative answers to the following questions: Will my use of these materials directly reward those who produce them? Will it in any way legitimize these activities and encourage their repetition? Am I morally compromised in my own and others' eyes by my association with activities to which I object? Those asking these questions will have to give careful attention to the actual causal connections between willingness to benefit and the possible encouragement of wrongful deeds. In some cases, even a modest willingness to benefit may subtly legitimize and thereby encourage wrongdoing (as conservative critics of President Bush's stem cell policy contend). In other cases, despite first appearances, a willingness to benefit may have surprisingly little connection with encouragement. Some who defend the use of spare embryos for stem cell research point out that the many thousands of frozen embryos will almost certainly be destroyed. Nothing that clinicians or patients do with regard to the use of tissues derived from these embryos will change that. Hence, they conclude, it cannot reasonably be said that the downstream use of cells derived from such embryos actually encourages embryo destruction.⁸⁹

Conclusion

In retrospect, we can see that the moral issue of "benefiting from evil" has been a central theme in much ethical and policy discussion of fetal and embryo research. The earliest debates over fetal tissue transplantation (FTT) revolved around the question of whether regulations could be elaborated that would prevent FTT from becoming an encouragement to abortion. Working in the context of Dickey-Wicker's legal prohibition of funding for embryo destruction, the NIH sought to find a way of avoiding federal involvement in embryo destruction while facilitating the downstream use of cells derived from embryos in its August 25, 2000, guidelines on pluripotent embryonic stem cells. Even President George W. Bush's permission for some forms of research on previously destroyed embryos represents a moral position-taking on the question of what might or might not encourage the further destruction of nascent life.⁸ Ongoing debates over the use of spare embryos versus those created for research are also partly driven by a concern to avoid direct involvement in morally controversial behavior.

The importance of this theme reveals how intractable the debates are over fetal and embryo research. Although bioethicists (the present author included) cherish the hope that more penetrating reasoning can resolve some of the vexing questions of moral status that fuel these debates, it is unlikely that the disagreements will soon go away. They are rooted in well-developed moral perspectives and deeply held religious views.

Progress in these debates will be slow. It will occur, in part, as a result of scientific or medical advances. For example, research that demonstrates the value of hESC therapies will certainly influence public opinion. Conversely, if adult stem cells demonstrate their value, appeals to use embryonic or fetal tissues may grow less urgent. Progress in resolving our disagreements will also require careful thinking about strategies for accommodating widely different perspectives. The distinction between active involvement in deeds one opposes and allowable benefiting from those deeds is one such strategy. It affords more flexible responses to controversial biomedical developments by making it possible for individuals to modulate their response. There is also room for new thinking about how to draw the line between strongly held personal moral convictions and appropriate public policy. If we cannot reach consensus on our moral conclusions about controversial research, perhaps we can agree on when those conclusions need not be embodied in laws or regulations. The separation of personal morality from public policy is a timeworn, but often overlooked solution to unbridgeable moral divisions.

Risk-Benefit Assessments

This page intentionally left blank

Risk-Benefit Analysis and the Net Risks Test

The goal of clinical research is to develop scientific knowledge that can guide the improvement of medical care for future patients. A central concern in research ethics is to protect participants from exploitation in the course of this socially valuable activity. To avoid exploitation, the risks to which research participants are exposed must be reasonable in relation to anticipated benefits.¹ This requirement raises a host of difficult questions. Must the potential clinical benefits to participants outweigh the risks they face? Or is it ethically acceptable to expose participants to some risks for the benefit of society? Assuming it is ethical to expose participants to some risks for the benefit of society, are there limits on the level of these risks? And if there are such limits, to what extent do they vary depending upon the participants in question, whether they can consent or not, whether they are children or not?

Developing answers to these questions is critical to protecting research participants from exploitation. In addition, implementing the answers in practice requires a method by which institutional review boards (IRBs) can assess the risks of research participation. For example, many guidelines allow individuals who are unable to consent to be enrolled in research that does not offer them the potential for clinical benefit provided the risks are minimal or, in some cases, a minor increase over minimal risk. To implement this safeguard, IRBs need a way to determine when research offers the potential for clinical benefit and to what extent the risks of research participation exceed its potential for clinical benefit. Unfortunately, as the U.S. National Bioethics Advisory Commission (NBAC) notes, “current regulations do not further elaborate how risks and potential benefits are to be assessed, and little additional guidance is available to IRBs.”²

The NBAC, as well as numerous commentators, endorses what we will call “dual-track” risk assessment.^{2–5} Dual-track assessment stipulates that IRBs should evaluate research risks using the widely accepted *components analysis*. That is, IRBs should evaluate the risks and benefits of individual interventions or procedures included in a research study, rather than simply conducting an overall risk/benefit assessment of the entire study. The distinctive feature of dual-track assessment is that it divides research interventions into two different categories with different risk standards, based on the distinction between therapeutic and nontherapeutic interventions. However, no clear definition exists for this distinction, and the use of different ethical standards appears unjustified. As a result, dual-track assessment provides IRBs with confusing guidance and has the potential to block valuable research that poses acceptable risks. Once it is recognized that the ethics of clinical research differ fundamentally from the ethics of medical care, the rationale for dual-track assessment is undermined.

Other guidelines, including the U.S. federal regulations for pediatric research, rely on the distinction between interventions that offer participants a *prospect of direct benefit* and those that do not. This distinction avoids the serious shortcomings of reliance on the distinction between therapeutic and nontherapeutic research. Unfortunately, this distinction also conflates research and clinical care, raising the need for a more appropriate method for assessing the risks of clinical research in particular. This chapter describes one alternative, the *net risks* test, and argues that this test offers a better approach for protecting research participants from excessive risks while allowing appropriate research.

Background

The research studies in which individuals participate often include a number of different interventions and procedures. To assess the risks of research participation, IRBs need a method for assessing the risks of these procedures and interventions. In particular, IRBs must assess each intervention or procedure to ensure that the risks to participants are not excessive and are justified by either the prospect of clinical benefits to the participants or by the social value of the knowledge to be gained from the research.

To consider one example, guidelines for clinical research must protect individuals who are unable to provide informed consent. One possibility, exemplified by the Nuremberg Code's stipulation that informed consent is "essential" to ethical research, would be to exclude these individuals from all research.⁶ However, this approach would block important research that needs to enroll individuals who cannot consent, including some research on dementia and severe psychiatric disorders, as well as emergency research and research with children.⁷ This approach would also prevent individuals from participating in research that may benefit them and research that poses only minimal risk.

Recent guidelines attempt to avoid these shortcomings, yet still protect individuals who cannot consent by allowing them to participate in clinical research provided additional safeguards are in place. In particular, most guidelines allow these individuals to be enrolled in research that does not offer the potential for clinical benefit when the risks are sufficiently low.^{4,8–16} To implement this safeguard, and to protect individuals who cannot consent from excessive risks, IRBs need a way to distinguish between research interventions that offer participants a compensating potential for clinical benefit from those that do not offer such potential for benefit.

To assess the risks of research interventions, IRBs cannot simply assess the absolute risk level posed by each intervention. Even serious risks may be ethically acceptable when the research intervention offers participants a compensating potential for clinical benefit. For example, many Phase III treatments pose serious risks to participants. Yet such risks seem *prima facie* acceptable when there is persuasive evidence that the experimental treatment offers a compensating potential for clinical benefit. The risks of a purely research biopsy, in contrast, are ethically worrisome because the intervention does not offer participants a compensating potential for clinical benefit. This difference suggests IRBs need a method that allows them to assess whether the risks of undergoing a given research intervention exceed its potential for clinical benefit. For simplicity, we refer to the risks of undergoing an intervention that exceed its potential for clinical benefit as the *net risks* of undergoing that intervention.

IRBs should begin to assess the risk-benefit profile of research interventions by first ensuring that there is good reason to include the intervention in the study in question. Unnecessary interventions should be eliminated at this point in the review process. IRBs should then enhance the benefits of the intervention and minimize its risks, consistent with sound research design. For example, investigators can eliminate initial screening procedures, such as blood draws, scans, or biopsies, when the necessary information can be obtained by consulting the results of procedures the participants have recently undergone as part of their standard medical care. Similarly, the benefits of a research intervention might be enhanced by providing research participants with results of the intervention that are relevant to their clinical care. Once it has been

determined that there is good reason to include a given intervention, and the benefits of the intervention have been enhanced and its risks reduced, IRBs need a method for assessing the acceptability of the risks of the intervention.

There is no regulatory consensus regarding whether there should be a limit on the net research risks to which competent adults may be exposed. The U.S. federal regulations, for example, do not mandate any such limits. Hence, in principle at least, competent adults may be exposed to serious net research risks as long as the societal value of the knowledge to be gained justifies the risks to which they are exposed. A noteworthy exception is the fifth requirement from the Nuremberg Code, which prohibits research when there is "a prior reason to believe that death or disabling injury will occur."⁶ We are not aware of any data that reveals whether IRBs ever allow competent adults to be exposed to very serious net risks for the benefit of society. In our experience, IRBs tend to be very reluctant to allow even competent adults to be exposed to substantially more than minor net risks for the benefit of society.

Research regulations around the world agree that individuals who are unable to provide their own informed consent should be enrolled in research only when the net risks are "minimal" or, at most, a "minor increase" over minimal. Here again, the Nuremberg Code is a noteworthy exception, stating that research participants' informed consent is "essential" to ethical research, seeming to imply that it is unacceptable to enroll in any research individuals who are unable to provide informed consent.

Many regulations define *minimal* risks based on the risks of daily life. Using this standard, for example, children may be exposed to research interventions or procedures only when the net risks are no greater than the risks children face in daily life.

Dual-Track Assessment

To assess the risks of research interventions and procedures, some commentators and guidelines direct IRBs to place the interventions into two different categories, typically labeled *therapeutic* and *nontherapeutic* interventions (see Figure 47.1). Proponents of this approach sometimes call it *components analysis*. In the present chapter, we reserve this term for the widely accepted approach of evaluating the risks of the individual interventions and procedures that make up a given study. This approach is designed to ensure that the risks of one intervention in a given study are not justified by the potential clinical benefits offered by another intervention in the same study. That is, this method is intended to address what has been called the "fallacy of the package deal."

Components analysis understood in this sense does not offer a particular, substantive method for assessing the risks of the individual interventions and procedures. It does not say, for example, that IRBs should evaluate all the interventions using the same ethical standard, or whether IRBs should first divide the interventions into categories and then use different standards for evaluating the risks posed by the interventions in those categories. The method under consideration in the present section, endorsed by NBAC and other groups, does prescribe such a method. It directs IRBs to divide research interventions into two different categories and then apply different standards to the two categories. Given that the distinctive feature of this method is the recommendation that IRBs divide research interventions into two categories, we will refer

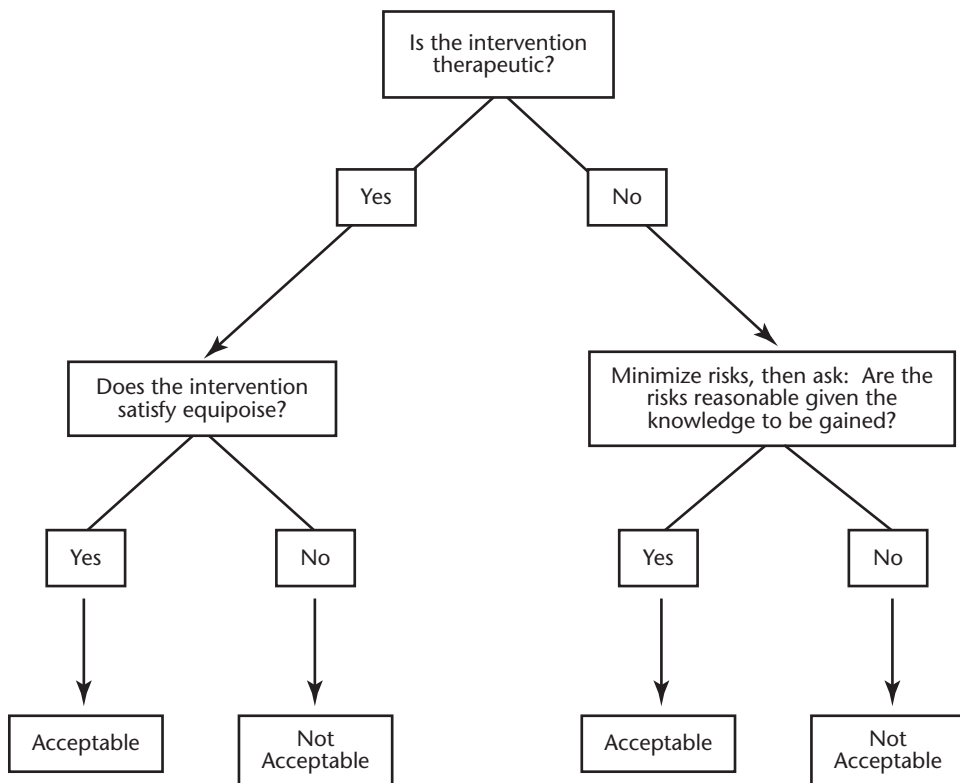

Figure 47.1. Dual-Track Assessment of Individual Interventions

to this substantive approach to assessing the individual interventions and procedures that make up a given study as *dual-track* assessment.

Under dual-track assessment, IRBs may approve interventions that are categorized as *therapeutic* only when they satisfy clinical equipoise. Clinical equipoise involves an assessment of whether the risk-benefit profile of a research treatment is at least as favorable as the risk-benefit profile of the clinically available alternative treatments.¹⁷ If it is, the research treatment satisfies the requirements of clinical equipoise; if the risk-benefit profile of the research treatment is less favorable by any margin than the risk-benefit profile of the available alternative treatments, it fails to satisfy the demands of clinical equipoise.

Although intuitively appealing and widely accepted as a necessary ethical requirement for clinical trials, clinical equipoise presents serious theoretical and practical problems.¹⁸ At the same time, the equipoise standard represents an essential aspect of risk-benefit assessment for clinical research, which needs to be recognized even if the dual-track approach is rejected. This aspect is the need to undertake a comparative analysis that examines the risks and benefits of research interventions for participants in comparison with the risks and benefits of interventions that would be appropriate for them in the context of medical care. The point of this comparison is not to insist that the risk-benefit profiles of research interventions must be the same as those in clinical practice, but to provide a benchmark for determining when interventions pose net risks to participants—risks that are not matched by clinical benefits to them.

One might wonder why there ever would be reason to conduct a study to evaluate an intervention when there was compelling evidence at the outset of the trial that the intervention has a

less favorable risk-benefit ratio than the existing clinical options. Why spend the time and money, and why expose research participants to risks, in order to test an intervention that the evidence suggests is not as good as the interventions that are currently being used in clinical practice? In fact, there are a number of reasons why one might want to evaluate such interventions.

To take one example, the existing treatment may be so expensive that few patients are able to afford it. Or, in countries that provide health care to all individuals the existing treatment might be so expensive that it precludes the national health system from offering other important treatments. In this context, it could make sense for the national health plan to test a new intervention that would be significantly cheaper, even when it is known that the new treatment is likely to be somewhat less efficacious or have somewhat greater side effects than the existing treatment. In this case, it may be vital to assess how much less efficacious or how much greater the side effects of the new medication are, with the assumption that a slight increase in some side effects (say, transient nausea) may be deemed acceptable in return for a dramatic decrease in cost and other benefits for the health-care system.

The fact that a research treatment offers a less favorable risk-benefit ratio than the available alternatives, as determined by the equipoise standard, highlights the fact that the intervention poses net risks to participants. Hence, IRBs need to assess the net risks to ensure that they are not excessive. That is, the IRB needs to ensure that the risk-benefit profile of the research intervention is not excessively less favorable than the risk-benefit profile of the standard treatment alternatives. Dual-track assessment assumes that satisfying clinical equipoise is an ethical requirement, such that a research treatment that offers a less favorable risk-benefit ratio than the clinically available alternatives is unethical in all cases.¹⁸

Hence, dual-track assessment prohibits IRBs from approving interventions that are categorized as therapeutic when they are not in participants' medical interests, even if the social value to be gained from the procedures is very important and the net risks to participants are very low.

In contrast, dual-track assessment allows IRBs to approve interventions that are categorized as nontherapeutic even when they are not in participants' medical interests, such as blood draws to measure study outcomes. Unlike therapeutic interventions, dual-track assessment allows the net risks of nontherapeutic interventions to be justified by the social value to be gained by including them in the study.

Concerns With Dual-Track Assessment

Unnecessary Use of Two Ethical Standards

The central goal of assessing the risks of research interventions is to ensure that they do not expose participants to excessive risks. To make this determination, dual-track assessment directs IRBs first to divide the interventions under review into two different categories. Although this process adds complexity to IRBs' risk assessments, proponents of dual-track assessment fail to explain why the use of two different categories is necessary to protect research participants.

One hypothesis to explain the need for a dual-track assessment is the conviction that participants receiving treatment interventions should not be knowingly exposed to greater risks than they would be in receiving treatment for their condition in the context of medical care. However, in view of the goal of clinical research—to produce generalizable knowledge, not to provide optimal or standard medical treatment—it is difficult to see why this conviction should be presumed as an ethical requirement. Furthermore, commentators agree that it is ethically acceptable to expose participants to some level of risks from research interventions that are not justified by the prospect of medical benefits to them, such as a blood draw or lumbar puncture to measure study outcomes in a randomized trial. If it is acceptable to expose participants to net risks in the case of these interventions, why should it not be acceptable to do so in the case of treatment interventions (or placebo controls) provided the study has important social value? Nor is it clear that this dual-track approach is needed to protect research participants from excessive risks. There does not seem to be any reason to think that the net risks of “therapeutic” interventions are ethically more or less worrisome than the net risks of “nontherapeutic” interventions. Without an explanation of why the net risks of these two types of interventions have different ethical status, the dual-track approach appears arbitrarily to add complexity without increasing protection. A better approach would be to identify a method that assesses the net risks of all research interventions using the same ethical standard.

Lack of a Clear Definition

Some commentators define nontherapeutic interventions as ones *designed* to “achieve beneficial results for the public.”¹⁹ Because all research is designed to benefit the public, this definition has the potential to categorize all research interventions as nontherapeu-

tic. Hence, the risks of all interventions might have to be justified by their social value alone. Using this definition, then, dual-track assessment would have the potential to inadvertently prohibit research interventions whose risks are justified by their potential clinical benefits to participants.

Others distinguish between therapeutic and nontherapeutic interventions based on the intentions of the investigators. The NBAC adopts this approach at least with respect to nontherapeutic interventions, stating that interventions qualify as nontherapeutic when “their sole intent is to answer the research question(s).”² Unfortunately, investigators often have mixed intentions, aiming to benefit both participants and society. Even in research with healthy volunteers, researchers often attempt to benefit participants, for example, informing them of any research findings that might be of clinical significance. Hence, this definition fails to provide IRBs with a clear method to distinguish between therapeutic and nontherapeutic interventions.

Finally, some proponents of the dual-track approach appeal to the concept of *therapeutic warrant*, defining interventions as therapeutic when they are “administered with evidence sufficient to justify the belief that they may benefit research subjects.” The therapeutic warrant approach then defines interventions as nontherapeutic provided they are “administered solely for the purpose of answering the scientific question.”⁵

By defining nontherapeutic interventions based on the *purpose* of administering them, this definition seems to appeal either to research design or investigator intention. As a result, this definition fails to avoid the problems mentioned previously: All research interventions are designed to answer scientific questions, and investigators typically have multiple intentions when administering research interventions.

Second, defining therapeutic interventions as those that *may* benefit participants has the potential to create further confusion. Many research interventions offer an often very low chance of benefit to participants. For example, radiological scans done in healthy volunteers for research purposes seem to offer a paradigm example of a nontherapeutic intervention. Yet data provide compelling evidence that research scans conducted in healthy volunteers offer a very low chance of identifying an undiagnosed and treatable brain tumor, a very important clinical benefit.²⁰ Hence, this definition may cause IRBs to categorize essentially all research interventions as therapeutic.

Third, the two clauses that make up the therapeutic warrant definition are not mutually exclusive. To take one example, an intervention may be administered for scientific purposes, even when there is evidence that the intervention may benefit the participants. Thus, it seems that many interventions would qualify as both therapeutic and nontherapeutic, a problematic result given that the dual-track approach applies different requirements to therapeutic and nontherapeutic interventions. Specifically, therapeutic interventions must satisfy the requirement of clinical equipoise, whereas nontherapeutic interventions do not have to satisfy this requirement. Dual-track assessment provides IRBs with no guidance on how to assess interventions that qualify as both therapeutic and nontherapeutic.

Lack of Familiarity

Many research regulations make no mention of the therapeutic/nontherapeutic distinction. For example, the U.S. federal regula-

tions for pediatric research refer to interventions that offer participants a *prospect of direct benefit*. To implement the dual-track approach, IRBs would have to reconcile a method that relies on the distinction between therapeutic and nontherapeutic interventions with regulations that do not include this distinction. In particular, IRBs would have to synthesize the concept of prospect of direct benefit which focuses on the impact of research on participants with the therapeutic/nontherapeutic distinction, which, depending on one's preferred definition, seems to focus on investigators' intentions or the design of individual interventions.

Arbitrary Judgments

Dual-track assessment allows IRBs to approve nontherapeutic interventions that are not in participants' medical interests, provided the net risks are sufficiently low and the knowledge to be gained justifies the risks. In contrast, dual-track assessment prohibits IRBs from approving therapeutic interventions that are not in participants' medical interests, even when the net risks are just as low or even lower, and the knowledge to be gained justifies the risks.

For example, to assess the pathophysiology of depression, investigators sometimes need to perform brain scans and other noninvasive procedures on persons diagnosed with depression who are not taking medication. The primary risk of such studies is the delay in receiving standard medically indicated treatment while individuals are on the study. Dual-track assessment allows such studies when they involve only nontherapeutic interventions. In contrast, dual-track assessment would not allow the very same

individuals to enroll in a clinical trial evaluating an experimental treatment for depression that included a nontreatment arm, even when the length of time off treatment, the risks, and the social value of the study are equivalent to those of the nontherapeutic, pathophysiology study.

This difference in judgment seems ethically arbitrary. In particular, it is not justified by the primary goal of risk assessment, namely, protecting participants from excessive risks. If it is acceptable to expose competent adults to these risks, then both studies seem acceptable. Conversely, if one thinks that it is ethically unacceptable to expose individuals to these risks for the benefit of society, both studies would be unacceptable. There does not seem to be any justification for claiming that IRBs should be allowed to approve the one type of study, but not the other, based on the distinction between therapeutic and nontherapeutic interventions.

Prospect of Direct Benefit Standard

Commentators have recognized that the therapeutic/nontherapeutic distinction is unclear, and that relying on it fails to offer adequate protection to research participants. As a result, many commentators and guidelines have rejected the therapeutic/nontherapeutic distinction. In its place, some guidelines rely on the prospect of direct benefit standard. For example, the U.S. National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research endorsed, and current U.S. federal regulations have adopted, the prospect of direct benefit standard^{21,22} (see Figure 47.2). The International Conference on

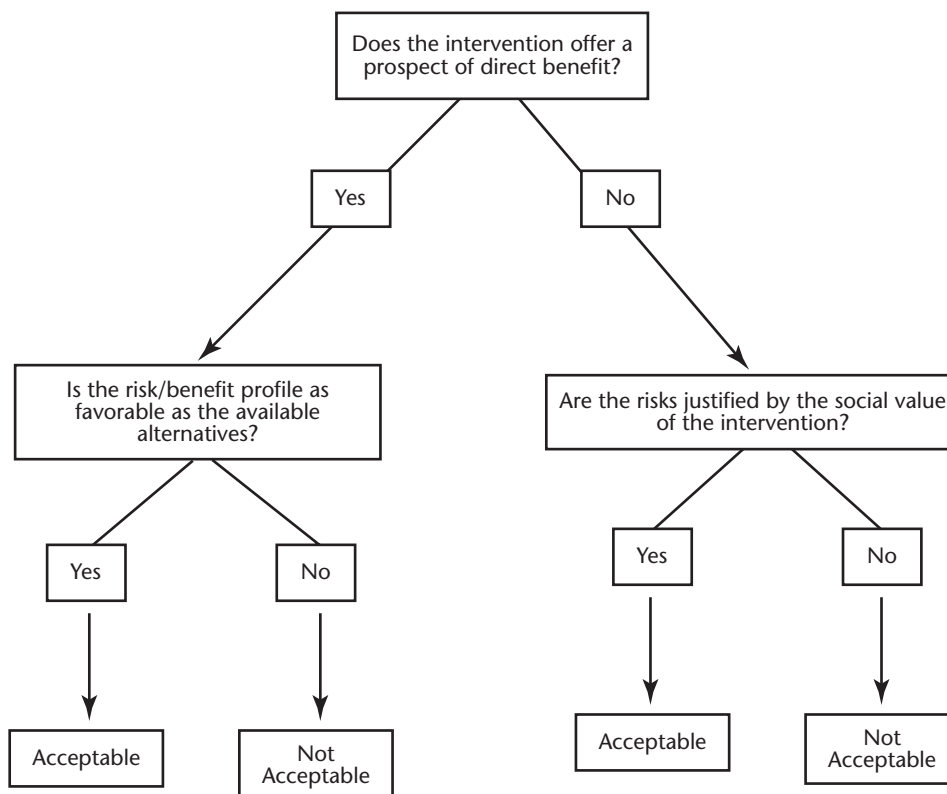

Figure 47.2. Prospect of Direct Benefit Assessment of Individual Interventions

Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH)²³ and the French Parliament²⁴ have done so as well. This standard mandates additional safeguards for research that does not offer participants sufficient prospect of direct benefit. By focusing on the impact that research has on participants, this approach provides better protection than the therapeutic/nontherapeutic distinction. Yet this standard still fails to provide sufficient protection.

The prospect of direct benefit standard focuses on the potential that research interventions offer for clinical benefit, rather than the risks they pose to participants. In general, this is problematic because it suggests that the ethical acceptability of clinical research depends upon whether it offers the potential for clinical benefit to participants. Although potential for clinical benefit is obviously a virtue, it is not required for the ethical acceptability of clinical research interventions. Rather research interventions are justified when they offer the potential for sufficient social value and do not expose participants to excessive risks. To make this determination, IRBs need a method that focuses on whether research interventions pose excessive risks.

More important, a requirement that IRBs may approve interventions only when the potential for direct benefit justifies the risks, and the risk-benefit profile is at least as favorable as the available alternatives, conflates the ethical standards for clinical research with the ethical standards for clinical care. Clinicians decide whether to offer patients a given intervention or treatment based on whether its potential clinical benefit justifies the risks. In the context of clinical care, interventions that do not offer patients sufficient potential for clinical benefit are unjustified.

Research interventions, in contrast, are justified when they offer important social value, and do not pose excessive risks.^{26,27} For example, a research blood draw that offers no potential for clinical benefit may be justified when the risks are very low, and the intervention has the potential to yield information with important social value. Similarly, giving participants a research treatment that offers a less favorable risk-benefit ratio than an available clinical alternative may nonetheless be ethical provided the research has important social value and the research treatment has only a slightly less favorable risk-benefit ratio.

The focus on the potential for clinical benefit has led some commentators to miss the fact that both types of interventions—the research blood draw and the somewhat less favorable research treatment—may be ethically acceptable when the information to be gained is important and the net risks to participants are not excessive. As mentioned previously, this mistake is exemplified by the erroneous claim that clinical equipoise is a strict ethical requirement on clinical treatment trials. Focusing on the net risks of research interventions and procedures, as opposed to the prospect of direct benefit that they offer participants, reveals that the ethical acceptability of all research interventions depends on the same ethical standard: Are the risks excessive given the potential for participant and societal benefit?

This line of reasoning reveals that the prospect of direct benefit standard may lead to a mistake similar to that made by the dual-track assessment. As we have seen, dual-track assessment uses different standards for evaluating the ethical acceptability of research interventions depending upon whether the IRB categorizes the intervention as therapeutic or nontherapeutic. Specifically, nontherapeutic procedures may pose some net risks. Under

dual-track assessment, therapeutic procedures are unethical if they pose any net risks, even when the level of risk is the same or less than the level of risk that would be deemed ethically acceptable for a nontherapeutic procedure.

Reliance on the prospect of direct benefit standard can cause similar errors. Specifically, directing IRBs to first assess whether research interventions offer a prospect of direct benefit ultimately leads to the need for two different assessments. The IRBs first must determine whether the intervention offers a prospect for direct benefit. However, as mentioned previously, interventions that do not offer a prospect of direct benefit may nonetheless be ethically acceptable provided the risks are sufficiently low and the interventions offer the potential for social value. Hence, IRBs then need to ask whether interventions that do not offer a prospect of direct benefit pose excessive risks. This process of dividing research interventions into two types leads to different standards for the two types of interventions.

This potential for instituting two different standards in practice is perhaps best exemplified by the U.S. federal regulations for pediatric research. As mentioned previously, these regulations allow children to be exposed to interventions that do not offer a prospect of direct benefit when the risks are minimal or, in some cases, involve only a minor increase over minimal risk. In contrast, the regulations allow IRBs to approve interventions that offer a prospect of direct benefit only when the potential benefits justify the risks and the risk-benefit profile is at least as favorable as that of the available alternatives.

These requirements on prospect of direct benefit interventions imply that IRBs may not approve an intervention that offers a prospect of direct benefit and also has a slightly less favorable risk-benefit ratio than the available alternatives, even when the net risks do not exceed minimal. Previously, we considered the possibility that public health officials might want to test an intervention that data suggest has a slightly less favorable risk-benefit ratio than established treatments, when the treatment costs significantly less than the existing treatments. Testing of this intervention might have vital social value and play an important role in ensuring adequate health care for everyone. In addition, imagine that the new treatment has the same efficacy as the established treatment, and a similar risk profile, except for a slightly higher risk of transient nausea. Presumably, children face a risk of transient nausea in their daily lives. Hence, the net risks of the new intervention may well be judged to be minimal by the IRB. In that case, the U.S. federal regulations would allow the IRB to approve the intervention if it did not offer a prospect of direct benefit. However, if the intervention does offer a prospect of direct benefit, then under the U.S. regulations it cannot be approved by an IRB because its risk-benefit profile is less favorable than the risk-benefit profile of some available alternatives. This double standard, similar to what we saw with respect to dual-track assessment, seems unjustified. In particular, this difference in assessment cannot be justified on the grounds that the one intervention, but not the other poses excessive risks to children.

This example highlights the fact that any approach to risk assessment that divides interventions and procedures into two categories based on whether they offer the research participants undergoing them a chance of clinical benefit is likely to end up establishing the same kind of unjustified double standard that plagues the dual-track approach. Once an intervention is catego-

alized as offering the potential for clinical benefit, then the almost inevitable next step is to assume that those interventions, but not the interventions that fail to offer a prospect of direct benefit, are acceptable only when they do not conflict with participants' clinical interests. In the end, then, this approach ends up conflating research and clinical care.

One might address this concern by revising the standards that apply to interventions that offer the prospect of direct benefit. Specifically, guidelines could stipulate that such interventions either must offer a compensating potential for direct benefit or the net risks of the intervention must be sufficiently low. This approach would address the problematic imposition of different ethical standards for the two kinds of interventions. However, all interventions would be judged based on whether the net risks were sufficiently low. On that approach, there would be no reason to distinguish between the different types of interventions. This suggests that IRBs need a single standard that focuses on the net risks of the interventions and procedures to which research participants are exposed.

The Net Risks Test

To ensure that research participants are not exposed to excessive risks, IRBs should minimize the risks and burdens of all interventions included in the study under review, consistent with sound scientific design. IRBs then need a method that allows them to assess the ethical acceptability of the remaining risks and burdens to participants. In particular, IRBs need a method to ensure that research interventions do not pose excessive net risks.

There are at least two scenarios in which research interventions pose net risks to participants. Most obviously, research interventions pose net risks to participants when the risks of the interventions exceed their potential clinical benefits. For example, a blood draw that offers participants no potential for benefit poses net research risks, represented by all the risks that participants face from the blood draw. In addition, research interventions that have a favorable profile of potential clinical benefits to risks nonetheless pose net research risks when their risk-benefit profile is less favorable to participants than the risk-benefit profile of one or more of the available alternatives.

To better understand the etiology of certain diseases, investigators sometimes use older generation drugs that have different mechanisms of action than current treatments. Typically, the potential clinical benefits of older drugs exceed their risks. Administration of the older treatment nonetheless would pose net research risks if participants were precluded from receiving the newer treatment that offers a more favorable risk-benefit profile compared to the older generation intervention. For example, the older and current treatments may offer similar potential benefits, but the current treatment may have a slightly lower incidence of one side effect, such as nausea. In this case, participation in the research study would pose net risks to participants represented by the increased incidence of nausea on the older drug as compared to the current treatment.

Whether the risks of studies that involve administration of older generation treatments are acceptable depends on whether the risks are minimized, the net risks to participants are sufficiently low, and the value of the research justifies the net risks. To

make this determination, IRBs need a method that focuses on the risks participants face and ensures that IRBs assess the two potential sources of net research risks. The net risks test, divided into the following three steps, provides such a method (see Figure 47.3).

1. Identify the Net Risk Interventions

The IRB first should identify the individual interventions included in the study under review. The IRB should assess the risk-benefit profile of each intervention by comparing its risks to the potential clinical benefits for participants. The IRB should then assess the risk-benefit profile of the available alternatives to each intervention, which, in some cases, may be no intervention at all, and then compare the risk-benefit profile for participants of each research intervention to the risk-benefit profiles of the available alternatives.

When the risk-benefit profile of the research intervention is at least as favorable for participants as the available alternatives, including not undergoing the intervention at all, it poses no net risks. Conversely, research interventions that offer participants a less favorable risk-benefit ratio than one or more of the available alternatives, including not undergoing the intervention at all, pose net risks. The magnitude of the net risks is a function of the extent to which the intervention presents increased risks or decreased potential benefits, compared to the available alternatives.

A study might provide an experimental treatment that is believed to have a risk-benefit profile equivalent to the standard of care, followed by a research PET scan. The treatment poses no net risks because its risk-benefit profile is considered as favorable for participants as the available alternative of standard of care. The PET scan, in contrast, poses net research risks from the use of low-dose radiation because it offers a negative risk-benefit profile to participants, compared to the alternative of not undergoing the intervention at all.

2. Assess the Net Risk Interventions

The IRB next should ensure that the risks of each intervention that poses net risks are not excessive and are justified by the social value of the knowledge to be gained by the intervention's use in the study. For example, the IRB should determine that the risks posed by the research PET scan are not excessive, and that these risks are justified by the information to be obtained by having participants undergo the PET scan.

3. Assess the Net Cumulative Risks

As the Institute of Medicine (IOM) warned in a 2004 study, limiting IRB assessment to the risk-benefit profile of individual interventions ignores the possibility that "research may involve several different procedures that may involve minimal risk or burden individually, but that may present more than minimal risk when considered collectively."²⁹ The finding that a single MRI and a single blood draw each pose minor risks fails to assess whether inclusion of a series of these procedures in a single study poses excessive risks. To address this concern, IRBs should calculate the cumulative net risks of all the interventions in the study, and ensure that, taken together, the cumulative net risks are not excessive.

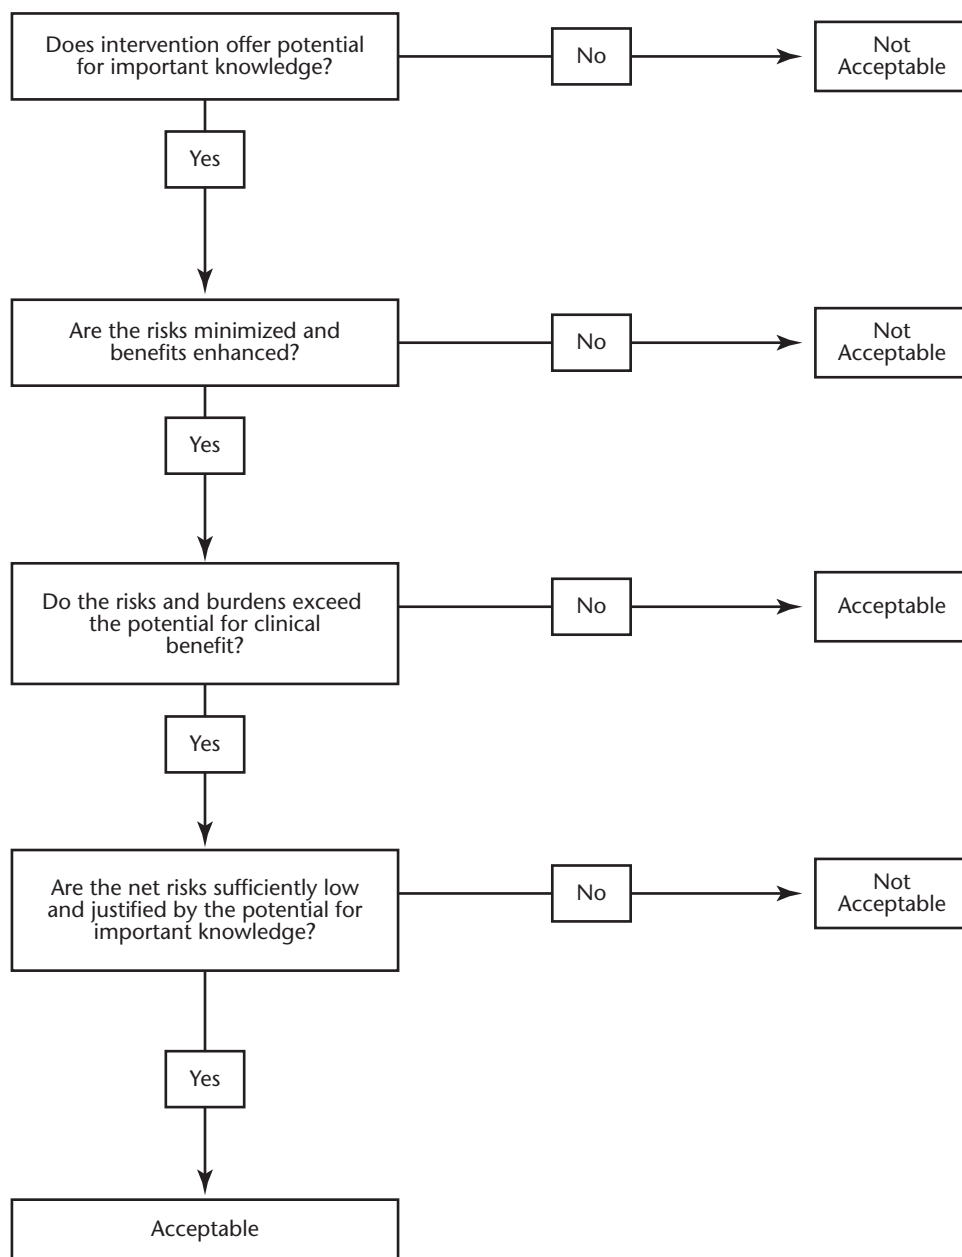

Figure 47.3. Net Risks Test for Individual Interventions

How should IRBs determine whether the net risks of individual interventions and the net cumulative risks of research studies are excessive? It is widely agreed that vulnerable research participants, such as children and adults who are unable to consent, should not be exposed to net risks that exceed a minor increase over minimal risk. In contrast, there is a lack of consensus over whether there should be a priori limits on the risks to which capacitated adults may be exposed for the benefit of society. For example, should capacitated adults be able to consent to enroll in a study that poses serious net risks to them, but offers the potential for profound social benefit, such as finding a cure for malaria? It seems that allowing such research raises the potential for serious abuses of research participants. This potential for abuse seems

especially grave given data on the extent to which research participants often fail to understand the nature of their research participation, including the risks, absence of direct benefits, and right to withdraw.

Conversely, precluding such research in all cases seems inconsistent with other contexts in which we sometimes allow capacitated adults to face serious risks for the benefit of society, such as firefighting and military service. Future research should address the questions of whether there should be a limit on the net risks to which capacitated adults may be exposed in the context of clinical research; if so, how this limit should be defined; and what safeguards, such as stringent assessment of informed consent, would be necessary to conduct high net risk research.

The net risks test is similar to the standard clinical assessment used by physicians to determine whether a given intervention is in patients' clinical interests. Both assessments evaluate the risk-benefit profile of the intervention in question compared to that of available alternatives. This similarity suggests that the net risks test should be more familiar to clinicians than the prospect of direct benefit standard. Granting this similarity, it is important to emphasize that, unlike the clinical setting, some net risks can be justified in the research setting. That is, the ethical standard for clinical medicine requires that the potential for clinical benefit justifies the risks of the intervention in question. In contrast, the ethical standard for clinical research is whether the net risks to participants, if any, are not excessive and are justified by the social value of conducting the research. Accordingly, risk-benefit assessment in clinical research is both similar to, but significantly different from, risk-benefit assessment in medical care.

Some might worry that the similarity between the net risks test and standard clinical judgment might foster the so-called therapeutic misconception, increasing the chances that patients fail to recognize the difference between clinical care and clinical research.³⁰ However, by focusing on the risks to participants and whether those risks are excessive in the effort to generate socially valuable knowledge, the net risks test seems to have less potential to foster the therapeutic misconception than would an approach that stipulates a distinctive standard for evaluating therapeutic interventions or that focuses on the extent to which research may benefit participants.

For example, the prospect of direct benefit standard seems to evaluate research participation based on the extent to which it offers clinical benefit to participants. If this message gets conveyed to research participants and investigators, they may confuse research with clinical care. Although the net risks test is not intended for use by research participants, if it is communicated to participants to explain the rationale for research interventions, it would be less likely to promote a therapeutic misconception than either the dual-track assessment or the direct benefits standard. In other words, it seems less likely that participants will confuse research with clinical care when told that the research in question poses a low level of net risks. This potential seems much greater if participants are informed that the intervention offers a prospect for direct benefit. The dual-track assessment seems even more worrisome in this regard. It is not difficult to imagine that research participants might confuse research with clinical care once told that the intervention being tested in the study was categorized by the IRB as therapeutic.

In the research setting, there often are few data available to make risk-benefit assessments. Recognizing this, IRBs will have to use their judgment to implement the net risks test, and they should err on the side of caution. When there are insufficient data to determine whether research participation poses risks in excess of the potential for clinical benefit, the IRB should mandate additional safeguards. Occasionally, the net risks test may reveal that research enrollment poses net risks, or greater net risks, to some eligible participants but not others. In these cases, IRBs might repeat the net risks test for individual participants at the time of research enrollment. On this approach, the IRB could require additional safeguards for only the individuals who face net risks or greater net risks. This individual level, or subgroup, assessment may be appropriate when little is known

about the experimental intervention or when the intervention poses high risks. Assessment of the study population as a whole is likely to be sufficient when the research poses few risks, or when the inclusion criteria are sufficiently narrow to ensure that participation does not pose net risks to those who are eligible to participate.

The Net Risks Test and Phase I Studies

To exemplify the net risks test, consider the assessment of Phase I studies—a controversial research design. IRBs reviewing Phase I studies should minimize risks by eliminating duplicative procedures and assessing whether the same information could be gained using less risky procedures. The IRBs then should identify the net risk interventions and compare their risk-benefit profile to the risk-benefit profile of the available alternatives, including the alternative of not undergoing the intervention.

This assessment is very similar to the assessment used by many research regulations. For example, the U.S. federal regulations require IRBs to compare the risk-benefit profile of the intervention under study to the risk-benefit profile of the available alternatives, including not undergoing the intervention at all when reviewing pediatric research interventions that offer a prospect of direct benefit (45 CFR 46.405).¹ To assess individual interventions that offer children a prospect of direct benefit, the federal regulations instruct IRBs to assess whether (a) the risk is justified by the anticipated benefit to the participants, and (b) the relation of the anticipated benefit to the risk is at least as favorable to the participants as that presented by available alternative approaches.

This assessment is essentially identical to the first two steps in the net risks test: Identify the risk-benefit profile of individual interventions and then compare them to the risk-benefit profile of the available alternatives. Notice that both approaches involve IRBs directly assessing the risk-benefit profile of research interventions rather than first dividing all interventions into two different categories as recommended by dual-track assessment. The similarity between the net risks test and the guidance offered by research regulations suggests that the net risks test, unlike dual-track assessment, should be relatively familiar to IRBs.

For Phase I studies in healthy volunteers, the preferred alternative would be not enrolling in the research at all. Hence, the net risks of the experimental agent, and the net risks of the other included interventions, such as blood draws, would be all the risks that these interventions pose to healthy volunteers. In this case, the IRB should approve the individual interventions only when the net risks to participants of each intervention are not excessive and are justified by the social value to be gained by inclusion of that intervention in the study.

For Phase I agents tested in patients, the IRB should determine the risk-benefit profile of all the interventions for participants, including administration of the tested agent, and then compare the risk-benefit profile of each intervention to the available alternatives. When other treatments are available, the Phase I agent should be compared to them. In the absence of treatment alternatives, this assessment should compare the risk-benefit profile of the Phase I agent to receiving palliative care or to no treatment at all. The IRB should approve each intervention only when the net risks it poses to participants, if any, are not excessive. Finally, the IRB should

assess the net cumulative risks of the study, ensuring that they are not excessive and are justified by the social value of the study.

Conclusion

Dual-track assessment, endorsed by NBAC and other commentators and groups, directs IRBs to assess the risks of research interventions by first dividing the interventions under review into two categories, *therapeutic* and *nontherapeutic*. This approach complicates the process of risk assessment without adding any protection for research participants. In addition, confusion over the definitions of therapeutic and nontherapeutic interventions suggests that the dual-track method will be difficult to implement.

Guidelines that instruct IRBs to determine whether research interventions offer a prospect of direct benefit address these concerns, but seem to conflate ethical standards for research with ethical standards for clinical care. The net risks test avoids this conflation by focusing on the extent to which research interventions pose net risks, thus offering a practical method, based on familiar clinical judgments, for assessing research interventions. The net risks test, unlike dual-track assessment, also focuses IRB attention on the central challenge for protecting research participants, namely, whether they face excessive risks, thereby providing clearer guidance to IRBs and more appropriate protection for research participants.

Assessing and Comparing Potential Benefits and Risks of Harm

I. Overview

Assessment of potential benefits and risks of harm is an essential component of the scientific and ethical evaluation of clinical research, for three fundamental reasons. First, it is essential to determining whether a line of research has scientific validity and scientific/social value.¹ It is the task of the institutional review board (IRB) to examine both the scientific validity of proposed research (whether the research has the potential to produce generalizable knowledge), and also its scientific and social value (whether the intervention being studied has the potential to eventually become a treatment for patients with the disease or condition of interest).

Second, assessment of potential benefits and risks of harm helps to protect research participants by ensuring that the risks of harm to which they will be exposed are minimized and are reasonable under the circumstances, and also by ensuring that the research is able to produce results justifying the use of humans (because it is exploitation to ask people to participate in research that is poorly designed or otherwise cannot contribute to generalizable knowledge that has social or scientific value). In some types of research with children and other potentially vulnerable people, this assessment may even require the potential for medical benefit to the participants (see discussion of decisionally incapable subjects, later in this chapter).

Finally, assessment of potential benefits and risks of harm helps to facilitate potential participants' informed decisions about research participation. Information about the potential benefits and risks of harm in a clinical trial helps potential participants to determine whether the balance between potential benefits and risks of harm makes sense for each of them individually.

Regardless of whether individuals participate out of altruism, desire for personal benefit, or both, their informed choices alone cannot morally justify the conduct of research. Individual decisions about research participation cannot even be considered unless the IRB has already made a favorable comparison of potential benefits and risks of harm for the study as a whole. This is true even if individuals' views of the balance of potential benefits and risks of harm are different from the IRB's perspective on the study. Both a favorable assessment of potential benefits and risks of harm and the participant's informed choice are necessary conditions of ethically sound research, but neither is sufficient, and the former is both logically and chronologically prior to the latter.

Assessment of potential benefits and risks of harm is thus an essential part of the ethical evaluation of all clinical research. Moreover, in any properly conducted clinical trial, the task of assessment of potential benefits and risks of harm falls to many individuals and entities, each making independent judgments: not only potential participants and IRBs, but also investigators, sponsors, and data and safety monitoring committees, among others. Although the IRB has the ultimate authority to permit or preclude research based on its assessment of a clinical trial's potential benefits and risks of harm, assessments by others—in particular by sponsors and investigators—serve both to guide the IRB and to promote the conduct of thoughtful and responsible research. Research should not even be submitted to an IRB for consideration if the investigator or sponsor is not confident of its validity and value. Further, having all of these parties make their own independent assessments of the risk of harm/potential for benefit ratio is one means of fulfilling the responsibility to minimize harms.

Existing guidance on assessing and comparing risks of harm and potential benefits is largely oriented toward Phase III randomized controlled trials (RCTs), thereby failing to address much that IRBs and others need to consider when reviewing both early-phase clinical research and clinical trials that do not fit into classical phase designs. This chapter addresses those often-neglected considerations.

We first provide a brief typology and discussion of terminology used in assessing and comparing potential benefits and risks of harm in research. Next we offer a brief overview of how several key clinical research guidance documents from around the globe address assessment and balancing of potential benefits and risks of harm. Then we consider some ongoing controversies about assessment of risks of harm and potential benefits; and finally, we address some special issues, circumstances, and concerns in assessing and balancing potential benefits and risks of harm outside the RCT context.

II. Harms and Benefits: A Typology

The previous chapter addresses risks of harm comprehensively; in this typology we attend more closely to potential benefit. Potential benefits in clinical research fall into two broad categories: *benefits to participants* (that is, benefits from study participation) and *benefits to society* (that is, future benefits from research results). Benefits to participants are further divided into two types: *direct benefits* from receipt of the experimental intervention, and *inclusion benefits* (also called collateral or indirect benefits), which result from participating in a study regardless of whether the participant receives the experimental intervention. Inclusion benefits encompass such diverse items as free goods or services provided as an enrollment incentive; diagnostic testing and standard treatments provided on-study at no cost to participants; the opportunity to be monitored closely by disease experts; and hypothesized psychological benefits to patient-participants from “doing everything possible.”²

Notably, direct benefits—arguably the benefits of greatest interest to potential participants—are by definition uncertain to materialize. However, some (but not all) types of inclusion benefits may be certain, whereas others are uncertain, and still others may be considered either benefits or harms, depending on how they are experienced by particular participants.

Potential harms to participants may similarly be divided into harms from the experimental intervention and harms from study participation regardless of whether the participant receives the experimental intervention. Potential harms from study interventions (experimental or otherwise) in clinical trials are often called side effects or adverse effects. And as with benefits, although the harms of greatest interest and concern are uncertain to occur, some harms (also sometimes referred to as discomforts or burdens) are inevitable. For example, drawing blood or obtaining a bone marrow specimen always causes discomfort, and making extra trips to the hospital for the purposes of study participation is always at least somewhat burdensome.

Both potential benefits and risks of harm should always be examined and characterized, to the extent possible, according to their nature, magnitude (size and duration), and likelihood. This kind of characterization is quite familiar to IRBs and investigators when it comes to risks of harm, and less familiar for potential

benefits; however, it is equally important for both sides of the harm-benefit balance.³

III. Balancing Risks of Harm and Potential Benefits: Existing Guidance and Its Limits

Essentially every clinical research guidance document in existence, whether local, national, or international in scope, addresses the assessment and comparison of risks of harm and potential benefits. However, few go beyond general assertions that there should be a favorable balance between the two. We have chosen to closely examine a cluster of U.S. guidance documents, which are meant to be understood together, and one set of international clinical research guidelines that consider risks of harm and potential benefits in somewhat more depth than most. The reader is also referred to those chapters in this volume that discuss these and other guidance documents in detail.

Common Rule

The federal Common Rule governing research with humans conducted in connection with institutions receiving federal funding provides simple but far from straightforward guidance to IRBs in balancing risks of harm and potential benefits (see Chapter 15). The IRB’s task is described as determining that “[r]isks to subjects are reasonable in relation to anticipated benefits, if any, to subjects, and the importance of the knowledge that may reasonably be expected to result. . . . The IRB should not consider possible long-range effects of applying knowledge gained in the research (for example, the possible effects of the research on public policy) as among those research risks that fall within the purview of their responsibility.”⁴

There are four key things to note here. First, the inclusion of “if any” signals clearly that, generally speaking, potential benefit to participants is *not required* to justify the conduct of research—not even when participants are patients with the disease or condition of interest. Instead, balancing risks of harm and potential benefits requires a more complex judgment. Second, the meaning of the critical balancing term “reasonable” is completely undefined. Third, the Common Rule directs IRBs to consider the long-range potential benefits from research but specifically to exclude consideration of “possible long-range effects of applying knowledge gained in the research . . . as among . . . research risks.” It might be thought that the reason for including potential future benefits to society in the calculation, while excluding long-term risks of harm from societal application of research data, is because long-range hazards are difficult to predict. Yet given the amount of attention paid to risks of harm generally, and the paucity of definition and precision in defining potential benefits, it is likely that long-range risks of harm are no more, and possibly less, speculative than future potential benefits. It is thus more likely that this asymmetry signals the inherent support of clinical research that is structured into the U.S. regulatory system. The Common Rule is not neutral; instead, the Rule as a whole, and the assessment and balancing of risks of harm and potential benefits in particular, is designed to promote clinical research while protecting participants.

This asymmetry in the consideration of long-term potential benefits and risks of harm has been challenged by IRBs faced with review of research whose results seem likely to lead to misuse.

Perhaps the most familiar example is when group harm seems likely to follow from the promulgation of research results, as has happened in some genetic research in which populations have been stigmatized by association with disfavored genetic conditions. For example, some genetic mutations, like BRCA in breast cancer, have been labeled “Jewish genes.” However, it can be argued that even though the IRB is precluded from disapproving research on the basis of the probable misuse of its results, there are either other grounds for disapproving such research (e.g., the IRB could require modifications in design or dissemination calculated to reduce the likelihood of misuse of results) or other avenues of disapproval (e.g., the institution could choose not to permit the research as failing to reflect local values, or other legal avenues could be employed to limit such research based on societal assessments of potential harms, such as federal funding bans or legislative prohibitions of certain categories of research).

Finally, it should be noted that the two types of potential benefits named in the Common Rule—benefits to participants and “the importance of the knowledge that may reasonably be expected to result”—are quite distinct. Not only do they apply to different individuals and groups, but they may be very different in kind—for example, the knowledge gained might be (in fact, often is) negative knowledge, that is, knowledge that further development of a particular intervention is *not* a viable line of research. It is important to remember that benefit to society from the knowledge that may reasonably be expected to result from the research has priority over potential benefit to participants, in that potential benefit to society is necessary to justify research, and potential benefit to participants generally is of secondary importance. Moreover, it may be technically difficult to combine both types of potential benefits for the purpose of weighing them against risks of harm.

Belmont Report

The Belmont Report⁵ is intended to elaborate the moral and conceptual foundations of the Common Rule (see Chapter 14). It goes beyond the Common Rule in setting forth an extensive discussion of the assessment of risks of harm and potential benefits. This discussion begins with a reminder that *risk* and *benefit* are not parallel terms, and that what is really being assessed is both the probability and the magnitude of various “possible harms and anticipated benefits.” It continues with explicit instructions about the “systematic assessment of risks and benefits”:

It is commonly said that benefits and risks must be “balanced” and shown to be “in a favorable ratio.” The metaphorical character of these terms draws attention to the difficulty of making precise judgments. Only on rare occasions will quantitative techniques be available for the scrutiny of research protocols. However, the idea of systematic, nonarbitrary analysis of risks and benefits should be emulated insofar as possible. This ideal requires those making decisions about the justifiability of research to be thorough in the accumulation and assessment of information about all aspects of the research, and to consider alternatives systematically. This procedure renders the assessment of research more rigorous and precise, while making communication between review board members and investigators less subject to mis-

interpretation, misinformation and conflicting judgments. Thus, there should first be a determination of the validity of the presuppositions of the research; then the nature, probability and magnitude of risk should be distinguished with as much clarity as possible. The method of ascertaining risks should be explicit, especially where there is no alternative to the use of such vague categories as small or slight risk. It should also be determined whether an investigator’s estimates of the probability of harm or benefits are reasonable, as judged by known facts or other available studies.

Belmont goes on to discuss further how risks of harm and potential benefits should be balanced, stating that “the risks and benefits affecting the immediate research subject will normally carry special weight,” but adding that “interests other than those of the subject may on some occasions be sufficient by themselves to justify the risks involved in the research, so long as the subjects’ rights have been protected.” Some harms can never be justified, all significant risks of serious harm must have unassailable justification, and risks of harm should always be minimized. Finally, Belmont says, “Relevant risks and benefits must be thoroughly arrayed in documents and procedures used in the informed consent process.”

One key implication of Belmont’s discussion of the “metaphorical character” of the assessment and comparison of risks of harm and potential benefits has to do with reproducibility. Should the calculation of risks of harm and potential benefits be such that any IRB that is doing its work correctly ought to come to the same conclusion about a given clinical trial? That is, should the outcome of the calculation be reproducible? Certainly that is what sponsors and investigators in multicenter trials would prefer. However, Belmont’s discussion seems instead oriented toward reproducibility of the calculation *procedure* rather than the *product*. The focus is on transparency—on explicit communication about how, and on what information, the assessment is made, so that investigators and IRBs can understand each other’s reasoning and so that the model of reasoning about risks of harm and potential benefits can be recapitulated by the IRB in all its assessments.

Reproducibility of process seems more useful—and more possible—than reproducibility of outcome in such a dynamic and contingent enterprise,⁶ but it does pose especially difficult questions for multicenter trials. It is therefore worth considering whether it is necessary to expand the typology of benefits and harms, as suggested earlier, and to develop further guidance for IRBs about the principles and information to be employed in the assessment and comparison process.

IRB Guidebook

The IRB Guidebook, produced by the Office for Protection from Research Risks (now the Office for Human Research Protections in the Department of Health and Human Services) also addresses the lack of parallelism in discussion of “risks and benefits,” but adds a distinction between two meanings of *risk*. It states that risks can refer either to the chances that individuals are willing to take to attain a desired goal, or to the conditions that make a situation dangerous. “The IRB is responsible for evaluating risk only in the second sense”—that is, the IRB’s task is to determine “whether the anticipated benefit, either of new knowledge or of improved health

for the research subjects, justifies inviting any person to undertake the risks.⁷ Key here is the recognition that a favorable assessment of risks of harm and potential benefits justifies the invitation to potential participants, which is logically and chronologically prior to the participant's informed decision about whether to undertake the risk in the first sense. The IRB is not to determine whether potential participants would judge the risk "worth it"; instead, the IRB is to judge whether the invitation is justified. The invitation may be justified even if no one decides that the risk is worth taking; similarly, many potential participants may be willing to take a risk that is deemed unreasonable by the IRB.

Thus, the Guidebook emphasizes that IRBs should be "sensitive to the different feelings individuals may have about risks and benefits," noting, for example that having the option of surgery instead of chronic medication might be viewed by some as a risk of harm and by others as a chance of benefit, and that some possible harms may loom larger to some potential participants than to others.

The Guidebook places somewhat more emphasis than Belmont on the contingent, nontechnical character of the assessment of risks of harm and potential benefits, stressing that "it is a judgment that often depends upon prevailing community standards and subjective determinations," such that "different IRBs may arrive at different assessments." It emphasizes the need for careful case-by-case determination that depends not only on currently available knowledge "but also on the degree of confidence about this knowledge."

Although the Guidebook acknowledges that different IRBs may assess and balance risks of harm and potential benefits differently, and that "IRB members should remember that their appraisals of risks and benefits are also subjective," it does not hold that IRBs should be free to use different standards altogether for assessing and balancing risks of harm and potential benefits. IRBs' assessments cannot be subjective in the same sense that someone's choices in weighing risks of harm and potential benefits are subjective. A participant's appraisal can be idiosyncratic or even arbitrary, as long as it is informed, whereas an IRB's cannot. Although there are no rules—or appropriate appeals mechanisms—to judge how participants should weigh risks of harm and potential benefits, for clinical research in the United States, the Common Rule, the Belmont Report, and the Guidebook do provide rules and procedures for IRBs' assessments. Nonetheless, some research has shown that American IRBs do indeed vary, perhaps excessively, in the standards they apply, even to the extent of approving only research that offers the possibility of direct medical benefit to participants.⁸

The Guidebook, like Belmont, distinguishes sharply between research that "involves the use of interventions that have the intent and reasonable probability of providing benefit for the individual subjects" (apparently synonymous with interventions "expected [or anticipated] to provide direct benefit to the subjects") and research that "only involves procedures performed for research purposes" (i.e., "solely to obtain generalizable knowledge"). The clarity and validity of that sharp distinction has been questioned for a variety of reasons, most notably by Robert Levine.^{9–11} From the perspective of this discussion, there are two reasons to discredit it. First, the distinction is irrelevant because the same assessment of potential benefits and risks of harm must be made in either case. Second, the distinction is insidious because it gives rise

to an almost overwhelming temptation—for investigators, IRBs, and participants alike—to exaggerate the potential for direct benefit when research is deemed to have "therapeutic intent." Therapeutic intent is likely to be imputed whenever the participant is a patient with the disease or condition of interest, and/or a member of a "vulnerable" group, such as minors, pregnant women, or persons lacking decision-making capacity, to whose research participation more stringent regulations apply.^{3,12–16}

It is controversial to characterize any clinical research enrolling patients with the disease or condition of interest as participants—even Phase I research—as not offering the potential for direct benefit. Because the ultimate goal of a line of clinical research is that the experimental intervention becomes a treatment, from which, therefore, patient-participants could theoretically benefit if all hopes about the experimental intervention are realized, IRB members often argue that it is acceptable for participants and investigators to believe and use some modest benefit language in all clinical trials. Nonetheless, it is highly problematic to characterize the tested intervention as having genuine potential for benefit under all such circumstances. Essentially, this conflates the theoretical possibility of some direct benefit with benefit at a future time from the hoped-for results.

A realistic potential for direct benefit is simply missing from the classic Phase I design, as the experimental intervention will not be assessed for benefit until Phase II. Moreover, the capacity of an experimental intervention to offer direct benefit in a Phase I trial is extremely limited at best, both by virtue of early-phase trial design and because most interventions do not become successful treatments—that is, few get as far as Phase II, let alone Phase III.

The *therapeutic misconception*—a misunderstanding of the essential difference between research and treatment, or an unrealistic overexpectation of direct benefit from research^{13,17}—is nonetheless pervasive, and its persistence is attributable in part to the origins of codes and principles of research ethics. Belmont, the Common Rule, the Declaration of Helsinki, and other guidance documents tend to see research ethics as derivative of medical ethics; similarly, common law principles of liability in clinical research have been derived from medical malpractice principles developed in the treatment context. This underlying treatment orientation deflects attention from some central issues and problems, including not only the therapeutic misconception (see Chapter 58) but also confusion about the nature of research roles and relationships.¹⁸

CIOMS

Most other guidance documents addressing clinical research, many of which are discussed elsewhere in this volume, address the balancing of risks of harm and potential benefits with little if any detail beyond that offered by the Belmont Report and the IRB Guidebook. Examples include the Council of Europe's Additional Protocol to the Convention on Human Rights and Biomedicine, concerning biomedical research (see Chapter 17); Canada's Tri-Council Policy Statement: Ethical Conduct for Research Involving Humans;¹⁹ and the Declaration of Helsinki (see Chapter 13).

One exception is the Council for International Organizations of Medical Sciences' (CIOMS') International Ethical Guidelines for Biomedical Research Involving Human Subjects (see Chapter 16).

Building on the Declaration of Helsinki's close identification of medical research with medical practice, CIOMS' Guideline 8 specifies differences in balancing risks of harm and potential benefits according to whether the experimental intervention does or does not "hold out the prospect of direct diagnostic, therapeutic or preventive benefit for the individual subject."²⁰

Given the practice orientation of both Helsinki and CIOMS, it is not surprising that interventions that hold out the prospect of direct benefit are addressed first in Guideline 8. These interventions "must be justified by the expectation that they will be at least as advantageous to the individual subject, in the light of foreseeable risks and benefits, as any available alternative." This apparently high benefit threshold is confirmed in the Commentary on Guideline 8, which restates it thus: "Beneficial interventions are justified as they are in medical practice by the expectation that they will be at least as advantageous to the individuals concerned, in the light of both risks and benefits, as any available alternative."

The phrase "as they are in medical practice" makes clear that what CIOMS considers a prospect of direct benefit has a direct referent in the evidence supporting an established diagnostic, therapeutic, or preventive intervention. However, it is difficult to argue that any investigational intervention could meet such a standard. Even the prospect of benefit presented by interventions being studied in Phase III trials can at best be said to be a matter of equipoise (that is, the possibility that an unproven intervention is as effective as standard treatment) rather than expectation (that is, a judgment based on evidence sufficient to consider a new intervention an effective treatment). It is all the more difficult to make credible any such expectation in early-phase research, regardless of how few or inadequate the alternatives might be. And although the Guideline appears to acknowledge the imperfection of the parallel between research interventions and practice by using scare quotes, the balancing of risks of harm and potential benefits conspicuously omits benefit to society: "Risks of such 'beneficial' interventions or procedures must be justified in relation to expected benefits to the individual subject."

In stark contrast, interventions not holding out the prospect of direct benefit for participants "must be justified in relation to the expected benefits to society (generalizable knowledge)." That is, "risks . . . must be reasonable in relation to the importance of the knowledge to be gained."

The questions thus left unanswered by CIOMS are easy to articulate, but difficult to resolve: Is the dichotomy between these two types of interventions as great and complete as presented? If so, where should the line be drawn between them? The Commentary attempts to clarify the distinction by referring to the purpose of the research: "Biomedical research often employs a variety of interventions of which some hold out the prospect of direct therapeutic benefit (beneficial interventions) and others are administered solely to answer the research question (non-beneficial interventions)." However, the research question in clinical trials testing experimental interventions in participants who are also patients with the disease or condition of interest is usually "Does the intervention in fact hold out the prospect of direct benefit?" That question can only be answered by a demonstration that some percentage of participants does in fact experience the hypothesized benefit. Thus, distinguishing between the potential for benefit on the one hand and the research question on the other hand does not seem to work when participants are also patients and the intervention is being tested for its therapeutic potential, except

perhaps by categorizing only those interventions being studied in Phase III trials as holding out the prospect of direct benefit. Although CIOMS attempts to sidestep Belmont's false dichotomy between *therapeutic* and *nontherapeutic* research by applying the dichotomy instead to individual interventions within a given clinical trial, this maneuver does not succeed in addressing the core problem of evaluating the potential for direct benefit of an experimental intervention.

IV. Comparing and Balancing Risks of Harm and Potential Benefits: Ongoing Debates

Weighing potential benefits to participants and society together against risks of harm to participants reinforces a favorable view of research with humans. In the IRB's assessment, potential benefits to society must be combined in some way with potential benefits to participants and then weighed against risks of harm; but because benefits to participants and benefits to society differ in fundamental ways, some IRBs and investigators have understandable difficulty in considering both categories of benefit.

Benefit to society is synonymous with contribution to generalizable knowledge. Negative study findings (to be distinguished from the absence of findings) have social/scientific value comparable to that of positive findings. Notably, benefit to society is a necessary finding for any and all research with human participants to go forward, but benefit to participants is not—even in clinical research enrolling patients with the disease or condition of interest (except sometimes when participants lack decision-making capacity, and/or belong to groups considered vulnerable in the clinical research context; see discussion in Section V.C below ("First-Participant Issues" [page 522]) and in Chapters 43–45).

Yet overprotectiveness toward potential participants should be avoided when evaluating research that offers no prospect of direct benefit.^{7,21,22} Such research can indeed provide an appropriate balance of risks of harm and potential benefits, and should not be disapproved solely because no direct benefits are reasonably possible. Should the IRB consider the balance of risks of harm and potential benefits inadequate, the IRB should require investigators to further reduce the risks of harm, or should determine that the research as designed is too risky to pursue, rather than attempting to increase potential benefits to participants. When clinical research poses significant risks of harm to participants, however, there is controversy about the appropriate response. Out of reluctance to expose any research participants to risks of harm without the possibility of direct benefit, some IRBs may be tempted to ensure that potential benefits to participants be found sufficient to balance those risks of harm; this may invite the therapeutic misconception or the addition of overly influential inclusion benefits. Other IRBs may focus on whether potential participants would be willing to enroll in the trial, out of altruism, self-interest, or both, and model their assessments thereon, which runs the risk of conflating the IRB's assessment with the participant's decision making.

Determining what counts as an appropriate balancing of risks of harm and potential benefits is one of the most important but least developed areas in research ethics.^{21,23} The limited available literature is largely focused on RCTs, and many important aspects of the assessment and balancing of risks of harm and potential benefits in early-phase trials and nonstandard designs remain inadequately addressed. Several key issues are briefly surveyed below.

Should Balancing Risks of Harm and Potential Benefits in Clinical Research Be Comparable to Balancing Them in Medical Practice?

One obvious starting point for determining whether a particular balance of risks of harm and potential benefits is reasonable is to compare it to what is considered standard treatment for the disease or condition of interest. Agrawal and Emanuel,²³ in addressing this issue for Phase I oncology trials, endorse setting standards for clinical research “based on socially acceptable determinations of risk-benefit ratios already used for cancer treatments,” using the risks of harm-potential benefit ratios for chemotherapeutic agents approved by the Food and Drug Administration (FDA) as examples. They provide numerous examples of agents with considerable toxicities and low probabilities of engendering partial or complete tumor responses of significant duration. They eloquently describe the frequent lack of connection between tumor response of any duration and prolongation of survival or improvement in quality of life. And they argue further that “[f]or patients in whom all standard therapeutic interventions have failed, a slight chance of therapeutic benefit is not unreasonable.” Thus, they maintain that if an experimental intervention in an early-phase trial holds out the potential for a balance of risks of harm and potential benefits comparable to that of an approved standard treatment, the balance of potential benefits to risks of harm for that research is acceptable; moreover, if no standard treatments are available or all have failed, a less favorable ratio of risks of harm to potential benefits is likely to be acceptable to patient-participants, and thus should be acceptable to IRBs.

Although these arguments appear compelling, there are several important countervailing arguments to consider, which make equating the balance of risks of harm and potential benefits in research with that in the treatment context potentially problematic.

1. In the research context, benefit to society is always a factor in the balancing of potential benefits and risks of harm, but it is never a factor in the balancing of potential benefits and risks of harm in treatment. Thus it is conceivable that when risks of harm and potential benefits are balanced in research, the potential benefits to participants might be considerably lower than would be acceptable in treatment. Indeed, benefits to participants might even be nonexistent. The benefits in the calculus could be primarily or exclusively benefits to society. If the calculus for treatment is a starting point, it still must be remembered that treatment and research are different enterprises, with different primary goals.

2. Moreover, precisely because research and treatment are different, even when the balance of risks of harm and potential benefits in a clinical trial appears identical to that of an accepted treatment for the disease or condition of interest, it cannot be identical. It is essential to remember that any balancing of risks of harm and potential benefits for an experimental intervention is unproven, and that a goal of the research is to determine whether the anticipated harms and benefits in fact materialize; that is, proving the hypothesized balance of risks of harm and potential benefits is a research goal. A proven ratio of potential benefits and risks of harm necessarily carries more significance for clinicians and patients than the same ratio in a clinical trial can or should carry for investigators and IRBs. (Potential participants may, however, have understandable difficulty in applying either to them-

selves, because no matter what the odds and no matter how well the odds are known, a given harm or benefit is always either going to happen or not to a given individual.)

3. Finally, Agrawal and Emanuel rightly point out that what makes a ratio of risks of harm to potential benefits acceptable in a clinical trial depends on the whole range of standard and accepted treatments for the disease or condition of interest, as well as on the experience of the population of potential participants and the alternatives genuinely available to them. Yet they fail to acknowledge that every time a new treatment becomes accepted, the availability of that new treatment option changes the overall ratio of potential benefits and risks of harm for each existing treatment. Thus, in reality the availability of more effective or less harmful or even cheaper treatments could make previously acceptable alternatives no longer acceptable. Using FDA approval as a yardstick is therefore potentially misleading. The FDA imprimatur is rarely withdrawn simply because the overall balance of potential benefits and risks of harm has become less favorable by comparison with newer, more effective or less toxic alternatives, but certainly the decision-making process engaged in by physicians and patients will change as the range of available treatments changes. What is reasonable to offer to patients may become unreasonable, even though still FDA-approved. Similarly, what is reasonable to offer to potential participants should change with context—not only as different alternatives become available, but also with different participant populations.

In the clinical trial setting, then, the IRB's determination of whether a given balance of risks of harm and potential benefits is reasonable must be exquisitely contextual. It has to depend on a comparison of the balance offered by the experimental intervention with the balances offered by the available alternatives. But the IRB's determination is fundamentally one of reasonableness. From the standpoint of both ethics and design, what potential participants deem acceptable should not control the IRB's determination of what is reasonable. Even when patient-participants are prepared to undertake risks of considerable harm, the IRB must make an independent assessment of whether the risks of harm and potential benefits are reasonable and whether risks of harm can be further reduced. The IRB's role in making this assessment, independently of what potential participants might wish to risk, is not paternalism toward potential participants, but rather fulfillment of the duty to let only sound and reasonable research go forward in the first instance. It is true that potential participants' willingness to accept an apparently excessive risk of harm, or an exceedingly low likelihood of direct benefit, may reflect an especially complex contextual picture of disease burden and a paucity of meaningful alternatives, and in that respect may influence the IRB's determination of reasonableness under the circumstances. But participants' willingness to accept high risk should not replace the IRB's judgment.

Should Inclusion Benefits Be Balanced Along With Potential Direct Benefits Against Risks of Harm?

Importantly, the preceding discussion focuses on the balance between risks of harm to participants and potential direct benefits to participants from the experimental intervention. Inclusion benefits derive from trial participation rather than from the

experimental intervention. The concept of inclusion benefits is specific to the context of clinical trials, and a key characteristic of most inclusion benefits is that they are in the control of the investigator. However, some inclusion benefits in some studies—namely, the psychological benefits for some seriously ill participants that can come from seeking out every potential benefit, no matter how small or unlikely, especially when all standard treatments have failed them—are analogous to the psychological benefits that comparable patients may gain from trying every available treatment, proven or innovative. Some other inclusion benefits are exclusive to research, such as the psychological benefit of altruism—that is, the benefit from knowing that one is contributing to generalizable knowledge, or the hope that one’s experience can help patients in the future. Should these and other inclusion benefits—including benefits in investigators’ control, such as obtaining desired experimental interventions, standard interventions and approved agents, or monitoring and diagnostic testing, for free or at reduced cost; or the increased attention and support that can accompany research participation in comparison with standard treatments or palliative interventions—be included in the calculus of risks of harm and potential benefits?

Agrawal and Emanuel,^{23–25} and Horng et al., both add inclusion benefits to the calculus.^{23–25} Indeed, they eloquently describe inclusion benefits and their importance. But their discussion of inclusion benefits simply and unwittingly conflates them with direct benefits. It’s not that simple, for several reasons.

1. Inclusion benefits are usually largely within the investigator’s control—they can be “designed into” a study—and thus could be employed, problematically, to add weight to the benefit side of the balance, in ways that at best might draw attention away from minimizing risks of harm and at worst could unduly influence potential participants in favor of participation despite the risks of harm. (For similar reasons, payment to participants is generally not counted as a benefit: It would be too easy to skew the risks of harm/potential benefits calculus by offering to pay participants more in an attempt to offset concern about excessive risks of harm.)

Thus, to count inclusion benefits, which often are within the control of the investigator, in the balance of risks of harm and potential benefits could improperly tempt investigators to “jack up” potential benefits to participants in order to outweigh significant potential harms. The morally preferable course of action is instead to minimize harms, to the maximum feasible extent. Minimizing harms is a fundamental duty of investigators and IRBs. Even in trials with a very favorable risk of harm/potential benefit ratio, investigators and oversight bodies should work to minimize harms out of a core duty of nonmaleficence. In addition, as a practical matter, to focus on increasing potential benefits may distract from requiring investigators to make an articulate argument about potential harms and how they may be minimized.

The possibility that inclusion benefits may serve as undue inducements to participation for participants is most likely to be of concern when potential participants have limited access to necessary medical care, and that medical care is offered as an inclusion benefit. To give just one example, in much HIV/AIDS research, standard treatments are often offered free as an inclusion benefit in studies that add experimental medications to standard regimens. (By contrast, in most oncology research, standard treatment is not provided free; the participant’s health insurer is expected to pay for it.) Thus, in some studies, inclusion benefits must be evaluated

very carefully by IRBs, to ensure that their provision does not substitute for appropriate risk minimization.

2. Some key inclusion benefits—especially the often-postulated “patients do better on study”—may pose especially problematic justice issues. Providing participants with more extensive and intensive individualized attention than they would normally receive as patients, including more study visits, greater support in disease management, and close relationships with investigators and study coordinators, permits investigators to hold out high-quality care as a quid pro quo of research participation, and to allow or excuse deterioration in access to and quality of off-study treatment. This is a significant ethical problem for the health-care system, especially as both reimbursement for treatment and contact time with patients shrink and the conduct of clinical trials grows more remunerative by comparison. It is likewise a problem of particular import for the uninsured and underinsured, who may increasingly seek participation in research as a means of obtaining treatment.

Of course, clinical investigators understandably wish to provide excellent care to participants. Moreover, they have clear duties as investigators to protect participants from harm by designing and following safe and reasonable inclusion/exclusion criteria and stopping rules, both for individual participants and for the study as a whole. These duties may be meaningfully discharged without regard to inclusion benefits. It is, however, increasingly true that in the current health-care system, investigators often perceive that the research environment enables them to feel as though they are being better caregivers for their research participants than for their patients, able to take more time and pay closer attention to their participants as people.²⁶ This unfortunate and poignant truth is in fact another reason to exclude inclusion benefits from the calculus, not a reason to include them. The case for excluding inclusion benefits is further strengthened by evidence that being on study results in no better outcomes for participants than for patients receiving treatment for the same conditions off study.²⁷

3. A complicating factor is the equivocal character of many inclusion benefits. Whether some inclusion benefits are in fact benefits rather than burdens is in the eye of the beholder. Thus, even if the above arguments are not barriers to the consideration of inclusion benefits in the calculus, it is still imperative to consider whether they are benefits to all potential participants. If they do not have this universal character, they cannot be effectively added to the balance. Direct benefits are clearly benefits to participants; even if they do not materialize, their beneficial nature is clear. This is true of some inclusion benefits, but by no means is it true of all. More tests, closer monitoring, more attention, and more study visits all could be viewed as beneficial or could be viewed as burdens. Some participants may consider extra monitoring and study visits to be excessively time-consuming or intrusive, whereas others may welcome the attention. Additional monitoring and diagnostic testing may provide valuable new health information for participants, or it may give rise to alarming false-positive results that cause unnecessary anxiety and incur additional costs, because they have to then be further investigated. Some seriously ill participants may indeed garner psychological benefits from believing they are doing “everything possible” to fight their own disease, or from contributing to knowledge that may be used to help future patients. But other participants may not find these possibilities important or valuable for themselves in research. Encouraging or validating a “do everything possible” attitude may also turn out to be very costly in terms of quality of life for those who are severely

or terminally ill, insofar as participation in a study can be incompatible with good palliative care.

Whether particular inclusion benefits are in fact perceived as benefits by participants is one question. But when the answer could be either yes or no, whether a particular factor can be characterized as an inclusion benefit by investigators, weighed in the calculus by IRBs, and offered as such in the consent form and process is a very different question. The possibility that some research requirements may be viewed as either benefits or burdens can be discussed in the consent form and process, but should preclude their being considered inclusion benefits.

V. Risks of Harm and Potential Benefits in Special Types of Clinical Research

Early-Phase Trials (Classic and Nonclassic Designs)

Most characterizations of direct benefit in clinical research lack specificity.⁸ This is not surprising; a similar lack of specificity about the nature, magnitude, and duration of potential benefits also characterizes much discussion of standard treatments in clinical medicine. Treatments are, generally speaking, supportable by evidence or clinical experience, whether or not that evidence or experience is communicated to the patient. And when research interventions are compared with standard treatments in randomized Phase III trials, it can plausibly be argued that potential benefits from the experimental intervention are implicitly described, at least to a limited extent, by the comparison itself—that is, by the existence of clinical equipoise.

For early-phase clinical trials, however, potential benefits merit further attention. Indeed, it may be morally necessary to describe potential direct benefits more thoroughly in early-phase trials, in particular to explain the limits of knowledge about potential benefits and the limited expectations of direct benefit that are reasonable therein. This additional specificity could assist patient-participants, investigators, and IRBs in preserving clarity about the distinctions between research and treatment, the goals of research, and the mixed and multiple goals of early-phase clinical trials.^{29,30} What remains entirely unaddressed is whether there should be a minimum threshold standard for potential direct benefit (that is to say, a minimal magnitude and likelihood of a particular potential benefit) that must be met in order for a clinical trial to be reasonably said to hold out the prospect of direct benefit for participants.^{2,3}

The balance of risks of harm and potential benefits in early-phase trials is somewhat different from that in Phase III RCTs. The classic Phase I study design, derived from drug studies, enrolls healthy volunteers in a cautious dose escalation format in order to make an initial determination of the side effect profile and to find the *maximum tolerated dose* (MTD)—that is, a dose beyond which the side effects and risks of harm are deemed excessive. In a changing research environment, this classic design is becoming less common, for many reasons. One primary reason is that new pharmaceuticals and biologics have substantially different modes of physiological action than ordinary pharmaceuticals, so that the dose-response relationship is often not linear, making MTDs both unreachable and potentially irrelevant. Assessing risks of harm is similarly affected by the use of nonclassic trial designs in early-phase trials. Although later-phase trials are better positioned to

predict harms by virtue of accumulated experience and constant dosing, if classic dose escalation designs are not employed in early-phase trials, then toxicities may be more difficult to predict. MTDs may not be reached, or they may be reached unpredictably or under unusual circumstances. Uncertain and unknown risks of harm may be more likely, or of more concern, when experience in humans is more limited.

The different modes of action of some new drugs can also make using healthy volunteers problematic, either because the side effects and risks of harm are deemed excessive for healthy participants, or because the physiological effects, whether harmful or beneficial, cannot be adequately assessed in participants who do not have the disease or condition of interest. Thus, many Phase I studies of otherwise classic design enroll patients with the disease or condition of interest. This poses interesting challenges in assessment of potential benefits to participants.

When patient-participants are enrolled in even the earliest human studies, the possibility of direct benefit arises, albeit in the most theoretical sense, simply because those with the disease or condition of interest are the intended beneficiaries of the future treatment, and therefore, if the experimental intervention functioned precisely as hoped, some direct benefit could in theory be possible for some earliest participants. Is this enough to reasonably anticipate direct benefit in the earliest studies? Is the reasonableness of the expectation increased if the design is changed—perhaps to start at a dose level expected on the basis of preclinical studies to have an efficacy-predictive effect?³¹

In Phase III RCTs, questions about the nature, magnitude, and likelihood of direct benefit to participants are usually addressed in terms of clinical equipoise—that is, by considering whether there is enough evidence of an appropriate balance of risks of harm with potential benefits to go forward with the research, without having so much evidence of a favorable balance that further research application of the intervention under study appears unjustified. A sizable literature on equipoise has been developed, and will not be rehearsed here (see Chapter 24). Here it is simply worth noting that applying the concept of clinical equipoise to early-phase research, although tempting, might obscure the need for careful attention to whether potential benefit is reasonably to be anticipated.

Freedman's definition of equipoise was designed to support research in which disturbing equipoise means determining whether a research intervention will become a treatment.^{32,33} This equipoise is defined in terms of Phase III RCTs comparing an unproven intervention to a proven one (or to a placebo). It seems clear that this equipoise was not intended to apply to earlier-phase trials, in which disturbing equipoise does not result in a determination that an intervention has or has not become a treatment.

Essentially, the results of early-phase trials determine whether an intervention will progress to the next stage of research—or not. Thus, in a classic Phase I study, the relevant community of investigators must be sufficiently divided about the safety of a new intervention to support going forward with research to demonstrate or disprove that it can be tolerated by humans. Then, a classic Phase II study might seek data supporting the intervention's capacity to produce some evidence of direct benefit—enough to move forward to definitive assessment in a Phase III trial.

Investigators base their optimism and desire to go forward with clinical research at all stages on promising preclinical and prior clinical data. Yet going forward with research does not mean treating patients—it means continuing research until the research

itself shows (or definitively fails to show) that the intervention has been proven to be a treatment. Each phase of clinical research demonstrates the tension between belief in the promise of a research intervention and scientific skepticism about what is as yet unproven.

Because clinical equipoise is so closely associated with Phase III RCTs, applying the concept in order to assess and balance the risks of harm and potential benefits in early-phase research is unlikely to be helpful. Instead, it could improperly strengthen the therapeutic misconception in early-phase trials, because equipoise has been traditionally and exclusively associated with issues of direct benefit. Further consideration is needed of the balancing of risks of harm and potential benefits in early-phase trials, and of the amount and nature of the evidence required to advance to the next phase, but this balancing ought not to overemphasize potential benefit when the participants, like all participants in classic Phase III RCTs, are also patients.

Surrogate Endpoints and Direct Benefit

Addressing questions about what expectations of benefit are reasonable in early-phase research requires careful consideration of the significance of surrogate efficacy endpoints (SEs). This is so because in early-phase research, SEs are commonly described as² or assumed to constitute^{23,24,41} direct medical benefits for participants who are also patients. Just as in Phase III trials, SEs are often routinely measured in early-phase trials and used as statistically predictive stand-ins for desired clinical outcomes. The most common example is, not surprisingly, from oncology trials, in which tumor shrinkage stands in for prolongation of survival. It is also commonly recognized that the connection between tumor shrinkage and living longer can be extremely tenuous at best.²³

Complicating the use of SEs in early-phase trials are two factors. First, the design and very short duration of the earliest trials generally work to attenuate the connection between SEs and clinical benefit even further. Much more significantly, the postulated relationship is meaningful in the first place only if it has been validated. That is, for traditional cancer chemotherapeutic agents, tumor shrinkage has been shown over time and in many studies to be reasonably predictive of increased survival by a measurable amount. However, tumor shrinkage resulting from agents with different biological action, if not similarly shown related to improved survival, cannot and should not be thought of as predictive of any clinical benefit at all.^{33–40} As a result, even when an early-phase trial (whether Phase I, I/II, or, as is traditional, Phase II) seeks to measure an SE, the meaning of that endpoint is questionable and contested. It is nowhere near as simple as offering an SE as a potential direct benefit to participants. Indeed, it is likely that most SEs measured in early-phase trials have no meaningful relationship to clinical benefit. Without persuasive justification, based not only on theory but also on preclinical and prior and related clinical evidence, SEs in early-phase trials probably should not be included in the calculus of potential benefits and risks of harm. This position is a better reflection of the reality of early-phase clinical trials than is the current habit of generally treating SEs as direct benefits.

Although this degree of caution about SEs may seem extreme in light of persisting public and policy confidence in the promise of research, it is borne out by the scientific warrant for early-phase

trials, which, as noted earlier, is distinct from that of RCTs. Because trial endpoints are often “translated” into potential benefits for participants who are patients, it is appropriate to reemphasize that the goals and endpoints of early phase clinical trials should translate very differently from those in Phase III studies, in order to promote clearer understanding of and reasonable expectations about direct benefit. Early-phase trials are characteristically different from RCTs in their designs, sample sizes, durations, and goals. These differences may be modified by nonclassic designs and new types of investigational agents, but it is far from clear that such modifications can significantly affect the nature, magnitude, or likelihood of direct benefit to trial participants.

First-Participant Issues

Who should be the first participants in early-phase trials, and how should participant choice affect assessment of risks of harm and potential benefits? From a trial design standpoint, a balance necessarily exists between minimizing potential harms to participants and maximizing the value of the knowledge to be gained from them. This balance is especially critical in early-phase trials, as minimizing harms is often most feasible in healthy volunteers, but the knowledge gained from enrollment of healthy participants may be minimal, irrelevant, or difficult to translate into the next phase of study.³

When participants with the disease or condition of interest are used, it is important to determine whether their role in the trial is like or unlike the role of a healthy volunteer. For example, in the gene transfer trial in which Jesse Gelsinger died, his role was similar to that of a healthy volunteer (see Chapter 10). Enrolling the sickest participants first—in that trial, enrolling newborns in the midst of a disease crisis—would have made it extremely difficult to distinguish the risks of harm from the gene transfer from the effects of the disease itself, lowering the value of the knowledge to be gained from the research. Thus, choice of participant can profoundly affect the assessment of risks of harm and potential benefits in a trial, including not only risks of harm and potential benefits to participants but potential benefit to society as well.

Seriously ill people, even those who are clearly dying, are enrolled in all phases and types of research. Assessing and weighing risks of harm and potential benefits for seriously ill participants is especially problematic. Investigators, IRBs, and potential participants may be tempted to assume that direct benefit is more likely when participants are very ill, when all standard treatments have failed, and when no standard treatments exist or no validated treatments are in use—as is often the case in emergency and critical care settings (see Chapter 27).

George Annas has argued that seriously ill and dying people should not be enrolled in clinical research.⁴² Although it is commonly reasoned that patients for whom nothing has worked have “nothing to lose,” he rightly points out that even patient-participants who are close to death always have something to lose from research participation. Possible harms include not only loss of the time expended on research visits that could have been spent with family and friends, but also toxic effects from the experimental intervention. Certainly it might be argued that the risk of death might be valued differently by potential participants with different prognoses, and might be least alarming to those who are dying. But how potential participants might evaluate a risk of harm

is, again, a question that may be asked only *after* the risks of harm have been minimized and the appropriateness of the balance of risks of harm and potential benefits has been established for a given clinical trial. More generally, the idea that anyone can confidently calculate the value of another person's losses, including the loss of life, is troubling and should be avoided. We might be tempted here to state as a truism that the death of a 25-year-old healthy volunteer in a research project is a greater tragedy than the death of an 85-year-old with metastatic cancer in a clinical trial. But to do so would be to rely totally on quantitative measures of value.

Assessing risks of harm and potential benefits in research with seriously ill participants is often complicated by the existence of "partial" alternatives, that is, accepted treatments that are only partially effective, provide only symptomatic relief, are extremely burdensome, drastic, or disfiguring, or are otherwise undesirable in comparison to the promise of a new type of therapy. Comparing the potential benefits of an unproven intervention that is hoped to become a curative treatment to proven treatments that are partial or symptomatic only is a complex process. Gene transfer for X-linked severe combined immune deficiency (X-SCID) provides a provocative illustration of the difficulty. This serious genetic immune deficiency, popularly known as "bubble boy disease," can be managed in a variety of ways, including bone marrow or stem cell transplantation. Children with perfect matches can essentially be cured by a successful transplant. Children for whom only a partial match can be found can experience partial reconstitution of their immune systems, but with important residual immune deficiencies. Genetic intervention appears able to accomplish a significant reconstitution of the child's immune system, with little information as yet about whether and to what extent the beneficial effect can persist over time. And it is now known to carry a significant risk of insertional oncogenesis resulting in leukemia. In an attempt to balance this complex mix of potential harms, benefits, and alternatives, the Recombinant DNA Advisory Committee has recommended that only X-SCID children who do not have an identical or haploidentical transplant match, or whose transplant has failed, should be enrolled in gene transfer clinical trials.⁴³

Decisionally Incapable Subjects

Many children and at least some seriously ill patients may lack decision-making capacity. When the decisional capacity of potential subjects is impaired, if they are to be enrolled in clinical research at all, protections must be instituted to ensure that they are not disadvantaged by the need to rely on substituted decision makers. Protections generally focus on limiting their research participation to studies with particular balances of risks of harm and potential benefits—in particular, to studies in which only minimal risks of harm are posed, or to studies thought to hold out a reasonable prospect of direct benefit. The central problem of this chapter—what constitutes a reasonable prospect of direct benefit, especially from the experimental intervention—is the same in these special contexts as it is in clinical trials generally. However, when research cannot go forward unless a reasonable prospect of direct benefit is identified, the temptation to find such a benefit is great—as is the temptation to set a very low, easy-to-meet threshold of reasonableness, regardless of the available alternatives to research participation. It is essential to interpret and apply such

specialized assessments of risks of harm and potential benefit cautiously, in order to protect participants from the temptation to overestimate potential benefits to ensure that important but risky research goes forward.

Genetic Research

Genetic research is discussed in detail in Chapter 29. We mention it here only to note that all types of genetic research potentially pose a particular challenge for assessing and balancing risks of harm and potential benefits, because genetic research often carries special risks of harm to participants, often without corresponding benefits. The collection of genetic information, including DNA samples, is often added to clinical trials. The collection and use of such information, as well as the maintenance of databases containing it, has privacy implications for participants, and can also adversely affect individual participants' sense of identity, self-esteem, and future life prospects, through common popular misunderstanding of the power of genetics, such as *genetic essentialism* (we are nothing more than our genes) and *genetic determinism* (our fate is determined by our genes). In addition to this overestimation of the importance and predictive power of genes in human health and welfare, it is also common to use genetic material and information to identify putative connections between genes and physical or behavioral characteristics in the absence of strategies for treating, preventing, or ameliorating the diseases or conditions so identified.

Genetic research also has the power to pose risks of harm to secondary participants,⁴⁴ and can also potentially stigmatize entire groups, such as ethnic, geographic, or religious communities.⁴⁵ As a result, IRBs are placed in the difficult position of needing to carefully consider how the balance of risks of harm and potential benefits for a particular study is affected by its genetic character, or by the addition of a genetic information-gathering component—which may have far-reaching social, familial, or economic ramifications for the participants.

Moreover, given that misconceptions about genetics are often widely repeated in both the popular and scientific press, IRBs must also determine whether *erroneous* beliefs about genetic illnesses or testing in research contexts constitute harms. For example, insurance companies and employers can still discriminate against persons who participate in genetics research, even if their reasons for discrimination are without scientific merit. The history of discrimination based on genetic misinformation in the United States, and in Europe, is extensive, and IRBs would be negligent to ignore this special risk of harm.

It is worthy of note that the risks of harm posed by research to secondary participants and nonparticipants are not unique to genetic research. Many clinical trials that include the collection of data through medical records, surveys, and questionnaires may implicate secondary participants. Similarly, many types of clinical research have the capacity to place third parties at risk of harm. Early gene transfer clinical trials often required participants to agree to remain in isolation until it was certain that they could no longer shed genetically altered viruses, even if they decided to leave the trial. Yet many clinical trials not involving gene transfer could place others at risk in a variety of ways, ranging from the risk of contracting an unusual infection from an immunosuppressed study participant to the risk of being injured by a research

participant whose driving skills have been impaired by an investigational drug. Generally speaking, risks of harm that are posed by exposure to the research participant should be addressed by the IRB as part of the task of risk minimization. However, the risks of harm that are posed to the participant and others by the acquisition and use of the research data themselves may in some cases be appropriately included in the risk of harm/potential benefit calculus.

Complementary and Alternative Medicine (CAM)

Roughly 40% of the U.S. population use CAM, and this number, especially for those who use herbal remedies, is on the rise.⁴⁶ The Dec. 30, 2003, move by the FDA advising consumers to stop using dietary supplements containing ephedra immediately and to remove ephedra from the market⁴⁷ signals a future in which CAM remedies, especially dietary supplements and herbal remedies, will be increasingly subjected to clinical trials.

Assessing and weighing risks of harm and potential benefits in research with complementary and alternative medicines can be especially challenging. CAM is essentially a negative designation—anything that is not allopathic medicine—and includes a dizzying array of practices, from chiropractic, acupuncture, traditional Chinese medicine, Reiki, massage, homeopathy, biofeedback, herbal remedies, and megavitamins to various forms of spiritual healing and intercessory prayer. These are variously *complementary* or *alternative*. Some, such as chiropractic, are already on the cusp of legitimacy, widely subject to licensing and accreditation laws, and often covered through insurance. For some, such as acupuncture for nausea secondary to chemotherapy, there is research available about safety and efficacy. For others, such as intercessory prayer to reduce hospital stays, it is difficult to see how to formulate a testable hypothesis (although some have tried). What is and is not CAM can be a function of scientific evidence, public acceptance, reimbursement by insurance, what physicians do, and so forth. None of these ways of defining and delineating CAM is the obvious or stand-alone criterion, and this makes questions about what should be researched all the more difficult.

Many CAM therapies claim to connect the physical and the metaphysical, or at least deal with health in a more holistic sense. Hence one of the key elements in assessing risks of harm and potential benefits is trying to factor in a notion of benefit that is broad and complex enough that a CAM therapy can be tested on grounds commensurate with its putative health claims. It is important to note that any such testing must be referenced to pluralistic medical and cultural norms, not simply to standard biomedical notions, in designing the research.⁴⁸ Moreover, for many CAM practices, the absence of standardization among practitioners, combined with imprecise measures of outcomes, makes the harm/benefit ratio more difficult to assess and thereby renders the informed consent process more vague and fragile. For example, many CAM therapies emphasize a concept of *wellness* that is more inclusive than typically found in outcomes research. Whether and how to incorporate this broad view of health into a notion of *benefit* in a clinical trial is a question of both epistemology and ethics. That is, understanding harm/benefit assessment in CAM research implicates both research methodology and the ends we value and seek to achieve through research.

Although IRBs should assess potential benefits and risks of harm in CAM research in much the same way as they do in investigations of allopathic interventions, expanded and sometimes novel notions of benefit will probably be needed to adequately assess research in this emerging area. It will be especially important for IRBs to have CAM practitioners as part of any review process when risks of harm and potential benefits are assessed.⁴⁹ It is important to recognize that the need to devise new understandings of direct benefit in this area is consistent with the need described elsewhere in this chapter to assess potential benefit with caution and circumspection. We lack a robust common vocabulary of potential benefit; in the current clinical research environment, which is characterized by fluidity and rapid change, development of that common vocabulary of concepts must likewise be both flexible and precise—a considerable but worthy challenge.

VI. Conclusions

How should IRBs compare risks of harm and potential benefits? Bearing in mind that the process of assessment and comparison should be transparent and reproducible,²² but that the product—an IRB's actual determination for a given study—may reasonably vary among IRBs, there are several things that IRBs can do to improve the process.

First, IRBs should ensure that investigators provide them with the information they need in order to assess and compare risks of harm and potential benefits effectively.⁵⁰ Second, they should directly address the challenge of making more explicit comparisons of risks of harm with potential benefits that are both consistent and appropriately flexible. Third, this explicit consideration should include all relevant dimensions of both risks of harm and potential direct benefits—nature, magnitude, duration, and likelihood. Fourth, IRBs should consider carefully how to address inclusion benefits, both in particular clinical trials and as a matter of policy.

Finally, to emphasize the primary role of benefit to society in the balancing of potential benefits and risks of harm, especially in early-phase research, IRBs should consider establishing “no direct benefit” as a rebuttable presumption except in Phase III studies comparing experimental and standard interventions. In order to rebut the presumption, investigators would have to provide evidence from prior studies supporting the existence of a reasonable chance of direct benefit under the circumstances. Rebutting this presumption would require the IRB to discuss and determine what likelihood of potential direct benefit of a given nature and magnitude is reasonable for a particular clinical trial. In this way, the IRB's model of comparing potential benefits and risks of harm can be both consistent and context dependent.

How should investigators view their obligations to participants based on the assessment of risks of harm and potential benefits? Clinical investigators understandably and genuinely seek to serve the best interests of their patient-participants, too often without directly addressing essential differences between treatment and research. Just as the moral framework of clinical research is derived from clinical practice, clinical investigators enrolling patients as research participants seem generally to derive their role morality from clinical care. It seems clear that a more robust ethic of participant-centered care in research is needed, in order to structure a moral role for investigators that is based on acknowledging the societal goals of research, ensuring that harms and risks of

harm to participants are minimized, and supporting the development of professional norms for care in research relationships with participants.

Such professional, participant-centered norms might go a long way toward reducing the temptation of researchers to feel that they are acting more like physicians by promoting research benefits that are only speculative or, at best, remote possibilities. Developing such a role morality could help to focus investigators' obligations on the appropriate design and conduct of clinical trials without promoting the therapeutic misconception, either among themselves or in research participants.⁵¹⁻⁵⁶

Risk-Benefit Assessment in Pediatric Research

Without clinical research on pediatric illnesses and medical interventions, children might receive dangerous or ineffective treatments. Yet society also has an obligation to protect children from excessive risks and foster their development, which could be threatened by enrolling them in research studies. Guidelines for pediatric research are needed to balance these aims, taking into account the fact that most children are not able to give informed consent.

Clinical research may offer some prospect of clinical benefit to the children who enroll in it. For example, in a study comparing two asthma treatments, the participating children may experience relief of their asthma symptoms as a result of being in the study. In such cases, if the potential for clinical benefit is great enough and the risks low enough, exposing participating children to the risks seems justified. Guidelines around the world reflect this view, allowing children to be enrolled in clinical research when it offers a potential for clinical benefit that compensates for the risks, and the risk-benefit profile of the research is at least as favorable as the available alternatives.

These guidelines raise the question of which benefits should be considered in this risk-benefit analysis. Clinical research may offer a prospect of *direct* benefit, such as improved health as a result of the study interventions; it also may offer *indirect* benefits to participants, such as payment, the opportunity to learn about the research process, or personal satisfaction from contributing to the research. Most commentators argue that research review boards should consider only clinical benefits from research procedures—but not any benefits from added services that are unnecessary for research purposes—when making risk-benefit

assessments.¹ Similarly, official guidelines for institutional review boards (IRBs) in the United States specify that payments for research participation should not be considered benefits to subjects.²

Very little work has been done to clarify precisely which types of benefits may be used to justify the risks of research, and more work in this area is needed. However, the present chapter focuses on research studies that do not offer participants any potential for clinical benefit. This type of research raises significant ethical concern and has been the subject of ongoing debate.^{3–9} Some commentators argue that research with children is inherently unethical when it does not offer them a compensating potential for clinical benefit. Paul Ramsey and Richard McCormick debated this question over the span of a decade, in one of the most famous debates in research ethics. McCormick offered a number of arguments in support of such research,^{10,11} including the claim that children would consent to it if they could, whereas Ramsey provided forceful objections to each of McCormick's proffered defenses.^{12,13}

The theoretical debate over the ethical acceptability of pediatric research that does not offer a compensating potential for clinical benefit continues. In practice, almost all guidelines around the world now allow such research, provided the risks are sufficiently low. This was not always the case, however. For example, the German guidelines of 1931 prohibit “non-therapeutic” research with children no matter how low the risks.¹⁴ Similarly, the Nuremberg Code, promulgated by the judges at the war crimes trial of the Nazi doctors following World War II, stipulates that informed consent of the subject is essential to ethical research, thereby seeming to prohibit all pediatric research.¹⁵

Research that does not offer the potential for clinical benefit is necessary to improve pediatric medicine. As a result, guidelines that prohibit such research may have enormous social costs. Caldwell and colleagues note that without trial-based data on therapies' specific effects in children, "clinicians, families and policy-makers are forced to extrapolate from results of studies in adults. This extrapolation is often inappropriate because children have a different range of diseases and metabolize medications differently, resulting in responses to treatment that are unpredictably different to adults."¹⁶

To take a specific example, when investigators wanted to determine whether the combination of lopinavir and ritonavir was safe and effective for children with HIV, they first needed to determine a safe dose that could be used in subsequent toxicity and efficacy trials. To make this determination, investigators gave children single doses of the combination to assess which dose levels they would tolerate. These studies, necessary preludes to future efficacy studies, did not offer the participating children any chance for medical benefit, and posed some risks to them. Similarly, the initial toxicity studies of the Dryvax smallpox vaccine, which were needed prior to future efficacy studies of the vaccine, posed risks to participants but did not offer them a prospect of direct benefit.¹⁷

Our historic reluctance to conduct such research on children appears to continue. It is estimated that approximately 75% of drugs prescribed for children lack adequate testing in children.¹⁸ As a result, physicians often prescribe medications for children that have not been proven safe and effective for them.¹⁶ To protect children from unsafe and ineffective medications, society needs to conduct and support pediatric research, including those necessary studies that do not have the prospect of direct benefit to participants.^{19,20} At the same time, society has an obligation to ensure that the risks to which children in these studies are exposed are not excessive. To achieve an appropriate balance between allowing important research studies to proceed and protecting the children who participate in them, most research guidelines around the world rely on the concept of *minimal* risk to regulate pediatric research without a prospect of clinical benefit.

The concept of minimal risk is used to regulate a range of research studies. The Indian Council of Medical Research and the South African Medical Research Council guidelines use the minimal risk standard to determine when research may be conducted with a waiver of informed consent.²¹ Other guidelines, including Nepal's guidelines for health research,²² use the minimal risk standard to assess research with prisoners, whereas those from Uganda use the minimal risk standard to define allowable non-beneficial research involving fetuses.²³

The use of a single standard for this range of studies has obvious practical virtues, requiring investigators, institutions, funders, and IRBs to learn only one standard in order to assess a wide range of research. However, the reliance on the concept of minimal risk raises the question of whether this or any other single standard provides the correct risk threshold for these myriad kinds of studies. For present purposes, we focus here on clarifying and assessing the minimal risk standard as it applies to pediatric research that does not offer participating children a compensating potential for clinical benefit. Although this analysis may be helpful for assessing the use of minimal risk in other contexts, we leave that analysis for another time.

Interpretation of the Minimal Risk Standard

Most research regulations, including those issued by the Council of Europe,²⁴ the Council for International Organizations of Medical Sciences (CIOMS),²⁵ the United States,²⁶ Australia,²⁷ Canada,²⁸ South Africa²⁹ and Uganda,²³ define minimal risks based on the risks of daily life. For example, at 45 CFR 46.102(i), the U.S. federal regulations define minimal risks as risks that are "not greater in and of themselves than those ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests."²⁶

This definition might be interpreted in several ways, depending upon which children's lives are used as the standard for assessing research risks. The *procedural* interpretation regards the "risks children ordinarily encounter in daily life or during the performance of routine examinations or tests" as referring to the activities children encounter in daily life, such as walking to school or taking paper-and-pencil tests. On the procedural interpretation, research interventions that children do not ordinarily encounter in daily life, such as PET scans, necessarily qualify as greater than minimal risk. This interpretation might be thought to be bolstered by the statement in the U.S. regulations that in order to approve research that poses more than minimal risk without a prospect of direct benefit, IRBs must consider whether the intervention in question "presents experiences to subjects that are reasonably commensurate with those inherent in their actual or expected" situations (45 CFR 46.406).²⁶ However, there are good reasons to think this interpretation is misguided.

First, section 406 of the U.S. regulations addresses a different category of research, namely, interventions that pose greater than minimal risk. The specific requirements of section 406 assume that the research has already been assessed with respect to the minimal risk standard. Thus, the requirement of commensurability with children's experience is not relevant to the interpretation of the minimal risk standard, but rather an additional constraint applied to research that has already failed to meet that standard. Further, in explaining its inclusion of this requirement, the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research—whose work led to the U.S. regulations—stated explicitly that it was intended as only one safeguard to ensure that research, even if posing greater than minimal risk, was not too psychologically distressing for the pediatric participants. Here the National Commission made clear that this requirement was not relevant to determining whether research poses minimal risk, but rather was an added safeguard on research that poses greater than minimal risk. The commissioners wrote:

The requirement of commensurability of experience should assist children who can assent to make a knowledgeable decision about their participation in the research. . . . More generally, commensurability is intended to assure that participation in research will be closer to the ordinary experience of the subjects.³⁰

In addition to helping children make an informed assent decision, the National Commission recognized that when a research procedure is unfamiliar to children, its psychological risks may increase. For example, children who undergo a PET scan for the first time may face a greater chance of experiencing stress or

nervousness than they would if the procedure were familiar. Yet psychological considerations do not exhaust the types of risks that research participation poses to children. Even children who are very familiar with a research procedure may face risks from radiation and other sources. For this reason, contrary to the procedural interpretation, most regulatory definitions of minimal risk are based on the level of risk, not the kinds of activities, children ordinarily encounter in daily life. Using this approach, whether hypnosis poses greater than minimal risk depends on whether the risks are greater than the level of risks children encounter in daily life, not on whether children ordinarily undergo hypnosis.

The *relative* interpretation regards the “risks children ordinarily encounter in daily life or during the performance of routine examinations or tests” as referring to the level of risks ordinarily encountered in daily life by the particular children who will be enrolled in the research. This interpretation would allow researchers to expose children who face greater risks in daily life to greater risks in research, even when the research does not offer them a prospect of clinical benefit. Children who live in violent neighborhoods, or who face greater than average environmental health hazards, could thereby be exposed to greater research risks simply because they face greater risks in their daily lives. This result seems unjust, a kind of societally induced double jeopardy.

To avoid taking advantage of some children’s unfortunate circumstances in this way, most commentators endorse the *objective* interpretation of the minimal risk standard. This interpretation regards the “risks children ordinarily encounter in daily life or during the performance of routine examinations or tests” as referring to the level of risks ordinarily encountered in daily life by average, healthy children.³¹ In the words of a recent Institute of Medicine report, the minimal risk standard should be interpreted based on the level of “harms or discomfort that average, healthy, normal children may encounter in their daily lives or experience in routine physical or psychological examinations or tests.”¹⁹

The risks that average, healthy children face in daily life vary enormously between countries. The risks currently faced by average, healthy Sudanese and Iraqi children are substantially higher than the risks faced by children in Norway or Costa Rica. Thus, although the objective interpretation blocks investigators from exploiting those children who face especially dangerous circumstances compared to other children in the same country, it does not prevent investigators from exploiting average, healthy children who live in especially dangerous countries. To address this concern, the South African guidelines limit the definition of minimal risks even further, to the risks of daily life for average, healthy children who live in *stable* societies.

Although the objective interpretation of the minimal risk standard appears to be appropriate in most cases, it does not seem to work in all cases, suggesting that it should be used as a default that allows for some exceptions rather than a strict requirement. One possible exception to the objective interpretation involves children’s participation in research as bone marrow donors. In some cases, research studies may use a bone marrow procurement procedure that is different from that which donors would face in the clinical setting. In such cases, all the risks of donation would count as research risks, and the reviewing IRB may determine that these risks exceed the risks in daily life for average, healthy children. It follows on the objective interpretation of the minimal risk standard that these studies would necessarily qualify as greater

than minimal risk. This seems a counterintuitive result in cases in which the risks of the research procurement *replace* the risks of the standard procurement, and the research risks are equivalent to or lower than the risks of the standard procurement. In these cases, the research risks seem acceptable if the risks of the clinical donation are acceptable. To achieve this result in practice, it seems IRBs will have to appeal to the relative standard for minimal risk, concluding that the procurement risks are no greater than the risks that pediatric donors would face otherwise.

This example illustrates an appropriate exception to use of the objective standard for minimal risks, one that may apply to other protocols meeting the same criteria. In general, IRBs may use a relative standard—basing decisions on whether research risks are greater than the risks the specific children face in daily life—when (1) the risks the children face in daily life are considered acceptable by society and (2) the research risks replace the risks in the children’s daily lives. Transplant research involving substantially different procurement procedures meets these conditions when the risks of research donation replace and are no greater than the risks of a standard donation.

Recognizing that there may be some exceptions, the objective interpretation appears to provide the appropriate standard in most cases. To determine whether the existing definition of minimal risk provides adequate protection, it is important to determine how IRBs apply this definition in practice. Do IRBs apply the minimal risk standard in ways that allow appropriate research, while protecting children from excessive risks? Or do IRBs apply this standard in ways that block valuable and appropriate research and/or have the potential to expose children to excessively risky research?

Implementation of the Minimal Risk Standard

A survey of the chairpersons of 188 IRBs responsible for reviewing and approving pediatric research in the United States provides some data on how IRBs apply the minimal risk standard under the *risks of daily life* definition.³² In this survey, the chairpersons were asked to categorize eight common research procedures as “minimal risk, a minor increase over minimal risk, or more than a minor increase over minimal risk when done in healthy 11-year-olds for research purposes only.”

A single 10 cc blood draw by venipuncture was the only procedure categorized as minimal risk by a majority (81%) of IRB chairpersons. Electromyography (EMG) was categorized as minimal or a minor increase over minimal risk by 53%, but as more than a minor increase over minimal risk, and hence too risky for IRB approval without a prospect of clinical benefit to the participants, by 41% of IRB chairpersons. Allergy skin testing was categorized as minimal risk by 23%, a minor increase over minimal risk by 43%, and more than a minor increase over minimal risk, hence too risky for IRB approval without a prospect of clinical benefit to participating children, by 27% of respondents. A single dose of a drug that had a 1/100,000 chance of death but no other side effects was categorized as minimal risk by 7%, a minor increase over minimal risk by 30%, but more than a minor increase over minimal risk by a majority (59%) of chairpersons.

This survey found that IRB chairpersons are significantly more likely to categorize a lumbar puncture (LP) without conscious

sedation as minimal risk when performed in sick children who had numerous LPs in the past, than when the same LP is performed in healthy children. This finding suggests that some chairpersons may be applying the minimal risk standard based on the risks in the daily lives of specific groups of children. Hence, it appears that at least some IRBs may be using the relative interpretation of the risks of daily life standard, even in cases in which its use does not seem justified. Further research will be needed to assess this possibility.

These data also suggest that IRBs may be implementing the minimal risk standard inappropriately in other cases as well. The U.S. regulations define *minimal* risk as the risk of harm or discomfort “ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests.” Yet, 70% of the IRB chairpersons categorized allergy skin testing as more than minimal risk, despite the fact that it is a routine physical test.

IRB chairpersons’ categorizations of research procedures varied widely. Overall, 27% of IRB chairpersons categorized allergy skin testing as too risky for IRB approval without a prospect of clinical benefit to the participating children, whereas 66% deemed it safe enough for IRB approval without a prospect of clinical benefit. Similarly, 59% would prohibit a pharmacokinetic study with a 1 in 100,000 risk of death as excessively risky, yet 37% would permit such a study as posing minimal risk or a minor increase over minimal risk. Although 19% of chairpersons considered a confidential survey of sexual activity to be too risky for IRB approval, 73% deemed it approvable by an IRB.

This variation seems unjustified. How can 37% of IRB chairpersons determine that the risks of a pharmacokinetic study are similar to the risks children face in daily life, whereas 59% determine that the same risks significantly exceed the risks children face in daily life? This level of variation raises concern that some IRBs may be categorizing overly risky procedures as only minimal risk, or other IRBs may be prohibiting minimal risk research based on the mistaken belief that the procedures pose greater risks than the federal regulations allow.

These data do not determine whether the risks of specific research procedures in fact are greater or less than the risks children face in daily life. Hence, these data do not determine which risk assessments are consistent with the risks of daily life standard in each case. However, the importance of protecting children from excessive risks while still allowing appropriate research suggests that errors in either direction are ethically troubling and need to be addressed.

The variation in IRB chairpersons’ risk assessments may trace, in part, to the fact that IRBs are responsible for assessing the risks of pediatric research but often do not have complete data on the risks posed to children, especially nonphysical risks. For example, the variation in chairpersons’ categorization of the risks of allergy skin testing may result from uncertainty over whether allergy skin testing poses more than a minimal risk of *anxiety* in children.

Implementation Without Empirical Data

Although the risks of daily life standard has been in effect in the United States for nearly 25 years, and data have been collected on the riskiness of some particular activities, no comprehensive empirical assessment of the risks average, healthy children ordinarily

encounter in daily life exists. Absent empirical data, IRB members must rely on their own perceptions to assess whether research risks exceed the range of risks that average, healthy children ordinarily encounter in daily life. Unfortunately, extensive psychological research demonstrates that individuals make systematic errors when they assess risks based on their own perceptions.^{33–36} Individuals focus on characteristics of activities that do not correlate directly with the activities’ risk level, including familiarity with the activity, perceived level of control over the activity, and reversibility of the activity’s potential harms. They consistently judge less familiar activities, as well as activities over which the participants seem to exert less control, such as snowboarding, to be riskier.³⁷ For this reason, flying in commercial airplanes is commonly perceived to be riskier than driving in a car.

Given these systematic biases, IRB members who rely on personal perception rather than empirical data may end up rejecting low-risk studies when they involve unfamiliar procedures, while approving studies that pose excessive risks when they involve familiar procedures. To avoid these mistakes, it is imperative to empirically quantify the risks average, healthy children ordinarily encounter in daily life and during the performance of routine examinations and tests. Gathering these data also would provide an opportunity to assess the ethical appropriateness of the risks of daily life definition of minimal risk.

The Risks of Daily Life and Routine Examinations

Average, healthy children in stable societies encounter a range of risks in daily life, from the risks of reading a book to playing soccer, from taking a bath to riding in a car. To qualify as minimal, where within this range of risks encountered in daily life by average, healthy children must research risks fall? Most regulations define minimal risks as risks that do not exceed the risks children encounter in daily life. To make this determination, IRBs must assess whether research risks exceed the upper end of the range of risks children face in daily life.

Estimates of the level of risks average, healthy children in the United States ordinarily encounter in daily life can be developed by combining data from the Centers for Disease Control and Prevention’s National Center for Injury Prevention and Control,³⁸ the National Highway Traffic Safety Administration,^{39,40} American Sports Data, Inc.,⁴¹ and other databases.

Mortality Risks

Riding in a car appears to pose the greatest risk of death for average, healthy children in the United States (see Table 49.1). For every million car trips taken by children aged 0–14 years, approximately 0.06 will die—that is, the risk of death is approximately 0.06 per million trips. The average risk of dying from a car trip for 15- to 19-year-olds is approximately 0.4 deaths per million trips. This average combines the mortality risks of riskier, but still ordinary, car trips with car trips that pose less than average mortality risks. The upper end of the range of mortality risks ordinarily encountered by average, healthy children can be estimated by identifying common factors that increase the risks of traveling by car. Young drivers increase the risk of dying on a car trip 2.0-fold.³⁹ Similarly, driving on rural highways increases the risk of

Table 49.1
Physical Risks in the Daily Lives of Average, Health Children^a

Harm	Activity	Risks per Million Instances of the Activity				
		< 1 yr	1–4 yrs	5–9 yrs	10–14 yrs	15–19 yrs
Deaths	Average car trip ^b	0.06	0.06	0.06	0.06	0.4
	Riskier car trip ^c	0.6	0.6	0.6	0.6	4.0
	Bathing/swimming ^d	0.05	0.08	0.02	0.02	0.04
Hospitalization	Average car trip	0.3	0.5	0.8	1.0	3.0
	Bathing/swimming	0.2	0.3	0.04	0.03	0.01
Emergency room visit	Average car trip		8.0	13.0	18.0	32.0
	Bathing/swimming	0.3	0.3	0.06	0.04	0.03

^aNumber of children in each age cohort (millions): < 1 yr = 4; 1–4 yrs = 16; 5–9 yrs = 20; 10–14 yrs = 21; 15–19 yrs = 20. ^bTo determine the average risk of mortality from a single car trip, we assumed an average of 2 car trips per day and divided the annual risk of mortality by 365 days.

^cTo estimate the risk of mortality from a riskier but ordinary car trip we calculated the extent to which the combination of a young driver (2-fold increase in risk), rural highways (2.6-fold increase in risk), and wet conditions (1.8-fold increase in risk) increases the risk of mortality of an average car trip. ^dEstimate assumes an average of 1 exposure per day to bathing, swimming, or another water activity.

Data adapted from Centers for Disease Control and Prevention's National Center for Injury Prevention and Control, and the National Highway Traffic Safety Administration.^{38–40}

dying on a car trip 2.6-fold.⁴⁰ Finally, driving in wet conditions increases the risk of dying on a car trip 1.8-fold.⁴⁰

Although car trips that include all three factors are riskier than average, these trips nonetheless seem ordinary for average, healthy children. Reasonable parents who live in the country routinely allow their teenage children to drive in the rain. Thus, combining these three factors provides one estimate for the upper end of the range of mortality risks ordinarily encountered by average, healthy children. Specifically, these data suggest that the upper end of the range of mortality risks is approximately 10 times the risk of mortality of the average car trip, or approximately 0.6 deaths per million trips for children aged birth–14, and approximately 4.0 deaths per million trips for children aged 15–19.

Morbidity Risks

Participation in sports appears to be the activity that poses the greatest risk of injury for average, healthy children in the United States (see Table 49.2).⁴¹ For every million times individuals in the United States play basketball, approximately 1,900 will be injured in some way, of whom approximately 180 will break bones, 160 will require surgery, and 58 will be permanently disabled. For every million times individuals play American football, approximately 3,800 (1 in 250) will be injured in some way, approximately 910 of whom will break bones, 270 will require surgery, and 42 will be permanently disabled (approximately 1 in 20,000). Because the data for sports injuries include all participants over the age of 6 years, it is difficult to estimate the extent of any age effects in these data. For younger children in the United States, bathing and swimming pose the highest risk of morbidity (see Table 49.1).

Psychological Risks

IRBs should consider all the risks that research participation poses to children, not just the physical risks. Although research participation typically does not pose economic or social risks to children,

it can pose psychological risks. No systematic data are available on the psychological risks children face from ordinary activities of daily life, such as riding on a roller coaster. However, a series of studies in thousands of healthy children in the United States found that approximately 27% of healthy children “sometimes” feel scared or afraid in daily life, and 26% “sometimes” worry about what will happen to them.⁴² In addition, 3% of healthy children “often” or “always” feel scared or afraid, and 7% of healthy children “often” or “always” worry about what will happen to them. Although the data do not characterize the severity of these psychological harms, they do suggest that feeling scared or anxious is an ordinary experience for many average, healthy children in the United States.

Risks of Routine Clinical Examinations

Existing data reveal that routine examinations and tests pose very low risks to children. Routine clinical measurements of height and weight pose no risks; routine psychological tests pose no physical risks and very low risks of anxiety or distress. Routine clinical blood drawing poses small risks of transient pain, anxiety, and minor hematomas.⁴³ The only risk of serious harm from blood drawing is syncope (fainting), with approximately 375 of every million blood draws leading to syncope.⁴⁴ Syncope is also the only risk of serious harm from allergy skin testing, with approximately 1,625 of every million individuals who undergo allergy skin testing experiencing syncope.⁴⁵ These data reveal that as long as children are seated and antiseptic methods are used, blood drawing and allergy skin testing pose only small risks of pain and anxiety to children.

Limitations of the Data

Because the risks of many ordinary activities have not been systematically assessed, the extant data likely underestimate the risks of daily life. In addition, the extant data on many morbidity risks include both children and adults; the risks to children may be

Table 49.2
Physical Risks From Sports in the Daily Lives of Average, Healthy Children^a

Sport	Risks per Million Instances of Participation				
	Total Injuries	Permanent Disability	Total Level IV Injuries ^b	Surgeries	Broken Bones
Football	3,800	42	500	270	910
Soccer	2,400	38	300	N/A	N/A
Basketball	1,900	58	300	160	180
Cheerleading	1,700	N/A	100	N/A	N/A
Baseball	1,400	60	300	120	30
Skateboarding	800	N/A	200	20	170

^aData are for all individuals over 6 years of age. ^bLevel IV injuries are those that resulted in emergency room treatment, overnight hospital stay, surgery or ongoing physical therapy, and that prevented participation in sports for at least one month. N/A = Not available

Data adapted from American Sports Data, Inc. *Comprehensive Study of Sports Injuries in the U.S.* (Hartsdale, N.Y.: American Sports Data, Inc. 2002).⁴¹

higher or lower than these figures. These data were gathered from U.S. sources, and even among stable societies there may be some variation in the incidence of injury from activities of daily life; for example, driving conditions may differ, as may the popularity of some activities such as particular sports. Finally, the data provide only approximate risk estimates. This uncertainty should not pose a serious obstacle to implementing the minimal risk standard in practice, however. IRBs rarely have precise estimates of the risks of research interventions. Hence, IRBs must make general comparisons between the estimates of the risks of daily life and the estimates of the risks of research procedures.

Cumulative Risks of Daily Life

Serially assessing the risks of individual research procedures fails to take into account the possibility that “research may involve several different procedures that may involve minimal risk or burden individually, but that may present more than minimal risk when considered collectively.”⁴ One way to address this possibility would be to compare the cumulative risks of all the non-beneficial procedures or interventions in a given study to the cumulative level of risks that average, healthy children ordinarily encounter during a similar time span in daily life (see Table 49.3). To determine whether the cumulative risks of a protocol that lasts eight hours and requires one overnight stay qualify as minimal

under the risks of daily life definition, IRBs could assess whether these cumulative risks exceed the upper end of the range of cumulative risks that average, healthy children ordinarily encounter in approximately one day.

The upper end of the range of ordinary, daily cumulative risks in the United States might be defined by (1) one roundtrip car ride with risks at the upper end of the range of ordinary mortality risks, (2) one instance of bathing, and (3) one episode of playing on a playground for children birth–4 years old or one instance of playing basketball for children 5–19 years old. Adding these risks together implies that, with respect to cumulative mortality risks, research studies qualify as minimal risk when the mortality risks participants face per day of participation are not greater than approximately 1.5 in a million for children 1–14 years old and approximately 10 in a million for children 15–19 years old (see Table 49.3).

Implications of the Risk Data

Data reveal that the ordinary activities of daily life, which are the basis of many definitions of minimal risk, pose up to a 1 in 250 risk of injury and a 4 in a million risk of death to average, healthy children in the United States. These findings are surprising. They suggest that the risks of daily life definition of minimal risk has the potential to expose children to significantly greater risks than most IRBs assume are allowable, and greater risks than many

Table 49.3
Cumulative Risks in the Daily Lives of Average, Healthy Children^a

Age	Risks per Million Children per Day				
	<1 yr	1–4 yrs	5–9 yrs	10–14 yrs	15–19 yrs
Deaths	0.5	1.5	1.4	1.4	10
Hospitalizations	0.0	1.3	1.7	2.1	6.0
Emergency room visits	0.4	16.4	26.0	36.1	64

^aThe cumulative risks healthy children face in an average day is calculated based on the risks of one “riskier” roundtrip in a car, one instance of bathing, and one instance of playing on a playground for children 1–4 years or participating in basketball for children 5–19 years.

commentators regard as acceptable.¹⁹ These data reveal that, under the objective interpretation of the risks of daily life definition, research *procedures* that pose up to a 1 in 250 risk of injury qualify as minimal risk. Similarly, nonbeneficial research *studies* that pose up to a cumulative daily mortality risk of 1 in 100,000 for children 15–19 years old qualify as minimal risk under this interpretation.

Using Data to Apply the Minimal Risk Standard

Research procedures sometimes pose the same types of risks that children face in daily life, such as a risk of death, thus allowing IRBs to compare the two risks directly. To determine whether these procedures pose greater than minimal risk, IRBs can directly compare the likelihood that children will die from undergoing the procedure to the likelihood children will die as a result of the ordinary activities of daily life, such as riding in a car.

In other cases, research interventions pose different types of risks than do the activities of daily life. Pediatric research participants may face a risk of airway abrasion from bronchoscopy; daily life for average, healthy children involves essentially no risk of airway abrasion. Hence, direct comparison would suggest that bronchoscopy necessarily qualifies as greater than minimal risk, no matter how low the chance of abrasion and how minor the abrasion. This result seems counterintuitive. If techniques advance to the point at which bronchoscopy poses a 1 in a million risk of airway abrasion and no other risks, it would seem less risky than a car ride that poses a 1 in a million risk of death. To avoid this counterintuitive result, IRBs must assess whether the level of risks is comparable to or exceeds the level of risks children face in daily life.

Although comparing risks of different types is conceptually complex, parents make these assessments every day. To decide how their children get to school, parents assess whether, taking into account both likelihood and magnitude, the risk of skin abrasions and broken bones from riding a bicycle is more serious or worrisome than the risk of injury or death from riding the bus. Applying this approach to research interventions requires a method for comparing the seriousness of research risks to the seriousness of the risks of daily life.⁴⁶ This approach could be clarified by using a systematic method, such as the comparative analysis method described below, to implement the minimal risk standard.

The Magnitude of Harms and Seriousness of Risks

Risk represents the probability that an individual will experience a particular harm. The seriousness of a risk is a function of the magnitude of the possible harm, together with the likelihood of experiencing that harm. For example, the seriousness of the risk of breaking a bone while riding a bicycle depends on the magnitude of the possible break, and the likelihood that riding will lead to a broken bone.

Harms can be understood as experiences that set back an individual’s interests: A broken bone sets back individuals’ interest in normal physical functioning; pain sets back individuals’ interest in avoiding unpleasant experiences.⁴⁷ The magnitude of a given harm is a function of the extent to which, taking into account both degree and duration, it sets back an individual’s in-

terests. A cramp lasting a few minutes represents a minor setback to one’s interests; amputation of a leg represents a severe setback.

The potential harms that children face in daily life can be categorized into at least five levels of magnitude, as presented in Table 49.4: (1) negligible harms involve minor and fleeting setbacks, such as mild, transitory pain—average, healthy children almost inevitably experience negligible harms as a result of the ordinary activities of daily life, such as playing sports; (2) minor harms involve setbacks of slightly greater degree or duration, such as mild pain that lasts a day, or moderate nausea that lasts a few hours—the symptoms associated with the common cold, such as mild fatigue and aches lasting a few days, represent a minor harm that average, healthy children may experience in daily life; (3) moderate harms involve setbacks of moderate degree or duration—bone fractures are a moderate harm that average, healthy children face from the activities of daily life, such as playing basketball; (4) severe harms involve setbacks whose degree or duration goes beyond moderate, such as permanent disability as the result of playing baseball; and (5) catastrophic harms involve complete setbacks to one’s interests, such as death or complete paralysis. Although this typology focuses on physical risks, it could be extended to include the other types of risks that research poses to children, including social and psychological risks.

The comparative analysis method would apply this typology to determine whether a research procedure is minimal risk. There are several steps an IRB using this method would carry out: The IRB would first identify the potential harms of undergoing the intervention and categorize the harms by magnitude into one of the five levels. For example, the IRB might find that airway abrasion due to bronchoscopy qualifies as a mild or a moderate harm. Then, the IRB would determine the likelihood of experiencing the harm from the research procedure, such as the likelihood of airway

Table 49.4
Harms of Daily Life Stratified by Severity

<i>Level</i>	<i>Examples</i>	<i>Likelihood Faced in Daily Life Activities</i>
Negligible	1. Transient pain 2. Transient nausea 3. Transient anxiety 4. Bruising 5. Superficial lacerations	Essentially 100%
Minor	1. Sustained nausea 2. Headache for a day 3. Small scar 4. Temporary claustrophobia	About 30,000 per million ^a
Moderate	1. Wrist fracture 2. Laceration requiring sutures	About 200 per million ^b
Severe	1. Hearing loss 2. Pulmonary fibrosis 3. Kidney failure	About 60 per million ^c
Catastrophic	1. Death 2. Persistent vegetative state	About 1 per million ^d

^aChild’s daily risk of contracting the common cold, generally due to contact with others in school/day care and other routine activities.⁶²
^bRisk of breaking a bone from playing soccer;⁸ ^cRisk of injury leading to permanent disability from playing baseball.⁸ ^dRisk of death from riding in the car.⁸

abrasion as a result of undergoing research bronchoscopy. To carry this analysis out, IRBs must have access to the available empirical data on the risks of the intervention under review. In the absence of published data, this approach may require investigators to collect data on clinicians' experience with the intervention. Next, the IRB would compare the likelihood of experiencing the harm due to the research intervention to the likelihood that average, healthy children will experience a harm of the same magnitude from the ordinary activities of daily life. For example, the likelihood of airway abrasion due to bronchoscopy would be compared to the likelihood of mild or moderate harm in daily life. If the likelihood of the research-related harm is greater, the procedure in question is greater than minimal risk; if not, the procedure qualifies as no greater than minimal risk. Because risk data represent uncertain point or range estimates, with accompanying confidence intervals, IRB members may have to use their judgment to determine whether two risk estimates are effectively equivalent. In cases of uncertainty, IRBs should err on the side of caution, categorizing interventions as greater than minimal risk.

Applying Comparative Analysis in Practice

Section 407 of the U.S. regulations allows the Secretary of the Department of Health and Human Services to approve pediatric studies that the reviewing IRB deems to have important value, but which pose risks too high for IRB approval.^{48,49} As of August 2005, 17 research proposals had been submitted to the Office for Human Research Protections (OHRP) for consideration under these provisions.⁵⁰ To clarify the application of the comparative analysis method to research proposals, drawing on the real life examples provided by the protocols submitted for so-called 407 review, the following three cases demonstrate different circumstances in which the framework may need to be applied.

Case 1

The first study proposed to enroll healthy children aged 8–11. Although the study involved a number of procedures, concern focused on the intravenous glucose tolerance tests (IVGTTs), which the reviewing IRB judged to pose greater than minimal risk.

In theory, IVGTT poses several possible harms: bruising and infection at the IV site, nausea and potential hypoglycemia leading to lightheadedness, and/or syncope. Yet IRBs should not attempt to categorize research interventions based simply on the harms that in theory are possible. The fact that an intervention might pose a risk of death does not establish that in practice it poses that risk.

At the time, there were no data in the medical literature detailing the likelihood of any of these adverse effects from IVGTT in children. However, IVGTTs have been performed in thousands of healthy children. The Diabetes Prevention Trial has performed 7,903 IVGTTs at sites across North America. Of these, 4,372 were performed in individuals less than 15 years of age, and 3,531 were performed in individuals 15 years of age or older. No serious adverse events were reported for any of these tests.⁵¹ Extra monitoring for adverse events in 1,333 of the tests found only two cases of suspected hypoglycemia, both of which resolved with food. At another site, an investigator reports conducting over 200

eu-glycemic-insulin clamp tests in children with no side effects.⁵² A third site systematically assessed the risk of hypoglycemia from frequently sampled IVGTT in 210 overweight Hispanic children. Hypoglycemia (plasma glucose less than 50 mg/dl) occurred in one child, who did not experience any symptoms.⁵³

This experience suggests IVGTT poses approximately a 1 in 3,000 risk of hypoglycemia, which resolves with food. Given the potential for greater than negligible reactions, hypoglycemia due to IVGTT might be categorized as a minor harm, worse than transient mild pain but not as bad as a bone fracture. Assuming that this is the only documented harm of IVGTT in the research setting, whether this procedure qualifies as minimal risk depends on whether the likelihood of this reaction exceeds the likelihood average, healthy children will experience a minor harm in daily life. The fact that the activities of daily life pose approximately a 30 per 1,000 chance of experiencing a minor harm suggests IVGTT poses no greater than minimal risk (see Table 49.1).

Case 2

A second study involved administration of a single 10 mg oral dose of dextroamphetamine to healthy children between the ages of 9 and 18. The IRB categorized this intervention as more than minimal risk because it might increase the chances that participants see drug use as nonhazardous, thus increasing participants' likelihood of future drug abuse. There are no data on the chances that a single 10 mg oral dose of dextroamphetamine will increase future drug abuse in a healthy child. In the absence of data, IRBs should make a more general comparison between the risks of the research procedure and the risks of daily life.

In the absence of empirical data, IRBs sometimes will be able to compare the chance of harm posed by the intervention to the chance that children will experience the same harm in daily life. For example, performance-enhancing and recreational use of other stimulants (especially caffeine) is widely promoted to children—for example, in sports drinks.⁵⁴ It seems unlikely that a single 10 mg oral dose of amphetamine in a research setting would validate stimulant use more than the messages children are exposed to in daily life. This suggests that the drug abuse potential, although it exists, does not exceed the risks of drug abuse that children face from the activities of daily life, such as watching television and reading advertisements. This analysis suggests the study poses no greater than minimal risk.

In other cases, research participation will present unknown risks that are unlike the risks children face in daily life. In these cases, IRBs might ask whether reasonable parents would be more concerned by the prospect of their children facing the risks of the research intervention or facing the risks of the same magnitude of harm in daily life. For example, assuming future drug abuse represents a severe harm, would a reasonable parent be more concerned about the risk of future drug abuse from one dose of dextroamphetamine, or the approximately 60 in a million risk of permanent disability associated with playing a game of baseball? (See Table 49.4.) If reasonable parents would be more concerned by the risk children face in daily life, or if they would be indifferent between the two risks, the research intervention qualifies as minimal risk. When it is unclear which option would more concern reasonable parents, IRBs should err on the side of caution and categorize the intervention as greater than minimal risk.

Case 3

A third study aimed to test the efficacy of diluted smallpox vaccine in 2- to 5-year-olds. The smallpox vaccine, Dryvax, has been used in the past, and data have been collected on adverse events associated with it. According to the manufacturer's package insert for the vaccine, many types of adverse events—ranging from widespread rashes to death—have been reported in children aged 1–4 and 5–19. One of these adverse events is generalized vaccinia, a disseminated rash that is usually self-limited, but which the investigators described as a major systemic reaction and stated would lead to hospitalization.⁵⁵ It seems, then, that generalized vaccinia could be classified as a moderate harm, worse than a common cold, but less severe than permanent disability due to a sports injury (see Table 49.4). According to the vaccine manufacturer, the rate of generalized vaccinia is 233 per million in 1- to 4-year-olds.⁵⁶ (Although a national study found much lower rates of generalized vaccinia, the methods of that study underreported many mild and moderate complications. The rates given in the package insert are based on smaller studies using survey methods that better capture these complications.) This is not effectively different from the approximately 200 per million rate of moderate harm children face in activities of daily life, making administration of this vaccine minimal risk.

These three examples demonstrate the application of comparative analysis, a systematic method for implementing the risks of daily life definition of minimal risk, in a variety of situations. Analysis of the risk level of research interventions is most straightforward when empirical data on risks have been collected and are available, as in the example of the smallpox vaccine trial. When data on the risks of a research intervention have not been previously published, as in the IVGTT example, prior clinical and research experience with the procedure can still provide useful information. Even when empirical data on a research risk are completely unavailable, as in the case of the dextroamphetamine study, a systematic method for applying the risks of daily life standard can still help clarify the categorization of an intervention as minimal risk or greater than minimal risk.

Policy Alternatives to the Risks of Daily Life Standard

Research regulations include multiple safeguards to protect pediatric research participants from excessive risks. IRBs may reject individual research procedures, parents may decline to enroll their children in research, even when it satisfies the minimal risk standard, and children deemed capable of providing assent may refuse to participate in research that does not offer them a compensating prospect of benefit. Granting the importance of IRB, parental, and participant judgment, society has an independent obligation to ensure that medical advances are not won at the cost of exploiting pediatric research participants. To discharge this obligation, society must establish a sound standard for determining what constitutes minimal risk in the context of nonbeneficial pediatric research.

The data on the risks that children in the United States face in daily life and the research risks that IRBs in practice classify as greater than minimal risk suggest that the risks of daily life defi-

inition of minimal risk may be inappropriate. In light of the findings that the current definition categorizes as minimal risk research procedures that pose a 1 in 250 chance of injury to children, and that IRBs seem in practice to be more conservative than this, it may be that the current minimal risk standard allows excessive risks in some cases. These findings should be regarded as providing context for a discussion about what levels of risk without direct clinical benefits to participants are ethically acceptable in pediatric research, and what policy standard might ensure that the risks of pediatric research do not exceed this level. Some possible alternatives to the risks of daily life standard are described below to provide context for this discussion.

The Reasonable Parent Standard

The risks children are actually exposed to may be an inappropriate standard for determining the risks children should be exposed to in research. Some of the risks children currently face may be at socially unacceptable levels, or children may be exposed to certain risks only because parents and others are unaware of the dangers. To address these concerns, some commentators have endorsed defining minimal risk in terms of those risks that a "reasonable" parent would intentionally expose their children to.^{5,57} Ross and Nelson state this definition of minimal risk as follows: "The probability and magnitude of physical or psychological harm is no more than that to which it is appropriate for a scrupulous parent to intentionally expose a child for educational purposes in family life situations."⁵⁷ This definition is useful in that it specifies a perspective from which investigators and IRBs ought to approach risk thresholds in pediatric research. In particular, it specifies that the nature and purpose of a minimal risk threshold should be to allow only research that scrupulous parents could reasonably enroll their children in. However, it leaves open the question of the standard by which a hypothetical parent qualifies as "scrupulous." Hence, this definition requires further interpretation before it can be implemented.

The Routine Examinations Standard

The present data reveal that the risks children face from the activities of daily life are much greater than the risks they face from routine examinations and tests. With this in mind, one might try to limit the risks allowed by the minimal risk standard by defining minimal risk based solely on the risks of "routine physical or psychological examinations or tests."^{58,59} Some existing guidelines take this approach; the CIOMS guidelines stipulate that children and other vulnerable groups should be subject to nonbeneficial research procedures only when the risks do not exceed "those associated with routine medical and psychological examinations of such persons."²⁵

The risks of routine examinations are justified by the potential benefit to the children who undergo them. Hence, it is not clear why this standard might be appropriate for assessing the risks of research that does not offer participants a prospect of clinical benefit. Recognizing this theoretical concern, what level of risks would this standard allow in practice?

The *Bright Futures* health guidelines, endorsed by the American Academy of Pediatrics, recommend that healthy children be assessed for height, weight, head circumference, vision, and

hearing.⁶⁰ The only invasive examination recommended for healthy children is a single heel stick at birth to screen for metabolic disorders. Whether infants receive even a single blood draw for lead analysis depends on whether their exposure is deemed greater than normal. Thus, in practice, the routine examinations standard would be extremely restrictive, categorizing all procedures beyond a single heel stick as greater than minimal risk.

The *De Minimis* Standard

Psychologically, reasonable individuals often ignore the risks of daily life—those we assume by living, moving around, and going about our daily routine—when the risks are sufficiently low. This practice suggests that it may be acceptable to expose children to research risks provided they do not exceed the negligible risks we ignore in our daily lives.^{1,6} This *de minimis* standard differs from the current risks of daily life standard because we ignore some risks of daily life, but not others. Parents typically ignore the risks involved in taking their child for a ride in the car; they often are painfully aware of the risks their children face while playing football.

Individuals tend to be less willing to accept risks that are explicitly brought to their attention, such as research risks outlined in a protocol or consent form. Future assessment of the *de minimis* standard should assess the ethical significance of this difference in our attitudes toward risks depending on our awareness of them. If explicitly stating a risk on a consent form alters an individual's ability to ignore or accept it, is this difference purely psychological or is it relevant to an ethical assessment of the risk in question?

The *Community Risk* Standard

Reasonable parents routinely expose their children to a risk of death on car trips to benefit their parents, siblings, and neighbors. Society accepts and even endorses this practice, provided the risks are not too great, because children derive important benefit from being part of a healthy and caring family. Children similarly gain tremendous benefits from living in a society that provides access to health care, clean water, and safe and effective medications and vaccines. One might argue that a price of living in such a society is that children are sometimes exposed to research risks for the benefit of other society members. Provided the risks are not too great, and the research is important, this practice seems acceptable in the same way that it is acceptable to expose children to risks for the benefit of others in family life.

Future research on the community risk standard should assess whether it is acceptable to expose pediatric research participants to the same, or somewhat lower, levels of risk compared to the risks children may be exposed to in the context of family life. May children be exposed to the same level of risks in order to benefit unrelated others as they are to benefit siblings and neighbors? Or should the risk threshold in the context of research be somewhat lower than it is in family and community life?

The *Charitable Participation* Standard

Many of the risks of daily life are deemed acceptable because the attendant activities offer children the potential for personal benefit. Parents allow their children to play basketball not because they

consider the risks inherently acceptable, but because children are thought to benefit directly from participation in team sports. In contrast, nonbeneficial research, by definition, does not offer participants a compensating potential for direct benefit. Its risks are justified by the potential to benefit others. Viewed in this way, nonbeneficial pediatric research involves a kind of charitable activity, exposing children to risks for the benefit of unrelated others.

This comparison suggests that it may make sense to develop a minimal risk standard based on risks to which children may be exposed in daily life for the benefit of others. Specifically, are the research risks greater than the level of risk society deems acceptable for children in the context of activities that benefit unrelated others? Many widely respected organizations, including the Red Cross and Habitat for Humanity, have established charitable programs for children.⁶¹ And parents often instruct their children to engage in activities that pose some risks to them for the benefit of others, such as shoveling the sidewalks and mowing the lawns of infirm neighbors.

Future research on the charitable participation standard should assess the appropriateness of the analogy between nonbeneficial research and charitable activities that society deems acceptable for children. Are these activities sufficiently similar that the risks of the latter provide a useful guide for assessing the ethical acceptability of the risks of the former? Or are there important differences between the two activities that undermine this approach?

Conclusion

Although it is understandably troubling to expose children, who cannot provide informed consent, to research risks without a compensating prospect of clinical benefit, almost all countries and international bodies recognize that such research is essential to provide children as a group with appropriate medical treatment. Guidelines have been written to ensure that the risks children face in research are not excessive, often relying on the concept of minimal risk to provide the threshold for acceptable risks in pediatric research that does not offer participants direct clinical benefits.

Minimal risk, in turn, has generally been defined in terms of the risks children face in daily life. The widely endorsed objective interpretation of this definition holds that minimal risks are those that do not exceed the level of risks that average, healthy children ordinarily face in daily life. Implementation of the minimal risk standard, however, may not consistently conform with this definition. IRBs must often implement the minimal risk standard without concrete data on either the risks of research procedures or the risks children face in daily life.

Data exist that can be used to estimate the level of risks children face in daily life. Systematically implementing the risks of daily life definition of minimal risk requires IRBs to identify risks of harm posed by research procedures, determine their magnitude and likelihood as specifically as possible, and compare these to the magnitude and likelihood of potential harm posed by activities of daily life. Assessment of research risks under this definition is clearest when empirical data on the risks of research procedures and risks of daily life are available and used, though the general framework still applies in the absence of data.

Analysis of IRB chairs' classification of research procedures suggests that IRBs may frequently classify as greater than minimal risk procedures that in fact are not riskier than the activities of

daily life. This could be due simply to the frequent lack of empirical data available to IRBs and to the fact that data indicate the risks of daily life are higher than many assume. But it may also point to a conceptual error in using the risks of daily life to define minimal risk. Several other standards have been proposed, and it may be that one of these would better capture when exposing children to risk is ethically acceptable, or would better ensure that pediatric research is not excessively risky.

The Origins and Policies That Govern Institutional Review Boards

Major turning points in history are often recognized only in hindsight. One example of a significant historical change that went almost unnoticed at the time is the statement made by James A. Shannon, director of the National Institutes of Health (NIH), before the National Advisory Health Council (NAHC) on September 28, 1965.

The NAHC had been created in 1930 to deal with a budget crisis faced by what was then a single, small federal agency called the National Institute of Health. Senator Joseph Randell, backed by Surgeon General Lewis R. Thompson, introduced sweeping legislation to authorize the National Institute of Health to carry out research that would address “all the ills that flesh is heir to.” In direct contrast, Senator Joseph M. Neely proposed sharply focused legislation to direct the spending of all federal medical research dollars onto a single program to overcome cancer in all its many forms.¹

The Randell bill was modified and enacted. It is now compacted into Section 301 of the Public Health Service Act as amended.² It grants the NIH authority to fund research into virtually any area that may be associated with human health or disease. Although the Neely bill failed in 1930, the concept of a concentrated research effort directed or targeted at one or several diseases remained alive in the Congress, and in the public mind. In succeeding decades, the Congress has enacted legislation targeted at virtually all major diseases and conditions—judged in terms of their impact on society as measured by morbidity and mortality. The plethora of institutes that make up the NIH, each dedicated to one or several diseases or disease clusters, is due in part to the concept of targeted research articulated by Neely. In 1930 the contest between those who supported the Randell con-

cept, which came to be known as *investigator-initiated research*, based on perceived scientific opportunities, and those who supported *targeted research* directed at public need as measured by morbidity and mortality data, created a tension that continues to the present time. In 1930 the debate threatened to stalemate the budget process and jeopardize the fragile existence of the NIH.

Congress addressed the Randell-Neely tension by a procedural compromise. It recommended creation of the NAHC—a standing committee of nonfederal advisers to establish or approve policies for both the surgeon general of the Public Health Service (PHS) and the director of the NIH (the research arm of the PHS) on a broad range of issues. As far back as 1902, the NIH had utilized ad hoc public advisory committees. But the creation of the NAHC marked the beginning of ongoing participation by nongovernment advisers in the formulation of national health research policies. The NAHC eventually evolved into a two-tiered peer review system consisting of initial review groups (IRGs—often called *study sections*) charged with assigning priority scores based on the perceived scientific merit of grant applications, and national advisory councils or boards to pass judgment on proposed research in the light of its expected social utility.¹

When Shannon testified in September 1965, he brought to the attention of the NAHC a complex long-standing problem of medical ethics that had not previously been addressed at a policy level by any federal agency. Fragmentary stenographic notes of the NAHC meeting attribute the following statement to him:

[R]esearch involving [humans] departs from the conventional patient-physician relationship where the patient's good has been substituted for by the need to develop new

knowledge. . . . [The] physician is no longer in the same relationship that he is in the conventional medical setting and indeed may not be in a position to develop a purely or wholly objective assessment of the . . . ethical act which he proposes to perform. [The PHS has] a dual responsibility. One is a minor one of keeping the Government out of trouble . . . but really the major one is . . . to try to encourage the flourishing of sound clinical investigation rather than discouraging it. I am searching for some way of creating a more profound sense of an institutional awareness of the importance of this aspect of the problem without tying [investigators] down and immobilizing them in their capabilities.³

Shannon was seeking a policy applicable to all research involving human subjects funded by the NIH. He wanted the policy to contrast and distinguish the relationship between research investigators and their subjects from the relationship between physicians and their patients. He identified several interrelated questions, which he put to the NAHC. First, how could the NIH make physicians aware that when they are functioning as research investigators, their responsibilities to subjects differ from their responsibilities to patients? Second, how could the ethics of research be incorporated into a workable public policy that would both protect the NIH from public criticism and protect subjects from physical or moral harms, without unduly restricting investigators?

Shannon knew that medical schools and science programs of his day provided little formal training in medical ethics.⁴ The dictum *Primum non nocere* ("First, do no harm") and the Hippocratic tradition of respecting the privacy of patients were conveyed by way of mentors, role models, and institutional traditions. Ethical guidance pertaining to the conduct of research involving human subjects was virtually unmentioned in the training given to medical students. At the time that Shannon met with the NAHC, responsibility for the ethical conduct of medical research was left to the untutored consciences of physician/investigators who had little formal training in ethics and whose behavior was shaped and guided by the social customs of the time. Albert Jonsen, for example, describes the ethics training in the following words:

For doctors, medical ethics was incarnate in their behavior and social character and in the social arrangements that sustained the solidarity, respectability, and educated competence of the profession. There were ethical battles to be fought such as those against quackery, but there were few ethical dilemmas about the doctor's duties.⁴

Shannon presented to the NAHC a draft resolution that recommended that the protocol design of an investigator proposing to conduct research involving humans be submitted to the judgment of "peers" to provide an independent determination of the risks and expected benefits of research, and to assure maximum protection for the rights and welfare of those enrolled in each study.

The 1965 NAHC meeting marks the first time that what was later termed the *therapeutic misconception*—confusion of the investigator/subject relationship with the physician/patient relationship—was addressed at the level of national policy. Perhaps even more startling is the fact that Shannon recommended that nonfederal advisers—Shannon called them "*peer reviewers*,"

but that terminology was soon discarded because the reviewers were not, strictly speaking, peers of the investigator—should exercise ethical oversight of federally funded research involving humans.

The policy that Shannon recommended was borrowed in part from a policy pertaining to normal research volunteers that had been implemented in 1953 when the NIH Clinical Center opened its doors. Shannon recognized, of course, that the review of protocols for scientific merit was already an established practice at the federal level. The new policy called for review of protocols for ethical integrity to be conducted at the local level by panels composed of both experts and nonexperts at the site where the research was to be conducted.

By calling for review by impartial observers, Shannon was reversing two traditions that had been in place at the NIH for more than 25 years. The first tradition held that the physician in charge of the research is the best qualified person to make the judgment of what is in the best interests of research subjects. The second held that nonscientists, that is, *laypersons*, were not qualified to pass judgment on the ethical aspects of medical research. To understand the dramatic difference between what Shannon was proposing and the prevailing practices and attitudes of the time, we need to consider a few historical facts.

David Rothman tells us the following:

Until World War II, the research enterprise was typically small-scale and intimate, guided by an ethic consistent with community expectations. Most research was a cottage industry: a few physicians, working alone, carried out experiments on themselves, their families, and their immediate neighbors. Moreover, the research was almost always therapeutic in intent, that is, the subjects stood to benefit directly if experiments were successful. Under these circumstances the ethics of human investigation did not command much attention.⁵

Rothman acknowledges that there were some notable exceptions to the state of affairs described above. What he fails to emphasize is that in the period leading up to World War II the NIH extramural programs, though small by today's standards, were gradually expanding. Many NIH research scientists, whether intramural or extramural, were not conducting innovative therapy intended to benefit their families, their patients, or their neighbors. They were conducting more fundamental research intended to explore the causes of disease, the workings and interrelationships of complex organ systems, and distinctions between normal and abnormal bodily functions. Therapeutic benefit was seldom a characteristic of such research projects.

In addition to the changes in the kinds of research projects that were pursued, changes on the issue of informed consent also emerged after World War II. Prior to this time, although a few research investigators sought informed consent from subjects, most investigators gave little if any information to their subjects concerning the purposes and risks associated with research studies. Concern for the rights and welfare of research subjects was left in the hand, or more precisely, in the conscience of the research investigator. Although a handful of investigators recognized and respected the rights of research subjects, a majority of investigators were unaware of these rights and saw little difference in ethical responsibility between functioning as a physician and functioning as a research investigator.⁶

Ruth Faden and Tom Beauchamp note the following:

“Informed consent” first appeared as an issue in American medicine in the late 1950s and early 1960s. Prior to this period, we have not been able to locate a single substantial discussion in the medical literature of consent and patient authorization. For example, from 1930 to 1956 we were able to find only nine articles published on issues of consent in American medical literature.⁷

After World War II, as Rothman notes, there was a fundamental change in medical ethics and its importance. He dates the change a little earlier than do Faden and Beauchamp, but both sources agree that a national awakening to ethical concerns in research, particularly the issue of informed consent, came after World War II. According to Rothman,

The transforming event in the conduct of human experimentation in the United States, the moment when it lost its intimate and directly therapeutic character, was World War II. Between 1941 and 1945 practically every aspect of American research with human subjects changed.⁵

Faden and Beauchamp date the transformation later than does Rothman. They write,

Shortly after the middle of the twentieth century a major transformation occurred. The influential forces and documents in ethics and policy began to take on *external* roots. Sometimes these external influences were greeted as an unwanted alien force on medicine; but in other quarters of medicine they were greeted with open admiration.⁷

It was against this changing backdrop—changes both in kinds of research projects and in the appreciation of ethical issues in medical research—that the new NIH Clinical Center commenced functioning in 1953. At that time, most NIH investigators conducting research involving humans still thought of themselves as medical practitioners. Clinical Center officials argued that it would be an unjustified intrusion into the doctor-patient relationship to allow any administrative body to interfere with the relationship between physician/investigators and their research subjects/patients.³ Nevertheless, even those who held this view recognized that this argument could not be made with respect to *normal volunteers*—that is, healthy people who volunteered to serve as research subjects.

During World War II, it was customary for the NIH to enlist conscientious objectors to serve as normal controls in medical research. Many investigators regarded conscientious objectors as being equivalent to military draftees. Were it not for conscientious objection to war, these investigators reasoned, such persons would have been serving in the military anyway. And this view had implications for how investigators thought of research volunteers. As Rothman notes,

Researchers [believed that they] were no more obliged to obtain the permission of their subjects than the selective service was to obtain the permission of civilians to become soldiers. One part of the war machine conscripted a soldier, another part conscripted an experimental subject, and the same principles held for both.⁵

Long after the war ended, this attitude on the part of principal investigators persisted. Reasons why it continued are not hard to

find. In 1941, President Franklin D. Roosevelt established the Office of Scientific Research and Development (OSRD) to conduct research to address a wide variety of health issues occasioned by or pertinent to the war. OSRD in turn created the Committee on Medical Research (CMR), which selected some 600 medical research projects to be conducted at 135 institutions across the country. After the war, in a political coup that catapulted the NIH to the forefront of domestic agencies, the research portfolio of the OSRD was transferred in its entirety to the NIH. In some cases, OSRD investigators also moved to the NIH to continue their work in the intramural program. Others moved to institutions in which CMR-initiated research was now conducted with NIH funds. NIH administrators admired the accomplishments of CMR during the war, and they admired the energetic and efficient manner in which the research results were obtained, published, and applied. Many NIH administrators adopted the aggressive “can do” CMR attitude. They believed that the CMR approach to research served the country well during the war, and they were eager to use the same techniques in peacetime.

The Growth of the NIH

From 1944 until 1958, federally funded medical research expanded at a furious rate. A health lobby headed by Mary Lasker and sympathetic heads of important Senate and House Appropriation Committees (Senator Lister Hill and Representative John Fogarty), produced an ever-increasing flow of research dollars. The NIH budget rose from less than \$1 million in 1944 to nearly \$1 billion by the end of the 1950s. In some years, the NIH research budget increased by as much as 100% over the previous year. Frankel says that prior to World War II, medicine was viewed as the art of healing the sick and comforting the dying; after the war, medicine was viewed as the conquering of diseases and the promotion of health.³

In the face of unprecedented expansion of the medical research budget during the 1950s, NIH staff persons were preoccupied with locating and training research investigators to conduct research. The NIH Clinical Center operated a two-year program of training for research fellows, whose time at the NIH counted as military service, exempting them from the draft. The “doctor draft” provided training for hundreds of physician/investigators who formed the backbone of the expanding research effort throughout the country. The NIH fellowship program was supplemented by research training grants (made mostly to Ph.D. scientists) developed to match the supply of investigators to the increasing torrent of research dollars. Although training grants offered sophisticated scientific mentorship to new investigators, they provided virtually no education in research ethics.

A notable exception to the lack of research ethics policy occurred in the NIH intramural research program shortly after the Clinical Center opened in 1953. Following World War II, normal volunteers for intramural research at the NIH were recruited from small colleges located in the nearby District of Columbia, Maryland, and Virginia. Only persons judged to be in good health were accepted as normal volunteers. Exposing healthy volunteers to risks from research interventions designed to develop knowledge pertaining to conditions and diseases the volunteers did not have was a major departure from acceptable medical practice. The practice of using normal volunteers was patently inconsistent with the

Table 50.1
Development of Federal Protections for Human Subjects of Research

Date	Event
1798	U.S. Congress creates the Marine Hospital Service for sick and disabled seamen. Signed into law by President John Adams.
1887	Congress authorizes the conduct of medical research at the Marine Hospital. This one-room laboratory, directed by Joseph Kinyoun, will evolve into the National Institutes of Health (NIH).
1902	The Marine Hospital Laboratory is redesignated as the Public Health and Marine Hospital Service, which is reorganized into the Public Health Service (PHS) 10 years later.
1918	Chamberlain-Kahn Act expands the size of the PHS, directs it to study venereal diseases, and creates a commissioned corps under the direction of a surgeon general empowered to make grants-in-aid of research. Twenty-five institutions receive the first grants-in-aid.
1930	Congress gives the NIH broad authority and creates the National Advisory Health Council (NAHC) to advise the surgeon general on grants-in-aid (including contracts), considering both scientific opportunities and the social utility of research.
1942–45	Conscientious objectors who are exempted from the draft in World War II are required to serve as healthy “volunteers” for research at the NIH and awardee institutions.
1953	NIH opens the Clinical Center, later called the Warren G. Magnuson Clinical Center, the largest and most advanced biomedical research center in the world. The Clinical Center issues the first public policy for the protection of human research subjects, entitled <i>Group Consideration of Clinical Research Procedures Deviating From Accepted Medical Practice or Involving Unusual Hazards</i> , and requires peer oversight of research involving healthy volunteers. Philippe Cardon, deputy director of the NIH Clinical Center, is careful to explain the risk of the research and to elicit volunteers’ informed consent. Although patient/subjects are often at much higher levels of risk than healthy volunteers, the oversight policy extends only to healthy volunteers.
1954–58	Saul Krugman conducts hepatitis studies in the Willowbrook State School for severely retarded children (see Chapter 7).
1956	Chester M. Southam and Emanuel Mandel conduct experiments at the Jewish Chronic Disease Hospital, injecting live cancer cells into elderly, indigent subjects without review of the research or consent from the subjects (see Chapter 6).
1959	Senator Estes Kefauver initiates hearings on the cost of products regulated by the FDA. In 1961, following reports of the thalidomide disaster in Europe and Canada, the hearings focus on protection of human subjects involved in testing of FDA-regulated products.
1961	Congress enacts the Kefauver-Harris amendments to the Food, Drug and Cosmetic Act, including a requirement for informed consent of subjects involved in the testing of FDA-regulated products.
1960–63	A three-year study by the Boston University Law-Medicine Research Institute concludes that only 16 PHS awardee institutions have policies for the protection of the rights and welfare of human research subjects, and in no case is an institutional policy satisfactory.
1963	NIH Director James Shannon creates the Robert B. Livingstone Committee to evaluate practices in institutions funded by the NIH and to recommend improvements. The Livingstone Committee reports that as research expands and becomes more complex, the risks to subjects will become greater, but it makes no formal recommendations.
1965	Shannon tells the NAHC that many research investigators confuse the role of principal investigator with the role of physician. He proposes the first federal policy for the protection of human subjects, calling for panels composed of both experts and non-experts to review research protocols for ethical integrity.
1966	In an article in the <i>New England Journal of Medicine</i> , Henry K. Beecher brands as unethical 22 research projects published in refereed journals. This article provides unexpected and powerful support for the establishment of ethics review panels, which initially are called <i>institutional review committees</i> .
1971	Donald S. Chalkley publishes the Yellow Book, an extension of the PHS policy to all research involving human subjects supported by any agency within the Department of Health Education and Welfare (DHEW).
1972	Senator Edward M. Kennedy begins a three-year series of hearings on human-subject research, including psychosurgery, whole-body radiation, forced sterilization of retarded women, a study of the contraceptive Depo-Provera in which some sexually active women were given placebo without their knowledge, and the Tuskegee Syphilis Study of the natural course of syphilis, during which treatment for the disease was withheld from impoverished black men in Alabama (see Chapter 8).
1972	NIH Director Robert Q. Marston calls for a broad study of the ethics of research involving human subjects. He appoints Ronald Lamont-Havers to create a task force to consider protections for many categories of vulnerable subjects.
1974	The National Research Act calls for the creation of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research. The National Commission meets on a monthly schedule for the next four years, completing 16 studies and making about 125 recommendations for the protection of human subjects (see Chapter 14).
1981	DHEW Secretary Patricia Harris signs a federal regulation implementing virtually all the recommendations of the National Commission. Many of the recommendations are incorporated into revised regulations issued by the FDA.
1991	After a seven-year effort, 16 federal departments and agencies that conduct or support research involving human subjects adopt the Common Rule, a package of regulations virtually identical to the Department of Health and Human Services Regulations for the Protection of Human Subjects.

Hippocratic tradition. After considerable discussion, in 1953 the NIH Clinical Center issued a policy to protect the rights and well-being of normal research volunteers.

The policy, entitled Group Consideration of Clinical Research Procedures Deviating from Accepted Medical Practice or Involving Unusual Hazard,⁸ required oversight of research involving normal volunteers by peers in the Clinical Center. Panels of reviewers were overseen by Philippe Cardon, deputy director of the NIH Clinical Center, who was careful to explain to the volunteers the risks of the research in which they were invited to participate, and to elicit their informed consent. Although patient/subjects were often placed at much higher levels of risk than normal volunteers, the oversight policy extended only to normal volunteers. The policy that Shannon recommended to the NAHC in 1965 borrowed and expanded the Clinical Center policy to all research subjects involved in both intramural and extramural research.

The Turbulent Decade of the 1960s

It was not until near the end of the 1950s that doubts concerning the beneficial results of research, and concern for the risks to research subjects and to society, began to surface in the public media. In 1959, Senator Estes Kefauver, chairman of the Senate Subcommittee on Antitrust and Monopoly, began a series of hearings concerned with the cost and availability of drugs. The hearings culminated in the 1962 Kefauver-Harris Amendments to the Food, Drug, and Cosmetic Act. Initially, the hearings were exclusively concerned with the economic aspects of drug production, distribution, and sale. Kefauver summoned pharmaceutical industry leaders to testify, and he demanded that pharmaceutical houses provide drugs to consumers at reasonable prices.

In 1961, while the Kefauver hearings were ongoing, the public media recognized that thalidomide—a drug administered to pregnant women in many countries as a sedative and to prevent morning sickness—was associated with limb anomalies in newborn infants. Thousands of infants whose mothers had used thalidomide were born without arms or legs. By 1961, a majority of U.S. homes had television sets, and televised images brought these tragedies into the living rooms of many thousands of Americans. Few of the birth defects occurred in the United States because the Food and Drug Administration (FDA) had not approved the drug. Nevertheless, the publicity given the tragic effects of thalidomide caused Kefauver to shift the focus of the hearings to the safety and efficacy of drugs. Senator Hubert H. Humphrey's Subcommittee on Reorganization and International Organization also held hearings on the thalidomide debacle. Frances Kelsey of the FDA was subsequently presented with a presidential medal because she had refused to grant FDA approval for marketing thalidomide in the United States. She based her refusal on the lack of animal research safety data.

Kefauver criticized the drug manufacturers' practice of providing experimental drugs to practicing physicians, who, in turn, treated their patients with the drugs. Patients were seldom informed that some of the drugs handed to them by their physicians were still experimental. Patients were unaware that they were sometimes used as de facto research subjects. The Kefauver bill was further amended to require FDA to certify that new drugs are both safe and efficacious. When the Kefauver-Harris bill was brought to the floor of the Senate, Senator Jacob Javits proposed an

amendment—which became law—requiring that research subjects provide informed consent prior to their participation in any FDA-regulated study. Several years passed before the FDA learned how to implement the 1962 amendments. Nevertheless the Javits provision marked the first time that any sort of protection for human research participants was included in a federal statute.³

In the years following the thalidomide uproar, a cascade of alleged research abuses came to the attention of the media and the public. A number of research projects that had involved children were challenged as unethical. The most notable of these was the so-called Willowbrook State School study of the 1950s, in which severely retarded children were infected with a strain of hepatitis virus⁴ (see Chapter 7). Similarly, failure by Chester Southam and Emanuel Mandel at the Sloan-Kettering Institute for Cancer Research and the Jewish Chronic Disease Hospital to obtain consent for the administration of live cancer cells to elderly, indigent patients in New York received critical newspaper headlines and eventually led to a condemnation by the New York State Board of Regents in 1965³ (see Chapter 6).

Shannon, who had never accepted the view that regulation of research was an intrusion into the doctor-patient relationship, grew more and more restive about the absence of a policy governing the ethics of research. Although the peer review system for scientific merit was steadily growing more sophisticated, a policy for the protection of human research subjects had not even been articulated, much less implemented. It was this worry that prompted Shannon's recommendation to the NAHC that the extant NIH policy for normal volunteers be expanded to cover all subjects involved in both intramural and extramural research.

The Boston University Study

In 1960, encouraged or perhaps even directed by Shannon, the NIH made a three-year "grant" (today it would be classified as a contract) to the Boston University Law-Medicine Research Institute to conduct a study of ethical, legal, and moral issues associated with the practice of clinical research in the United States.³ The Boston group conducted a survey that indicated that only 16 U.S. institutions used consent forms or documents, and only 2 had policy guidance for research involving humans. The group forwarded its report, including the survey, to the NIH in 1963.

Shannon acknowledged that he sought a policy to protect the rights of research subjects because he felt that failure to do so would jeopardize the medical research enterprise in the United States—an enterprise that after World War II was centered in the NIH. He believed that protection of the rights of subjects was essential to the development of the NIH mission. He was particularly upset when he learned that a U.S. surgeon, without prior consultation or approval from the NIH or anyone in his institution, transplanted a baboon's kidney into a human being. The patient died within minutes. The surgeon called his action "research."⁹

The Livingston Committee

The results of the Boston University Study, the publicity given to alleged research abuses, and discussions with the FDA—including discussions about how to implement the Javits amendment to the

Kefauver-Harris Act—prompted Shannon to appoint an NIH committee under the leadership of Robert B. Livingston to address these problems. The Livingston Report reached several conclusions:

[A]s the number of investigators, subjects, and institutions engaged in clinical research increases, and as the nature of the risks . . . changes according to the extension of research into new areas, a mounting concern is expressed over the possible repercussions of untoward events which are increasingly likely to occur, and which may occur in an unfavorable pattern of [sic] context. . . . The NIH is not in a position to shape the educational foundations of medical ethics. . . . In our view, it would add to existing insecurities if the NIH were to assume an exclusive or authoritative position concerning the definitions of ethical boundaries or conditions necessary for clinical research.¹⁰

Shannon was in full agreement with the report's warning of increasingly frequent untoward events; but he found "wholly unsatisfactory" the report's conclusion that the NIH should set no ethical boundaries. He argued that the NIH was well within its authority to require institutions to meet ethical standards as a condition of receiving support for research involving humans. Following receipt of the Livingston report, Shannon forwarded four recommendations to the NAHC:

1. A professional group should . . . formulate a statement of principles relating to the moral and ethical aspects of clinical investigations.
2. There is a need for more factual information regarding actual research practices.
3. The NIH should consider providing advice concerning ethical problems, and risk-reducing practices.
4. Research grant documentation relating to clinical investigations using human subjects should be identified for special consideration throughout the PHS-NIH review process.³

Policy and Procedure Order #129, February 8, 1966

Following Shannon's presentation in September 1965, the NAHC deliberated for several months and then issued Policy and Procedure Order #129 (PPO #129) on February 8, 1966. The policy required awardee institutions to

provide prior review of the judgment of the principal investigator . . . by a committee of his institutional associates. This review should assure an independent determination: (1) of the rights and welfare of the individual or individuals involved, (2) of the appropriateness of the methods used to determine informed consent, and (3) of the risks and potential medical benefits of the investigation.³

The slow pace of implementation of PPO #129 contrasted sharply with the energy that senior NIH officials had devoted to having it approved by the NAHC. Within months of its promulgation, Surgeon General William H. Stewart ruled that PPO #129 applied both to clinical research and to behavioral and social science research involving humans conducted or supported by any agency within the PHS. The policy was also extended to those enrolled in projects conducted under research training grants. PPO #129 required each awardee institution, domestic or foreign,

to submit an Assurance of Compliance with each application for funding. These documents, at least in theory, were to be completed and signed before any PHS project involving human subjects could begin. Had the requirement of PPO #129 been strictly enforced, federal research involving humans would have slowed to a crawl or come to a standstill. Neither the PHS nor the NIH had made provision for a well-staffed office to implement the requirements of the policy.

The Role of the Institutional Relations Branch

Shannon assigned the task of administering PPO #129 to the institutional relations branch within the Division of Research Grants (DRG-IRB). This tiny office, which included only four professional employees with experience in the peer review system, had many other duties besides implementation of PPO #129. Staff members could give only part of their time to implementing the new policy. Staff from the DRG-IRB traveled to institutions and negotiated the required assurance documents with these institutions. Each assurance was tailored to accommodate the organizational framework of each institution. This process could often take up to a week. Before long it became clear that the policy would never be implemented if this snail-like process remained unchanged.

The NIH, by far the largest agency in the PHS, soon altered its interpretation of the policy. For the most part, general assurances replaced single project assurances. Thus an institution could negotiate one assurance document that covered all research involving human subjects for a period of three to five years. Model assurances were developed and the policy was clarified. Surgeon General Stewart, in the face of fierce protests by nonmedical researchers, made clear that the new policy also applied to behavioral and social science research involving human subjects. The policy was amended, clarified, and reissued in July 1966, in 1967, and again in 1969. The FDA found that it could implement the Javits amendment by "piggybacking" onto the institutional review committees (IRCs) established in accord with PPO #129.

Donald S. Chalkley, director of the DRG-IRB, said,

To many it was an entirely new and strange concept. The PHS provided few guidelines. . . . Institutions were permitted to review proposals [protocols] any time prior to their actual acceptance. Understandably many institutions followed the practice of reviewing only after the actual awarding of a grant. While this was an administrative advantage for the institution as well as the investigator, it was a cause for concern among NIH officials.³

PPO #129 received unexpected support from the 1966 publication of an influential article written by Henry K. Beecher in the *New England Journal of Medicine*.¹¹ Beecher identified 22 studies published in refereed journals that contained serious ethical flaws. Because of Beecher's exalted reputation among his peers, the article was considered to be entirely credible. Although other criticisms of research ethics had been published, the Beecher article seemed to have greater impact than any of the others. The article was a stinging rebuke to those who still considered research to be beyond the purview of committees because such committees were an intrusion into the doctor-patient relationship.

Within the PHS, the duties of the surgeon general's office were divided. The surgeon general continued to issue annual reports on

the health of the nation and to exercise command over the Public Health Service Corps, but the line of authority from the Secretary of the Department of Health, Education, and Welfare (DHEW) to the agencies within the PHS ran through the assistant secretary for health (ASH), not through the surgeon general. In 1970 Philip Lee, a veteran health policy official, was assigned to the position of ASH. Lee quickly realized that PPO #129 needed clarification and improved implementation. He appointed Eugene A. Confrey to chair a task force to review and revise PPO #129. Among other statements, the task force issued the following recommendation:

The primary duty of institutional committees was to protect the rights and welfare of human subjects. In doing so, the committee was to concern itself with the appropriateness and adequacy of efforts to obtain informed consent from subjects; weigh the risks to subjects against the potential benefits to subjects or the importance of the knowledge to be gained.¹²

The assertion that research could be justified by the “importance of the knowledge to be gained” constituted an important addition to PPO #129. It made possible the conduct of research that did not hold out the prospect of direct benefit to research subjects.¹

The Yellow Book

Ernest Allen, director of the DHEW Division of Grants Administration Policy, recognized that the DHEW was supporting research involving human subjects with funds provided by agencies within the DHEW but outside the PHS. He therefore recommended that the policy be extended to cover all research involving humans conducted or supported by any agency within the DHEW. Donald S. Chalkley, special assistant to the director, DRG, was assigned to direct the DRG-IRB. In 1970, Confrey asked Chalkley to redraft the PPO #129.

In 1971, Chalkley published a DHEW-wide version of the policy in pamphlet form with a bright yellow cover. It was known thereafter as the *Yellow Book*. The document included the clearest version of the policy published up to that time. The *Yellow Book* also added commentary to help institutions understand and comply with each of its provisions.

The policy had matured to the point at which most awardee institutions considered it both workable and acceptable. Clinical investigators grudgingly accepted its requirements, and brought their studies into compliance. Nevertheless, implementation was far from ideal. Some institutions included ambiguous language in their assurance documents that provided enforcement loopholes. Almost all institutions understaffed the offices charged with implementing the policy, and only a few offered the staff training necessary to provide support for IRCs. Nevertheless, government staff learned by experience, and institutional staff members began to provide improved assistance to principal investigators and to IRCs. Many institutional staff members learned how to comply with the policy by networking with one another.

Chalkley wrote hundreds of longhand letters to heads of institutions urging them to comply, criticizing their shortcomings, and exhorting them to take their responsibility to protect human subjects seriously. Because Chalkley's letters often contained sarcasm and stinging criticism, Charles R. McCarthy, chief of the legislative development branch in the NIH's Division of Legislative

Analysis [and author of this chapter], was assigned by Associate Director Ronald Lamont-Havers to edit Chalkley's letters.

Senate Health Subcommittee Hearings and the Tuskegee Study

In 1971, Senator Edward M. Kennedy became chairman of the Health Subcommittee of the Senate Labor and Public Welfare Committee. He initiated a series of hearings spaced at intervals of three or four months. Many of the hearings dealt with research issues. Kennedy made no secret of the fact that he was accumulating evidence for the creation of a national commission to deal with health research. Kennedy held hearings on the following: contraception research, including the Depo-Provera study in which some women were given placebo instead of contraceptives without their knowledge; psychosurgery research involving frontal lobotomy; lethal whole-body radiation experiments to treat military cancer victims; and the need for a national agency or commission to oversee research in the United States. Among these hearings was one that considered S.J. Res. 75, a bill introduced by Senator Walter Mondale calling for a national commission on health, society, and science.¹

The centerpiece of the Senate Health Subcommittee hearings turned out to be the Tuskegee Syphilis Study¹³ (see Chapter 8). The hearings brought to public attention the PHS study that for 35 years had monitored the natural course of untreated syphilis in approximately 400 African American men who resided in Macon County, Alabama. Most of the men were illiterate, and most did not know they were research subjects. The infamous study had continued within the PHS since 1932. Initially, it was thought that not treating syphilis might be better for people who had the disease than the standard treatment with the heavy metals arsenic and mercury. But the study, which deprived subjects of all treatment for their disease, continued for more than 25 years after the discovery of penicillin, the drug of choice for treatment of syphilis. It continued for five years after promulgation of PPO #129 in 1966, and after review and approval by an IRC at the Tuskegee Institute (now University). At the time of the hearings, the study had been assigned to the Center for Disease Control (CDC, now the Centers for Disease Control and Prevention).

Portions of the hearings on the Tuskegee Study were televised. Monte DuVal, who was the ASH at that time in the Nixon administration, created a citizen's commission chaired by Jay Katz of Yale University to examine the study. DuVal ordered the PHS to take a posture of “anticipation” of legislative constraints on research rather than try to defend the Tuskegee Study. Upon receiving a recommendation from the Katz Committee, DuVal terminated the study. Senators Kennedy, Javits, Humphrey, John Sparkman, and Mondale introduced legislation intended to prevent research abuses. Representatives Edward Roybal and Paul Rogers introduced similar legislation in the House of Representatives. Kennedy and Rogers continued to hold hearings on the provisions in the bills that had been introduced.

In 1972, Robert Q. Marston, who succeeded Shannon as NIH director, renamed the DRG-IRB and transferred it to the Office of the Director, NIH. The new unit, still headed by Chalkley, was called the Office for Protection from Research Risks (OPRR). In that same year, Marston delivered a major address at the University of Virginia in which he called for a broad expansion of the

DHEW policy for the protection of human subjects. He assigned Ronald Lamont-Havers, associate NIH director for extramural affairs, to chair a PHS task force made up of a number of subcommittees dealing with research involving human fetuses, children, prisoners, cognitively impaired persons, and persons who were socially deprived. These subject categories came to be known as *vulnerable subjects* categories. In 1974, DHEW Secretary Caspar Weinberger, at Marston's suggestion, created a committee chaired by Seymour Perry to make recommendations for the compensation for research subjects injured in research process.

In the spring of 1974, congressional compromises led to the introduction of two bills, one in the Senate and one in the House of Representatives. Each included features of bills that been introduced in both houses of Congress. Kennedy's bill included a provision that would create a permanent government commission, patterned after the Securities and Exchange Commission, to oversee research. Rogers' bill called for a national advisory commission to make recommendations to the DHEW secretary. After considerable negotiation, Kennedy agreed to support the commission set forth in the Rogers bill. As a condition of this agreement, Kennedy insisted that the DHEW policy for the protection of human subjects be upgraded and reissued as a federal regulation. The DHEW, preferring to deal with a temporary advisory commission rather than with a permanent oversight agency, quickly formed a drafting committee that included Charles U. Lowe, Jane Fullerton, and Charles R. McCarthy. Richard Riseberg, a young attorney in the DHEW Office of General Counsel provided legal advice concerning provisions of the Administrative Procedures Act. Because the NIH had never before issued regulations, no one on the committee had any experience in producing regulations. Nevertheless, under pressure from Kennedy, the committee hurriedly drafted regulations for the protection of human subjects based primarily on Chalkley's Yellow Book. In its rush to placate Kennedy, the DHEW waived the usual clearance requirements and the Regulations for the Protection of Human Subjects (45 CFR 46, Subpart A) were published on May 30, 1974.¹⁴ This version of the regulations had a number of flaws, but it sufficed to advance the protection of human subjects until such time as the National Commission could complete its work and the regulations could be carefully revised in the light of the Commission's findings and recommendations.

The publication of the regulations cleared the way for Rogers and Kennedy to agree to support an advisory commission for the protection of human subjects. One of the duties of the commission would be to measure the impact of research on society, as requested by Mondale. A study of psychosurgery supported by Roybal (who called psychosurgery "murder of the mind") was included, and in response to false rumors that the NIH was conducting research on living human fetuses, Representative Angelo Roncallo added a ban on fetal research. Rogers later persuaded him to accept a temporary moratorium on fetal research until the new commission could issue recommendations. Rogers and his staff drafted a new bill that included enough features of each of these initiatives to forge a compromise. The DHEW, in response to a request from Rogers for technical assistance, directed Charles R. McCarthy to draft a list of responsibilities that would be assigned to the new commission. McCarthy's draft of duties remained unchanged in the final version of the bill. The Rogers bill used a new term—*institutional review board (IRB)*—for the first time. The term *IRB* replaced *institutional review committee (IRC)*, the term that had

been in vogue since the passage of the Kefauver-Harris amendments to the Food, Drug, and Cosmetic Act in 1962.

Meanwhile, subcommittees of the Lamont-Havers task force were busy drafting pieces of what was intended to be a major report on the protection of human research subjects. Before this report could be finished, however, Congress enacted the National Research Act (PL 93–348), and President Nixon signed it into law on July 12, 1974. Title II of the Act addressed protection of human subjects. Foremost among its provisions was the creation of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (National Commission). The PHS turned over the drafts of the Lamont-Havers task force to the new commission.

The National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research

Beginning in December 1974, the National Commission met for two days of each month, with rare exceptions, for the next four years. In 1975 it issued a report on fetal research that called for regulations allowing fetal research under stringent conditions.¹⁵ In succeeding years it published reports on research involving prisoners, children, and those institutionalized as mentally infirm, as well as a report on IRBs. Perhaps its most important contribution was the report entitled *Ethical Principles and Guidelines for the Protection of Human Subjects*. This was popularly called the Belmont Report, named after the conference center in Maryland where it was conceived.¹⁶ The Belmont Report identified and applied three overarching principles of research ethics: (1) respect for persons, (2) beneficence, and (3) justice. These principles were explained in simple but eloquent language, presented as guiding norms under which all research involving human subjects should be conducted. They provided a guide for the decisions of IRBs and a framework for the drafting of future regulations (see Chapter 14). The findings, reports, and recommendations of the National Commission were, for the most part, polished and carefully presented. Each new report was published by the OPRR in the *Federal Register*.

National Commission reports and recommendations were similar in many respects to those made by in the Lamont-Havers task force. However, National Commission reports differed in several important ways. First, they were thoroughly researched and their findings were meticulously documented. Second, they included many scholarly background documents that provided depth and credibility seldom associated with reports of federal advisory bodies. Third, because they were drafted in public hearings, they enjoyed support of the public—who were given an opportunity to testify at nearly every meeting—and of the press, which was allowed to be present for all of their deliberations.

During the four-year period when the National Commission was at work, the OPRR was also making significant progress. It finally managed to negotiate acceptable assurances with all of the research institutions that were supported by the DHEW. These assurances extended the regulations not only to subjects participating in DHEW-funded research but to all human subjects involved in research conducted within each institution.

In 1975, following the National Commission's report on fetal research, the OPRR issued Subpart B of the regulations to address

research involving pregnant women and human fetuses. In 1977 OPRR Director Chalkley suffered a major stroke and retired from federal service. In 1978 the OPRR published Subpart C, entitled "Additional Protections Pertaining to Biomedical and Behavioral Research Involving Prisoners as Subjects." This report had been nearly completed before Chalkley retired. In September 1978, McCarthy was selected as the new director of the OPRR. He was assigned several additional duties, including staff director of the DHEW Secretary's Ethics Advisory Board and chair of the PHS drafting committee to incorporate recommendations of the National Commission into regulatory form."

The National Research Act contained what has come to be known as a *forcing clause*. This was a requirement that the DHEW secretary must either accept and implement the recommendations of the National Commission or publish in the *Federal Register* the reasons for not accepting them. Because few cabinet officers are ever willing to reject findings of a highly respected ethics commission, virtually all of the National Commission's suggestions (approximately 125) were accepted. The drafting committee worked for nearly two years to incorporate each of the commission's recommendations into a new version of 45 CFR 46 Subpart A, preparing a comprehensive regulation that would reflect the Belmont Principles and both the letter and spirit of the National Commission's work. The drafting committee considered about 1,500 public comments on the National Commission reports and proposed regulations.

In November 1980, Ronald Reagan was elected president of the United States. In the course of his campaign, Reagan had threatened to repeal all federal regulations. OPRR officials felt sure that he would not literally carry out that threat, but Reagan's transition team advised them that it might be very difficult to get regulations for the protection of human subjects published after he took office. The OPRR submitted Subpart A of the revised regulation to Health and Human Services Secretary Patricia Harris for final approval soon after the election. (The DHEW had been transformed into the Department of Health and Human Services, DHHS, earlier in 1980, when a separate Department of Education was created.) Harris's office called for a number of minor revisions and ordered a new preamble to be drafted. The regulations were returned to the OPRR for revision on January 16, 1981. The OPRR worked around the clock for several days, before it was finally able to secure approval from Harris on January 19, only a few hours before she left office.

The President's Commission and the Common Rule

After the National Commission disbanded, a new advisory body, the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research (President's Commission), was created. During its first year, the new commission operated on money that had been set aside for use by the Secretary's Ethics Advisory Board. Consequently, the ethics board was disbanded at the end of the Carter administration in January 1981. Much of the energy of the President's Commission was directed, not at research, but at problems in the health-care delivery system of the United States. However, the President's Commission issued two reports and one major directive concerning research involving humans. The Commission praised the DHHS "Regulations for the Protection of Human Subjects" and recommended

that all federal departments and agencies that conduct or support research involving human subjects should follow a Common Rule modeled after them.

The task of persuading 16 federal departments and agencies to follow the same regulations and to coordinate their efforts with the White House Office of Science and Technology, the Office of Management and Budget, and the State Department (for research conducted outside the United States) was assigned to the OPRR. It proved to be very difficult for two reasons: (1) Departments and agencies felt that regulations should be geared to specific programs operated within each department or agency, not to general standards designed for a vast array of programs across the government; and (2) turnover in departments and agencies meant that agreements had to be renegotiated whenever new appointees assumed senior positions in the agency or department. Joan P. Porter, special assistant to the director of the OPRR, worked tirelessly under direction of the OPRR director to fulfill the commission's recommendation. It took nearly 10 years to gain simultaneous agreement from all of the affected departments and agencies. The Common Rule was promulgated June 18, 1991¹⁷ (see Chapter 15).

After 14 years, McCarthy retired as the OPRR's director. During his tenure, he also was staff director of the DHEW Secretary's Ethics Advisory Board, serving as liaison to two national commissions and implementing their recommendations, completing the assurance process for all institutions that receive funding from the DHEW, and publishing the Common Rule. (He also chaired the committee that issued a new policy for humane care and use of laboratory animals.) McCarthy emphasized education. When he was liaising with the staff of Congressman Rogers on the legislation that became the National Research Act, he had inserted a clause in the legislation that required the DHEW to conduct education as well as enforce compliance with the regulations governing research involving human subjects. His calendars show that during his tenure, OPRR personnel participated in at least 187 educational programs concerning the protection of human research participants. He strongly encouraged a fledgling organization called Public Responsibility in Medicine and Research (PRIM&R) to conduct workshops and educational events pertaining to the protection of human subjects. PRIM&R steadily improved the quality and breadth of its programs and underwent steady growth. Gradually the research community in the United States and in other research-intensive countries came to understand and carry out their responsibilities to human research subjects under rules that had been fashioned by the DHEW and honed by the National Commission.

Gary Ellis was named director of the OPRR in the fall of 1992. He emphasized conducting site visits and inspections to assure strict compliance with the regulations. He stressed improved record keeping and he often said, "If there is not a written record, it didn't happen." Under his aggressive leadership, the OPRR suspended the assurances of compliance of more than 13 domestic research institutions between 1992 and 2000. Until the suspension of an institution's assurance document was lifted, no research involving human subjects could be undertaken in that institution. Each suspension affected large numbers of personnel in the affected institutions, and also affected many of the institutes of the NIH, the PHS, and other funding agencies.

Ellis and many others contended that because the OPRR was regulating research funded by the NIH, the location of the OPRR within the NIH constituted a potential (and occasionally an actual)

conflict of interest. He sought to have the OPRR transferred to the Office of the Secretary in order to avoid conflict or the appearance of conflict of interest. The assurance suspensions and the desire to move the OPRR to the level of the secretary, DHHS, made Ellis a controversial figure within the entire human research community.

When 45 CFR 46 was promulgated in 1981, most research projects were conducted under awards made to a single investigator in a single institution. Gradually the NIH and other funding agencies decreased the number of grants made to single institutions and increased the number of awards made multiple institutions. In the decade of the 1990s, awards often were made to a consortium of institutions conducting projects under the same protocol. Adjustments had to be made in the oversight process to avoid unnecessary duplication of review while protecting human subjects. Some institutions utilized central IRBs and commercial IRBs to address the problem.

The OPRR under Ellis's leadership moved from communication via regular mail and telephone to electronic mail, documentation, and record keeping. Guidance was published on the Internet rather than mailed to each awardee institution. New kinds of filing systems were created. Foreign institutions could communicate as swiftly and easily as domestic ones. Complex questions of how to apply the rules to institutions outside the United States involved diplomacy. Adjusting and adapting to these realities characterized Ellis' time in the OPRR.

In 2000, acting on recommendations from the National Bioethics Advisory Commission (NBAC), the DHHS moved the OPRR out of the NIH and placed it in the Office of the DHHS Secretary. The relocated office was called the Office for Human Research Protections (OHRP). In September 2000, Greg Koski, a Harvard University physician, was selected to be the new director. Koski worked closely with the Institute of Medicine within the National Academies of Science and with PRIM&R. He strongly endorsed creation of a nongovernment accrediting agency to assist research institutions to remain in full compliance with the Common Rule. He played an important role in persuading the Association of American Medical Colleges and other professional health organizations to join with PRIM&R in funding an independent, private accrediting agency to certify the adequacy of institutional research protection programs. By 2006, that organization, the Association for Accreditation of Human Research Protection Programs (AAHRPP), had announced full accreditation for approximately 43 institutions, and well over 100 institutions were seeking accreditation. Accreditation is seen as a mark of excellence and appears to be the wave of the future. Moreover, it offers institutions the opportunity to evaluate their programs from time to time, to make sure that they are in compliance with regulations and that human research participants are well protected.

In January 2003, Bernard Schwetz was named acting director of OHRP, and a year later, he was named director. Schwetz again stressed the need for education of a growing and changing research community. He emphasized the need for human research protection programs including, but extending well beyond, IRBs. Schwetz also offered the services of OHRP as an aid to institutions rather than an enforcer of regulations. He increased the number of "not for cause" site visits, in which OHRP representatives offer assistance to institutions to improve their programs rather than cite them for noncompliance. OHRP published a number of documents on the Internet to assist institutions to interpret and apply the regulations. Schwetz also created the Secretary's Advisory

Committee on Human Research Protections (SACHRP) to provide outside advice on how best to provide protections for human research subjects.

In the meantime, the funding of both clinical and behavioral-social science research steadily increased. The need for protection of the rights and welfare of human subjects has grown apace. As stem cell research, genetic research, and proteomics research have expanded the traditional areas of research involving human subjects, so will the need for vigilant oversight need to change.

Growth With Continuity

From James Shannon's 1965 testimony to the National Advisory Health Council until the present time, progress has been made in protecting human research participants. The insights that Shannon presented to the NAHC found expression in PPO #129. Each expression of policy and each new regulation has included all of the best characteristics of the past. Progress in recognizing the rights and welfare of human research participants has been captured in each succeeding set of regulations. Progress in the understanding and application of sound research ethics has taken place in both domestic and the foreign settings. IRBs are established in more than 80 nations worldwide. They have become more insightful and sophisticated in conducting review and oversight of research protocols involving human subjects. Clinical investigators and behavioral and social scientists have come to know, understand, and apply the rules to their own research protocols. Administrators have come to understand that the regulations require institutions to train and oversee their personnel so that those enrolled in research will receive the protection that they are owed. Although the protection of human subjects has expanded in countless ways, IRBs continue to stand at the center of the program.

With the advent of funding for multicenter research involving humans, a single phrase in the 1981 version of the regulations has become extremely important. Section 46.111(a)(6) authorizes IRBs to make adequate provision for monitoring the data collected to ensure the safety of research participants. That clause provided for the creation of data and safety monitoring boards (DSMBs) to monitor the data collected in trials involving many sites (see Chapter 53). The DSMB has become a major and often essential tool in protecting human research participants in multicenter trials. The OHRP now faces the challenge of finding an efficient method of coordinating the work of IRBs and DSMBs.

The IRB has served the United States and many other countries well. It is here to stay. But unless it is considered to be an evolving and expanding mechanism, adapting to the problems of each period of history, it is in danger of becoming fossilized and ineffective. Administrators, research investigators, ethicists, regulators, Congress, and the general public bear the responsibility of creating mechanisms and methods for the IRB to continue to protect human research participants in a manner that is demanded by the highest principles of ethics.

Models of Institutional Review Board Function

History

Many models of the institutional review board (IRB) have developed in the United States and other countries as awareness has increased within the research community that a need for such oversight bodies existed.¹ The Nuremberg Code and the Declaration of Helsinki both called upon other institutional structures, such as medical associations and legal systems, to oversee ethical behavior in both medical practice and research. The Declaration of Helsinki promoted physicians' awareness of their traditional responsibilities to patients, regardless of pressures to do otherwise. Research at that time was less a concern than were the practice of medicine and adherence to the traditional ethical standards of professional behavior.

In 1962, an amendment to the federal Food, Drug and Cosmetic Act required all new medicines marketed in the United States to have research showing them to be effective as well as safe for their intended use.² This amendment changed the research landscape dramatically. The Food and Drug Administration (FDA) began the process of bringing drugs already on the market back into testing to assess their safety and efficacy. This new requirement necessitated the commitment of vast sums of money to the research community by pharmaceutical manufacturers.

During the 1960s, the National Institutes of Health (NIH) was also rapidly growing. Hundreds of eager young researchers trained at the NIH migrated to medical schools across the United States to conduct research. It was a time of great energy in medical research and a time of great trust from the community at large that there would be public benefit from these research efforts. Patients were eager to enroll as participants in this new enterprise of medical research.

All of this activity caused James Shannon, then director of the NIH, to worry about the oversight of such things as scientific integrity and the maintenance of professional standards in research. He quietly implemented a requirement that scientists receiving federal funds should have an oversight committee composed of "peers" that would review and approve a research proposal prior to its implementation. Because virtually all federal funding went to universities and large medical centers, these institutions founded research review panels, often called "investigator judgment committees."

Shannon was also concerned about revelations of abuses in clinical research, including the Jewish Chronic Disease Hospital Study and the cases reported by Henry Beecher³ (see Chapters 6 and 7). The policy of peer review proposed by Shannon was incorporated in the 1966 "Statement of Policy" by Surgeon General William H. Stewart and was aimed at the protection of research participants. But the initial committees formed in response to this policy were not focused on research protections, except for poor science or protocol design. No enforcement was designed into Stewart's guidance, and it was widely ignored.⁴

During this same era, William H. Masters and Virginia E. Johnson published their book *Human Sexual Response*,⁵ in which they reported on a series of experiments they had conducted between 1959 and 1964 at Washington University in St. Louis. These studies recorded the many physiologic responses to sexual stimulation. Volunteers were recruited from the community and included commercial sex workers and other paid volunteers. Although the book was a scholarly work aimed at the medical profession, Washington University was profoundly embarrassed because it had not been aware that the work was being conducted in

its facility. The work was widely covered by the lay press and much unwanted publicity ensued. Inevitably “wronged spouses” surfaced in the courts and the publicity continued well into the 1970s.⁶ The book became a best seller.

This was a key event in raising institutional consciousness that protections needed to be developed for institutions themselves. Many institutions began to take precautions to prevent similar surprises from their own researchers. The committees established to do this work were similar to the investigator judgment committees, but their sole function was protection of the institution. No concern for the research participants was evidenced.

During the mid-1970s, following disclosure of the Tuskegee syphilis experiment (see Chapter 8), the Department of Health, Education and Welfare (now the Department of Health and Human Services, DHHS) promulgated regulations directed toward the protection of those who were institutionalized, regulations that prohibited their participation without an oversight mechanism in place.⁷ Responsibility for forming oversight committees, called *institutional review boards*, was left with the institution, and an oversight body was established within NIH—the Office for Protection from Research Risks, now the Office for Human Research Protections (OHRP) within DHHS. This body had oversight of the NIH IRBs as well as all federally funded research. Nongovernmental institutions filed a promissory letter with the DHHS promising adherence to the guidance documents. It was a collegial system, without active enforcement, until the mid-1990s, when a more active approach began under the leadership of Gary Ellis. Widespread noncompliance was immediately apparent.

In the meantime, the pharmaceutical industry had set up a network of clinical investigators that were located in small hospitals, clinics, and private physician practices. Much, if not most, of this research was in support of medicinal compounds that were in development or of compounds already on the market and targeted by the FDA as requiring further documentation of safety and/or efficacy. At first these clinical investigators were not required either by the FDA, DHHS, or their institutions to have oversight for this work. It is of interest that some of these investigators set up, or caused to be set up, their own oversight committees, which were also called IRBs. Such committees were then converted to independent IRBs, not associated with a particular institution, when FDA regulations requiring them (21 CFR 50 & 56) were promulgated in 1981.^{8,9} A federal policy for the protection of human participants was enacted at this time and is known as the Common Rule (45 CFR 46 Subpart A).¹⁰ Government agencies had the option to adopt this rule or not. It was subsequently adopted by 17 agencies including DHHS.

Other countries with both government funding for research and a research-based pharmaceutical industry also have developed systems for the purpose of protecting research participants. Countries without either industry or U.S. government funding remain less developed in the protection of research participants. Much privately funded research remains exempt from enforceable oversight. As research has become increasingly competitive and the U.S. public less trusting of the research enterprise, there is more outreach by U.S. companies and universities to developing countries. There is concomitantly more interest in developing systems for protection of research participants in these nations.¹¹ Systems vary, but tend to be loosely patterned after the current U.S. models.

Research Review Systems in the United States

It is apparent from this brief historical overview how the U.S. system has become so diverse. The national tendency toward institutional autonomy reinforces the preference for local decision making over a central oversight model. The current U.S. models can be roughly categorized into institutional, independent, and private. These are similar in many respects but differ in a few fundamental areas.

Government Agencies

The 17 agencies of the federal government that have accepted the Common Rule have some kind of ethics review process directed to human participant protection. These agencies are as diverse as the Department of Defense, the Department of Agriculture, and the Agency for International Development. These committees are usually composed of agency employees and an outside member. This structure permits direct knowledge of both the research focus and the principal investigator and maximizes local knowledge and control. Any special considerations such as national security, confidentiality of materials, or even the title of the research can be closely held.

Such a structure could be worrisome if special care is not given to the protection of the employee members. For example, if research conducted by higher ranking employees of the agency is reviewed by lower ranking employees, the potential for coercion or the fear of coercion is a concern. Lower ranking employees might fear reprisal by those of higher rank. This concern could be ameliorated by careful selection of IRB members and strict institutional reinforcement of independent decision making by the IRB. A more effective measure might be to increase the number of outside members who will bring different perspectives to better balance that of agency members.

The IRB is generally accountable to the director of the agency, but they are also accountable to the FDA, in the case of regulated drugs or devices, and the OHRP for federally funded projects. Funding for the IRB comes directly from each agency's budget.

National Institutes of Health

There are 14 separate IRBs within the NIH. Each of the larger institutes maintains its own IRB to oversee intramural research with humans. Members are chosen from the staff of the institute and are supplemented by at least one public member. Each IRB is required to have a member with training in bioethics. Their workloads are variable and each is staffed separately. Each is funded by its own institute, which in turn is funded by congressional appropriations. Each IRB is accountable to the clinical director of the institute and ultimately to the NIH deputy director for intramural research. These IRBs are also accountable to the FDA and the OHRP.

The National Cancer Institute (NCI) formed a central IRB in 2000, then divided this into two panels in 2004—one covering treatment of adults and the other covering treatment of children.^{12,13} The plan was that the central IRB would review all multicenter cancer protocols and that local IRBs would have the option of accepting this review. The adult-oriented NCI-CIRB has been meeting monthly since January 2001, whereas the NCI

Pediatric CIRB began meeting in November 2004. This has received only modest acceptance to date; institutions have generally preferred to conduct local review. These boards are responsible to the NCI, FDA, and OHRP. Funding is provided by the NCI.

Military Hospitals

These entities operate under the Department of Defense, which has adopted the Common Rule. Their IRB structure is similar to that of other governmental agencies, and the concerns are much the same. The strong military culture of rank recognition and *esprit de corps* may impair individual autonomy in decision making even more than in other governmental agencies. Special attention to internal conflicts of interest is necessary in these situations. In addition, outside or community members often are retired military. Accountability is to the commanding officer of the hospital, and to the FDA and the OHRP. Funding is through the Department of Defense.

States

Most states have a dedicated state IRB that reviews research done in or by state agencies, state prisons, and state hospitals. For many years research in state institutions for the mentally ill and in prison systems has been discouraged except when direct benefit to the participant is expected. These situations place an uncommonly heavy burden on IRB members. Prisons, in particular, have unique cultures and processes permitting coercive actions to occur that would not exist within a free population. Special knowledge of prison systems and greater awareness of these extraordinary responsibilities by all review board members is important.

Social and behavioral research is commonly reviewed through these state IRBs when it is to be conducted in state-run institutions. Members are usually chosen from the various state agencies. There may or may not be a member from the community. Accountability is to the Department of Social and Health Services (DSHS) in some states and to the governor of the state in others. These IRBs are also subject to oversight by the FDA when regulated drugs, devices, or biologics are involved and to the OHRP when federal funding applies. State IRBs may be subject to state regulations in addition to the federal regulations.¹⁴ Funding usually comes from the state's general fund.

Academic Institutions

All U.S. academic institutions that conduct federally funded research hold either a multiple project assurance (MPA) agreement with DHHS or a federalwide assurance (FWA) agreement. These agreements bind academic institutions to uphold the regulations of both the OHRP and the FDA. Academic institutions consequently structure their IRBs according to the guidelines and regulations promulgated by these regulatory bodies.

Members are chosen from the faculty, often by conscription, and are supplemented with the traditional outside or community member (or members). The different schools within the university (nursing, pharmacy, medicine, etc.) are usually represented by one or more members. Few academic institutions have more than one community member. Transparency would be increased if wider

community representation existed. Community members can provide a powerful bond between the institution and the nonacademic community. This can be especially useful to the institution when complex and socially sensitive research is being conducted or if a research tragedy occurs.

Many universities with active research programs have multiple panels or IRBs. These committees operate as parts of a whole, following common standard operating procedures and policies. They are often coordinated through an executive policy committee (EPC) composed of the various panel chairs and others. Through this committee, the panel chairs agree on the common policies under which all panels operate. This lends a modicum of consistency to the process.

Some universities contract with independent IRBs to supplement or replace one or more of the internal panels. The outside IRB may operate as one of several panels or, in some situations, as the sole IRB. Under these conditions, the independent panel reports to the institution and adheres to previously agreed upon institutional policies. These panels extend capacity of the in-house panels and can provide relief from internal conflicts of interest that institutions commonly face when university-owned intellectual property is the subject of the research.

Universities sometimes collaborate to form a conjoint committee that reviews research from any member institution. Such joint review boards have been formed in New York, Tennessee, and the Midwest.^{15,16} Members are chosen from the faculties of each member institution. Resolution of issues such as liability, insurance, and interinstitutional rivalries has been problematic.^{17,18} Member institutions contribute funding from industry grants and other sources.

Accountability of these IRBs varies at the institutional level but all are accountable to the usual regulatory authorities. University IRBs usually report to the dean for research, the vice provost, or some other highly placed administrator of the institution. Accountability is therefore to the institution and through it to the federal regulatory authorities.

Institutionally based IRBs account for the bulk of the 3,000 to 5,000 IRBs said to exist in the United States. Funding is provided indirectly through funds from governmental sources and grants or fees from the pharmaceutical and medical device industries.

Independent or Fee-for-Service Review Boards

These review boards are usually operated under a corporate structure and are otherwise unassociated with a research institution. They take many forms, but all are subject to FDA oversight and some also to OHRP oversight. Board members may be employees of the corporation—and if so, must be supplemented by at least one outside or community member—but some boards are composed entirely of nonaffiliated community members. Like their institutional counterparts, they must have standard operating procedures and policies and are subject to audit by the regulatory authorities.

Much of the research reviewed by these boards is related to new drug and device development, so they are primarily funded by pharmaceutical or device manufacturers through a fee for service. This is thought to be one of the primary areas in which conflicts of interest may be problematic.¹⁹ Wide client diversity

can ameliorate this potential conflict, because less economic dependence on a single client could lessen the impact of pressure from a client to approve research. A second area of concern is the presence of stockholders on the review board. OHRP prohibits this practice for review of federally funded research. The presence of equity owners as board members is generally unacceptable. However, these review boards are remarkably free from many other conflicts that plague institutionally based IRBs. It is noteworthy that two of the first three review boards to receive full accreditation from the Association for the Accreditation of Human Research Protection Programs²⁰ were independent boards.

Independent review boards are accountable to the chief executive officer of their companies and through them to the usual regulatory authorities. Their funding comes from the corporation, which is generally supported by a fee for service collected from clients.

Hospitals

This category includes both small and large hospitals and clinics where research is conducted. These facilities are numerous but their research, with a few notable exceptions, is small in volume. Hospital-based IRBs are often challenged by inadequate volume to maintain the interest and experience of their board members. Funding may also be problematic, because hospitals rarely have large federal grants as a source of indirect funds.

IRB members are usually chosen from the medical staff and serve as a condition of staff privileges. There is rarely a dedicated staff on such review boards. Rather, staff is usually appropriated from other positions. These review boards usually have a solid knowledge of the local context and may surpass all other models in firsthand knowledge of the investigator and of community attitudes. This may be an especially important benefit when investigator diligence is in question. However, conflicts of various kinds may abound. Accountability is either to the president of the medical staff or the hospital administrator. Of these, the president of the medical staff is usually preferable to physician-investigators, but the hospital administrator controls the funds available for the review board. In the case of large multispecialty clinics and managed care organizations, there may be a vice president for operations or administration as the final authority.

These review boards are also accountable to the FDA and sometimes to the OHRP—for example, if there are large oncology practices located in an area where NCI studies are conducted. Funding, if any, is usually provided from general funds of the institution.

Private

This category is quite diverse and includes both for-profit and not-for-profit entities. The reporting structures are quite different and the review boards may not be subject to the same regulatory oversight as conventional boards unless the research involves regulated articles, in which case the FDA is the regulatory authority. The OHRP is rarely involved with these review boards because the research they review does not commonly have federal funding. This category includes companies that maintain in-house boards to review research conducted only within their facilities. Examples of such research include a pharmaceutical company with a dedi-

cated Phase I facility, or a device manufacturer that needs to evaluate a reported malfunction of a marketed device.

These facilities often recruit employees as research participants for these studies. If the product is not regulated by the FDA, it may fall outside the guidelines and regulations requiring research review. The company may nevertheless want IRB review for its own corporate oversight. These situations usually occur in companies with regulated products. The review board members tend to be employees without an outside member. They are responsible to the director of compliance or some other officer in mid-management. Funding comes from corporate sources.

There are many small private foundations that receive funds from other private foundations. If their research projects fall outside the federal regulatory arena—that is, if the projects are neither federally funded nor aimed at winning federal regulatory approval—they may be totally unregulated. In these circumstances, if an IRB exists it may be the only oversight for the research, and it would be dependent upon the trustees of the foundation for authority to restrict certain behaviors. Therefore, unless the foundation is committed to the mission of human participant protection, the IRB is unlikely to prevail if the investigator resists its oversight recommendations.

Frequently, a small panel is set up to review the research of a single investigator or a small sponsor. These panels may be composed according to federal regulations and are generally responsible to the FDA. They are rarely attached to an institution and they tend to employ a fee-for-service funding model. Many examples of this model exist in and around the small device community.

Discussion of the U.S. System

It is apparent that U.S. IRBs can take many forms. Virtually all review committees in the United States conform to the regulations of the OHRP and the FDA. These regulations set minimum standards but are subject to much variation. Review boards most commonly have more than the five members required by the regulations, and it is not uncommon for IRBs to have 18, 20, or, in one case, 36 members. In the case of the 36-member board, it is necessary to have 19 members present for the entire meeting—an impractical and unusual event.

The common rationale for a large number of members is broad representation of the institutional departments and the availability of multiple medical specialties. Such IRBs frequently have trouble gaining a quorum and are often cited on audit for making decisions without a quorum. A better practice is to have fewer members who are faithful attendees and to have a broad roster of alternate members who can be called for special expertise when needed. The use of consulting, nonvoting members is acceptable when additional expertise is needed. It is probably not wise or practical to attempt complete coverage of all needs within the voting membership of the panel.

Research Review in Other Nations

When U.S. investigators conduct research in another country, a local board may review that research. These research ethics committees, as they are often called, may follow guidance from the World Health Organization (WHO),¹¹ the Council for International

Organizations of Medical Sciences (CIOMS)²¹ or the International Conference on Harmonisation (ICH).²² There are strong similarities among these various guidance documents; all were loosely based on U.S. regulations, and various members of the U.S. human participant protection community assisted in their development. The goal was to have as much common ground with U.S. regulations as possible and still include representation of the local cultures. However, these boards may not conform to all U.S. regulations and consequently may be supplemented with additional review by a U.S. IRB.

Canada adheres to ICH guidelines and to its own Tri-Council Policy Statement.²³ Most European countries have adopted the ICH model, although France and Germany have added unique local requirements. Both countries require research sponsors to provide insurance to cover research-related injuries. France also requires review by a French board.

It is important to recognize, however, that research ethics committees in most countries provide only recommendations and thus do not have the same authority as U.S. IRBs. United States boards have the authority to stop research by withdrawing approval or suspending the investigator. No such authority is vested in review committees in most other countries. Likewise, there may be little or no enforcement of research ethics committee review standards, committee composition, or operating procedures. In most cases, guidance emanating from the review board is strictly advisory to the investigator, who may choose to disregard it. If we have learned anything from a quarter century of experience, it is that regulatory enforcement is necessary for the protection of human research participants.

The Scandinavian countries use central committees and regional review. Review is generally limited to the initial protocol without continuing oversight. Regulatory oversight is limited. Denmark's system is unique in that its membership is composed entirely of nonscientists.

Many developing countries also have adopted either the CIOMS or ICH guidelines. Usually each government makes amendments to these international guidelines to better represent the local culture. Rarely do they meet the requirements of the U.S. FDA, but they are nonetheless valuable adjuncts to U.S. review of international research. Dual review—by a U.S.-based IRB in addition to the local review—is often conducted if the research has a U.S. sponsor.

The United Kingdom began with only local, institutionally based IRBs. That system resulted in lack of timeliness and consistency. Complaints from investigators and sponsors led to the establishment of regional boards. Local boards were then able to accept the review provided by the regional board or to conduct their own additional review. This process led to even greater delays because most local boards did not accept the central review. Local review is still dominant in the United Kingdom.^{24,25}

Many Asian countries are making rapid progress in meeting both international and U.S. standards. Thailand, for example, has an aggressive program of IRB member training and is evaluating performance of review committees through a nonregulatory process. Taiwan, Korea, Malaysia, and the Peoples' Republic of China are all moving to codify regulations similar to those in the United States. It is likely that regulatory oversight may be adopted in these countries because they are on a path of harmonization with the U.S. FDA.

Singapore began with a single, state-run IRB model that reviewed all research conducted there. Most clinical trials conducted

in Singapore are ultimately subjected to U.S. FDA review for drug or device approval. Singapore authorities are currently redeveloping their system to an institutional model, in which IRBs are based at individual research institutions.

Form and Function of IRBs

Until recently, there had been little in the way of systematic study of IRB models. Although public interest in the ethical review of medical research began in the 1970s, interest in the process and procedures of ethical review was not apparent until the late 1990s. As injuries occurring during the research process became front-page fare in the nation's newspapers and recruitment for study participants became more aggressive, Congress prompted the General Accounting Office (now the Government Accountability Office, GAO) to study the regulation of clinical research in 1996.²⁶ This was followed by a thorough assessment by the DHHS Office of the Inspector General (OIG) in 1998–2000.^{1,27–29} Interviewing many IRB members, OIG investigators produced a survey that contains the most objective information available on the form and function of the various kinds of ethics review boards that exist in the United States. Recommendations for improvement of the system followed.³⁰

In its reports, the OIG catalogued perceived flaws in the system and in 1998 it recommended remedial actions. In 2000 the secretary of the DHHS commissioned the Institute of Medicine (IOM) to thoroughly study the problem and to make consensus-based recommendations. This report was issued in 2002 and represents an attempt by the scientific and medical communities to inform and shape any remedial action.³¹

The initial part of the IOM report focused on accreditation. The IOM panel's interest stimulated two national bodies, the National Committee for Quality Assurance (NCQA)³² and the Association for the Accreditation of Human Research Protection Programs (AAHRPP),²⁰ to set up systems of accreditation for the nation's system of human subjects protection. So tepid was the response that only three IRBs were accredited during the first year, all by the AAHRPP. The NCQA later joined forces with the Joint Commission on Accreditation of Healthcare Organizations³³ to form the Partnership for Human Research Protections. However, this effort was subsequently abandoned—the Partnership for Human Research Protections was dissolved Nov. 15, 2005—leaving the AAHRPP as the sole accreditation body.

The IOM attempted to assess what the effect of the accreditation process would be on the performance of the national system and concluded that the process would be helpful in extending their resources and would improve consistency between IRBs. Many others believe the process and attendant public notice will be beneficial to human participant protection. In 2006, approximately 200 institutions were said to be undergoing the preliminary self-assessment process as a prelude to accreditation.

The IOM encouraged the adoption of systems that had been shown to work in practice and to follow that with continuous quality improvement. These recommendations are as close to consensus as we have come in the development of a standard approach to the IRB function. The IOM rightly stressed the importance of an institutional culture that facilitates ethical behavior by the IRB members, clinical investigators, and other study personnel. The IOM report outlined four specific conditions that should

exist: accountability, resources, ethics education, and transparency in process.

Accountability

It is apparent that the structure of the parent organization is important and that leadership is vital. The responsibility for functional human participant protection systems rests at the highest level of the institution, and this is true whether the institution is a university, a government, a hospital, or a corporation. The lines of authority should be clearly drawn, and each member of the human participant protection systems team should know his or her responsibilities and authority within the institution. IRBs are accountable to the volunteer research participants whose interests they represent. IRBs are also accountable to the institution that has entrusted them to provide the protections that the institution has assured the OHRP will be provided. In a way, they are also accountable to the investigators whose research they review. This level of accountability involves fairness in review, confidentiality of documents, adherence to federal regulations, and full disclosure to the prospective research participant in the consent document. Under FDA regulations, it is the investigator's responsibility to assure that the IRB is compliant with the FDA regulations, whereas under OHRP regulations, it is the institution's responsibility to assure IRB compliance. This is one of several areas in the regulations in which there are differences between the OHRP and FDA regulations.

Resources

Both the GAO and the OIG reports lamented the lack of resources provided to IRBs to do their work. Resource allocation usually comes from the top of an organization. Without resources, the very best IRB will soon founder. Adequate resources should include provision for well-trained staff members to assist the IRB in assembling materials for review. Staff should provide assistance with follow-up and tracking of approved protocols including, but not limited to, adverse events. United States regulations require at least annual review of approved research, but much research would benefit from more frequent scrutiny. Electronic systems can be used to perform tracking tasks and, if properly validated, much of the regulatory documentation as well.

Ethics Education

Many observers of the human participant protection process have cited inadequate research ethics training among those involved in research and its review. Certainly this training should be a part of the early preparation of career researchers and should be in depth. There has been a lack of national attention to structured systems for the production of well-trained clinical investigators. On-the-job training has too often replaced the structured research fellowships so common in earlier years. Pharmaceutical and device companies have recruited as clinical investigators many internists and family physicians who may or may not have been adequately prepared for conducting clinical research. A more structured approach to investigator training would be beneficial to the research enterprise. The University of Rochester implemented such a program to provide formalized training in the fundamentals of pro-

ocol writing, statistics, and regulatory adherence in the late 1990s. Completion of this core curriculum was required prior to beginning research activity. With wide acceptance, this kind of program could be a prerequisite for engaging in clinical investigation.

Bioethics has been a buzzword in research for over a quarter of a century and yet it has only recently been integrated into biomedical and behavioral medicine curricula. Regrettably, many premedical programs no longer require fundamental training in ethics, humanities, and history. It is therefore necessary to offer remedial training during the busy years of medical education. Most researchers will benefit from additional training in ethics, especially as it relates to research, early in their training. Solid programs in medical ethics should be in place and required for practicing physicians as well as researchers. Many supplemental courses are offered online.³⁴⁻⁴⁵ NIH-funded researchers are required to complete a bioethics primer prior to receiving funding.

Many IRB members will not be scientifically trained and may lack even a basic knowledge of bioethics. It is incumbent on institutions to provide training for IRB members prior to board participation. A program of continuing education for members should be ongoing. There are many resources available, both web-based and in written format, that can provide training materials for members. Such training is recognized as best practice but not yet widely adopted.

Transparency

Transparency in the conduct of research is no longer optional. Research participants must be aware of the protocol and their role in its execution. The institution must cultivate and maintain an open interaction with the local community about research activities and the process of human participant protection. Key to this latter point is the importance of community members on the IRB. These members serve as a powerful conduit to the community, both to provide insight to the institution and to carry awareness of the research process to the local community. They will serve the institution well in times of tragedy or public relations debacles by providing an "outsider's" verification of the university processes. They also help scientific members of the IRB recognize problems in understanding consent documents, because scientists are often unaware that consent form language can be difficult and not readily comprehensible. Active lay members can correct this problem if allowed to participate as equals in the discussion. Both the OIG report and the IOM recommendations stress the need for greater numbers of nonaffiliated IRB members on the grounds that nonaffiliated, lay members provide greater transparency. Both recommended that 25 percent of panel members be nonaffiliated. Western IRB, a large independent organization, has traditionally constructed entire review boards of community members.³⁴

Placing nonaffiliated, lay members on IRBs requires a structured training process to ensure that members are knowledgeable about the regulatory and ethical basis of the work, their responsibility to human participants, and the process of clinical research. These members provide important balance for institutional conflicts of interest. The institution should provide indemnification for legal liability because IRB members are sometimes named as defendants in lawsuits. The shift to more community members is vitally important to the success of any human participant protection program, because such members more fully represent research

participants in their knowledge base and attitudes toward research risk and benefit.

Conclusion

It will be apparent to the reader that there are many models of IRBs and that structure can foster good decision making or perpetuate poor decision making. Identifying where hidden conflicts may exist or may arise will permit selection of a model that best fits the need. Strict accountability of all participants, adequate resource allocation, good educational programs, transparency in deliberations, and fierce independence in decision making by review board members will serve us all well.

Evaluating the Effectiveness of Institutional Review Boards

Everyone who is part of the research enterprise—investigators, institution officials, government agencies, sponsors, and institutional review boards (IRBs)—has an idea about the way IRBs are supposed to function. Although there is no agreed upon set of criteria to measure the function of IRBs, there is consensus that IRBs do not function as well as interested parties would like.^{1–5} Complaints overshadow compliments of the IRB: It takes a long time to get a protocol approved; IRBs that review the same multisite protocol require different changes at least to the consent document; IRBs miss issues important to research participant protection or regulatory compliance; IRBs cannot function as they aspire to because they lack sufficient resources; there is no institutional support of the IRB process; and so on. Rarely do we hear positive things about IRBs, such as that an IRB identified several important deficiencies in the protocols, or an IRB's review led to a better designed research study, or an IRB identified risks that the investigators had not considered, or that investigators are glad the IRB is there to help keep them out of regulatory trouble. Yet when an IRB functions well, it not only enhances the protection of research participants but also supports investigators in their research endeavors, both of which contribute to the public's trust in the research enterprise.^{6,7}

Definition of the IRB

The idea of having committees to review research dates back to the 1960s, when the then director of the National Institutes of Health (NIH), James Shannon, required independent review of research by a committee of the investigator's "institutional associates," but

offered virtually no guidance on the content of the review.⁸ A couple of years later, and in response to debates about the Willowbrook State School experiments, the NIH developed further guidance for review committees, in the form of its so-called Yellow Book,⁹ and finally codified the requirements for review committees in regulations in 1974.¹⁰ These research review committees became known as institutional review boards (see Chapters 7 and 50).

The name of these review boards reveals how the research community thinks about them. Although IRBs are charged with determining the ethical justifiability of a proposed research study, some critics have argued that calling them institutional review boards indicates they are designed to protect the institution, not the prospective research participants. The risk-averse behavior of IRBs observed in recent years, and the upsurge of atrociously long and complicated consent documents, give support to the ultimately incorrect belief that IRBs function primarily to protect institutions.

Additionally, the term *institutional* reflects an intention that the locus of review should be at the institution conducting the research. This concept was reinforced by the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, which argued that the local institution was in the best position to know the investigators and the community from which prospective research participants would be enrolled into studies⁵ (see Chapter 14). The commissioners did not consider the inherent conflict of interest that IRBs would have between protecting research participants and protecting the institution. Only recently has this difference between single institution and central IRBs been raised.

Composition and Responsibilities of the IRB

The functions of the IRB are defined in the U.S. federal regulations for the protection of research participants at Title 45 Code of Federal Regulation Part 46 (known as 45 CFR 46), for the Department of Health and Human Services (DHHS),¹¹ and at Title 21 Code of Federal Regulations Parts 50 and 56, for the Food and Drug Administration (FDA).¹² (Further citations of the regulations will refer only to those of the DHHS.)

Composition

Whereas function generally relates to what an entity does, here it is also relevant to define function in terms of structure, because the composition of an IRB is assumed to directly affect the quality of the ethical analysis it performs. For example, it would be difficult for an IRB to properly consider the needs and perspectives of adults with impaired decision making if there were no one on the IRB with expertise or experience with this group.

The federal regulations at 45 CFR 46.107(a) require that “at least five members with varying backgrounds to promote complete and adequate review of research of research activities commonly conducted by the institution” sit on the IRB.¹¹ The role of the IRB is indirectly defined in the regulations: The IRB should be constituted in such a way as to promote the respect for its advice and counsel in safeguarding the rights and welfare of research participants (45 CFR 46.107(a)).¹¹ Although the regulators offered no definition of *respect*, it appears that they intended the IRB to have a form of legitimacy in the eyes of the institution and from the community. The IRB derives legitimacy within the institution by being sufficiently qualified through the experience and expertise of its members and legitimacy in the community through its diversity—including consideration of race, gender, and cultural background—and sensitivity to community attitudes. The regulations go on to require that no IRB consist of all men or all women, and that IRBs have at least one member whose primary concerns are in scientific areas, at least one member whose primary concerns are in nonscientific areas, and at least one member who is not otherwise affiliated with the institution (this requirement extends to immediate family members; 45 CFR 46.107(b)(c)(d)).¹¹ Finally, no IRB member who has conflicting interest may participate in the initial or continuing review of a proposed study, except to provide information requested by the remaining IRB members (45 CFR 46.107(c)).¹¹ A quorum for the IRB to conduct its business does not require that members unaffiliated with the institution be present (45 CFR 46.108(b)).¹¹ Further, there is no requirement that a layperson who represents the community from which the research participants are drawn, serve on the IRB. In the end, it rests upon the IRB and institution to compose a properly constituted board that will provide a meaningful review of the ethics of each research study.

Assuming the regulatory requirements pertaining to composition have moral relevance and relate to measuring the effectiveness of IRBs in protecting research participants, potential measures for evaluating whether IRBs represent the perspectives of the community are the number and presence at meetings of nonscientists, individuals who represent prospective research participants, and unaffiliated members, as well as the presence at IRB meetings of members who have expertise about certain populations such as children, adults with decision-making impairments, or other vul-

nerabilities that might subject individuals to undue influence when such research is reviewed. More refined measures would include whether such individuals participate in IRB deliberations or are selected as primary or secondary reviewers. Another measure is whether conflicts of interest are disclosed, and if so, whether members with conflicting interests leave the room during deliberations and voting.

Responsibilities

What IRBs must do is defined in the U.S. federal regulations and by the Office for Human Research Protections in DHHS (OHRP, formerly the Office for Protection from Research Risks in NIH), the FDA, institutions, and by the IRBs themselves. Tables 52.1 and 52.2 list typical IRB responsibilities. In Table 52.1, responsibilities are separated into two columns to distinguish those that are required under U.S. regulations and those that have been delegated to the IRBs, de facto, by agency guidance. According to the federal regulations (45 CFR 46.109, 46.110, and 46.111),¹¹ the business of the IRB is to conduct initial and continuing review of research. The review may be conducted by the full board or by using the expedited procedure, in which the IRB chair or a designee who is an experienced IRB member reviews the protocol.

The federal regulations are silent on who has the responsibility to decide whether an activity is research involving participants. This responsibility is generally shared between the IRB and investigators when on a daily basis investigators decide whether an activity is research involving human-subject participants or something else, such as patient care, quality assurance, or program evaluation. However, when an investigator is unclear, the IRB generally has the authority to make a final decision.

Once an activity is determined to be research involving participants, it is generally a responsibility of the IRB to determine whether the research qualifies as exempt from the federal regulations, and therefore, exempt from review by the IRB. Although the regulations do not state that this is the responsibility of IRBs, the responsibility is often delegated to the IRB because guidance from OHRP states that investigators should not make such determinations.¹³

Table 52.2 describes federal regulatory requirements of institutions. These responsibilities are generally delegated to the IRB. In addition to carrying out their primary function of research review, IRBs have a number of other tasks. Institutions that receive federal funding must have an assurance of compliance, now known as a federalwide assurance—a document in which the institution pledges to follow the federal regulations for protecting research

Table 52.1
Requirements in Federal Regulations Versus Those by OHRP

<i>Requirements in Federal Regulations</i>	<i>Requirements by OHRP</i>
<ul style="list-style-type: none"> • Initial review and approval of research • Primary reviewer systems • Expedited procedures for review • Informed consent • Notification of investigators • Continuing review • Records retention 	<ul style="list-style-type: none"> • Research determinations • Exemption determinations • Relevant materials for review

Table 52.2
Federal Requirements of Organizations That Are Often Imposed on IRBs

-
- Assurance of compliance
 - IRB roster
 - Procedures the IRB will follow for conducting initial and continuing review of research and reporting its findings to the investigator and the institution
 - Procedures for determining which projects require review more frequently than annually
 - Procedures for prompt reporting of unanticipated problems involving risk to subjects or others
 - Procedures for prompt reporting of serious or continuing noncompliance
 - Procedures for prompt reporting of suspensions and terminations
 - Procedures for verification by a third party of no material changes since the last IRB review
-

participants in federally funded research.¹⁴ The IRB office is generally responsible for completing the document, keeping it current, and filing it with OHRP. As part of the assurance, IRBs must supply copies of their rosters complete with information about board members.¹⁵

IRBs also are delegated responsibility for developing the procedures they will follow when conducting initial and continuing review of research, determining when research studies require more frequent than annual continuing review, and reporting their findings and actions to investigators and the institution. At 45 CFR 46.103(5),¹¹ the federal regulations require that institutions have written procedures for promptly reporting unanticipated problems involving risk to participants or others, serious or continuing noncompliance, and suspensions and terminations. These three requirements are more complex than it might appear. Recently, OHRP released draft guidance on one of these requirements—defining and reporting unanticipated problems involving risk to participants or others.¹⁶ Each requires not only a definition of the time frame for reporting and to whom results should be reported, but also a definition of each type of event, the process for determining whether the event is legitimate, the actions the IRBs might take, and more.

An additional responsibility rarely noticed in the regulations at 45 CFR 46.103(4)¹¹ is that the institution must develop procedures describing the circumstances under which verification by a third party of no material changes since the last IRB review is required. IRBs have added all these functions to their duties.

The movement toward delegating institutional responsibilities to the IRB makes sense because these responsibilities are germane to the IRB's primary function. Many institutions and IRBs did not have written policies and procedures for these functions until recently. Beginning in the 1990s, OPRR (now OHRP) restricted or suspended assurances of compliance because institutions either lacked these procedures or had ones that were less than fully developed.^{5,17} It is only within the past several years that many institutions have developed these procedures. Current OHRP determination letters indicate that some IRBs are still in need of developing these procedures.^{18–21}

Finally, other responsibilities are sometimes added to the IRB's portfolio of responsibilities. These responsibilities do not exist in

the principal research regulations but have been promulgated through DHHS Final Guidance and NIH Guidance regarding disclosure and management of investigator conflicts of interest (COI) and education of investigators. With respect to managing COI of investigators, many institutions have separate COI committees. DHHS recommends that there should be communication between the IRB and the institutional COI committee. IRBs should see the determinations of the COI committee and review conflicts to ensure that they do not adversely affect the protection of research participants.²¹

It was not until 2001 that any type of education in participants' rights was required of investigators. At that time, NIH made it mandatory for all grant applications that principal investigators and research staff were certified to have received training in research participant protections.²² The implementation of this requirement generally falls to the IRB or to the research oversight office within the institution. Although this is a positive step toward enhancing the knowledge of investigators, it requires that IRBs develop (or adapt) an educational training program for investigators, monitor training, and issue certificates. Surprisingly, there is still no regulatory requirement for IRB chairs, members, or staff. Nevertheless, it appears from numerous institutional web sites that IRBs offer training to members and staff.

The propensity to place more and more responsibilities on IRBs continues. Legislation introduced in Congress in 2004 and 2005 proposed that IRBs act as the principal site for monitoring clinical trial registration.^{23,24} Were these bills passed by Congress and signed into law, IRBs would have to certify that certain clinical trials, as defined in the legislation, are registered in a clinical trials registry operated by the NIH before the IRB could approve the protocol. The relevance of this responsibility to the IRBs' primary function of ethics review is unclear. Moreover, it would be an unnecessary burden for IRBs that should lie with sponsors or the lead investigator.

In summary, the functions and responsibilities of the IRB are prescribed in federal regulations governing the protection of research participants. Although IRBs' primary function is to conduct an ethics review of the proposed research study, they have many additional functions. In recent years, there has been a trend to identify the IRB as the centerpiece for protecting research participants, placing all responsibilities for protection with the IRB regardless of whether this is a strategically effective decision for human research protection. This trend is being reversed somewhat by institutions adopting the framework of a human research protection program whereby they define the roles of the organization, investigators, research staff, and the IRB—and in which more often than not they recognize the obligations of other entities for protecting research participants. This is particularly the case with investigator and institutional conflict of interest and management of noncompliance.^{1,25}

Measures to Assess IRB Effectiveness

Although the function of IRBs has been at the forefront of discussions about the protection of research participants, few studies have examined their effectiveness. Attention was drawn to IRBs in the late 1990s when the U.S. General Accounting Office (now the Government Accountability Office) and the Office of Inspector General in DHHS released many reports that described IRBs as

overwhelmed and overworked, understaffed, and not appropriately composed to review research studies.^{26–34}

Several studies have documented inconsistencies among IRBs in the time it takes to review a study,³⁵ in the number and types of revisions required by the IRB,^{35–43} and in the approval of research involving children.^{39,44,45} Although concluding that IRBs are inconsistent and add burden to the oversight system, none has differentiated between legitimate inconsistency due to the differences in the local setting or in state law and inconsistency that results from lack of knowledge of the federal regulations, inexperience, or risk-averse behavior. These studies are nonetheless important because they make clear why investigators are often frustrated with the IRB process.

Given the paucity of studies that have examined effectiveness of IRBs, I propose five general categories of potential measures of IRB effectiveness. The first two—protection of participants and compliance—stem from the federal regulations that govern IRBs. The next three—efficiency, investigator satisfaction, and sponsor satisfaction—derive from any user-based system.

Protection of Research Participants

Simple, cost-effective measures of participant protection can be evaluated using information found in protocol files and minutes of IRB meetings. The Belmont Report⁴⁶ and the federal research regulations lead us to look at four general types of protection to be measured and assessed: informed consent, including recruitment methods; risks and potential benefits; selection of research participants; and additional protections for those who are deemed vulnerable.

Informed Consent

Much attention is paid to the consent process and to its documentation, with an unfortunately greater emphasis placed on the latter.^{5,47} This misplaced emphasis is, in part, driven by the federal regulations that strictly require a written, signed consent document, as opposed to the generic requirements of a consent process. The consent process should provide sufficient opportunity for a potential participant to consider whether to participate in the research, should minimize coercion; should provide information in an understandable language; and it should include no exculpatory language. Further, when OHRP cites IRBs for informed consent violations, the citations have been based on findings from the documentation, rather than the process (see any OHRP determination letter citing informed consent violations as an example).^{17,18}

Although many have argued for a better understanding of the consent process and some research has been funded in this area,⁴⁸ the conclusion of the few studies that have been conducted appears to be that it is extremely difficult to measure whether participants understand the parameters of the protocol in which they are being asked to enroll.⁴⁹ It is also unclear whether individuals make truly voluntary decisions to participate in research (see Chapter 59).

Measures that document that there was a consent process and that individuals agreed to participate in a study would provide some evidence that participants are protected. These would include documentation that a consent process was reviewed and approved by the IRB, including all the required elements of dis-

closure, and evidence that the IRB had considered whether any additional disclosure elements were appropriate for inclusion. When there is no consent process, there should be documentation that the IRB has approved a waiver according to the criteria in the federal regulations. When the IRB approves alterations to the consent process it should do so according to the federal regulatory criteria.

Other measures might be appropriate in special circumstances, such as the use of translators to administer consent, translated consent documents when the prospective study population includes non-English speakers, and the use of assent when children or adults with diminished decision-making capacity are involved in the research.

Risks and Potential Benefits

IRBs are required to assess the risks and potential benefits of a proposed study. This includes the risks and potential benefits for the prospective participants, as well as the value of the knowledge expected to be gained from the research. IRBs must also determine that risks are minimized and that they are reasonable in relation to the potential benefits. The federal regulations specify two criteria for determining that risks are minimized: (1) The research involves procedures that are consistent with sound research design and do not unnecessarily expose participants to risk; and (2) the research uses procedures already being performed on participants for diagnostic or treatment purposes. Unfortunately, however, the federal regulations provide almost no guidance on how IRBs should determine that risks are reasonable in relation to potential benefits. Some have proposed models for making such a determination, but few IRBs seem to follow an identifiable model.^{5,50,51}

Measures used to assess IRB effectiveness might include documentation that the IRB asks about and considers risks involved in the research, including nonphysical risks, and that it evaluates the relationship between risks and potential benefits—in particular, that it evaluates risks versus the importance of the knowledge that would be gained from the study and versus the potential for direct benefit to research participants.

Selection of Research Participants

The U.S. federal regulations stipulate that the selection of participants must be equitable (45 CFR 46.111(3)).¹¹ In making this assessment, IRBs need to take into account the purpose of the research, the setting in which the research will occur, and the recruitment of individuals who are especially vulnerable to undue influence or coercion, such as children or adults with impaired decision-making capability.^{52,53} At the level of the individual study, protection could be measured by determining whether the IRB considered the characteristics of the study population in terms of the purpose and the location of the research. As a protection issue, participant selection should ensure that the burdens and benefits of research are fairly distributed across populations. Protection could thus be measured by looking at whether the same community groups or hospital patients are recruited repeatedly for different research studies.

The criterion for determining equity in the selection of research participants is not straightforward because of the differences between an individual investigator-initiated study conducted once and at one site, an individual investigator-initiated study conducted either multiple times or in multiple settings, and

a sponsor-initiated, multisite clinical trial.⁵⁴ Whereas equity judgments might seem clear in the most simple study design—an individual investigator-initiated study at one site—the clarity blurs as the study design becomes more complicated. For example, in a multisite clinical trial involving hundreds of sites, the overall selection of participants across all recruitment sites might be equitable: Individuals are selected from a large cross-section of society including adult men and women and all races/ethnicities. However, at an individual site, participants might be from only one racial, ethnic or gender group, or from one social class stratum. In such cases, equity at the local level would not exist, even though it might be achieved for the study as a whole.

Protection of Vulnerable Individuals

Vulnerability as defined by the federal regulations refers to individuals who are subject to undue influence or coercion to initiate or continue participation in a research study. Several groups are considered to be vulnerable: pregnant women and fetuses, children, prisoners, persons with mental disabilities, economically disadvantaged persons, and educationally disadvantaged persons. Additional regulatory protections exist, though not consistently, for pregnant women and fetuses (Subpart B), prisoners (Subpart C), and children (Subpart D) in the DHHS regulations.¹¹ Both the FDA and the Department of Education have codified Subpart D into their regulations for protecting research participants. And although the Department of Justice has additional regulations for research involving prisoners, they are different from those issued by DHHS. Although the regulations of the different governmental agencies generally provide similar protections, there are subtle differences requiring IRBs to be knowledgeable about the regulations that apply when a research study is subject to various regulations. For the other categories of vulnerable persons, the IRB is left to its own wisdom to ensure that additional protections are provided.

Additional protections generally fall into three distinct categories:

1. Vulnerable individuals should not be enrolled in research unless it is necessary. If the research can be carried out using those who are not vulnerable, then this should be done.
2. Additional regulatory requirements not relating to informed consent apply to such research. For example, when research involves pregnant women, IRBs must determine that when scientifically appropriate, studies involving pregnant non-human animals or studies with nonpregnant women have been conducted and provide data for assessing potential risks to pregnant women and fetuses. As another example, IRBs can approve research involving prisoners or children only when it falls into one of the permissible categories of research (see Subpart C for research involving prisoners and Subpart D for research involving children).¹¹ In addition, when carrying out research involving prisoners, IRBs must make certain protocol-specific determinations pertaining to payments, parole, and other factors in order to satisfy the demand for increased protections for prisoners.
3. Additional consent requirements are imposed. Children should provide assent in addition to parents giving their permission, 45 CFR 46.408(a); and adults with impaired decision-making capacity should also provide assent and a

legally authorized representative must give consent, 45 CFR 46.116.¹¹

Documentation of these additional protections can be found in protocol files, minutes of IRB meetings, or in the IRB's policies and procedures (e.g., its definition of a legally authorized representative and statements about whether the institution conducts research involving vulnerable populations).

The systematic exclusion of vulnerable populations is not necessarily the measure of a well-functioning IRB. IRBs that routinely exclude children or prisoners because the regulatory requirements are too burdensome or that do so out of ignorance do not operate in the best interests of research participants. This issue was hotly debated in 2000 and 2001 at the time of the reauthorization of the pediatric studies provision in the FDA Modernization and Accountability Act, leading the FDA to adopt Subpart D of the DHHS regulations, the additional protections for children involved in research.^{55,56}

Regulatory Compliance

The United States is one of the few countries that enforces its protection system for research through regulations. Institutions must comply with the federal regulations. If they do not, they risk losing their federal funding, having their research programs suspended, or having the FDA reject data that are submitted in support of licensing an investigational drug or device. For this reason, institutions and sponsors define IRB effectiveness as operating consistently with federal regulatory requirements.

OHRP and FDA determine institutional compliance by evidence of policies and procedures and by documentation of specific requirements. The former follows directly from regulations that require institutions to have certain written policies and procedures, such as reporting policies and procedures for serious or continuing noncompliance, suspensions and terminations of IRB approval, and unanticipated problems involving risk to research participants or others.^{19–21,57–59} Very few studies have examined the findings of OHRP or FDA audits and no study has created a regulatory compliance index or commented on degree of compliance. This is not surprising because audits, whether for cause or not for cause, do not review an institution's full set of policies and procedures.

There are two possibilities for measuring compliance. The first is through evidence that an institution has the required written procedures. The second is documentation that is required of certain IRB actions. This can usually be found in protocol files and IRB minutes. Documentation of specific requirements occurs, for example, when the IRB waives or alters the consent process and records protocol-specific findings in support of the criteria for waiver or alteration; or when it records protocol-specific findings to justify the category of permissible research when children or prisoners are involved.

An aggregate measure of compliance could be formed based on regulatory requirements. For example, an aggregate measure of at least 18 IRB functions could be developed from Tables 52.1 and 52.2. Such a measure could be more granular, increasing the number of items in the overall index, or more basic, concentrating only a few key regulatory functions.

The obligation to protect research participants and comply with the federal regulations extends beyond the IRB or institution

to the investigator and research staff. Thus, an IRB's effectiveness is dependent upon investigators and research staff adhering to the terms of the IRB-approved protocol and any other conditions of approval. As part of implementing either of the two measurement categories mentioned above, an institution or IRB might include data from routine auditing of ongoing research. In the past few years, many institutions and IRBs have initiated auditing functions to ensure that protocols are followed, and they are likely to have readily assessable data.

Efficiency

It is unlikely that an IRB would be judged effective if its operation were not efficient. One factor that seems to matter is the time it takes to review and render a decision on a protocol. Anecdotal evidence suggests that review times in the range of one month are considered efficient. This implies that the IRB is meeting more than once per month. A period of approval of three months or longer is long, especially for review of industry-sponsored research. However, time to approval is highly dependent upon factors outside the control of the IRB, such as the time it takes an investigator to respond to an IRB's review of a protocol. A more accurate measure of IRB efficiency would be the amount of time from receipt of protocol until initial review.

Other measures of efficiency are the use of the expedited procedure for review of research involving no more than minimal risk, use of exemptions for research that qualifies, and use of other review mechanisms such as subcommittees, scientific review committees, or prereview by IRB staff to reduce times for review.

Investigator Satisfaction With IRBs

The U.S. system of protection is based on trust and goodwill by all involved. The system works because all parties at least tacitly agree to follow the rules. IRBs not only require the support of their institutions, when they are institutionally based, but also depend upon the cooperation of investigators to be effective. No studies were identified that looked specifically at investigator satisfaction with the IRB process.

Key variables of concern to investigators are length of approval times, confidence that the IRB has the expertise to understand the proposed research, fairness of the IRB in conducting its reviews, and transparency of the review process.⁵ Combining these variables into an outcome measure would enable researchers to determine investigator satisfaction. Further, investigators could be asked how satisfied they are with their IRBs.

Compliance with the IRB determinations and with the approved protocol is another potential measure of investigator satisfaction. To the extent that investigators perceive the IRB as fair and objective, it is more likely they will follow the protocol, the IRB's determinations, and the federal regulations.

Sponsor Satisfaction With IRBs

Sponsor satisfaction also provides a measure of IRB effectiveness. Sponsors have the ability to place research at sites where the IRB functions effectively and efficiently. Industry wants both. A quickly approved protocol that lacks appropriate protections for participants or is out of compliance with the regulations is harmful. Although no empirical studies were found that examined sponsor satisfaction with the IRB process, sponsor satisfaction can

be assessed by variables such as approval time and regulatory compliance.

Responsibility for Measuring the Effectiveness of the IRB

Like most responsibilities of oversight, ensuring the effectiveness of the IRB is a shared responsibility. Many parties have a vested interest in IRBs performing effectively, beginning with those who participate in research as subjects and extending to IRBs themselves, investigators and research staff, institutions, sponsors, and federal regulatory agencies. The question of who audits or collects data on effectiveness seems less important than each party being interested in being held accountable for the IRB's efficiency and effectiveness.

In the past, and even today, IRBs argue that they do not want to be the "police." But auditing investigators and research staff by reviewing protocol files, or monitoring the consent process (as is permitted by the federal regulations), is not police work if done from a perspective of quality improvement. Likewise, investigators and research staff should not view monitoring or auditing as policing when the goal is to identify and fix what is not working.

At least three arguments favor having a third party rather than the IRB measure its own effectiveness. First, IRBs are already overworked, and inclusion of an auditing function would be another addition to their long list of responsibilities. Second, IRBs might not be objective about their effectiveness, especially their willingness to look internally for problems. And finally, the ultimate responsibility for an IRB rests with the institution. Thus, a third party, such as a compliance office within the institution, might be a better vehicle for assessing IRBs' effectiveness.

Through mechanisms like the accreditation that requires organizations to have activities in place to monitor the effectiveness of the human research protection program,²⁵ the quality assurance program offered by OHRP,⁵⁹ and the general movement toward greater accountability for universities supported by the professional organizations, such as the Association of American Universities and the Association of American Medical Colleges,⁶⁰⁻⁶² institutions are implementing audit or monitoring programs that include the function of the IRB.

Conclusion

I have suggested that the definition and measurement of IRB effectiveness derives from the regulatory requirements placed on IRBs and the service component of IRBs. The major indicators and potential measures are summarized in Table 52.3.

This chapter clearly points to the need for further research on the assessment of IRBs. After 30 years of experience with IRBs, we know embarrassingly little about how they function—what variables influence effectiveness or what variables increase or decrease efficiency. Government reports in the late 1990s highlighted many of the problems with the current IRB system. However, no reports have proposed measures to assess IRB performance. The Association for the Accreditation of Human Research Protection Programs (AAHRPP) was awarded a grant in 2003 from the Centers for Disease Control and Prevention to develop performance indicators and measures for evaluating the effectiveness of accreditation

Table 52.3
Indicators of IRB Effectiveness and Their Outcome Measures

Indicators of IRB Effectiveness	Outcome Measures
Composition of the IRB	<ul style="list-style-type: none"> • Number of nonscientists on the IRB • Presence of nonscientists at meetings • Number of members who represent the view of the participant • Presence of members who represent the view of vulnerable individuals • Management of conflict of interest in IRB members
IRB responsibilities	<p>Protection of research participants</p> <ul style="list-style-type: none"> • Informed consent • Analysis of risks and potential benefits • Selection of research participants • Protection of vulnerable individuals <p>Regulatory compliance</p> <ul style="list-style-type: none"> • Institutional compliance • IRB compliance • Investigator/research staff compliance
Efficiency	<ul style="list-style-type: none"> • Time to initial review after submission to IRB • Use of the expedited procedure • Use of exemptions • Use of other review mechanisms
Satisfaction with the IRB	<ul style="list-style-type: none"> • By investigators and research staff • By sponsors

in improving research protections.⁶³ To my knowledge, this is the only federally funded project to develop such measures. Although the grant is focused on accreditation, it is related to the subject at hand because accreditation standards examine IRB function as it relates to the protection of research participants and regulatory compliance. Pilot tests of potential indicators and measures were to be complete in 2005 with final indicators and measures disseminated in 2006. But this one endeavor is not enough, echoing the call of the Institute of Medicine and the DHHS Secretary's Advisory Committee on Human Research Protection that the oversight system for protecting those enrolled in research must be evaluated with changes based on data.^{1,64}

Federal regulations provide a foundation from which measures of IRB function can be developed. Evaluations can easily be conducted locally or nationally using data that already exist in protocol files, minutes of IRB meetings, policies and procedures, or internal audits. For the other measures, surveys conducted either locally or nationally would suffice. However, evaluations of IRBs are unlikely until there is an agreed upon set of measures.

Data and Safety Monitoring Boards

Monitoring of Clinical Research Studies

All research studies involving people need ongoing oversight. For many, probably most, clinical research studies, this oversight is provided by the investigators, under the aegis of the local institution in which the research is being conducted, and with the oversight of the institutional review board (IRB) or its equivalent. Certain kinds of clinical research studies, though, might require different kinds of oversight. This oversight is not necessarily more intensive, but the features specific to the study might call for modifications in the oversight.

In particular, clinical trials that involve interventions (i.e., in which something is done to or administered to study participants) need different sorts of oversight or monitoring than do observational studies or surveys. Among the broad range of clinical trials, the phase of the trial, whether the trial is blinded (masked) or unblinded (open), and whether the trial is conducted at one or more than one site affect the kind of monitoring that is required. Also relevant is the nature of the study population and what sort of intervention is being administered to the participants. For example, studies involving participants who are at particularly high risk or procedures that carry exceptional risk would merit additional safeguards. Data and Safety Monitoring Boards (DSMBs)—which also go by other names such as data monitoring committees, safety monitoring committees, or safety and monitoring efficacy committees—can provide this additional monitoring. This chapter will discuss what monitoring of clinical studies by DSMBs entails, why it is done, what kinds of studies specifically require DSMBs, and how monitoring is done differently among different kinds of studies.

Single center, early phase clinical trials that do not involve particularly dangerous interventions, and that are uncontrolled (that is, trials that have no comparison group) or are not blinded, are often monitored by the investigators, with appropriate reporting to the IRBs. Sometimes, in order to avoid concerns about bias on the part of the investigator, another individual may be appointed to perform the monitoring function. What sorts of clinical trials require a DSMB? Several guidelines exist,^{1–3} but the criteria are similar. In general, late-phase trials, especially those with an intervention that might produce adverse effects—such as drugs, devices, biologics, and surgical procedures—require DSMBs. It can be argued that potentially less harmful interventions, such as dietary changes or educational programs, should not need DSMBs. But even these interventions might cause possible psychological or emotional harm. Early-phase trials should also have DSMBs or other ongoing oversight independent of the investigator if the intervention and control groups are blinded to the investigator, or if the trials are multicenter, making it difficult for IRBs to provide the necessary monitoring, or involve study participants who need an extra layer of protection, or have interventions thought to convey extra risk such as gene transfer studies. (For a comprehensive, in-depth text on this topic, see Ellenberg, Fleming, and DeMets.⁴)

History of DSMBs

One of the earliest studies with a DSMB was the Coronary Drug Project (CDP)⁵ initiated by the National Heart Institute (now the National Heart, Lung, and Blood Institute, NHLBI) of the National Institutes of Health (NIH). The CDP was planned in the early

1960s, began enrolling participants in 1966, and ended in the mid-1970s. It was a multicenter trial testing the effects of several lipid-modifying drugs in people who had had a myocardial infarction. There were 53 clinics, a data coordinating center, a central laboratory, and an electrocardiogram reading center. The study organizers realized early in the trial that for participant safety reasons, accumulating data needed to be monitored regularly. An external Policy Board was established to provide study oversight and review outcome data. At first, accumulating outcome data were also provided to investigators.

Because multicenter trials were then quite new, in 1967 the National Heart Institute convened a committee of clinical research experts, the Heart Special Project Committee chaired by Bernard Greenberg, to make recommendations on the organizational structure and function of multicenter clinical studies.⁶ Some of the recommendations of the *Greenberg Report* applied to monitoring:

A Policy Board or Advisory Committee of senior scientists, experts in the field of the study but not data-contributing participants in it, is almost essential for a large complex cooperative project. . . . A mechanism must be developed for early termination if unusual circumstances dictate that a cooperative study should not be continued. Such action might be contemplated if the accumulated data answer the original question sooner than anticipated, if it is apparent that the study will not or cannot achieve its stated aims, or if scientific advances since initiation render continuation superfluous. This is obviously a difficult decision that must be based on careful analysis of past progress and future expectation. If the National Heart Institute must initiate such action, it must do so only with the advice and on the recommendation of consultants.

In line with the Greenberg Report recommendations, the CDP formed a Data and Safety Monitoring Committee in 1968 that regularly reviewed accumulating data. Investigators who enrolled or followed study participants were not members of this committee. However, it was far from independent. Members included staff from the coordinating center, other key central groups, and the sponsor. There were also several outside experts on the committee. Recommendations from this committee went to the Policy Board.⁵

After the CDP, the NHLBI modified its approach to monitoring committees. Perhaps most importantly, committees became more independent, with all voting members being separate from the study and the sponsor. With this change, it was no longer necessary to have a second oversight group, so most future NHLBI trials did not have an additional policy board.

In the 1970s and 1980s, other NIH institutes adopted the NHLBI model or variations on it.^{7,8} One modification adopted first by the National Cancer Institute as part of its Cooperative Studies Program and by the Division of AIDS in the National Institute of Allergy and Infectious Diseases was to form DSMBs that monitored more than one trial.^{9,10} In the 1990s, the NIH developed guidelines for the establishment of DSMBs. Most late-phase and many early-phase trials sponsored by NIH now include DSMBs. Other U.S. government sponsors of clinical trials, such as the Department of Veterans Affairs, routinely have monitoring committees. Industry, however, was slower to incorporate independent monitoring committees in its clinical trials. Only in recent years have they become fairly frequent. With the development of Food and Drug Administration (FDA) guidelines,² this trend will pro-

bably continue. Internationally, trends in the kinds of studies using DSMBs have been similar to those in the United States.¹¹

More recently, the Issues in Data Monitoring and Interim Analysis of Trials (DAMOCLES) group¹² has surveyed monitoring committee practice.^{13,14} One of its key recommendations was that more standard policies, including the use of structured charters, would aid in developing consistency in the kinds of trials employing DSMBs and in the management of monitoring committees.

Responsibilities and Functioning of the DSMB

The primary responsibility of a DSMB is to ensure, to the extent possible, that study participants are not unduly harmed. A second responsibility is to ensure the integrity of the clinical trial, so that valid data can be provided to the public and the medical community. These two responsibilities are not completely separate, but conflicts between them may arise. Examples of such conflicts are given later in the chapter.

The DSMB has several specific tasks. Before the study gets started, it reviews the study protocol. Generally, the review is not of the same depth as a scientific peer review. Rather, the DSMB considers whether the protocol is sufficiently well designed to answer the question being addressed by the trial. This includes factors such as the quality and safety of the intervention, participant eligibility criteria, outcome measure assessment, sample size, and the analysis plan. Are the safety measures adequate? Is there reasonable quality control? Before it agrees to spend months or years monitoring the trial, the DSMB needs to accept that the research question is important enough to put participants at risk of possible harm and that the trial has a sufficiently sound design to answer the question. The DSMB also reviews the consent form template. Each participating site will likely have an IRB (unless there is a "central" IRB) that will closely review the consent form. But a study-wide template is typically prepared so that the consent forms at all sites will contain the same key messages.

The DSMB must be comfortable with the monitoring plan that is proposed by the investigators. How often will the data be reviewed? What kinds of data will be reviewed? What criteria will be used to consider stopping the study ahead of schedule? Are there certain adverse events that must receive more intensive monitoring? The study should start to enroll participants only after the DSMB is comfortable with all of these factors.

A typical DSMB consists of from three to six or seven members, and occasionally more. The members have expertise in the particular field being studied, trial design, and biostatistics. Often, DSMBs include bioethicists and patient advocates. It is also essential that at least some of the members have prior experience in serving on DSMBs.

Independence of the DSMB is a major consideration. The members should not have a current or close connection with the investigators or with the sponsor. They need to be able to make objective judgments about the study. What constitutes independence is sometimes fuzzy. Can a member be from the same institution as one of the investigators? If yes, what about the same department? Can a member have been a past colleague or co-authored a paper with one of the investigators? Ideally, the more separate, the better. But if the best, most knowledgeable candidate is someone with some past connection, it may be appropriate to select expertise over complete independence.

Similar considerations arise involving financial conflict of interest. DSMB members should have no vested financial interest in the outcome of the trial. They should not hold stock in, be advisers to, or be on speakers' bureaus for the company that is manufacturing the product being tested. They also should not have connections with direct competitors of the manufacturer. But what about being an investigator in another study funded by that company? There may not be a clear answer to that question, so judgments may be needed.

Intellectual conflicts may be a more difficult problem. Those with expertise in the area will have conducted other studies or may be conducting other studies concurrent with the trial for which they are being proposed as DSMB members. They therefore have at least an intellectual interest in how the study turns out. As with independence, these sorts of interests should not prevent those who are most knowledgeable from serving on DSMBs. All potential conflicts should be disclosed to the sponsor and the other DSMB members and must be updated regularly.

The DSMB is usually appointed by the sponsor of the clinical trial, whether it is one of the NIH institutes, another government agency, or a pharmaceutical or device manufacturing company. Study investigators often provide input into the selection of members. The DSMB generally reports to and provides recommendations to the study sponsor. The nature of these reports and how any recommendations should be communicated to the sponsor and the investigators are matters of some debate, and will be considered later in the chapter.

A typical DSMB meeting consists of three sessions: open, closed, and executive. During the open session, study progress and "process" data for the study as a whole (not separated by treatment group) are reviewed. In addition to the DSMB members, this session may be attended by one or more investigators (usually including the chairperson of the trial), by staff from the group managing and analyzing the study data (often a data coordinating center), by one or more employees of the sponsor, and perhaps by someone from a regulatory agency. During the closed session, process, outcome, and other data broken down by treatment group are presented. Therefore, only those who should be aware of such data are present. This would include the biostatistician who presents the data and perhaps others from the data coordinating center and the sponsor. Again, this is an area of controversy and will be discussed later. The executive session is the time when the DSMB members can discuss what they wish in the absence of any other attendees, except perhaps for an executive secretary.

At the end of each DSMB meeting, recommendations (and they are recommendations, not decisions) are made. If the trial is proceeding well, the DSMB should clearly state that it thinks that the study should continue with the protocol unchanged. Other recommendations can consist of relatively minor items such as the need for clarification of data reports or forms; more serious matters such as modifications to the informed consent form or the protocol—for example, changes in eligibility criteria or in kind or frequency of assessment of biomarkers or outcome measures and adverse events; or major recommendations such as dropping a subgroup of participants, dropping an entire treatment arm, or completely ending the study ahead of schedule. Studies may be stopped early for five general reasons: (1) The intervention is more effective than originally thought, (2) there are unacceptable adverse events, (3) it is highly unlikely that additional data will alter a currently null result or provide other sufficiently important in-

formation if the study were to continue to its scheduled end, (4) the study is proceeding so poorly in terms of participant accrual or data quality or that no useful answer will likely be forthcoming, or (5) the question has been answered by external evidence that is reported while the trial is underway.

Typical Reports Reviewed by DSMBs

The typical report that the DSMB reviews contains several sorts of data. First, the report contains data regarding the conduct of the trial, or process data. That is, it has information showing how well the trial is doing in participant screening, accrual, and follow-up; performance of procedures and other measurements; quality control measures; and any problems such as inadvertent enrollment of ineligible participants or randomization mistakes. Second, it contains information on the kinds of participants who are being enrolled (i.e., baseline characteristics). Third, it has information about interim measures like biomarkers and other laboratory or imaging data, and measurements of adherence to the protocol. Fourth, it contains tables and figures showing the outcome measures at the time of the report. These are often accompanied by monitoring boundaries. Fifth, it includes reports of adverse events other than outcome or laboratory measures.

This chapter will not go into detail about monitoring boundaries. However, the basic concept is that repeated assessment of data, which is essential to protect study participants, can increase the type 1 error—the probability of incorrectly rejecting the null hypothesis. By convention, the type 1 error, or alpha, is often set at 5%. It will be 5%, however, only if the study data are analyzed just once, at the end of the trial. Examining the data once during the trial and again at the end would increase the probability of incorrectly rejecting the null hypothesis from 5% to about 8%.¹⁵ If the null hypothesis is tested five times, the type 1 error would be 14% instead of 5%. Therefore, in order to maintain the type 1 error at the prespecified level, it is necessary to require more than simply finding a nominally statistically significant difference partway through the trial. If the protocol sets a two-sided alpha level of 0.05, a more extreme difference than the statistic nominally associated with that alpha level is required before the scheduled end of the study to declare that the trial has found a statistically significant result.

Monitoring boundaries are developed to assist the DSMB in deciding if an early result is truly statistically significant and to minimize the likelihood of a false positive result being found. Several kinds of monitoring boundaries have been used, but the most common ones all use quite extreme differences early in the trial, with less extreme differences near or at the scheduled end. The rationale for this is that early in the study, when only a small amount of data is available, the numbers are more unstable and likely to change, sometimes dramatically, as seen in one of the examples given later. It should be emphasized that because participant safety is paramount, monitoring boundaries are often asymmetric. That is, they require less evidence to stop a study early for harm than for benefit. For those interested, several references to development and interpretation of monitoring boundaries are provided.^{16–20}

Reports for a DSMB are prepared by the data coordinating center or by an independent biostatistician. The frequency of the reports depends on the rate at which data are accumulating, but reports often are made every 6 or 12 months. Sometimes, in order

to limit the problem of the type 1 error that is raised by interim looks at the data, some investigators and DSMBs prefer to see reports that contain outcome data less frequently than reports with adverse events and other data. Although this process has its advocates, it can impair the ability of the DSMB to do its job adequately. Almost always, recommendations to continue or stop a study or to change a protocol are based on judgment as to the balance of benefits and harms. Therefore, information about both is usually needed. Properly constructed monitoring boundaries can reduce concerns about frequent looks at outcome data.

Sometimes, because of serious adverse events, the DSMB may ask for interim or special reports. It is the obligation of the data coordinating center or biostatistician to provide whatever data are reasonably necessary for the DSMB to fulfill its responsibilities to study participants.

A different sort of concern when analyzing data is the so-called type 2 error. The type 2 error involves accepting the null hypothesis when in fact it is false. This kind of error is often due to a study that has inadequate power to detect what is thought to be a clinically meaningful difference between groups. From the perspective of the DSMB, type 2 errors are most important when a seemingly large difference between groups for an important outcome fails to reach statistical significance because the number of study participants or the number of events is too small. The DSMB needs to use its judgment in deciding whether the observed difference in, for example, an adverse event, is important or clinically significant, despite not reaching statistical significance. Table 53.1 summarizes the type 1 and type 2 errors.

Examples of Ethical Issues in DSMB Deliberations

The results of several DSMB deliberations have been published, and for those interested, a recent book contains almost 30 cases.²¹ A few selected examples of DSMB deliberations are provided here.

Cardiac Arrhythmia Suppression Trial

The Cardiac Arrhythmia Suppression Trial²² (CAST) was a placebo-controlled trial of three antiarrhythmic agents in people with heart disease and ventricular arrhythmias. The objective was to see if suppression of the ventricular arrhythmias would lead to a reduction in sudden cardiac death. Unfortunately, rather early in the trial, two of the three agents were found to cause an increase in both sudden death and total mortality.²³ Subsequently, the third agent was also shown to cause an increase in sudden death.²⁴

When CAST was developed, it was designed as a one-sided test of hypothesis, with $\alpha = 0.05$. The investigators did not envision that suppressing ventricular arrhythmias could possibly be harmful. The DSMB, when it reviewed the protocol at its first

meeting, asked that the design be modified. It remained a one-sided test, but with $\alpha = 0.025$, and an advisory boundary for harm. This boundary for harm was set at the same level of significance as the boundary for benefit. It should also be noted that the DSMB decided to remain blinded to the identity of the treatment groups.

Differences in numbers of sudden deaths and deaths from all causes appeared early. However, the number of events was quite small, and the DSMB recommended that CAST continue and the identity of the groups continue to be withheld. Shortly after, however, the difference increased, and the DSMB was informed that the number of deaths was greater in the active treatment group, concentrated in two of the three antiarrhythmic drugs. The difference had crossed the advisory boundary for harm, which, as noted above, was symmetric with the boundary for benefit. The two drugs were discontinued and the trial was redesigned using only the remaining drug versus placebo. This time, the advisory boundary for harm was asymmetric, requiring less evidence for harm than for benefit to stop the study early. With time, the third drug also proved to be harmful and was discontinued.

Among the lessons of CAST were that the DSMB has to be prepared early and that harm, even though not anticipated, must be planned for. Also, there is usually little rationale for the DSMB to remain blinded to the identity of the treatment groups. But if it chooses to do so, in the name of objectivity, there needs to be a mechanism for unblinding whenever it becomes necessary.

It should also be noted that when the first two antiarrhythmic drug arms were stopped, CAST was essentially redesigned as a new study. The changes to the protocol, which included a new sample size, were sufficient in magnitude and scope that even though the relatively few participants who had originally been randomized to either the third drug or its placebo remained in the trial, it was considered a new trial. On the other hand, if the only sorts of changes that had occurred were those relating to modifications of eligibility criteria or frequency of assessment of outcome, they would not have likely been sufficient to start over as a new trial.

A more problematic situation is when there is a modest change in the intervention. In that case, a judgment must be made as to how similar the new intervention is to the old one, and whether the data from both can legitimately be combined.

Physicians' Health Study

The Physicians' Health Study^{25,26} (PHS) was a factorial design (2×2), placebo-controlled trial of aspirin and beta carotene in healthy U.S. male physicians. The objectives were to see if aspirin reduced the incidence of cardiovascular mortality and if beta carotene reduced the incidence of cancer. The aspirin component of the PHS was stopped ahead of schedule for two main reasons. One, the incidence of cardiovascular mortality was very low, and it would have taken many more years than planned to reach the projected number of events. Two, there was a large, highly significant benefit for a secondary outcome, myocardial infarction, which was mainly nonfatal.

The DSMB considered whether stopping the aspirin study early for a beneficial finding in a secondary outcome was appropriate. Given the importance of the outcome and the remote likelihood of seeing anything for the primary outcome, the DSMB recommended to the principal investigator that the aspirin component end.

Table 53.1
Possible Decisions About the Null Hypothesis

Decision	Null Hypothesis	
	True	False
Accept null hypothesis	OK	Type 2 error
Reject null hypothesis	Type 1 error	OK

Breast Cancer Prevention Trial

The Breast Cancer Prevention Trial^{27,28} (BCPT) was a placebo-controlled trial with the objective of evaluating if tamoxifen would reduce the incidence of breast cancer in women at high risk. The study was stopped ahead of schedule because the monitoring committee observed a large reduction in breast cancer in the tamoxifen group. A one-sided test of hypothesis, with $\alpha = 0.01$, was used to determine benefit. A less extreme value was used for harm. Because tamoxifen was thought to have multiple effects in addition to the primary outcome of breast cancer, a global index incorporating several outcomes was also used to monitor the data.

A strong favorable trend for breast cancer appeared relatively early in the trial, as did the expected adverse trend for endometrial cancer. The monitoring committee, however, was concerned about an unexpected finding of ocular toxicity. As a result of this, all enrolled participants were provided with the information about ocular toxicity and asked to consent.²⁷

The monitoring committee's recommendation to end the study occurred almost two years after the monitoring boundary for breast cancer had been crossed. The importance of getting sufficient information about adverse events with an intervention that would be used to prevent breast cancer in women who did not have it led to this delay.

Candesartan in Heart Failure Assessment of Reduction in Mortality and Morbidity Program

The Candesartan in Heart Failure Assessment of Reduction in Mortality and Morbidity^{29,30} (CHARM) program consisted of three trials that compared candesartan against placebo in patients with heart failure. The primary outcome for each trial was cardiovascular death or hospitalization for heart failure; the primary outcome for the combined trials was death from all causes. The program continued to its scheduled end despite the fact that, early on, the monitoring committee had noted a large benefit with respect to overall mortality (see Table 53.2). Early results presented to the DSMB on March 27, 2000, were nominally statistically significant, with more than a 30% relative reduction in event rates. At the DSMB's March 1, 2001, meeting, the relative reduction was less, but the results had crossed the preestablished monitoring boundary. However, the results were not convincing for the primary outcome or for two of the three trials. In addition, DSMB members were concerned that early data might not be borne out by later data and that the results needed to be definitive in order to change medical practice. Therefore, the monitoring committee recommended continuing the trial. At the scheduled end of the trial, the results showed nowhere near the magnitude of benefit that had been observed earlier.

Trials of Antibiotic Treatment in Patients With Lyme Disease

Two trials of antibiotic treatment were conducted in patients with a history of Lyme disease³¹ and persistent symptoms. The primary outcome for both trials was health-related quality of life. One trial, with seropositive patients, had a projected sample size of 194. This trial was designed to have 90% power to detect a 25% difference in the primary outcome between the antibiotic and placebo

Table 53.2
Deaths in the CHARM Program at Each Interim Analysis and at Study Closeout

Analysis Date	Overall Program		P-value
	Candesartan Arm	Placebo Arm	
August 9, 1999	8	4	0.3
March 27, 2000	76	123	0.0007
July 27, 2000	133	198	0.0002
March 1, 2001	260	339	0.0006
August 9, 2001	337	474	0.0010
February 22, 2002	556	631	0.009
August 1, 2002	682	756	0.015
Final report**	886	945	0.055

Modified from Pocock S, et al.³⁰ and used with permission of publisher; ** final report on September 6, 2003, based on follow-up to March 31, 2003.

groups. A second trial, with seronegative patients, had a projected sample size of 66. This was designed to have 80% power to detect a 35% difference between the antibiotic and placebo groups.

When 129 patients had been enrolled (78 seropositive and 51 seronegative), of whom 107 had been followed for 180 days, the planned duration of the trials, the DSMB determined that there was only a 1.4% chance that the seropositive study would yield a significant difference between antibiotic and placebo, were the study to continue to its scheduled enrollment. Similarly, for the seronegative study, there was only a 4% chance of seeing a difference. Therefore, the DSMB recommended that both studies be stopped, because continuation in order to achieve the goal of showing benefit from antibiotic treatment would be futile. Although additional information about treatment might have been obtained if the trials had enrolled the full sample sizes, the DSMB needed to weigh the value of that information against the risks to study participants when there was little hope of demonstrating benefit from the intervention.

These examples demonstrate the inherent tensions, and at times conflicts, between the responsibilities of DSMBs to ensure the safety of the study participants and the goal of obtaining information important in the clinical management of patients and in the prevention of disease. DSMBs must weigh the benefits to society and to patients of continuing a trial against their duties to the study participants. Despite the general guideline that the safety of the participants is paramount, often, there is no clear "right answer," and vigorous discussions take place at DSMB meetings. If a study is stopped too soon, the wrong answer may be obtained and study participants will have volunteered without contributing to obtaining valid knowledge. These situations point out the need to have DSMBs made up of thoughtful members with different backgrounds and perspectives.

Unresolved Issues

As noted in several places in this chapter, unresolved or even controversial issues exist with regard to DSMBs. Some of these involve what might be considered aspects of real or perceived conflict of interest.

DSMB Reporting Practices

The DSMB is usually appointed and has its expenses paid by the sponsor of the trial. But the DSMB is responsible to more than just the sponsor. It is also responsible to the study investigators and, of course, to the study participants. Meeting minutes and recommendations are often provided to the sponsor, which then communicates the recommendations to the study investigators. One reason for not reporting directly to the investigators is that not all DSMB recommendations may be accepted by the sponsor. A second reason is that the sponsor may have other information that might cause it to question a recommendation. Third, there may not be unanimity among the DSMB members as to the recommendations; sometimes the DSMB deliberations are quite divisive. The sponsor then needs to make some decision, perhaps by convening an additional body. This happened in the Women's Health Initiative trial of estrogen.³²

On the other hand, the investigators are closer than the sponsor to both the implementation of the protocol and the participants. Therefore, some clinical trial methodologists believe that direct communication between the DSMB and investigators would be more appropriate.³³ In addition, especially if the sponsor is a drug or device manufacturer, there may be strong financial reasons for it to accept or decline certain recommendations. Reporting directly to the investigators would reduce those pressures.

Regardless of to whom the DSMB reports, after each DSMB meeting a report needs to go to the IRBs. This report should not contain data that would unblind the study. However, it must mention the overall recommendation (continue or stop the trial); any recommended changes in protocol or informed consent, or other information that should be presented to the participants; and any adverse events not fully discussed during the consent process—for example, unexpected adverse events or any that are occurring more frequently or with greater severity than originally described.

On occasion, IRBs have refused to accept the judgment of the DSMBs and have asked to see the actual study data. It is important that the ground rules be established in advance, when the IRBs first review the protocols. IRBs need to accept that the DSMBs will perform their functions appropriately and that all necessary feedback will be provided. Some IRBs may not be willing to cede the responsibility of monitoring while still possibly being liable. If so, that needs to be understood at the beginning of a trial, not partway through. This whole area needs more discussion and clarification.

Access to Blinded Outcome Data

As noted above, various investigators and sponsor representatives may attend open sessions of the DSMB. Generally, in industry-sponsored trials, the sponsor is not present at the closed sessions, in which blinded data are presented. This is in line with FDA guidelines.² In many, if not most, NIH-sponsored trials, several institute staff are present and are routinely made aware of the blinded data. The arguments in favor of this practice are that NIH employees are responsible for public funds and must have full knowledge of the progress (including outcome data) of the trial in order to perform their duties. In addition, unlike employees of pharmaceutical or device manufacturers, they do not have direct

financial stakes in the results of the trial. The arguments against this practice are that any knowledge of outcome trends can bias the conduct of the trial. Protocol modifications often need to be made to enhance the feasibility of a trial, such as changes in eligibility criteria to improve accrual, or changes in outcome measures to increase power. If the sponsor is aware of the accumulating data, suspicion might arise that these changes were based on the blinded data, not simply on process data.²

The same argument applies to data coordinating center personnel. Some have proposed that there be a firewall between the biostatisticians who analyze, tabulate, and present the data to the DSMB and those who perform the daily management functions of the trial.^{34–36} This would be accomplished either by a group completely separate from the data coordinating center or through a separate group at the center. The counterargument is that anything that impairs the ability of the DSMB to obtain the best information about the study is inappropriate. Using a biostatistician who is not completely familiar with the study protocol to present data to the DSMB might mean that some questions about the protocol could not be answered in a timely fashion. Complete independence of the DSMB and its management might not lead to optimal monitoring and safety of the study participants. When the two desirable goals of independence and safety are weighed against each other, safety must always win.

Control of Data by the Sponsor

Either the sponsor manages and analyzes the data and prepares the data tables for review by the DSMB or it arranges with another group to perform these functions. Some have argued that when the sponsor analyzes the data, there is an inherent conflict of interest. Whether this conflict is effectively managed by the use of a contractor is a matter of opinion. One can argue that even if the functions are contracted to another group, the contractor has an interest in satisfying the sponsor. Many would say that anything that distances the analysis functions from the sponsor is useful, if only for the sake of appearance. Ideally, accumulating data should be managed and analyzed by a group independent of the sponsor. In the end, however, one always has to rely on the integrity of the people doing the data analyses.

Confidentiality Issues

While a trial is ongoing, it is expected that all members of a DSMB will exercise caution to keep information about the trial confidential. That is, they are expected to refrain from discussing their deliberations and trends in data with anyone who is not already privy to that information. This bar includes discussions with study investigators as well as with investors. The only communications should be the official recommendations at the end of each meeting.

Instances of inappropriate discussions of ongoing trials with investors have occurred. Most reports cited study investigators, who generally would not know about trends in the data. But at least one report cited a DSMB member.³⁷ These actions on the part of DSMB members during a trial are completely inappropriate. It is less clear, however, whether confidentiality should apply after a trial ends. It is probably reasonable to maintain confidentiality until the main results have been presented and published. After that, as long as proprietary information is not disclosed, there may

be good reasons for members of the DSMB to describe their experiences, with the goal of providing important guidance to future monitoring committees.

Disagreements Between DSMB and Sponsor or Investigator

On occasion, there may be disagreements between recommendations made by the DSMB, or by certain members, and actions taken or not taken by the sponsor or investigators. Most of these disagreements involve relatively minor protocol issues. More serious disagreements may revolve around management of adverse events and whether or not to stop a trial. Sometimes, the sponsor chooses to stop a trial earlier than scheduled, even when the DSMB has recommended continuing it. This may be done for scientific, ethical, or marketing reasons. The first two reasons can be legitimate, and the DSMB must acknowledge the right of the sponsor to do so. The last has rightly been harshly criticized.³⁸

It is also a serious situation if the DSMB recommends early discontinuation of a trial and the sponsor or investigator wants to continue. An instance of this has been reported, due primarily to a lack of prior understanding of the responsibilities of each.³⁹ Because of safety concerns, the monitoring committee for a pilot study comparing various doses of candesartan, alone and in combination with enalapril, and against enalapril alone in patients with heart failure recommended early termination. After receiving the recommendation, reviewing the data, and noting that clear monitoring guidelines had not been established in advance, the lead investigators raised questions about the recommendation and asked to meet with the monitoring committee. When the monitoring committee rejected this, the investigators sought the opinion of another outside expert panel. This panel concluded that although there was lack of strong evidence of harm, the recommendation of the monitoring committee should be accepted. Therefore, the trial was discontinued. A clear charter for the DSMB, as advocated by the investigators in this trial³⁹ and by the DAMOCLES Group¹³ would be helpful in similar situations.

Another kind of disagreement involves the interpretation of the data. In letters to the editor, two members of the DSMB for a trial of vitamin supplementation for retinitis pigmentosa challenged the investigators' conclusion that vitamin A was beneficial.⁴⁰⁻⁴² Regardless of the merits of each position, such squabbles are unfortunate. The DSMB can argue that it has lived with the data for considerable time (often years) and has a better understanding of the data than do the investigators, who may have seen the data for only a few weeks or months before they prepared their publication. The investigators can argue that they saw the final (and full) results, that they have a better appreciation of how to put them in the context of the entire area of research, and that data interpretation is their responsibility; they take either the plaudits or blame for the publication. One possible approach to minimizing such conflicts is for the DSMB to review draft presentations and publications. If the suggestions of the DSMB members are reasonable, most investigators would be appreciative of them. The DSMB members need to remember, though, that they are not the investigators or authors.

Sometimes, publications are inappropriately delayed (or never produced). It is particularly troublesome if serious adverse events were identified during the trial and, because of the lack of publication, are never made public. It is unclear what role or responsi-

bility the DSMB has in such cases, and how it is to discharge that responsibility. This issue becomes particularly difficult if a confidentiality agreement has been signed that prevents DSMB members from disclosing information without the approval of the sponsor.

Conclusions

All clinical research studies must have monitoring procedures. For certain kinds of studies, generally late phase clinical trials, an external committee, such as a DSMB, is essential. DSMBs provide expert judgment and oversight independent of the investigator and the sponsor.

The procedures for how a DSMB will function, and how it will monitor the data and conduct of the study, must be established in advance. IRBs also must understand and be comfortable with the monitoring process before they approve the study protocol. Because some events, especially adverse events, can occur rapidly, the system for collecting, analyzing, and reviewing the study data needs to be in place early.

Monitoring boundaries and guidelines for deciding if and when a study should be stopped early are essential. But these are guidelines, not rules, and cannot replace judgment. Rigidity in the face of unexpected events serves neither the study nor the participants. Therefore, it is necessary to have experienced, thoughtful members of the DSMB. Independence is important, but it cannot come at the cost of doing the best job of safeguarding the study participants.

The Food and Drug Administration and Drug Development

Historic, Scientific, and Ethical Considerations

The regulation of drug development, especially human clinical trials and the evidence needed for drug marketing, has major implications for research ethics. Food and Drug Administration (FDA) oversight and direction derives from federal legislation—principally the Federal Food, Drug, and Cosmetic Act of 1938, as amended in 1962—from the regulations written under that law, and from FDA guidance and policy documents that interpret the law and regulations. In this chapter, we provide a historical review of those rules and policies, noting both their obvious ethical implications and some of the less apparent, but critically important, ethical aspects of drug regulation. Table 54.1, below, summarizes the important FDA milestones.

General History

The roots of the current FDA date back to 1867, when the Division of Chemistry, housed within the Department of Agriculture, was formed to investigate the adulteration of agricultural products. Harvey Washington Wiley, a chemist and physician, became the chief chemist in 1893 and focused his attention and efforts on chemically altered foods and food additives, and their impact on health, which he believed was a greater public health threat than fraudulent or misbranded drugs. The original Pure Food and Drug Act of 1906 was a response to revelations of false claims for adulterated and dangerous patent medicines. This statute, which is still operative today, prohibited the interstate and foreign commerce of adulterated and misbranded foods and drugs. The Division of Chemistry changed names and location repeatedly, be-

coming the FDA in 1930 and eventually coming to rest in the Department of Health and Human Services (DHHS).

The FDA's responsibility for drug regulation evolved substantially in the last century. Prior to 1938 its responsibility was minimal; it could try to attack fraudulent claims, but had a considerable burden of proof and little authority. Drugs could be marketed without any contact with the FDA. There was no requirement even for notification of intent to market and no required submission of evidence. Beginning in 1933 there were discussions about expanding FDA's standard-setting authority, but the result was a legislative standoff. Then, in 1937, an elixir formulation of a new sulfa antiinfective was marketed; its solvent, diethylene glycol, the active ingredient in antifreeze, was untested except for being smelled and tasted by the formulating chemist. More than 100 people, many of them children, died as a result of ingesting Elixir Sulfanilamide, and the Food, Drug, and Cosmetic Act of 1938 was passed in response to this catastrophe. The effects of the 1938 Act and subsequent regulatory and legal developments have been described at some length elsewhere.¹

The Food, Drug, and Cosmetic Act of 1938 mandated profound changes in the drug regulation process. It required that drugs be tested for safety and shown to be safe for use and that they be labeled with adequate directions for safe use. Just as important was the new requirement for preclearance by the FDA. Anyone seeking to market a drug had to submit an application to the FDA, which could then reject it. There was no requirement for positive FDA action; the drug was approved if the FDA did not object. Preclearance was a giant step.

Although well armed with new authority, the FDA needed time and experience to develop its skills at evaluating drug safety.

The safety requirements placed into law in 1938 are identical to the current legal requirements—at least in the language of the underlying legislation—but there is a world of difference between current safety assessments and those of the 1940s, 1950s, and 1960s. For example, two drugs approved in the early 1950s, the antidepressant iproniazid (Marsilid) and the antituberculosis drug isoniazid (INH) were approved with no recognition of their serious hepatotoxicity, which would have been obvious in any reasonable clinical trial. Only after six years and hundreds of deaths was iproniazid removed from the market. Isoniazid was considered only mildly hepatotoxic until a prophylaxis study carried out in young Public Health Service officers revealed a 1/1000 mortality rate.² In contrast, since the 1990s, significant hepatotoxins have commonly been identified before marketing and, if not, are usually identified a relatively short time after marketing, as were bromfenac and troglitazone.

Although what might be called the “Age of Safety” had arrived in 1938, it started with no clear requirements as to what sort of studies manufacturers should conduct or what amount or type of data they would need to collect, no internal FDA standard procedures for reviewing the safety data provided, and no formal post-marketing safety surveillance. It was not understood that controlled trials often provided the most robust safety data, at least for common events. In 1938, the appropriate trials were rarely conducted. Ethical principles that might be applicable to research appear not to have been considered at this time, and the FDA did not really regulate the drug development process.

A critical expansion of FDA authority followed yet another medical disaster, commonly known as the thalidomide tragedy, in 1962. Thalidomide was developed as a sedative intended for use during pregnancy. Unfortunately, it causes phocomelia, a major teratogenic effect in which the long bones of the fetus’s limbs fail to develop. Thalidomide was marketed in Western Europe, and thousands of babies were affected. But the drug never received U.S. approval for this use, thanks to the alertness of the FDA’s medical reviewer, Frances Kelsey. The United States might therefore have been spared this disaster, but after the marketing application for thalidomide had been withdrawn from consideration in March 1962, the FDA found that about 1,100 physicians had received more than 2.5 million tablets of thalidomide and had dispensed them to almost 20,000 women, including 624 pregnant women, although information submitted to the FDA had indicated that only 40 to 50 doctors had been given the drug product.^{3,4} Worse, as the manufacturer had not kept good distribution records, recall of the drug proved to be a near impossibility. The result was that some cases of phocomelia appeared in the United States, most of them after the abnormality’s relationship to thalidomide was known. These terrible events spurred public support for stricter drug distribution controls by the FDA. Ultimately, in 1962, such controls were incorporated into the Kefauver-Harris Amendments to the Federal Food, Drug, and Cosmetic Act, cosponsored by Sen. Estes Kefauver (D-Tenn.) and Rep. Oren Harris (D-Ark.).⁵

But that is not all the 1962 amendments did. Although the requirement would seem to bear no relationship to the thalidomide disaster, the Kefauver-Harris Amendments required, for the first time, premarket demonstration of the effectiveness of a drug, in addition to the previously required evidence that the drug was safe for its intended use. Furthermore, the 1962 amendments required affirmative FDA approval before a drug could be marketed, radically altering the dynamic of the review process.

The law, at section 505(b)(1) of the Food, Drug, and Cosmetic Act, also required that an applicant provide the FDA with “full reports of investigations which have been made to show whether or not such drug is safe for use and whether such drug is effective in use.”⁶ Although full use of these data in FDA reviews took many years to develop, the “full reports” requirement made possible a kind of detailed review by the FDA that was previously impossible.

Moreover, the 1962 amendments added specific requirements related to human subject protection, most notably the requirement for informed consent. Congress thus identified the fundamental importance of consent before the appearance of the first version of the Declaration of Helsinki in 1964 (see Chapter 13). The law also provided an explicit expectation that the FDA would develop a process for the regulation of investigational drugs. The law, at sections 505(i)(1)(A)–(C) of the Food, Drug, and Cosmetic Act, offered only a few details of how to do this, saying that the Secretary of the Department of Health, Education, and Welfare (DHEW, predecessor of DHHS) should promulgate regulations to allow qualified experts to investigate the safety and effectiveness of drugs. Congress suggested that investigations be conditioned on the following:

1. Submission to the secretary of DHEW of preclinical tests (including tests on animals) adequate to justify the proposed human testing.
2. A signed agreement by each investigator that patients will be under his or her personal supervision or under the supervision of investigators responsible to him or her, and that he or she will not supply drugs to anyone else (a clear response to thalidomide).
3. Maintenance of such records and submission of such reports, of the results of the investigational use as the secretary of DHEW would need to evaluate the drug should an application be submitted.⁶

In addition to those suggestions, the law was explicit in saying that the regulations to be written had to provide that informed consent would be obtained.

Regulations written in response to this provision, generally codified at 21 CFR 312,⁷ describe the investigational new drug (IND) application process, under which drugs in the United States must be studied. These regulations set forth the responsibilities of investigators and sponsors for the conduct of studies and for monitoring research participants, reporting adverse effects, and making a variety of reports to the FDA. In the Kefauver hearings, Congress had been strongly urged to require animal studies prior to human exposure, and by the end of the 1960s many of the now familiar animal testing requirements were in place. Animal carcinogenicity requirements were developed in the 1970s. Many of the preclinical study expectations were further refined in international safety guidelines developed under the auspices of the International Conference on Harmonization in the 1990s.⁸ The preclinical requirements reflect the view that ethical research required testing for unacceptable toxicity in animals before exposing humans to a drug.

The new effectiveness requirement was the most recognized change created by the 1962 amendments. This change had no obvious connection to the thalidomide case. Where did it come from? Thalidomide probably put the Food, Drug, and Cosmetic Act in play, giving critics of existing law an opportunity to propose changes. There had been years of testimony before the Senate Subcommittee on Antitrust and Monopoly, headed by Kefauver,

on the sorry state of data supporting the effectiveness of marketed drugs and the grossly inflated labeling claims that were common. The ground was therefore prepared for the subcommittee to propose an effectiveness requirement when the opportunity to amend the law arose. The specific new requirement in section 505(d)(5) was that the FDA could refuse to approve an application if “there is a lack of substantial evidence that the drug will have the effect it purports or is represented to have under the conditions of use prescribed, recommended, or suggested in the proposed labeling [of the drug].”⁶

The idea that effectiveness was relevant was not wholly novel. Congressional testimony by FDA Commissioner George Larrick in 1964 indicated that even before the 1962 amendments, the FDA was giving thought to a drug’s value in deciding whether it was safe, at least in some cases involving life-threatening diseases.⁹ But even if the FDA had wanted to be more concerned with effectiveness, the poor study designs used in the drug trials conducted in the 1940s and 1950s, especially the limited use of controlled trials, would have given the FDA little basis for an effectiveness assessment in most cases.

Moreover, although the 1962 amendments are known for promulgating the requirement, this requirement was not the most important change. More important was the way in which substantial evidence was to be obtained. The *substantial evidence* requirement was on its face not a high standard. In legal terms, the highest level of evidence is “beyond a reasonable doubt,” the standard in criminal trials. A lower level of evidence is *preponderance*, which means a more than 50% probability, the standard typical in civil cases. *Substantial evidence* is a still lower level. But in an artful compromise, the law not only described the standard of evidence but also identified controlled clinical trials as the one acceptable source of that evidence. Thus, in section 505(d) of the Food, Drug, and Cosmetic Act, *substantial evidence* is said to mean the following:

Evidence consisting of adequate and well-controlled investigations, including clinical investigations, by experts qualified by scientific training and experience to evaluate the effectiveness of the drug involved, on the basis of which it could fairly and responsibly be concluded by such experts that the drug will have the effect it purports or is represented to have under the conditions of use prescribed, recommended, or suggested in the labeling or proposed labeling thereof.⁶

Legislative history indicated that the use of the plural—investigations—was intended. The Food and Drug Administration Modernization Act of 1997,¹⁰ however, explicitly recognized that the substantial evidence requirement can be satisfied by a single study in some cases (with “confirmatory evidence”) and the FDA has developed guidance on this issue.¹¹

The 1962 law thus set a relatively weak legal standard of evidence but stipulated that only the best-designed kind of study (indeed, more than one such study) could fulfill the standard, producing what is recognized today as a high standard for the evidence needed to support marketing approval. The promulgation of this standard, which influenced all drug studies intended to support marketing, has contributed greatly over the past 40 years to the fundamental change in the kind of data that is expected to support any effectiveness claim for a drug, device, or other intervention. It is the principal basis for evidence-based medicine. The adequate and well-controlled clinical trial became the evidentiary standard.

In enacting the law, Congress also recognized concerns that the standard not be so high that new drugs would be difficult to develop. The legislative history clearly stated that there was no relative effectiveness requirement. That is, a new drug need not be better than, or even as good as, available therapy, so long as it worked. Congress, in the legislative history of the 1962 amendments, sought to explain the balance it had tried to reach:

The committee [Subcommittee on Antitrust and Monopoly of the Committee on the Judiciary] believes that this provision strikes a balance between the need for governmental control to assure that new drugs are not placed on the market until they have passed the relevant tests and the need to insure that governmental control does not become so rigid that the flow of new drugs to the market, and the incentive to undergo the expense involved in preparing them for the market, become stifled.¹²

Plainly, the balance reflected in the history is highly pertinent to current discussions of rapid availability of drugs for serious diseases with poor treatment options.

Since 1962 there have been substantial refinements of the broad requirements for adequate and well-controlled studies. The FDA wrote regulations in 1970 that for the first time described the characteristics required for such studies, a regulation that was somewhat modified in 1985 and is now codified at 21 CFR 314.126 (“Adequate and well-controlled studies”).¹³ The Adequate and well-controlled studies rule, however, was only an introduction to three decades of growing sophistication about study design and analysis—recognizing, for example, such issues as specifying in advance the outcomes and endpoints to be analyzed in a study, correcting analyses for multiplicity (that is, for examining more than one endpoint, considering subsets, etc.), accounting for all randomized patients,¹⁴ performing intent to treat analyses, remaining blind to interim results of studies or using group-sequential methods, the problems of equivalence/non-inferiority studies,¹⁵ and appropriate study designs for assessing dose-response. The increasing awareness of critical elements of study design was supported by substantial growth of medical and biostatistical staff at the FDA. This was matched, perhaps as a matter of necessity, by a vast increase in statistical support in the regulated industry. It became necessary to maintain industry and medical academic awareness of these matters, which was accomplished through guidance documents, industry-FDA meetings, great numbers of workshops and medical meetings, and public advisory committee meetings. Beginning mainly in the 1980s, with the basic standards for evaluation of the safety and effectiveness of drugs well established, two important new themes began to draw public, FDA, and congressional attention: (1) assuring reasonably prompt availability of drugs, especially promising drugs for serious diseases without adequate treatment, and (2) individualization of treatment, especially for age, sex, and racial subsets of the population.

Availability of Therapeutics

Almost from the first passage of the 1962 amendments, concerns arose that drug development was slowing and that a *drug lag* had emerged.¹⁶ It was fairly clear that, on average, drugs were entering the U.S. market later than they were available in Europe. This actually saved the United States some bad experiences. Drugs

withdrawn in Europe for toxicity prior to any U.S. introduction included practolol, lidoflazine, perhexilene, Aminorex, and others. But delayed market entry of new therapeutics was not a desired FDA goal, nor was it defensible as a matter of policy. Since the late 1970s, a variety of legal, regulatory, and policy initiatives have sought to speed the development and approval of drugs that meet the standards specified by law. These initiatives are of long-standing, beginning in the 1970s and 1980s, predating the appearance of AIDS (to which the changes are sometimes attributed). They have been supported importantly in some cases by patient advocacy groups. The changes represent a clear evolution within the FDA from a perception of its role as wholly one of protection against unsafe or ineffective drugs to a role that also includes facilitation of the development of valuable agents.

This evolution within the FDA reinforced and coincided with changes in societal attitudes, with research moving from an activity perceived as risk-laden to one viewed as hope-laden. It could be said that the avoidance of harm was the FDA's and society's operating principle during the 1940s through the 1960s and even into the early 1970s. But the rapid growth of useful therapies led to a new focus on the attainment and availability of benefit, with continuing attention to drug safety.

A necessary step toward a more active FDA role in drug development was recognition that the FDA had an obligation to define its expectations and explain to manufacturers how they could provide the data needed for drug approval. In the 1960s, many reviewers believed that too much involvement by the FDA in

the development process would leave the agency “co-opted,” unable to be appropriately neutral, analytical, and critical when the time came to review the data. But the cost of not describing its expectations, allowing inadequate studies to proceed without comment, and criticizing those studies only when they were submitted to support a drug application, came to be seen as unacceptable in terms of waste, avoidable delays in development, and inappropriate and possibly unethical exposure of research participants in trials of no value. The first major effort to end the FDA's relatively passive approach was the preparation of more than 30 clinical guidelines in the late 1970s, often with involvement of FDA advisory committees and public workshops. These guidelines described the FDA's expectations for study designs and data for various therapeutic classes such as antianginal drugs, antidepressants, and drugs for peptic ulcer disease.

Development of guidance for specific drug classes continues to the present day. Several other critical guidance documents help drug companies generate the data needed to document the effectiveness and safety of a drug and present the data in a reviewable form. These include the FDA's 1988 Guideline for the Format and Content of the Clinical and Statistical Sections of Drug Applications,¹⁷ as well as guidelines promulgated by the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) that deal with exposure to drugs and clinical safety (ICH E-1),¹⁸ the structure and contents of study reports (ICH E-3),¹⁹ the proper assessment of dose response (ICH E-4),²⁰ the use of statistical methods (ICH

E-9),²¹ and the choice of control group (ICH E-10).²² ICH E-10, apart from its scientific value, has been a crucial document in the debate over the use of placebo controls.

The second major change, also continuing to the present, was increasing willingness of the FDA to meet with drug sponsors at critical times in the development process to discuss the planned studies and the overall database intended to support approval. Recent estimates are that about 2,300 such meetings take place each year, during which FDA staff respond to questions regarding the sponsor's planned approach, analyze overall development plans and specific study designs, and offer views about what will be needed to support approval. That the industry finds these very helpful is indicated by a 70% increase in requests for such meetings between 2000 and 2006. There seems little doubt that the decline in drug approval times since 1990, although importantly the result of increased staff and timeliness goals arising from the Prescription Drug User Fee Act of 1992, also reflects the FDA's increasing willingness to make its expectations clear.

The third significant change was facilitating broad public access to the FDA's evaluations and policies, reflected in the initiation and subsequent growth of open FDA advisory committee meetings and the availability, after approval of a drug, of the FDA's scientific reviews and administrative records. The result is the sharing with drug developers and the interested public of a great deal of information about the FDA's current expectations for data and analyses.

A more direct effort to shorten the time taken to review and act on marketing applications was the Prescription Drug User Fee Act, passed by Congress in 1992, and reauthorized in 1997, by the Food and Drug Administration Modernization Act, in 2002, by the Public Health Security and Bioterrorism Preparedness and Response Act, and in 2007 by the Food and Drug Administration Amendments Act of 2007.²³ FDA review staff had grown little since the 1970s, even while the size and complexity of new drug applications had grown and the FDA's efforts to give advice during development had increased. The FDA contended, and Congress and industry agreed, that review times could not change materially, while maintaining review quality, without a significant increase in staff. To provide such an increase, fees were assessed for submission of applications, and the revenues were used to substantially enhance the FDA clinical review staff from about 90 clinical reviewers to well over 200 in 2006, with similar increases in other disciplines. The FDA agreed to time goals for completion of reviews and action on applications—initially 12 months, later reduced to 10 months, for *standard* applications, that is, for drugs that do not appear to offer a clinical advantage over available treatment, and six months for *priority* applications involving drugs that do appear to offer a therapeutic advantage. Although the agency did not agree to goals for approval time, which obviously would have represented an inappropriate “preference for yes,” proponents of the user fee program expected that timely action would decrease the time from submission to approval—and it has done so, from approximately 27 months in 1990–92 to approximately 13 months in recent years. The most striking results are for priority drugs, with action times averaging about six months during the first half of the decade.

One of the most important additions to the FDA's ability to facilitate development of drugs for unmet needs was a process providing for accelerated approval. In 1992, the FDA promulgated the Accelerated Approval Rule (codified at Subpart H of 21 CFR 314),¹³

part of which was incorporated into the 1997 Food and Drug Administration Modernization Act. It allowed a drug for a serious or life-threatening disease without good treatment to be approved on the basis of a surrogate endpoint that was “reasonably likely” to lead to a clinical benefit, on condition that such clinical benefit be established on the basis of controlled clinical trials after marketing. A surrogate endpoint is “a laboratory measurement or physical sign that is used in therapeutic trials as a substitute for a clinically meaningful endpoint that is a direct measure of how a patient feels, functions, or survives and that is expected to predict the effect of the therapy.”²⁴ Although nothing in the law bars reliance on surrogate endpoints, and surrogates such as blood pressure, hemoglobin A1c (used in diabetes), and lipid levels have long been used, the “reasonably likely” standard represented an explicitly weaker standard of evidence than those well-established surrogates. The evidence supporting the effect of the drug on the surrogate endpoint must meet the usual adequate and well-controlled studies standard. Accelerated approval has been used primarily for drugs to treat AIDS, using the surrogate endpoints CD4 lymphocyte count and viral load, and cancer, using tumor response as the surrogate endpoint.

Making promising drugs available to patients even before they were approved for marketing was an additional step toward greater availability. This was not an entirely novel idea. In the 1970s and 1980s, many thousands of patients had received important new agents like nifedipine, for vasospastic angina, metoprolol, a cardioselective beta blocker, and amiodarone, an antiarrhythmic agent, under various arrangements before formal marketing approval. Concern with whether such extensive distribution, without changes in regulation, could legally represent *investigational use*, with the term's implication that the studies were intended to develop evidence to support marketing, led the FDA to propose in 1982 a regulation for the *treatment IND* or *treatment protocol*, now codified at 21 CFR 312.34.⁷ The rule allowed wide distribution of a drug under the IND process for serious or life-threatening diseases without satisfactory treatment if the drug was under active development and there was sufficient evidence of effectiveness and safety—which is explicitly less than that needed for marketing approval—and if clinical studies to evaluate the drug's effectiveness and safety were ongoing or complete.

Made final in 1987, the Treatment IND Rule was thought by many to be a response to AIDS. However, it was originally proposed in 1982, when AIDS was not yet a well-described clinical entity and there were no promising therapeutic interventions for the disease. What the Treatment IND Rule tried to assure, in addition to the availability of a promising drug prior to its approval, was that the availability of such a drug would not be limited to patients whose physicians had inside knowledge, but would go to any patient with the condition to be treated. If the FDA finds that the expanded access under a treatment protocol is interfering with the conduct of the well-controlled studies needed to evaluate the drug's effectiveness, it can stop the treatment protocol.

Individualization of Treatment

Beginning in the early 1980s, there was growing recognition that responses of individual patients to drugs could be very different. The first differences to be well studied were pharmacokinetic differences. It had long been known that disorders of excretory

function could lead to drug accumulation, and slow and fast acetylators of isoniazid and hydralazine were known, with adverse consequences to the slow acetylators. The 1980s and 1990s saw an enormous growth in understanding of metabolic pathways and individual differences in the activity of those pathways, including the potential for inhibition of those pathways by concomitant therapies (a kind of drug-drug interaction). The “poster child” for these interactions was the interaction of terfenidine, the first non-sedating antihistamine, with cytochrome P450 3A4 inhibitors such as ketoconazole. The inhibitors blocked metabolism of terfenidine to its active metabolite, resulting in substantial accumulation of the parent drug, which caused fatal torsades de pointes arrhythmias. Assessment of metabolism and interactions is now a routine part of all drug development.

Apart from individual pharmacokinetic differences, interest also grew in possible differences in clinical responses among demographic subgroups of the population, such as groups defined by gender, age, and race. Advocacy groups for women, the elderly, blacks, and children, and the medical community were instrumental in raising this interest. Beginning in 1982, the FDA developed a series of guidance documents and regulations that drew attention to these demographic subsets and called for appropriate analyses of potential differences in response among them. The FDA did not find that members of these groups had been excluded from trials,²⁵ as has sometimes been asserted, but did find that there had been no attempt to see whether responses differed by group.

In the revised new drug application (NDA) regulations of 1985, now codified at 21 CFR 314.50,¹³ a novel requirement for integrated summaries of safety and effectiveness data specifically called for analyses of safety and effectiveness by subgroup, and identified pediatric or geriatric patients and those with renal failure. This did not really address the breadth of demographic groups of interest, however. Consequently, in the 1988 Guideline for the Format and Content of the Clinical and Statistical Sections of New Applications,¹⁷ the FDA called for analyses of safety, effectiveness, and dose response by demographic subgroup—in particular, subgroups based on age, gender, and race—in both individual studies (if large enough) and in the integrated summaries. In 1998, the FDA went further, stating in 21 CFR 314.50, the regulation describing an NDA submission, that the overall analyses of effectiveness and safety had to examine effectiveness, dose response, and safety by age, gender, and racial subgroups. An application that lacked these analyses was thus incomplete and would not be reviewed.¹³

In 1989²⁶ and 1993,²⁵ respectively, the FDA published guidelines on studying the elderly and both genders. Neither guideline gave specific numbers or percentages of patients in the subgroup that needed to be included in studies but both urged attention to their inclusion and specifically called for analyses of data by subgroup. The 1993 *Federal Register* notice announcing the gender guidelines also specifically revoked previous guidance urging that women be excluded from Phase 1 and early Phase 2 trials until animal teratogenicity studies had been completed, an exclusion representing concern over reproductive toxicity.²⁵ Further, in 2000 the FDA ruled (21 CFR 312.42)⁷ that it could stop any early IND study of a life-threatening disease if patients were excluded solely because of the risk of reproductive toxicity. The encouragement to include a diverse population and insistence on analyzing databases for possible demographic differences in drug response reflected the growing scientific appreciation of individual differences in responses to treatment. But it also reflected a view

that a manufacturer was responsible for collecting data that described effectiveness and safety in the larger relevant population, a view that reflects the ethical principles of beneficence and justice, not only for the subjects in trials but for the whole community.

Since the 1980s, the FDA has increased efforts to encourage studies that enroll children. In general, children represent a small market and studies in children pose potential ethical and logistic difficulties. Through the mid-1990s only about 25% of drugs widely used in children had been studied in them.²⁷ Since then, two principal approaches have been tried to correct this imbalance: requiring studies in children, and granting extended marketing exclusivity, that is, an additional period of protection from generic competition, to manufacturers that carry out the pediatric studies requested by the FDA.

The Food and Drug Administration Modernization Act of 1997 created a powerful stimulus to conduct pediatric drug trials.¹⁰ It allowed manufacturers six months of additional market exclusivity, added to whatever patent or marketing protection the manufacturer already had, if the manufacturers conducted studies specifically requested by the FDA to evaluate the drug in children. The studies did not have to succeed—that is, to show effectiveness—but they needed to be scientifically sound and to study the indication in the manner outlined by the FDA. It was expected that studies would often lead to appropriate labeling of drugs for children. The exclusivity provision was later reauthorized in the Best Pharmaceuticals for Children Act of 2002,²⁸ and most recently in the Food and Drug Administration Amendments Act of 2007.²³ Conduct of the studies requested by the FDA under this Act is voluntary.

A 1998 regulation titled Pediatric Use Information, codified at 21 CFR 314.55,¹³ generally referred to as the Pediatric Rule, required manufacturers submitting a marketing application to include information about the use of the drug in pediatric age groups unless the requirement was waived or deferred until the postmarketing period. The Pediatric Rule was enjoined in 2002 by a federal court, but many of its elements were reinstated in the Pediatric Research Equity Act of 2003, which mandates pediatric studies of certain drugs and biological products “if there is a new element to the application (e.g., indication, dosage form, route of administration, dosing regimen, or active ingredient) or if the innovator product represents a meaningful therapeutic benefit over existing therapies for treatment, diagnosis or prevention, or if there is a need for additional therapeutic options.”²⁹

One further issue relevant to research ethics should be noted: the use of data from studies conducted outside the United States and not under a U.S. IND. These studies would not have been conducted under the specific ethical rules applicable in the United States, yet rejecting them and causing unnecessary duplication of studies would be ethically problematic. In 1987 the FDA adopted a regulation, codified at 21 CFR 312.120 and entitled “Foreign clinical studies not conducted under an IND,”⁷ that described the criteria for acceptance of such data. The rule said, among other things, that the studies had to be conducted in accordance with a specific version of the Declaration of Helsinki (at the time, the 1989 version) or the laws of the country in which the study was conducted, whichever “represents the greater protection of the individual.” The primary goal of 21 CFR 312.120 was to make sure that foreign studies on which the FDA relied met appropriate ethical norms, but it was also critical to assure that they were scientifically valid. In 2004 the FDA proposed a modification of

the rule to emphasize both ethical conduct and assurance of data quality, and to eliminate reference to the Declaration of Helsinki, a document for which the FDA has no responsibility and that, in its 2000 revision, had included several provisions at odds with FDA rules and guidance. The modification to the rule instead refers to Good Clinical Practice, such as practices described in the ICH Good Clinical Practice consolidated guideline,⁸ (ICH E-6), which was adopted by the FDA in 1997, and which helps assure both ethical conduct of trials and a high level of data quality.

Overview: Dietary Supplements

By law, dietary supplements are classified as foods and are subject to requirements quite different from those that apply to drugs, a difference established by the Dietary Supplement Health and Education Act of 1994 (DSHEA).³⁰ The distinction is important because dietary supplements are often accompanied by claims about beneficial effects on the structure or function of the body; that is, they bear some of the same claims as drugs. Section 201(c)(1) of the Federal Food, Drug, and Cosmetic Act defines a drug as the following:

1. An article intended for use in diagnosis, cure, mitigation, treatment, or prevention of disease.
2. An article (other than food) intended to affect the structure or any function of the body.⁶

Dietary supplements are defined as products that, among other things, are intended for ingestion, are intended to supplement the diet, and that contain one or more of the following dietary ingredients: a vitamin, a mineral, an herb or other botanical, or an amino acid. Under DSHEA, a dietary supplement is subject to regulation—including premarket approval, evidence of safety, and substantial evidence of effectiveness—only if it is marketed as a treatment for disease. On the other hand, a supplement manufacturer can claim an effect on structure or function (such as “builds strong bones”) on the basis of the manufacturer’s own conclusions about the available evidence. The claim is not subject to prior FDA review, and there are no specified standards for reaching a conclusion about effectiveness.

Structure-function claims are subject to other requirements, however; they must be accompanied by a disclaimer noting that the FDA has not evaluated the claim and that the product is not intended to diagnose, treat, cure, or prevent any disease. Structure-function claims are also subject to a postmarket notification requirement. The FDA has issued a regulation, codified at 21 CFR 101.93, that distinguishes between “disease” claims and structure-function claims for dietary supplements.³¹

Dietary supplements must be safe, but there is no expressed standard for safety and, except for certain dietary supplements that contain a “new dietary ingredient” (a dietary ingredient not marketed in the United States before Oct. 15, 1994) that is not present in the food supply, no safety documentation is required. The FDA may declare dietary supplements unsafe via rulemaking if the scientific evidence is sufficient to prove adulteration under the legal standard established by DSHEA.

Not surprisingly, in the absence of a requirement for substantial evidence of effectiveness, dietary supplements at present fall largely outside the realm of adequate and well-controlled studies, at least with respect to structure-function claims. In recent

years, however, the National Center for Complementary and Alternative Medicine, part of the NIH, and other groups have conducted randomized trials of such supplements in the treatment of disease, including trials of B vitamins for lowering homocysteine and reducing coronary events,³² echinacea for mitigating upper respiratory infections,³³ saw palmetto for treating benign prostatic hypertrophy,³⁴ St. John’s wort for treating depression,³⁵ and chondroitin sulfate and glucosamine³⁶ for treating arthritis. Most of these trials have failed to demonstrate effectiveness. As noted above, a dietary supplement becomes a drug if it is marketed to treat, mitigate, or cure a disease. Thus, for example, if saw palmetto were marketed to treat benign prostatic hypertrophy, the FDA would regulate it as a drug.

Ethical Issues

The FDA’s regulatory authority clearly gives it the ability to implement and enforce ethical norms for research with humans. In addition, many of the FDA’s broader activities in regulating drug investigation and approval have ethical implications pertaining to (1) protecting the clinical research participant, (2) providing access to treatments, and (3) effective drug development.

Protecting the Clinical Research Participant

FDA regulations require the informed consent of research participants, independent review of studies, and a favorable risk-benefit ratio of studies at their commencement and as they progress. The early regulation of clinical trials focused almost entirely on the need to protect participants from harm and from being misled or deceived. This is not surprising, given scandals such as the Tuskegee syphilis study³⁷ and other instances of abusive investigation³⁸ (see Chapters 6, 7, and 8). The protections built into the Federal Food, Drug, and Cosmetic Act and its regulations are straightforward and readily understood. The first law giving the FDA a significant role in monitoring investigational studies included a requirement for informed consent, reflecting early attention to the basic ethical principle of autonomy. The law also called for prior animal tests to justify human exposure and close personal supervision of studies by investigators. The FDA IND regulations at 21 CFR 312 focus heavily on sponsor and investigator responsibilities for detecting and reporting adverse effects of test drugs.⁷ The FDA is authorized to stop (“hold”) a study if subjects would be “exposed to an unreasonable and significant risk of illness or injury.” The development of the requirement for review of every study by a group external to the interests of the investigators—that is, an institutional review board (IRB)—reflects a similar concern with subject protection, within the FDA and the government in general.

Informed Consent and Respect for Participants

The FDA’s informed consent regulations, developed following enactment of the Kefauver-Harris amendments, initially tried to distinguish between therapeutic and nontherapeutic research, but by 1981 the regulations applied to all research studies and described the critical elements of consent. FDA regulations mandate that eight basic requirements delineated in 21 CFR 50.25, “Elements of informed consent,” be part of consent in all FDA-regulated

research.³⁹ These mirror requirements in §46.116 of the federal Common Rule⁴⁰ (see Chapter 15). The basic requirements are (1) a statement that the study involves research, (2) a description of any reasonably foreseeable risks, (3) a description of any benefits to the subject or others, (4) disclosure of alternatives to research participation, (5) a description of mechanisms to ensure confidentiality, (6) an explanation as to whether any compensation and medical treatments are available if injury occurs for research involving more than minimal risk, (7) the name of a contact person for questions about the research, and (8) a statement that one's participation in research is voluntary.

FDA regulations permit a legally authorized representative to give (or withhold) consent for those with decisional incapacity, but the regulations do not allow for the total exemption of the requirement of either informed consent or consent by a legally authorized representative except under two circumstances. One, codified at 21 CFR 50.23, allows research involving a person participating in a military operation, without informed consent, in emergency situations or with a presidential waiver when consent is not feasible and nonuse of the investigational drug is contrary to the interests of the person or national security.³⁹ The second, codified at 21 CFR 50.24, allows an exception to informed consent for emergency research in life-threatening situations in which the study subject is incapacitated and no one is available to provide valid consent.³⁹ This exception is accompanied by several protections, including community consultation, public disclosure, a required data monitoring committee, the prospect that the intervention may provide direct benefit to subjects, and a plan for obtaining informed consent from either the subject or a legally authorized representative as soon as possible.

Monitoring Patients: Maintaining a Favorable Risk-Benefit Ratio

In addition to requiring consent, rules for investigators and sponsors of clinical trials require continuous monitoring of adverse effects by the investigator and the sponsor, reporting of serious unexpected events to the FDA and all investigators by sponsors, and reporting to IRBs by investigators of unexpected problems. The investigators' brochures and consent forms are modified as needed. The FDA's review, which can incorporate information gleaned from related drugs, adds a layer of protection beyond that provided by the investigator and sponsor. The more general requirements under the IND process, enforced by the FDA, also protect research participants. Thus, the need for animal data prior to any human exposure, the requirement for longer animal studies to be carried out before the longer human studies, the conduct of studies on the reproductive systems of animals early in drug development, and the progression of human data from initial short studies involving just a few patients to longer, larger studies, all contribute to maintaining a favorable risk-benefit ratio in ongoing studies. A significant safety concern at the start of a trial or during it can lead the FDA to place a *clinical hold* on the study, preventing further exposure.

In addition, the FDA's Bioresearch Monitoring Program examines the conduct of investigators in carrying out their responsibilities, including obtaining valid informed consent, appropriately monitoring research participants in accordance with the protocol, and overseeing the activities of other's participating in the study under their direction.⁴¹

Independent Review

The need for review of a protocol by an independent body was an early ethical concern; it first appeared at the FDA in a rule proposed in 1969 that would have required peer-group committees to review studies of new drugs. Independent review was endorsed in the 1975 version of the Declaration of Helsinki. The FDA made several proposals in the 1970s, and by 1981 the current FDA regulations at 21 CFR 56, which describe the composition and activities of IRBs in detail, were codified.⁴² Every drug trial conducted in the United States, including studies exempted from the need to file an IND, as per 21 CFR 312.2,⁷ must have review by an IRB; foreign studies, to be accepted in support of an application, must have been reviewed by an independent research ethics committee. IRBs must avoid or minimize conflict of interest on the part of the members, must interact with the community—generally including representatives of the community on the IRB—and must assure the integrity of the research enterprise by providing independent review. In order for an IRB to approve a protocol, it must determine that risks to subjects are minimized and are reasonable in relation to the importance of the knowledge that the study may produce and the anticipated benefits, if any, to the research subjects. IRBs also evaluate the merits of the patient inclusion and exclusion criteria, for both their scientific and ethical justification.

Access to Treatments: Fair Subject Selection and Social Value

If concerns about autonomy and nonmaleficence reflect primarily a concern about possible harm to those participating in a trial, concerns about access to potentially important benefits of therapy arise principally from ethical concerns about beneficence and justice. Moreover, these concerns focus not primarily on the protection of individuals in a trial, but on ethical concerns related to the whole community or to particular subsets within that community. Just as the FDA evolved from an organization almost solely interested in subject protection, at least during the IND phase, to one concerned also with designing clinical programs that would efficiently assess the value of a drug so that it could become available for use by the community, the FDA and the community have recognized that the potential value of drugs raises ethical concerns about access, both to investigational agents and to marketed drugs, and about the fairness of participation in clinical studies.

This has led to two principal changes in attitude: (1) a desire for inclusion of a wider range of subjects in studies, reflecting both a concern about fairness of subject selection and about the broad applicability of results, and (2) a desire for greater and earlier access to investigational agents and, to some degree, to marketed drugs.

The recognition of potential differences among individuals or groups was accompanied by a strong belief that subject selection was unfair because women, the elderly, and blacks were being excluded from the clinical trials of new drugs. Apart from concern about possible exclusion from the direct benefits of being in the clinical studies, there was also concern that there would be inadequate knowledge about how to use new drugs properly in those groups once the drugs were marketed. In most cases, however, the FDA found that the groups had not been excluded but that there had been no attempt to analyze data for possible differences in

response in demographic subsets of the population.²⁵ These analyses are now required, a clear manifestation of the view that failing to study how drugs work in the whole population is unjust and that it is the duty of the community to benefit the broad, not a narrow, population.

Demand for greater, and earlier, access to treatments is an unequivocal reflection of a belief in the potential benefits of those treatments. The principle of autonomy, or self-determination, is commonly invoked to support this demand, but it also reflects belief in the social value of research, in terms of both specific product development and attainment of generalizable knowledge. Although AIDS and cancer are the most conspicuous loci for the sense of urgency with respect to new treatments, similar feelings arise for neurological and other serious conditions for which few good treatment options exist. There are, however, persistent tensions between early access to investigational treatments in a study and early marketing of drugs, and the need for good data on the safety and effectiveness of a drug. Even people with a serious disease can be made worse by a toxic drug that has not been adequately evaluated, and no one is well served if a marketed drug proves ineffective, especially for a serious illness.

In the face of these tensions, drugs have been made available more quickly for serious illnesses with a more limited database than drugs for less serious illnesses, reflecting the greater risks that are acceptable when treating very serious diseases. Despite the increased speed of availability, FDA reviewers continue to pay attention to the need to develop the valid evidence of effectiveness and safety that is called for in law and that is also owed to the community.

Just as the Treatment IND process provides early access to drugs for serious illnesses that are still being studied, drugs for serious illnesses can also be marketed earlier than other drugs. The Accelerated Approval Rule allows the FDA to approve such a new drug based on the effect on a surrogate endpoint that is “reasonably likely” to predict a clinical benefit, even if it has not been fully demonstrated as predictive. As clearly stated in the rule, there are risks in this approach. A plausible effect on a surrogate may fail to predict benefit, and the drug may be harmful. The most striking example of this comes from the Cardiac Arrhythmia Suppression Trial (CAST) study.⁴³ Although the antiarrhythmics encainide and flecainide had never been approved for use after a heart attack—labeling specifically disclaimed any data on such use—the drugs were widely used in clinical practice after a heart attack to suppress the ventricular premature beats (VPBs) that were well known to predict an increased risk of sudden death. Suppression of the VPBs was, in most people’s eyes, a plausible surrogate endpoint to use when trying to modify risk of death. The results of CAST were shocking. The drugs suppressed the VPBs dramatically, but more than doubled mortality among study subjects.

Despite the risk that drugs that are given accelerated approval might prove ineffective or even harmful, most accelerated approval drugs have been shown effective and none has had an adverse outcome, although some have not yet yielded demonstrable clinical benefit. The program is generally considered a valuable way to enhance the therapeutic armamentarium for treatment of life-threatening diseases with no good treatment.

In addition, the amount of safety data needed to support an application varies according to a sliding scale. Drugs with a major benefit in life-threatening and severely debilitating diseases can be approved with smaller safety databases. A detailed discussion of

this issue is beyond the scope of this chapter; but in 21 CFR 312.80 (subpart E: Drugs Intended to Treat Life-threatening and Severely-debilitating Illnesses),⁷ which addresses development of such drugs, the FDA offers to have meetings earlier in development than usual so that the first controlled trials (Phase 2) can be definitive and serve as the basis for approval. Approval after Phase 2 trials, not uncommon in oncology, plainly represents a smaller than usual safety database, but is nonetheless appropriate under the circumstances.

Assuring Scientific Validity

Although they may not be generally recognized as ethical issues, two other FDA activities constitute major contributions to the ethics of drug development—policing the scientific validity of the process and assuring the social value of the endeavor. The FDA also conducts much of its business in public, providing access to the detailed basis for its decisions, creating informative labeling for approved products, and considering significant problems at public advisory committee meetings. Through meetings, protocol reviews, guidance, and public availability of the basis for its decisions, the FDA endeavors to assure that human studies are at least potentially useful. The ethical obligation to provide such assurance is suggested, if not stated in so many words, in the various versions of the Declaration of Helsinki, all of which stress the need to base research on generally accepted scientific principles. A considerable part of the FDA’s resources and efforts over the years has been devoted to providing this assurance. The result is that studies are designed rigorously and incorporate the best available medical and statistical advice.

Moreover, the FDA assures the public that marketed drugs are in fact effective for the uses claimed in the package insert, have been evaluated for safety by all tests *reasonably applicable* (the legal standard) and have been shown to be *safe*, meaning that their benefits outweigh their risks. Drugs—and in slightly different ways medical devices and biologic products—are thus treated differently from the vast array of other products sold to people. They must be evaluated and approved by the FDA before they can be sold. This is a requirement that is not generally discussed as a matter of ethics, except perhaps by Congress in passing the 1962 Kefauver-Harris amendments, but it is surely based on a perceived ethical obligation to have solid evidence to support the marketing of health-care products.

Over the years, in pursuit of its legal obligation, the FDA has developed methods and practices for reviewing the evidence submitted in support of applications and has provided extensive guidance to manufacturers on how to develop good evidence of effectiveness and safety. Its efforts on occasion result in published analyses of trials¹⁴ or commentaries on important research practices,^{44,45} but far more often lead to internal reviews (which are publicly available in many cases), letters to manufacturers, and advisory committee presentations.

The FDA certainly does not work alone in this effort. Drug manufacturers, academics, practicing physicians, and patients all make significant contributions to the agency’s efforts at improving the design of studies and analysis of data. But there is no independent body that has comparable capability or resources for the close examination of clinical trial design and results. Journal peer reviewers, diligent and qualified as they are, rarely have the clinical

trial protocol, much less the raw data for the study, in the manuscript they are reviewing. The FDA has full access to all such information.

The FDA's advice and the expectation of careful review of data has led over the years to a wide range of stimuli to best practices in study design and conduct in such areas as randomization, blinding, specification of study hypotheses and analyses, dealing with multiplicity, appropriate selection of the control group, examination of dose response, and examination of demographic and other baseline variables, and in general, to studies of high scientific quality that can answer the questions they are designed to examine. Assurance of study quality is not regularly recognized as an ethical question, but adequate scientific quality is an essential component of an ethical clinical trial.⁴⁶

The entire purpose of biomedical research, conveyed in many guidelines, ethical frameworks, and the Declaration of Helsinki, is to improve therapy and understanding of disease, and poorly designed studies cannot do this. A subject participating in poorly designed studies is exposed to risk without the possibility of personal or societal benefit. Guideline 11 of the International Ethical Guidelines for Biomedical Research Involving Human Subjects, produced by the Council for International Organizations of Medical Sciences (CIOMS), speaks to this as well by stating that "a clinical trial cannot be justified ethically unless it is capable of producing scientifically reliable results." The guideline also notes that "a placebo-controlled trial is often much more likely than an active control to produce a scientifically reliable result."⁴⁷

A recent well-publicized debate over a change in the Declaration of Helsinki illustrates the FDA's role in assuring the usefulness of clinical trials and the validity of evidence used to support new drugs. In 2000, the World Medical Association proposed this substantial modification of the Declaration of Helsinki, including paragraph 29:

The benefits, risks, burdens and effectiveness of a new method should be tested against those of the best current prophylactic, diagnostic, and therapeutic methods. This does not exclude the use of placebo, or no treatment, in studies where no proven prophylactic, diagnostic, or therapeutic method exists.⁴⁸

This paragraph essentially barred the use of placebo controls whenever there was existing therapy, even for conditions where a short period of nontreatment represented no risk at all of harm to the patient, such as in trials of mild analgesics, antimigraine drugs, antihistamines, anxiolytics, hypnotics, baldness treatments, or dermatologic treatments. This proposal was not accompanied by any rationale or ethical justification, and would have made it difficult or impossible to evaluate many treatments properly.

Just months before, FDA scientists had published two papers exploring both the ethics of placebo-controlled trials and the interpretive problems posed by the active-control noninferiority trials that are the alternative to placebo study design.^{44,45} They had pointed out that there was no ethical basis for objecting to placebo when receiving it would not lead to harm and that active control trials are uninterpretable in evaluating many symptomatic conditions. In addition, in 2000 the International Conference on Harmonisation also noted these interpretative problems and enunciated a different ethical standard in a guidance document called "Choice of Control Group and Related Issues in Clinical Trials."²² When there is no serious harm, the ICH said, it is "generally

considered ethical to ask patients to participate in a placebo-controlled trial, even if they may experience discomfort as a result," although patients must be given treatments that prevent serious harm—such as death or irreversible morbidity—if such treatments are available.²²

Concerned that the Declaration of Helsinki's paragraph 29 would make it impossible to provide valid evidence of effectiveness for many classes of drugs, representatives of the FDA, the National Institutes of Health, the Department of Health and Human Services, many academics, and representatives of the World Medical Association participated in conferences and meetings that led to a clarification of paragraph 29 in 2001. The "clarified" paragraph said placebo-controlled trials may be ethically acceptable, even if there is effective therapy, under the following conditions:

1. Where for compelling and scientifically sound methodological reasons its use is necessary to determine the efficacy or safety of a [treatment], or
2. Where a prophylactic, diagnostic, or therapeutic method is being investigated for a minor condition and the patients who received placebo will not be subject to any additional risk of serious or irreversible harm.⁴⁸

This resolved the apparent absolute ban on placebos but left remaining questions, notably the doubtful ethics of suggesting that when a placebo was needed for interpretability, known life-saving treatment could be omitted. That was surely not intended, and such a study would be considered unacceptable by the FDA and most others. There has generally been agreement with the FDA's and ICH's position on placebos.^{49,50}

The unusually public FDA effort to preserve the option of using placebo controls when they were needed and when patients would not be harmed by their use was a visible part of the continuing effort by the FDA to assure that well-designed studies provide the evidence of effectiveness and safety the public and medical community expect and deserve.

Conclusion

Familiar ethical issues, such as autonomy and patient protection, are implicit in much of what the FDA does in the course of regulating the clinical studies that are necessary for product development. But the need to treat disease, especially when no good therapy exists, and the importance to physicians and patients of having reliable information introduce another set of ethical concerns that involve the methods used to assess treatments and the level and quality of evidence needed to support wide availability and marketing. By virtue of its responsibility and its concerns and interests, the FDA has been at the forefront of the development of effective methods of drug evaluation and the interpretation of results—two issues not always recognized as having ethical implications.

Informed Consent

This page intentionally left blank

A History of Informed Consent in Clinical Research

This chapter traces the evolution of informed consent as a concept and practice in biomedical research, attending to the evolving content and justification of consent, and when possible, the actual consent practices of researchers. We include the predecessors of informed consent, some of which bear only a faint resemblance to the concept and practice as we understand them today. These precursors lack what are now considered essential features of informed consent, having evolved from mere acquiescence to become informed, comprehending, and voluntary. As there was no clear policy delineation between medical research and clinical care until perhaps the 1960s, we find that the evolution of informed consent doctrine occurred in both contexts and actually helped to distinguish these medical encounters.

The plasticity of informed consent can be attributed not only to the emergence of new medical sciences, diseases, and research contexts, but also, and more importantly for the purposes of this chapter, to the growing collective understanding of and demands for the ethical treatment of persons who participate in research. The assessments and distinctions we make among various conceptions of consent reflect a currently and commonly held normative account of informed consent. As such, our analysis tracks whether consent is informed, comprehending, voluntary, and justified on the basis of individual autonomy.¹

These essential features of informed consent have been forged in response to two persistent themes in research with humans: the misrepresentation of research and the unfair selection of participants. Historically and currently, the research community often has faltered in its duty to present sufficient and clear information about the nature, purpose, risks of, and alternatives to research and to clearly distinguish research from clinical care. Because

medical research emerged within the conceptual parameters and physical settings of clinical practice, the task of distinguishing one from the other took researchers and onlookers more than a century. The distinction was not formally codified until the 1960s and not widely recognized until the early 1980s. Still, the tendency to present research as a form of therapy remains today. Informed consent doctrine also evolved in response to researchers' failures to ensure that participants had the capacity to decide, to fully understand the information presented, and to make truly voluntary decisions. Together these features of informed consent—full disclosure, comprehension, and voluntariness—are intended to promote the autonomy of potential participants, enabling them to make choices about research participation that align with their values and interests.

Our analysis traces the evolution of these ethical ideas more so than the reasons for their emergence and change. We point to the people, events, and movements related to or responsible for the turning points in this concept and practice in research with humans, but we do not attempt a detailed analysis of the larger societal forces within which these actors operated and activities took place. Changing conceptions of the individual and the civil rights movement, the reorganization of medicine and its delivery, and the emergence of new sciences and their accompanying power and prestige are important histories.² But these topics are beyond the scope of this chapter. This chapter also draws largely, though not exclusively, on U.S. cases and events. Much of the history of informed consent, especially in the research context, occurred in the United States, and the history in other countries often is unknown or as yet unwritten. Table 55.1 presents some important events in the evolution of the informed consent doctrine.

Table 55.1
Informed Consent Timeline

Date	Event
c. 400 B.C.	<ul style="list-style-type: none"> • Hippocratic texts, first set of Western writings about medical professional conduct, discusses truth telling, advises physicians to hide as much as possible from patients.
1260–1325	<ul style="list-style-type: none"> • Henri de Mondeville, surgeon and anatomy teacher, instructs physicians to compel obedience by threatening patients.
1724–1773	<ul style="list-style-type: none"> • John Gregory advocates public/patient education and honesty, but justified on basis of patient beneficence, not autonomy.
1746–1813	<ul style="list-style-type: none"> • Benjamin Rush, “American Hippocrates,” advocates sharing information with patients, but does not advocate seeking consent or respecting patient decisions that diverge from those of the physician.
1767	<ul style="list-style-type: none"> • <i>Slater v. Baker and Stapleton</i> cited as first informed consent case but no direct or indirect line to modern legal doctrine.
1803	<ul style="list-style-type: none"> • Thomas Percival publishes landmark work that emphasizes physician virtues; basically upheld Hippocratic approach.
1847	<ul style="list-style-type: none"> • American Medical Association (AMA) establishes and issues first code of ethics based on Percival’s work; enhanced physician authority.
1849	<ul style="list-style-type: none"> • Worthington Hooker publishes <i>Physician and Patient</i>, an uncompromising denunciation of deception in medicine. Had little impact on practice of medicine.
1874	<ul style="list-style-type: none"> • AMA condemns Cincinnati physician Robert Bartholow’s experiments on dying patient, who he claimed gave “cheerful assent.”
1884	<ul style="list-style-type: none"> • Reports of the anesthetic properties of cocaine fostered widespread self-experimentation among surgeons and medical students.
1886	<ul style="list-style-type: none"> • Boston physician Charles Francis Withington advocates that patient consent should be sought when studies involve risk and discomfort and offer no potential benefit.
1888	<ul style="list-style-type: none"> • Gynecologist James W. Etheridge advises colleagues that patient consent is essential for most difficult and risky procedures.
1891	<ul style="list-style-type: none"> • French and German physicians graft cancerous tissue onto cancer patients to see if it was contagious. Victor Cornil analyzed tissue grafted on by another surgeon; act denounced as “criminal.”
1897	<ul style="list-style-type: none"> • Prussian government enacts regulation to insure that tuberculin would “in no case be used against the patient’s will.” • Giuseppe Sanarelli announces discovery of bacillus of yellow fever and maintained that he had produced yellow fever in five patients. Act is condemned as criminal by William Osler.
Turn of 20th century	<ul style="list-style-type: none"> • Growing number of lawsuits over unauthorized surgical procedures prompts increasing use of written consent forms, even though verbal and implicit consent remain legal.
1900	<ul style="list-style-type: none"> • Written contracts used in Walter Reed’s yellow fever experiments.
1903	<ul style="list-style-type: none"> • Proposal for regulation of human experimentation (and animal cruelty) introduced in Washington, D.C., legislature, requiring disclosure of investigator’s purpose and procedures and written consent in experiments with no potential benefit. Legislation fails.
1905	<ul style="list-style-type: none"> • Boston physician Richard Clarke Cabot reports study results showing that patients and families benefit from truth about prognosis.
1906	<ul style="list-style-type: none"> • <i>Mohr v. Williams</i>, court opinion uses language of “the free citizen’s right to himself.”
1907	<ul style="list-style-type: none"> • <i>Pratt v. Davis</i> opinion cites <i>Mohr</i> language.
1907	<ul style="list-style-type: none"> • William Osler’s address to Congress of American Physicians and Surgeons proposes three criteria for human experimentation: (1) tried on animals, (2) absolutely safe, and (3) full consent.
1913	<ul style="list-style-type: none"> • <i>Rolater</i> ruling strengthens patient consent.
1914	<ul style="list-style-type: none"> • <i>Schloendorff v. Society of New York Hospital</i> produces Judge Cardoza’s widely cited opinion: “Every human being of adult years and sound mind has a right to determine what shall be done with his own body; and a surgeon who performs an operation without his patient’s consent commits and assault, for which he is liable in damages.” Subsequent cases adopted self-determination as justification for informed consent. • Walter Cannon, chair of the Council for Defense of Medical Research, requests that research participant’s consent be made a requirement of journal publication.
1916	<ul style="list-style-type: none"> • Cannon proposes uniform guidelines be developed for human experimentation. No agreement could be achieved.
1925	<ul style="list-style-type: none"> • Cannon publishes editorial in <i>JAMA</i> outlining ethics of experimentation on humans and recommends that the AMA adopt formal code explicitly recognizing patient consent. Idea rejected.
1925	<ul style="list-style-type: none"> • Army regulation to promote infectious disease research specifies that volunteers be used in experimental research.
1930–1956	<ul style="list-style-type: none"> • Only nine published articles on consent and patient authorization.
1931	<ul style="list-style-type: none"> • Germany issues world’s first guidelines for human experimentation and innovative medical therapies; later deemed more adequate than Nuremberg Code.
1932	<ul style="list-style-type: none"> • Richard Clarke Cabot develops code of conduct for hospital physicians requiring patient consent.
1932	<ul style="list-style-type: none"> • U.S. Public Health Service begins Tuskegee Syphilis study (1932–1970). • U.S. Navy requires research volunteers to be “informed.”

Table 55.1
(Continued)

Date	Event
1941	<ul style="list-style-type: none"> • John Bonner, 15-year-old black student in Washington, D.C., seriously harmed by experimental skin graft conducted without his or his parent's consent; court rules in favor of physician.
1943	<ul style="list-style-type: none"> • Secretary of Navy requires all research receive prior approval from secretary; Navy uses "waivers" in wartime experiments using prisoners and conscientious objectors.
1945	<ul style="list-style-type: none"> • International Military Tribunal to try Nazi physicians and other war criminals established.
1946	<ul style="list-style-type: none"> • AMA adopts first formal statement on human experimentation.
1947	<ul style="list-style-type: none"> • Atomic Energy Commission general manager, Carroll Wilson, uses language of "informed consent."
1948	<ul style="list-style-type: none"> • Trial of Nazi physicians produces 10-principle Nuremberg Code. • AMA's expert witness at Nuremberg trials, Andrew Ivy, publishes report on which Nuremberg Code is later partly based, in <i>JAMA</i>.
1950	<ul style="list-style-type: none"> • Atomic Energy Commission (AEC)-sponsored Oak Ridge Institute for Nuclear Studies (ORINS) research hospital institutes policy to advise incoming patients of experimental nature of procedures and requires signed consent forms.
1951	<ul style="list-style-type: none"> • Perhaps first ethics code for behavioral sciences; includes a strict consent requirement.
1952	<ul style="list-style-type: none"> • Pope Pius XII endorses principle of consent for both healthy volunteers and sick patients at First International Congress of Neuropathology.
1953	<ul style="list-style-type: none"> • Department of Defense, following proposal by Armed Forces Medical Policy Council, adopts Nuremberg Code for defensive research on atomic, biological, and chemical weapons. • Department of Health, Education and Welfare adopts policy on research for NIH's new hospital devoted to experimental work; includes detailed definition of informed consent. • American Psychological Association adopts ethics code that includes a strict consent requirement, which remained in tension with profession's routine use of deceit as a methodology. • Irwin Berg publishes article in <i>American Psychologist</i> arguing that research is unethical if informed consent not obtained.
1953-1954	<ul style="list-style-type: none"> • Army-sponsored, secret research carried out under supervision of Harvard's Henry Beecher in which hallucinogens given to uninformed healthy persons.
1954	<ul style="list-style-type: none"> • Willowbrook study begins.
1956	<ul style="list-style-type: none"> • AEC advises Los Alamos researchers to fully inform healthy research participants.
1957	<ul style="list-style-type: none"> • <i>Salgo v. Leland Stanford Jr. University Board of Trustees</i> ruling requires physicians to disclose all pertinent information, including risks and alternatives.
1958	<ul style="list-style-type: none"> • Veterans Administration's research program recognizes consent requirements for participants.
1959	<ul style="list-style-type: none"> • National Society for Medical Research acknowledges Nuremberg Code as Western world's guide to research. • Henry Beecher publishes "Experimentation in Man" in <i>JAMA</i>.
1960	<ul style="list-style-type: none"> • <i>Natanson v. Kline</i>.
1961-1962	<ul style="list-style-type: none"> • Law-Medicine Institute Study finds that few institutions have procedural guidelines governing research with humans.

Prehistory: Voluntary Consent

The emergence of new sciences, technologies, and social structures during the 19th century ripened the practice of medicine for research on humans.³ Once associated solely with the physician's role as healer and provider of care, medicine during the 1800s increasingly became associated with the physician's role as experimenter and collector of data. By the century's end, medical experimentation had redefined the practice and image of medicine

in the United States and generated considerable agreement among members of the public and medical profession about the ethical criteria that should guide research.³ The relative safety of untried treatments and procedures, the possibility of therapeutic benefit, and the voluntary consent of patients and participants were considered essential for ethical research.³

These ideas remain relevant 100 years later. They have undergone significant analysis, augmentation, and transformation as the result of focused, sustained discussion in the latter half of the

20th century. During the dawn of medical research, however, the formulation of ethical criteria did not benefit from focused discussion on how to protect the health and dignity of persons while enabling the advancement of medical science. Protagonists and antagonists were engaged in a battle over more basic questions about whether human experimentation should be permitted at all and whether participant consent was even necessary. Inchoate ethical criteria were often embedded in attacks on and defenses of physicians' nascent forays into medical research. "Hostile exchanges, extravagant accusations, and vehement denials eclipsed any candid public discussion of the moral problems posed by clinical and laboratory research," writes historian Susan Lederer.³

Many critics who sought to abolish this novel enterprise belonged to a movement to protect not only human beings, but also animals from medical experimentation. The antivivisection movement, formally organized in the United States in 1866 with the establishment of the American Society for the Prevention of Cruelty to Animals, was originally devoted solely to the abolition of animal experimentation, but grew to contain many factions and over time split into separate movements. A reformist faction came to view the inclusion of humans, particularly vulnerable groups such as children, as central to its mission. Lederer has argued that "American opposition to animal experimentation cannot be understood independently of the expectation . . . that unrestrained experimentation on animals would culminate in the scientific exploitation of vulnerable human beings."³

At stake in this debate were not only the lives and welfare of vulnerable persons, but also the goals of medicine. As growing numbers of physicians began to search for the underlying causes of human disease and to develop new techniques for diagnosis, treatment, and prevention, their attention shifted from the therapeutic needs of current patients to research that would serve future patients.³ With this shift in the priorities of research-oriented physicians came a need for new norms. Physicians' traditional commitments to promote patient welfare and "at least do no harm" derived from the Hippocratic oath written around 400 B.C. With the advent of medical research, these commitments needed to be replaced with moral rules to guide interactions between clinical investigators and research participants.

During the latter decades of the 19th century there was general agreement that in principle patients should not be subjected to research that did not promise them benefit unless they were true volunteers. The absence of injury and willingness to self-experiment also worked to shield researchers from scrutiny. Experimentation that transgressed these ethical boundaries received sharp and certain criticism. Yet, clarity and certainty in principle yielded neither in clinician practice. None of the key terms was well analyzed. What constituted an experiment, whether research offered the possibility of benefit, when potentially beneficial research could be considered standard medical care, and what *volunteer* meant were questions mired in confusion and controversy. The issues were not academic; they had direct implications for the issue of consent. In general during this time, physician-researchers were not inclined to share their uncertainty with patient-participants. Research thought to offer potential benefits to patient-participants was often presented to patients as "medical therapy." Physicians had no duty to seek patient consent when providing therapy; on the contrary, they were considered to have a duty to hide potentially harmful information from patients. Phy-

sicians' professional ethics, from ancient Greece through much of the 20th century, required them to keep medical information from patients in the belief that doing so promoted the patients' welfare. This practice, called *benevolent deception*, justified not only withholding information from patients, but also lying, manipulation, and even threats.¹

Physicians who advocated honesty with patients were the rare exception. Influenced by Enlightenment ideas, the 18th century Scottish physician John Gregory, for example, advocated public and patient education.¹ His student, Benjamin Rush, brought those ideas to the United States, where he encouraged physicians to share much information with patients, on the belief that free choice was a condition of good health.¹ Still, Rush did not advocate seeking the consent of patients nor honoring decisions that diverged from that of the physician. The authority of physicians still ruled the day.

The absolute authority of physicians was tempered only when the risks posed by experimental treatment were significant. The advice of U.S. gynecologist James W. Etheridge to colleagues in 1888 is illustrative. He emphasized the necessity of obtaining patient consent, without coercion, when procedures were difficult and dangerous, as was the case at the time with caesarean section.³ But there was no expectation that patients be presented with information about the procedures, only that they "volunteer." The term *volunteer* not only lacked formal definition, but practice patterns surely deflated the practical force of this expectation among physicians and patients. Physician authoritarianism coupled with patients' general trust of physicians and medicine likely compelled many patients to comply with physician requests. Although patients could in principle decline participation, physician expectations ran high. Some viewed the fact of hospitalization as a license to experiment on patients.³ This expectation was a function not only of physicians' professional ethics but of blatant prejudice. Hospitals during much of the 19th century served largely as custodial institutions for poor people who were sick and dying. Some physicians viewed patients' participation in research as appropriate repayment for the free care they received.

Although consent practices left much to be desired, 19th century ideas about consent standards were more rigorous. Insight into these ideas can be gained by examining attitudes toward the involvement of various kinds of people in research. The use of members of groups deemed incapable of understanding or volunteering for research was uniformly and swiftly criticized by antivivisectionists. Those deemed most vulnerable were children living in orphanages. Others considered vulnerable were persons with cognitive impairments, poor people, new mothers and their infants, prisoners, and soldiers. Although strident antivivisectionists included professional participants (those paid for their participation) among those vulnerable to coercion because of the inducement of compensation, others endorsed the practice of compensation for research participation.³

The participant pool that yields the most interesting insights into 19th century attitudes, however, is researchers' use of themselves. Today, cases of self-experimentation are reported occasionally, but it is an uncommon practice and there is no public expectation of it. During the 19th century, however, self-experimentation was a widely accepted and some believed obligatory practice. The reasons for its widespread acceptance were not analyzed or articulated explicitly at the time;³ however, an analysis of self-experimentation yields a formula for consent that meets

current standards. Researchers considering self-experimentation would know better than anyone the purpose of the research and the nature and degree of risks; they were best prepared to comprehend this information and speculate as to potential consequences; their self-administered inoculations and applications clearly demonstrated voluntariness; and this action was grounded in autonomy by furthering their interests and promoting their values. Self-experimentation was a radical act of “self-determination.” Researchers’ consent duties to other participants would not reach such high-bar standards until well into the 20th century.

A number of events at the turn of the 20th century, however, signaled the beginning of a shift in researchers’ duties to participants. Instances of self-regulation, increased efforts by antivivisectionists to regulate human experimentation, and landmark court decisions regarding medical care began a shift in attention from a researcher’s duty to obtain consent to the content and quality of consent. Proposed and implemented reforms addressed issues such as disclosure requirements, written consent forms (then usually called *contracts*, *releases*, or *waivers*), decision-making capacity, and fairness in participant selection, albeit all in cases of research with no intended benefits. Consent standards for potentially beneficial research would continue to languish in the shadows of the Hippocratic tradition of benevolent deception for decades to come.

In 1900, in what seems to be the first such case, researchers used written contracts with participants. The yellow fever research conducted in Cuba led by Walter Reed required potential participants (American soldiers and local workers) to sign written agreements that outlined the risks and benefits of participation (see Chapter 1). The agreement explained that exposure to yellow fever endangered participants’ lives; it also implied that the chances of becoming infected on the island were great and that intentional infection would ensure access to the “greatest care and most skillful medical service.”³ Scholars suggest that the written contracts were flawed in several respects: They offered compensation excessive enough to exert undue pressure on potential participants; they overstated the inevitability of natural infection; and they understated the danger to life posed by yellow fever. Nonetheless they “marked a significant departure in the history of human experimentation,”³ according to Lederer.

That same year, pressures to regulate human experimentation came from outside the medical profession. Antivivisectionists persuaded an ally in the U.S. Senate to propose a bill to regulate human experimentation. Jacob H. Gallinger, a physician and past surgeon general of New Hampshire, introduced a proposal to regulate research in the District of Columbia. Senate Bill 3424 addressed requirements for prior disclosure of the purpose of and procedures involved in research, written consent, and protection of vulnerable populations. The bill would have made it illegal to do research with a long list of people incapable of granting consent or those especially vulnerable to coercion.³ The bill failed due to fierce and effective lobbying by the American Medical Association (AMA), which two years earlier had established a task force to track such legislative efforts.

The failed Senate bill and Walter Reed’s yellow fever study are significant for several reasons. Prior to 1900 debate centered primarily on a researcher’s duty to obtain consent in advance of experimentation. Reed’s investigation and the Senate bill began to raise the bar by focusing on the content and quality of consent. To different degrees, they addressed the information to be disclosed

to potential participants. By requiring written consent, they also could be interpreted as efforts to convey the seriousness of research participation and to promote careful consideration among potential participants. Of course, sheer self-interest may also have been operative. As researchers became increasingly aware of cases in which physicians were successfully prosecuted for transgressing the bounds of ethical research, written contracts may have been seen as mechanisms for self-protection.

One such case was that of German bacteriologist Albert Neisser, who discovered the leprosy bacillus and gonococcus. His testing of a syphilis vaccine on three young girls and five female prostitutes, who were neither informed nor asked for their consent, resulted in Neisser’s criminal prosecution and culminated in extensive German legislation.³ In 1900, the German minister for religious, educational, and medical affairs issued a directive that required a “proper explanation of the possible negative consequences” of the experiment and that insisted that the person give his or her “unambiguous consent.”⁴ Despite all this, the directive “was not legally binding and little is known of its impact on human experimentation,”⁴ according to Vollmann and Winau. Thirty-one years later, the Reich government issued detailed and formidable guidelines that distinguished between therapeutic and “non-therapeutic” research and required consent from participants. These guidelines were not annulled during the Nazi period in Germany but tragically had no deterrent effect on Nazi physicians during World War II⁴ (see Chapter 2).

In the same period, a number of U.S. lawsuits over unauthorized surgical procedures, along with increasing use of hospitals by middle- and upper-class patients, sensitized surgeons to the need for more formalized consent records, even outside the research context.⁴ Four court decisions within the first 14 years of the 20th century introduced important new ideas about the nature and justification of consent. The 1905 *Mohr v. Williams* (Minnesota Supreme Court), 1906 *Pratt v. Davis* (Illinois Supreme Court), 1913 *Rolater v. Strain* (Oklahoma Supreme Court), and 1914 *Schloendorff v. Society of New York Hospital* (New York Court of Appeals) cases are largely responsible for developing the basic features of informed consent to medical care in U.S. law.¹

These cases were preceded by a 1767 English case, *Slater v. Baker and Stapleton*, often cited as the first medical consent case.¹ Although the patient’s consent was at issue in this case, the judicial reasoning would in subsequent centuries be categorized as malpractice law.¹ Leading scholars claim there “is no direct, or even indirect, line between *Slater* and the modern legal doctrine” of informed consent.¹ The judicial reasoning in the U.S. cases, however, reveals a growing appreciation for the patient’s decision-making process and right to self-determination. Together these court decisions raised expectations for physician disclosure, expanded patients’ rights to specify the meaning and content of consent for particular procedures, and justified informed consent on grounds of patient autonomy.^{1,5} Indeed, the court’s language in *Schloendorff* would become the most widely quoted in the current informed consent literature.¹ Technically it was not a consent case, and the court neither found a violation of consent nor commented on consent requirements. Nonetheless, Justice Benjamin Cardozo’s language became a classic statement for patient self-determination: “Every human being of adult years and sound mind has a right to determine what shall be done with his own body; and a surgeon who performs an operation without his patient’s consent commits an assault, for which he is liable in damages.”¹

Two years later, the chair of the AMA's Council for the Defense of Medical Research used strikingly similar language in the context of research.

In 1916, Walter Bradford Cannon recommended uniform guidelines for human experimentation and published a sharply worded editorial in the *Journal of American Medical Association* in response to a young researcher's morally outrageous experimentation on six syphilitic, parietic patients at Pontiac State Hospital in Michigan. Cannon wrote, "There is no more primitive and fundamental right which any individual possesses than that of controlling the uses to which his own body is put. Mankind has struggled for centuries for the recognition of this right. Civilized society is based on the recognition of it. The lay public is perfectly clear about it."⁶ Udo Wile's failure to obtain consent from the patients whose brains he punctured to determine the presence of active spirochetes, his use of a dental drill to do so, and his utter lack of contrition for doing either worked together to prompt even staunch defenders of medical research, such as Cannon, to propose uniform guidelines. Cannon's recommendation was not heeded by his American Medical Association (AMA) colleagues, who were preoccupied by the United States' entry into World War I. U.S. clinical investigators would continue to work without guidelines until 1946, when the AMA amended its code of ethics as part of its involvement in the prosecution of Nazi physicians for atrocities committed during World War II.

In the decades between the world wars, researchers would continue to struggle with the meaning of voluntary consent in principle and practice. A number of research activities set in motion during the 1930s came under scrutiny only decades later, including the notorious U.S. Public Health Service syphilis study involving poor African American men in Tuskegee, Ala., and the advent of radiation medicine, which led to the abuse of hospitalized patients and others.² During the 1930s, however, U.S. medical researchers experienced a reprieve from public scrutiny. The U.S. medical profession was held in unprecedented esteem in the first decades of the 20th century as the public began to become aware of and benefit directly from the fruits of medical research, such as the discovery of insulin and sulfa drugs.³ People also became aware of increasing numbers of researchers who lost their lives by "going first." Novels popularized the yellow fever research led by Reed and memorialized the medical "heroes" and "martyrs" who lost their lives for the sake of research.³ Although the antivivisectionists regained their momentum after World War I, their crusade against researchers' use of vulnerable groups did not persuade most Americans.³ Indeed, as World War II approached and throughout the war effort, experimentation on those unable to consent was viewed by many Americans as no different than the military draft. The sentiment that all citizens needed to contribute to the war effort—whether against totalitarianism or disease—seemed to justify the use of vulnerable persons, even when their participation came "at great personal cost," according to Rothman.⁷

This positive attitude toward medical research persisted even after World War II, when Nazi physicians and administrators were indicted for horrific crimes committed on concentration camp inmates in the name of "medical science" (see Chapter 2). The 1947 judgment in the Nuremberg Doctors' Trial, *United States v. Karl Brandt et al.*, not only addressed the defendants' guilt or innocence, it produced 10 principles to guide ethically justifiable research. These 10 principles—the first of which is the absolute requirement to obtain the participant's voluntary consent—

make up what posterity has come to know as the Nuremberg Code (see Chapter 12). The Nuremberg Code defines consent as having four fundamental characteristics: voluntary, competent, informed, and comprehending.¹

It appears the judges drew the 10 principles from two sources: a 22-page report prepared by physiologist Andrew Ivy, who had been appointed by the AMA to testify on medical ethics at the trial, and a memorandum written by their court-appointed expert, neurologist Leo Rosenberg. Ivy's report also was sent to the AMA's Judicial Council (the ethics group), which in December 1946 approved a distilled version of Ivy's rules and published them in *JAMA*.⁸ This was the first time formal guidelines for research with humans were widely available to U.S. medical researchers; the guidelines required both voluntary consent and prior animal testing.

The consent provisions in both the AMA amendment and the Nuremberg Code seem to have been interpreted at the time as applying only to healthy volunteers, not patient-participants. Although transcripts from the trial suggest that Ivy viewed patients and healthy volunteers as morally equivalent for purposes of obtaining voluntary consent, and it is clear that Rosenberg did, this view did not find expression in Ivy's reports. "At that time, and for many years to come, patient trust and medical beneficence were viewed as the unshakable moral foundations on which meaningful interactions between professional healers and the sick should be built," according to the 1996 report of the Advisory Committee on Human Radiation Experiments.⁹

Despite the drama of the Nuremberg trials and the events leading up to them, the U.S. public remained relatively unaware of them. Departing from its watchdog role during the late 19th century, the press gave only limited coverage to the trials. Assuming that research with humans conducted in the United States occurred only with volunteers, most of the press viewed it approvingly. A small number of press accounts voiced concern about human experimentation taking place in the United States. Some accounts focused on experiments with volunteers; others on research with patients.¹⁰

Mainstream physicians who were aware of the Nuremberg trial and resulting code had varied reactions to them. Some physicians believed the code had no relevance to them or their work. Alienated by the gruesome nature of the experiments and settings in which they took place, these physicians viewed the Nuremberg Code as unnecessary for the ordinary physician. Others felt personally implicated by and compelled to follow these new standards, but unsure how to go about it in practice. Groundbreaking work by medical sociologist Renée Fox during the early 1950s, in which she followed the daily activities of physicians and patients in a metabolic research ward, suggests that physicians had difficulty translating the abstract norms into action guides for their work.¹⁰ Isolated anecdotes and events throughout the 1950s suggest that some physicians did struggle to learn more about and comply with these new standards for clinical research, but they were a distinct minority.¹⁰

In the United States, the Nuremberg Code's greatest impact was felt within the defense establishment as it entered the cold war. The newly created civilian Atomic Energy Commission (AEC) and the Department of Defense (DoD) were planning for defense against atomic, biological, and chemical warfare and viewed research as essential to their plans. The national security establishment's discussion of the Nuremberg Code was discovered by the

Advisory Committee on Human Radiation Experiments (ACHRE), established in 1994 by President Bill Clinton in response to an *Albuquerque Tribune* series published the year before on human radiation experiments conducted by the federal government during the Cold War. Although some of the experiments had been the focus of a 1986 congressional investigation,² they did not catch the public's attention until journalist Eileen Welsome reconstructed the story of 17 plutonium injections of hospitalized patients in 1945. President Clinton tasked the ACHRE with unearthing the history of human radiation experiments conducted by the government and intentional releases of environmental radiation between 1944 and 1974, identifying ethical and scientific standards for evaluating these events, and making recommendations to prevent such activity in the future.

Early Signs of Change: Written Consent

The AEC developed rules for research with human participants that were progressive but not widely communicated or implemented. Yet they were the first known instance in which the term *informed consent* was used and the first time sick patients were included in the consent provisions. Created in January 1947 to oversee the nation's nuclear stockpile, the AEC had good reason to develop mechanisms to prevent abuses occurring during research with humans.¹¹ The AEC inherited the contracts and projects of the Manhattan Project, which included secretive and sensitive studies involving the injection of 17 hospitalized patients with plutonium. The AEC also would be the sole distributor of radioisotopes used in thousands of human radiation experiments and an equally rich source of funding for other research.

In preparation for this research and in light of the human experiments already conducted under the auspices of the Manhattan Project, AEC General Manager Carroll Wilson spelled out rules for research with humans in two separate and slightly different letters in April and November 1947. Both letters are significant for requiring consent from patient-participants. Wilson specified that the "patient give his complete and informed consent in writing."¹¹ Although he neither explained nor defined the meaning of informed consent, Wilson's union of the words *informed* and *consent* predated by a decade what scholars had thought to be its earliest use.¹¹

The AEC had ample opportunity to disseminate Wilson's rules on human participant research, but largely failed to do so. Frequent requests came from researchers under contract with the AEC, and the AEC routinely disseminated educational and administrative materials for funding opportunities and radioisotope applicants. Although Wilson's research rules were not disseminated, the ideas contained in them penetrated at least one research setting. The AEC-sponsored Oak Ridge Institute for Nuclear Studies (ORINS), which opened in 1950, implemented a local process for informing patients of research risks. The process provided potential participants written information and required their signature to indicate they were "fully advised" about the "character and kind of treatment and care," which would be "for the most part experiments with no definite promise of improvement in my physical condition."⁹

During this same period, the DoD also faced ethical questions regarding the use of humans in atomic, biological, and chemical weapons research. Standards that would ultimately be signed into

effect in February 1953, like the AEC policy, would both raise the bar for consent requirements and suffer from a lack of dissemination and implementation. The policy ultimately endorsed is notable for being the only instance of a U.S. agency (or any agency of any government) adopting the Nuremberg Code, an event that took place amid deep and widespread opposition among internal Pentagon advisory committees to regulations of any kind.¹² Concern about the DoD's legal authority to conduct atomic, biological, and chemical research on humans, however, forced the question. Still, the discussions that took place in internal Pentagon committees focused not on how such research should occur, the matter addressed by the Nuremberg Code, but rather on whether it should take place at all. Preoccupied with the wrong question, officials failed to address vitally important ones, such as the meaning of *volunteering* in the military context.¹²

Two years of discussions led to the conclusion that research with humans was unavoidable. Seeking input from other government agencies developing such research rules, the DoD involved the National Institutes of Health (NIH) in some of its policy deliberations. As the emerging leader in biomedical research, with plans to open a state-of-the-science research hospital, the NIH had started drafting human research rules. When the NIH Clinical Center opened in 1953, its policy required of all research participants, including patient-participants, "voluntary agreement based on informed understanding," and it required signed consent from some patient-participants involved in especially risky research.⁹ One year later, signed consent forms were required of all healthy volunteers. Although the AEC's policy requiring consent from patient-participants predated this provision by six years, the NIH policy was a far clearer expression and endorsement of the requirement to obtain consent from patient-participants.

DoD policy would parallel the AEC and NIH Clinical Center policies. Eventually referred to the top-ranking medical advisory body in the Pentagon at the time, the Armed Forces Medical Policy Council (AFMPC), the matter received prompt attention from Stephen S. Jackson, who staffed the council and was an assistant to the Pentagon's general counsel. Jackson argued that the Nuremberg Code had international judicial sanction and should be adopted verbatim with the addition of a statement prohibiting the use of prisoners of war in research. Jackson's superior, Assistant Secretary for Manpower and Personnel Anna Rosenberg, the highest-ranking woman to serve in the defense establishment up to that time, added the requirement for written and witnessed consent. The AFMPC's proposal passed swiftly into policy when President Eisenhower's newly appointed secretary of defense, Charles E. Wilson, approved it shortly after taking office.

Had Wilson explored the level of support for the policy, he would have discovered support lacking among those who would have to implement it.¹¹ As Wilson signed the policy into effect, defense officials continued to debate whether regulations were necessary at all. Implementation was further complicated by the means used to communicate it: a top secret memo to the secretaries of the Army, Navy and Air Force. The memo remained classified until August 1975, although efforts were made to communicate its content down the chain of command. Levels of awareness varied, interpretations were inconsistent, and implementation sporadic throughout the 1950s and 1960s; however, by 1973, the Army, Navy, and Air Force had promulgated regulations that required written informed consent from both patient-participants and healthy volunteers.⁹

Opposition to formalizing and regulating consent standards was expressed not only by military and mainstream researchers but also by some critics of medical research, most notably Harvard physician and researcher Henry K. Beecher. A forceful and frequent critic of research abuses, Beecher also opposed rule-based regulations externally imposed on clinical researchers. His role in exempting Harvard researchers from the Army's newly endorsed Nuremberg rules in 1961 illustrates his persuasive power. When the assistant dean of Harvard Medical School, Joseph W. Gardella, expressed concern to his board about new rules that applied to their army medical research contracts, Beecher, in his capacity as a board member, crafted a statement of Harvard's principles for human research.⁹ His statement not only served to exempt Harvard from the Army's rules but a later paper of his became one of the most influential articles in research ethics.¹³

Beecher faulted the Nuremberg Code on three grounds. First, he believed the Code's absolutist consent provision would prove problematic in practice; he like many medical researchers believed the complexities of some research would be too difficult to communicate to participants, especially those burdened by serious illness and disease. He also objected to the Code's requirement that research be neither "random" nor "unnecessary in nature." Beecher believed valuable medical tools and drugs, such as X-rays and penicillin, could be attributed to chance experimentation and that the phrase *unnecessary in nature* defied definition. Finally, and most importantly for Beecher, he believed that rules would not prevent research abuses.⁹ In Beecher's view, unscrupulous researchers would conduct unethical research, regardless of rules prohibiting it. That pre-Nazi Germany in 1931 issued human participant research rules that now are described as more adequate than the Nuremberg Code makes his point in tragic terms.¹

Beecher's suggested solution to research abuse was self-regulation by the "truly responsible investigator."¹³ Physicians needed to be sensitized to the complexity of the moral problems in human research, but they should not be forced to comply with "rigid rules."¹ Beecher's faith in virtuous physician-researchers extended to participant consent. Beecher endorsed the necessity of obtaining consent but believed disclosure should vary in accordance with the type of research and the pool of participants. Like most physicians of his time, he did not believe researchers needed to fully disclose information to patient-participants who might benefit from the research. For Beecher, sick patients remained a "protected" class.

Beecher's influence was significant and, ironically, helped to promote the very regulatory regime he resisted. His identification of research abuses prompted the Public Health Service to commission a study of ethical and administrative practices of U.S. researchers and their institutions. The 1961 study, conducted by the Law-Medicine Research Institute at Boston University, found vast inconsistencies among institutions and concluded that "internal institutional regulation of research was generally insensitive and sporadic."¹ Moreover, transcripts revealed that status as a patient not only failed to protect people, but endangered them. Physician interviews portray attitudes and practice patterns disturbing not only by today's standards but also, no doubt, by those of Beecher in 1960. Physicians reported their discomfort with informing and seeking consent for research not intended to benefit patients and their ease with enrolling unconsenting patients in low-risk research; their view of patients as "rats from a laboratory" and their own status as "king or queen"; and their facility at pre-

ssuring sick patients into participation and their expectation that indigent patients repay their debt through research participation.⁹

Meanwhile, physician practices in the clinical context were coming under intense scrutiny. The 1957 *Salgo v. Leland Stanford Jr. University Board of Trustees* ruling by a California appellate court continued to press consent standards in the direction of patient rights. Martin Salgo, who suffered permanent paralysis after undergoing translumbar aortography, sued his physician not only for medical negligence but also for failing to disclose the risk of paralysis. The court ruled in his favor and in its opinion used the term *informed consent*. The court held that Salgo had clearly consented to the procedure but without all the pertinent facts, which it ruled precluded his ability to make "an intelligent consent."⁵ Although the phrase *informed consent* had been used a decade before in Carroll Wilson's 1947 memo to a handful of AEC contract researchers and medical advisors, *Salgo* put informed consent on the map for the mainstream U.S. medical community working in a clinical rather than a research context.

The court's explicit attention to the information on which a patient's decision is based bolstered the patient's right to make an autonomous choice. The court tempered this move toward patient autonomy with a step back toward physician paternalism: "[I]n discussing the element of risk a certain amount of discretion must be employed consistent with the full disclosure of facts necessary to an informed consent."⁵ The court provided no analysis or explanation of the allowable *discretion*, leaving patient self-determination at the feet of physician judgment. As Jay Katz has noted of the ambiguity, "[T]he court did not appreciate the futility of its endeavors, for it gave an undefined task to a group that has had neither the experience with nor the commitment to patient self-determination."⁵

Great Scandals of the 1960s and 1970s

Deference to professional judgment, especially physician paternalism, imploded in the 1960s. A series of incendiary cases cast a bright light on researchers' struggle to balance the dual responsibilities of being both investigators and physicians. Congressional hearings, scholarly critiques, print and broadcast media coverage, and the public's outrage in response to these cases all led to significant reforms by the mid-1970s. For the first time, informed consent for research with humans was put before a public body for explicit discussion, analysis, and recommendation. The resulting reports and regulations would plant informed consent firmly in the ground of patient autonomy and would expand and elaborate on the meaning and the requirements of informed consent.

Tragic events surrounding the use of the sedative thalidomide set this reform process in motion. Thalidomide was approved for clinical use in Western Europe and was used extensively, especially in West Germany and Sweden, before its devastating effect on fetuses was identified. Although safe for pregnant women, the drug commonly caused fetuses to be born with missing or deformed limbs. The drug was considered experimental in the United States, yet physicians were given free samples by pharmaceutical companies and paid to collect patient data, a practice that led to some birth defects in newborn infants in the United States. Hearings held by Tennessee Senator Estes Kefauver, combined with television coverage and corresponding public outcry, helped to push the passage of the 1962 Kefauver-Harris amendments to the Food,

Drug, and Cosmetic Act, which among other conditions required patient consent when testing investigational drugs.

This was the first time in U.S. history that researchers were required to inform participants of a drug's experimental nature and obtain their written consent.¹ However, just as the *Salgo* ruling retreated from patient consent in deference to physician discretion, so, too, did the new Food and Drug Administration (FDA) policy. Physicians were not required to obtain consent when it was "not feasible" or was deemed not in the best interest of the patient.¹ The vaguely worded best interest clause and FDA Commissioner George P. Larrick's refusal to clarify it caused confusion for the next two years.

In 1966 the new FDA Commissioner, James Lee Goddard, appointed a small task force of FDA officials to study and settle the matter. The resulting policy drew heavily on the Nuremberg Code and the recently passed World Medical Association (WMA) policy regarding human experimentation, commonly known as the Declaration of Helsinki (see Chapter 13). Importantly, the FDA policy accepted wholesale the WMA's distinction between *therapeutic* and *nontherapeutic* research and its accompanying consent standards. The Declaration of Helsinki embraced the Nuremberg Code's absolute requirement for consent in nontherapeutic research, but qualified consent standards for therapeutic research. Continuing the traditions of benevolent deception and therapeutic privilege, the Declaration allowed physicians to determine whether or not consent was "consistent with patient psychology"¹ It also permitted third-party consent by a legal guardian for both types of research, another noteworthy deviation from the Nuremberg Code.

This FDA policy, which applied only to experimental drugs, devices, and biologics, was one among many factors that prompted NIH Director James Shannon's advocacy of formal controls on research with humans. As the director of the largest funder of U.S. human research, Shannon's commitment to formalizing human research rules was bolstered by unprecedented public and professional scrutiny, including the lackluster results of the Law-Medicine Research Institute's study; the 1963 attempt to transplant a chimpanzee kidney into a human at Tulane University; the WMA's 1964 adoption of the Declaration of Helsinki; Beecher's high-profile activism; and, in particular, a controversial study conducted on poor, elderly patients at the Jewish Chronic Disease Hospital (JCDH) in New York City, funded in part by the Public Health Service.

The research conducted at JCDH achieved notoriety not only for what the researchers did, but also for how they did it (see Chapter 6). Principal investigator Chester M. Southam of the Sloan-Kettering Cancer Research Institute had been studying the role of the body's immune system in cancer for a decade and persuaded JCDH's medical director, Emmanuel E. Mandel, to allow him to inject 22 indigent patients with live cancer cells. Although some patients were informed orally of their involvement in an experiment, neither their oral nor written consent was sought. The failure to obtain consent was not Southam's only transgression. He failed to disclose any information about the nature and risks of the research, a well-established responsibility by this time; he proceeded without review by the hospital's research committee and over the objections of three physicians; and he used frail, vulnerable patients in research obviously intended not to benefit them but to answer a scientific question. Despite these numerous and obvious infractions, the people and institutions responsible for

them went relatively unpunished. Both Southam and Mandel were originally censured and their medical licenses suspended, but subsequently they were put on probation for one year, still a remarkable punishment for the day.⁹ Their respective institutions escaped untouched.

In response to this case, Shannon created a committee to study the issues and make recommendations. He appointed NIH's associate chief for program development, Robert Livingston, to lead the commission's work. The Livingston report, delivered one year later, recommended no changes in NIH policies and warned that policy reforms would thwart research progress and interfere with the physician-patient relationship. The report concluded that the NIH was "not in a position to shape the educational foundations of medical ethics, or even the clinical indoctrination of young investigators."¹ Disappointed but determined that NIH should play a pivotal role in ensuring responsible research, Shannon, joined by U.S. Surgeon General Luther Terry, in 1965 took his concerns to the National Advisory Health Council (NAHC), an advisory committee to the surgeon general of the Public Health Service. The NAHC affirmed their concerns and issued a statement that recommended PHS funding be given only to investigators willing to meet key ethical criteria, including obtaining the informed consent of participants.

The statement failed to define informed consent but led to the creation of landmark government regulations. In February 1966, the new surgeon general, William H. Stewart, accepted the NAHC recommendations and issued a policy that compelled PHS grantee institutions to provide prior committee review of proposed experiments and for the first time recognized patient-participants in the consent provisions. Specifically, the PHS policy required that independent review committees at grantee institutions address the following: (1) the rights and welfare of the individual(s) involved, (2) the appropriateness of methods to secure informed consent, and (3) the risks and potential medical benefits of the investigation.⁹ The policy, like the statement that inspired it, failed to address the substantive content of informed consent, leaving its meaning and criteria to determination by local committees.⁹

A detailed, substantive account of informed consent was soon after provided by the NIH Clinical Center. The new policy required an oral explanation of the research, suited to participant's comprehension level; detailed disclosure regarding the nature, purpose, and risks of the study and procedures to be performed; and signed consent forms. The policy also addressed issues such as voluntariness and compliance with FDA policy. The policy has been described as the "most careful and comprehensive statement" on informed consent up to that point in U.S. history.¹

Continued efforts to update the Department of Health, Education, and Welfare (DHEW) policy culminated in 1971 in *The Institutional Guide to DHEW Policy on Protection of Human Subjects*, better known as the Yellow Book because of the cover's color. The policy extended requirements to all DHEW programs and activities, provided detailed analyses of a number of issues, and retained the procedural requirement of committee peer review. Ironically, informed consent was both strengthened and weakened. The policy required that consent be obtained from both patients and healthy volunteers, or authorized representatives, after explaining the procedures; describing the risks, discomforts, benefits, and alternatives; offering to answer all questions; and ensuring that participants know they may withdraw consent and discontinue at any time.¹ However, the policy permitted consent to be either oral

or written, obtained after research participation if a complete and prompt briefing was done, and in some cases to be considered implicit in the act of volunteering, if the nature and terms of the research were adequately advertised.¹ The policy's inadequacy would soon be illustrated.

Meanwhile, Beecher continued his activism and in 1965 he broke with professional protocol by taking his concerns to the press. Addressing a group of science journalists, Beecher presented 22 instances of ethically dubious human research. He pointed a finger at the nation's leading medical schools, university hospitals, the military, governmental institutes, industry, and even himself. His presentation was eventually published by the *New England Journal of Medicine* in June 1966 (after having been rejected by *JAMA*) and spurred several articles in popular magazines. The public's gaze now joined that of the U.S. government; when Willowbrook and Tuskegee caught light, all would be watching.

One of the studies Beecher cited in his article was conducted by New York University (NYU) researcher Saul Krugman at the Willowbrook State School for the Retarded on New York City's Staten Island (see Chapter 7). Willowbrook posed vexing questions about informed consent, research with children, and risk-benefit analysis. The institution housed children with severe mental and physical disabilities, most of whom had an IQ below 20 and many of whom were incontinent. According to Krugman, nearly all the children contracted a fecally borne, mild strain of hepatitis within 6 to 12 months of residency. Krugman and his team were highly regarded scientists, having identified hepatitis A and B in 1959. In their attempt to develop a prophylaxis, they deliberately infected some of the newly admitted children and cared for them in a well-equipped, well-staffed hepatitis unit, where the children were protected from exposure to other infectious diseases prevalent at the school. Only children whose parents consented were enrolled in the study, and wards of the state were never included. Moreover, the research received approval from Armed Forces Epidemiological Board and an NYU committee. The researchers' approach to seeking consent from the children's parents evolved over the years, as Willowbrook's population doubled from 3,000 to 6,000. Originally the researchers sought consent after conveying information about the research to parents through personal letter or interview; eventually they resorted to group discussions of the project.

The debate that surrounded this case, like so many before it, turned on assessments of *therapeutic benefit*, validity of consent, and the fair selection of participants. That the Willowbrook case involved institutionalized children with severe cognitive impairments made it all the more controversial. Research with children would not receive clarification and guidance until 1983, when the federal government adopted regulations based on the work of the nation's first federally appointed bioethics commission. Subpart D of these regulations permits children to be used in research with the assent of the child, if the child is capable of assent, and the permission of the parent(s) only after meeting certain risk requirements. For research involving possible benefit to the child, the risk must be "justified by the anticipated benefit to the subjects," and such research is acceptable only if "the relation of the anticipated benefit to the risk is at least as favorable to the subjects as that presented by available alternative approaches."¹⁴ The requirement to obtain the assent of the child may be waived for research that holds out an important medical benefit to the child that can be received only in a research context.¹⁴ Research not

presenting possible benefit must present "no greater than minimal risk." Moreover, participation in research involving more than minimal risk may be approved by the reviewing institutional review board (IRB) only if the risk "represents a minor increase over minimal risk, the procedures involved are commensurate with the general life experiences of subjects, and the research is likely to yield knowledge of 'vital importance' about the subjects' disorder or condition."¹⁴ Riskier research may be approved only by the secretary of the Department of Health and Human Services (DHHS), following appropriate review.

Against the backdrop of such carefully articulated guidelines, one can fault the Willowbrook physicians on a number of counts. But at the time, the issues were far less clear. The physicians justified their research on grounds that they had obtained parental consent and offered the children the therapeutic benefits of "immunity," protection from other infections, and skilled medical care.¹⁵ Critics, however, pointed out that the children might have become infected and developed immunity naturally, and that they were denied possibly protective doses of gamma globulin, thought by many to be an established and effective means of controlling viral hepatitis and shown to reduce the incidence of hepatitis by up to 85%. Critics also attacked the informed consent on procedural and substantive grounds.¹⁵ The consent forms suggested the children would receive a vaccine; admissions to the special unit were expedited; when overcrowding precluded admission to the school, the hepatitis unit continued to accept children; and group meetings were characterized by financial and social pressure. The question of whether these severely retarded children possessed even limited capacity to assent to research was left untouched. This case continues to be debated and has become a paradigmatic research ethics case.

On the heels of Willowbrook came a case of blatant research abuse. The notorious 40-year Tuskegee syphilis study conducted by the U.S. Public Health Service (PHS) breached research rules well established not only in 1970 but even when the research began in 1932 (see Chapter 8). Poor African American men living in and around rural Tuskegee, Ala., were used by PHS researchers to study the natural history of syphilis. Originally designed as a six- to eight-month project, the study was extended for four decades. Some 400 syphilitic men and 200 nonsyphilitic men were induced to "participate" by being told they would receive free treatment for "bad blood," a term used in the community to describe many ailments but which the researchers assumed referred to syphilis. The researchers disclosed nothing about the research to these men nor sought their consent for participating in it. The men were not told that they had syphilis or that they would not benefit from participation. Their free treatment was limited to purely diagnostic procedures such as lumbar punctures. The research protocol was designed to impede their awareness of and access to available treatments, including penicillin, which was used in the treatment of syphilis by the late 1940s.

Despite many opportunities to halt the research, the syphilis study was not stopped until a 1972 front-page article in the *New York Times* caught public attention and stirred moral outrage. The DHEW established an ad hoc panel to review the study and the department's research rules, which found them inadequate across the board. The panel ordered the research stopped and recommended the establishment of a "permanent body with the authority to regulate *at least* all federally supported research involving human subjects."¹

The panel's call for direct oversight of all federally funded research by an independent body with punitive authority was met with a compromise, delivered in the 1974 National Research Act. The Act established the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, a four-year advisory body, in return for the DHEW's conversion of research policies into regulations applicable to the entire department.⁹ The regulations required grantee institutions to establish IRBs and charged them with reviewing research proposals for safety and informed consent provisions. Informed consent requirements were made slightly more stringent, closing waiver and documentation loopholes, and all research, not just risky protocols, was required to undergo review. Still, the regulations did not apply to all federally funded research and suffered from ambiguities and unanswered questions that would become the work of the National Commission.

The National Commission was charged with developing and delivering recommendations to the DHEW Secretary. It produced seventeen reports and appendices, including the Belmont Report, which remains a touchstone for U.S. human participant research (see Chapters 14 and 19). The Commission made the first formal attempt to clearly state the ethical import of the distinction between medical research and medical practice and addressed many other issues including the role and function of IRBs, informed consent and third-party permission, and research involving vulnerable populations. Its extensive and detailed recommendations largely became U.S. government policy.¹

Central among the Commission's tasks was the development of basic ethical principles that could become the basis of research oversight, especially research with vulnerable populations. The Commission created a framework of three principles, each of which was to guide and justify a key function of the IRB process: respect for persons, beneficence, and justice. These "Belmont principles" were proposed as ethical guides and justifications for informed consent provisions, risk-benefit analysis, and selection of participants.¹⁶ The Commission's elaboration on the intent and function of respect for persons made respect for *autonomy* fundamental to informed consent. "[M]ore decisively than any previous publication in case law or research ethics, the Commission's volumes reflected the view that the underlying *principle and justification* of informed consent requirements, at least for autonomous persons, is a moral principle of respect for autonomy, and no other [emphasis in original]."¹

The Commission's attention to informed consent produced an analysis of its content and criteria that remains standard. The Commission identified three necessary conditions for informed consent: information, comprehension, and voluntariness. These conditions were used to analyze consent for vulnerable classes of participants, such as children, prisoners, and institutionalized persons with cognitive impairments. The Commission devoted a report and two appendices to informed consent, but these volumes are so complex and detailed that their usefulness for IRBs has been questioned. However, they are among the most widely read sections of the Commission's many reports.

By the time the National Commission had completed its work in 1978, informed consent had currency in mainstream U.S. society. Scholars, courts, hospital board rooms, classrooms, and state legislatures were focused on patients' rights to make autonomous decisions about their health care. Commentary on informed consent flooded the medical literature.¹ Three 1972 court rulings left

no doubt about patients' right to make medical decisions based on their values and information a reasonable person, not a medical professional, would need to know. The following year the American Hospital Association published "A Patient's Bill of Rights," which included informed consent provisions. Between 1975 and 1977, 25 states enacted informed consent legislation.¹

Revised AMA policy issued in 1981 cinched the place of informed consent in modern medicine. The AMA Code of Ethics had undergone numerous revisions since its creation in 1847, including a 1980 revision that acknowledged the physician's obligation to respect patients' rights. Not until the following year, however, did the AMA issue a policy explicitly addressing informed consent, using much of the language in one of the three landmark 1972 court decisions. The ruling by the U.S. Circuit Court for the District of Columbia in *Canterbury v. Spence* described consent as "the informed exercise of choice" based on "enough information to enable an intelligent choice."¹⁷

Post-Belmont

The National Commission's pioneering work largely became policy in 1981. The DHHS regulations were based on the National Commission's recommendations and influenced by a subsequent bioethics commission, the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research, which worked from 1980 to 1983. Established to address unresolved and new issues, the President's Commission stressed the importance of the informed consent recommendations to federal officials drafting the regulations.¹ The subsequent regulations provided in-depth guidance on informed consent, particularly disclosure requirements. In addition to disclosing the purpose and nature of the research, potential risks and benefits, and alternatives, researchers were now also obligated to provide an explanation and information about the confidentiality of records, compensation for injury and medical treatment, if necessary, and a contact for pertinent questions.¹ The new regulations also required researchers to disclose information discovered during the study that could influence someone's participation. The regulations applied to both biomedical and behavioral research, but they effectively exempted much of behavioral research by providing broad exceptions for research entailing minimal risk, such as interviews, surveys, or observational research.¹

The President's Commission continued to prove its influence. Its recommendation that the regulations be adopted by all federal agencies led to the development of what has become known as the Common Rule (see Chapter 15). Adopted in 1991 by 16 federal departments and agencies, the rule details how research with humans should be reviewed and conducted and applies to research conducted by both governmental and, in some cases, nongovernmental agencies. Although all 16 federal agencies conduct research according to the Common Rule's requirements, the administrative structure of their oversight programs varies. Any institution that conducts clinical research must make assurances that protections will be provided and enforced in order to receive federal funding.

As in the prior DHEW and DHHS regulations, the IRB continues to serve as the key protective mechanism. IRBs have the authority to approve, disapprove, require modifications of, suspend, and oversee all human research conducted at the institution. Predominant among IRBs' numerous responsibilities is ensuring

the adequacy of research protocols' informed consent provisions; however, several conditions must be met prior to considering the use of humans in research. The research must have scientific value; the research design must be sound and must achieve a reasonable balance of benefits to the participant and society over risks to the participant; and the use of humans must be absolutely necessary, and they must fairly selected.^{15,18} Only after these conditions are met can an IRB consider an investigator's informed consent provisions. The rule specifies items that must be disclosed to potential participants and emphasizes that obtaining informed consent should be an ongoing "process" of communication between researcher and participant.⁹ Ideally, the process entails an exchange of questions and answers that promotes the potential participant's ability to make a choice that aligns with his or her values and interests.

The Common Rule represents a significant achievement in many respects. It applies uniformly to all federally funded research, carries binding authority, and reflects the focused analysis and discussion of knowledgeable, dedicated members of diverse sectors of the society. The Common Rule also strives to achieve a balance of values central to U.S. society, the advancement of scientific and medical frontiers and the protection and promotion of human health and individual autonomy. Moreover, the Common Rule is fortified by a climate of heightened public and scholarly interest and scrutiny. The ethical principles of medical research are now the subject of ongoing articulation and refinement.

Still, significant gaps remain in the system of human participant protections, including informed consent provisions. Informed consent as a concept and practice was challenged by a number of scandals and new developments in the last decade of the 20th century. These scandals and developments reveal the difficulty of achieving informed consent, especially for the most vulnerable classes of participants, and even cast doubt on the adequacy of individual autonomy as an ideal.

The provision to potential participants of accurate, complete, and candid information about the purpose and risks of research continues to challenge the research community. Although significant energy and attention is now directed to the development and articulation of policy, and such policy is the subject of much public scrutiny, the actual practice patterns of researchers have proven more difficult to reform. The ACHRE's review of 125 research proposals attests to this difficulty. Together, the committee and an individual committee member's separate inquiry found in 1999 that consent forms were "flawed in morally significant respects, not merely because they are difficult to read but because they are uninformative or even misleading."⁹ Specifically, consent forms often presented inadequate information about risks that might be significant to patients; lacked important information about alternative treatments and preliminary data gathered from earlier experiments; and used the language of *treatment* and *therapy* to describe research that *might* yield therapeutic benefit even though therapy was not its purpose.

Two cases that occurred in close proximity at the turn of the 21st century highlight the research community's reluctance to share risk information with potential participants. In September 1999, 18-year-old Jessie Gelsinger died four days after receiving an infusion of new genes as part of an experiment intended to determine whether this *gene therapy* might lead to a cure for an inherited liver disease, ornithine transcarbamylase deficiency (see Chapter 10). Among the many infractions committed by the

University of Pennsylvania researchers was their failure to reveal in the consent form the deaths of four monkeys subjected to higher levels of similar gene infusions; they also failed to notify the FDA of *adverse events* that occurred in participants in the study of which Gelsinger was a part.¹⁹ The fact that Gelsinger was living a relatively healthy life, controlling his disease through medication and diet, made his enrollment in the study all the more controversial. Two years later, an asthma study with healthy volunteers at Johns Hopkins University resulted in the death of 24-year-old Ellen Roche. Like the gene therapy experiment, the study was cited for numerous infractions, including the failure to disclose risk information. The consent form failed to indicate that the drug being used to create symptoms similar to an asthma attack, hexamethonium, was not an approved medication but, rather, was intended to provoke a physiologic response.²⁰

Such deficient consent practices may mislead many potential participants into research participation. But sick patients may be particularly vulnerable. Patients with poor prognoses who have exhausted their options for medical treatment may feel that they have no choice but to participate in research; yet they also may fail to understand that they are *in fact* participating in research.⁹ A study of participants conducted by the ACHRE revealed that most patient-participants believed they would personally benefit from participation and that their physicians would not offer them opportunities that did not benefit them.⁹

These data stand in contrast, however, to a recent study of cancer patients in Phase I trials.²¹ Over 70% of patients studied understood that they might not directly benefit from the intervention, even though they hoped they would. Researchers of this study concluded that patients who enrolled "provide adequate informed consent."²¹

Still, a 1999 report by the National Bioethics Advisory Commission (NBAC) on research involving persons with mental disorders that may affect decision-making capacity reaffirmed the ACHRE's findings. In addition, NBAC found that existing policy fails to adequately guide researchers and IRBs on the complex matter of determining a person's capacity for making decisions. Mental disorders can compromise decision-making capacity to varying degrees, and no consensus exists as to what degree of incapacity counts as a lack thereof.²² NBAC made a number of recommendations, including that researchers indicate to IRBs who will conduct the assessment and which method they will use; NBAC also recommended the development of more specific guidance on the definition of decisional capacity and improved assessment procedures.²²

Important questions about decision-making capacity also have been raised for another class of vulnerable persons: potential HIV vaccine research participants in sub-Saharan Africa. Some African scholars have argued that severe and persistent poverty confounds not only the ability to achieve the basic elements of informed consent but also decision-making capacity itself. Widespread illiteracy and language barriers may complicate disclosure requirements, and the offer of free medical care and pay may constitute undue pressure for people living in dire material circumstances. In addition, some scholars have suggested that the precondition of informed consent—competence—may itself be at risk for these potential participants. The effects of persistent and severe poverty, malnutrition, and illiteracy may render potential participants unable, or limited in their capacity, to understand the complexities of biomedical science.^{23,24} This possibility is exacerbated by cultural beliefs about illness and causation that differ

drastically from those of Western medical science; for example, the word *randomization* may not exist in some cultures.²⁵

The aim of informed consent—to promote individual autonomy—has also been questioned in this research context. Many African cultures place more value on human collectives than on individuals.²³ In these cultures, family elders or community leaders may be viewed as appropriate decision makers for others on many issues, including research participation. Some have argued that both traditions—of individualism and collectivism—can be accommodated.²⁶ The most widely used international guidelines for human research, developed by the Council for International Organizations of Medical Sciences (CIOMS) in collaboration with the World Health Organization, stress the importance of obtaining *both* individual consent and community review and involvement.²⁷ (see Chapters 16) The “International Guidelines for Biomedical Research Involving Human Subjects,” issued first in 1982 and revised in 1993 and 2002, emphasize community involvement in decisions about research design and participant participation but rely on the same principles specified in the Belmont Report to address the requirements of individual informed consent. Whether both the community and individual can or should be respected in the informed consent process is a matter of significant debate. Serious concerns exist about whether women’s interests can be adequately protected in patriarchal societies.²⁸

Conclusion

During the 100-plus years detailed here, significant strides have been made in articulating the conditions under which people may be invited to participate in research and the conditions under which they may be permitted to participate. Informed consent is a central criterion for research participation. In this chapter we have traced the history of informed consent, from its precursor forms of voluntary consent to current, more rigorous forms that require participants to volunteer on the basis of information and understanding. A series of U.S. commissions during the latter half of the 20th century have created numerous reports that detail and elaborate on the conditions and ethical justifications of informed consent. U.S. regulations, in turn, have created numerous mechanisms designed to promote the review of research protocols and the protection of humans involved in research.

Despite these advances, the system of research protections remains fragile. Informed consent, a cornerstone of all modern research ethics codes, has been challenged conceptually and practically. The research community and regulatory infrastructure too often have faltered in their duties to present potential participants with complete, clear, and candid information about the purpose and risks of research; to promote and ensure the understanding and voluntariness of participants’ decisions; and to accurately assess the decision-making capacity of potential participants. All of these elements are essential to a truly autonomous decision, an ethical idea which itself has come under scrutiny as HIV research has been exported to societies that may not prize this moral norm.

As this chapter shows, the concept of informed consent in research involving humans has marched steadily toward the ideal of individual autonomy as an expression of respect for persons. Led by the United States, the criteria for informed consent have been designed not only to promote an individual’s informed de-

cision but to protect that decision from the interference or influence of others. Some contend that to impose this value on other cultures runs the risk of “ethical imperialism.” But we believe the ethical goal of universal respect for persons—regardless of race, gender, caste, or tribe—remains a worthy one.

Philosophical Justifications of Informed Consent in Research

The rule that, with a few exceptions, research with humans should not take place without participants' informed consent is a settled ethical and legal principle.¹⁻⁷ This chapter explores the philosophical foundations of this principle. Exploring these foundations helps to clarify how the requirement of informed consent should be understood as well as what limits, if any, should be placed on its implementation. No such requirement exists for the use of things or nonhuman animals, such as microorganisms or mice. The simple explanation of the difference, of course, is that things and animals are not capable of giving informed consent, so it would not be possible to require it of them, whereas human beings or persons are so capable. But that tells us only why it is possible to require informed consent of human research participants, not why we should do so. Why can't people be used in research in the way that we use things? We have reason not to be wasteful of things and animals because they have instrumental and economic value to others, but that is a limitation on their use for the sake of other persons, not for the sake of the things or animals themselves.

What is it about human beings, or persons—I will use these interchangeably here—that gives them a moral status that things and animals do not have, specifically that requires their informed consent to take part in research? Some people will give a religious answer to this question, grounding persons' moral status in their special relationship to God, but public policy about the use of humans in research is not generally understood to have a religious foundation, or at least an exclusively religious foundation. Nor should public policy, which governs all citizens, be grounded in reasons that only have force within a particular religion that some citizens may reasonably reject. So we need a secular answer to the

question. Probably the most common answer is appeal to respect for persons or, similarly, respect for persons' autonomy, as a fundamental moral principle; respect for persons certainly is relevant to our question, but it leaves open what it is about persons that requires respect, and what respect requires in our treatment of persons in the context of research.^{8,9}

Philosophical Conceptions

Philosophical conceptions of autonomy derive largely from the work of Immanuel Kant and are often highly abstract and not well suited to the role autonomy has come to play in bioethics and in the doctrine and practice of informed consent. Instead, we need a conception of autonomy that is empirically ascertainable and within the reach of ordinary persons, for the principle of respect applies to persons generally.¹⁰⁻¹²

Although other animals engage in goal-directed behavior guided by instinct and environment, only persons have the capacity to reflect on what kinds of beings they want to be, what kinds of activities they want to pursue, what kinds of lives they want to live. Persons have the capacity to form values, not just desires; indeed, persons sometimes find their values in conflict with their desires and can take steps, within limits, to bring their desires more into conformance with their values. Persons have the capacity to form, and act on, a conception of the good life. So our interest in autonomy is our interest in making significant decisions about our lives for ourselves and according to our own conceptions of a good life, and then to be free, at least within limits, to act on those decisions without interference from others. In this way,

persons are self-directed agents, not just beings acted upon by external forces.

Each individual person has a life of his or her own to live, with the capacity to take control over and responsibility for directing that life. This is not to say, of course, that individuals are not deeply influenced by other persons and subject to many constraints and limitations in carrying out their life plans. But it is this capacity for self-governance, for autonomy or self-determination, that respect for persons requires us to respect.

The reason things may be used to suit people's purposes is because things have no interests, purposes, or values of their own. Persons, on the other hand, do have purposes, interests, and values of their own, and it is the capacity for these that a principle of respect for persons requires us to respect. Persons are what we can call normative agents. Even higher animals are not normative agents in this sense. For purposes of understanding the ethical basis of the requirement of informed consent, we need an understanding of when persons are making autonomous choices.¹⁰ Choice implies selection from among alternatives, in this context in the simplest terms the choice whether or not to enroll in a particular research project. I shall argue that the three central requirements of informed consent—that the choice is informed, voluntary, and made by a competent person—can be understood as spelling out a conception of autonomous choice in the context of decisions about research participation. Respect for autonomy in this context then requires obtaining the informed consent of those who are competent, able to understand and make a voluntary choice, and are being invited to participate in the research.

Other Considerations

There are other moral considerations besides respecting autonomy that support the general practice of informed consent, although they do not support it as a universal requirement in the way that respect for persons and their autonomy does.⁵ Respect for persons and their autonomy grounds a moral right not to be experimented on without one's consent. The other considerations are consequentialist—the good consequences that usually, but not in every instance, come from not experimenting on persons without their informed consent.

The first consideration rests on an assumption that individuals are generally, though of course not always, the best judges of their own interests, and so if they are left free to decide whether to participate in research projects they will generally do so when it serves their interests and values.

Second, public support for medical research rests on the belief that it is being conducted ethically; obtaining participants' informed consent is essential to sustain that belief. The lack of informed consent was one feature of notoriously unethical research like the Tuskegee experiment that created great public mistrust of medical research (see Chapter 8). Public support for medical research is of obvious importance for maintaining continued substantial public funding of research by government institutions like the National Institutes of Health, which is necessary for securing the continued public health benefits of that research. Public trust of the research enterprise is also important for maintaining public willingness to participate in research trials.

Third, informed consent encourages rational decision making by those contemplating research participation, and it also en-

courages self-scrutiny by investigators about the design and protections incorporated into the research. No doubt there are other examples of good consequences that come from the practice of securing consent from research participants, but the general point is that these examples hold in most, but not all, cases and so need to be supplemented by respect for autonomy in order to ground a universal requirement of informed consent.

Contrast of Therapy and Research

The goal of medical therapy is to improve the patient's medical condition. Yet even medical therapy should not proceed without patients' consent. In research, however, the primary goal is the production of generalizable knowledge, not the research participant's benefit, even if both researcher and participant may sometimes hope for or even expect benefit.¹³ As a result, there is always an inherent conflict of goals between researchers and participants, a conflict between participants' typical goal of securing their well-being and the researchers' goal of producing knowledge. This is what gives special importance in the research context to the ethical injunction against using persons for the benefit of others without their consent; the goals of research always include at least in part the benefit of others, namely, those who stand to benefit as a result of the knowledge produced by the research.

Sometimes a distinction is made between therapeutic and nontherapeutic research, with the suggestion that this conflict of goals does not obtain in the context of therapeutic research, which is thought to have the goal of the participants' own clinical benefit. This is a mistake. Some research may have therapeutic components, but all research has the goal of producing generalizable knowledge, implying that the conflict of goals arises from the components of the research that serve research aims, rather than participants' therapeutic goals.

Research investigators often are also physicians who in other contexts function in a therapeutic role, and this can result in confusion about the different roles on the part of physician/investigators or others.¹⁴ This confusion can be compounded when a potential research participant is also a patient—particularly if the participant is a patient of the investigator—and is considering entering a research trial in the hope of therapeutic benefit. In these cases, it is especially important that the potential participant understand how his or her relationship with the physician will be altered in the research context.

Elements of a Valid Informed Consent

Valid informed consent is typically understood to have three distinct components: Consent must be informed, voluntary, and given by a competent person. More specifically, what does each of these components require, and what obligations do they place on investigators?

Information

The requirement that consent be informed places a demand on the investigator to provide the appropriate information in an understandable form to each potential participant. Because the goal of

this component is to enable people to make an informed decision about participation, the investigator also has a responsibility to invite and answer any questions that potential participants may have about the research. One difficult issue about this condition is how to decide what information should be provided.⁵

U.S. federal regulations specify what information is always legally required to be given to potential participants. This includes the following: a statement that the project is research, not therapy; the purposes of the research; a description of the research—in particular, what will happen to the participants; a description of foreseeable risks and discomforts, as well as benefits; appropriate alternatives, if any; the extent of confidentiality that can be expected; an explanation of any medical treatment available for injury and/or compensation for disability; a pledge that that participation is entirely voluntary and participants can withdraw at any time without loss of benefits to which they are otherwise entitled; and whom to contact for answers to questions.¹⁵ This is the information that federal regulators have determined should always be included in the informed consent process and on the informed consent form. Other information may be appropriate in particular circumstances or for particular research projects.

Although this specifies the kinds of information that should be provided as part of the informed consent process, it leaves open how much detail should be provided, in particular details about the potential risks and benefits of participation. In the law, there are two principal legal standards that most states have adopted on this question, though they have generally been applied to medical therapy rather than research.^{16,17} The so-called professional practice standard directs the investigator to provide the information that most other professionals would provide in similar circumstances. This standard has the obvious defect that it assumes professional practice is adequate, which may not always be the case. It implies that criticism of past practices—in which little or even no information was provided to patients or research participants—was unwarranted provided the practice in question was widely adopted. A widespread practice of providing little or no information would seem to be an additional reason to object to the practice, not a reason to regard it as ethically appropriate.

The other standard is the so-called reasonable person standard, which directs the investigator to provide the information that a reasonable person would want in order to make the decision in question. This standard provides less clear guidance than the professional practice standard, which allows examination of the actual practices of other professionals. Although the reasonable person standard lacks the defect just noted in the professional practice standard, it is not always clear what information a reasonable person would want, particularly with regard to the potential risks and benefits of the research. For example, would a reasonable person always want to know that research participation poses a risk of death, no matter how small or remote that risk? If not, how probable must the risk be before the reasonable person would want to be informed of its presence? This standard requires looking at the probability of particular risks and benefits—how common they are, as well as how serious or important they are—and uncertainty and controversy will remain about where to draw the line in particular cases.

It is common practice to spell out the risks of research projects in considerable detail. In part this is for protection against legal liability, not for ethical reasons. However, many investigators fail

to spell out the potential benefits of research, including potentially therapeutic components, in comparable detail, and they fail to provide any basis for judging the probability of the benefits. Of course, in some medical research there is no expected benefit to participants, which should be clearly stated. In research with potential benefits to participants, however, one often finds little more than a statement to the effect that it is unknown what benefit, if any, participants will receive from the research. Because it is a nonvalidated therapy that is under investigation in clinical research—for example, in a clinical trial of a new oncology treatment—this statement is true. Moreover, it has the benefit of helping disabuse participants of the therapeutic misconception that the goal of the research is to benefit them.^{18,19}

Nevertheless, merely stating that it is unknown whether participants will receive any benefit is insufficient to allow potential participants to make a rational decision about whether the potential risks of the research are warranted by its potential benefits. Certainly, in a Phase III clinical trial there will be some preliminary data from earlier Phase I and II trials, from animal studies, from studies of biologically related compounds, or from basic laboratory research to give some basis for assessing the potential for individual benefit. Some summary of these preliminary data should be provided to participants as part of the consent process to enable them to make a rational decision about whether to participate in the study.

In the context of medical therapy, a third subjective standard for what information informed consent requires is sometimes ethically defended: What would *this* person want to know in order to make a decision about therapy? This standard directs the physician to tailor the information provided to any known special concerns or interests of the patient in question. Because information to be provided to all participants on a consent form for a research project cannot be individualized in this way, it might seem that this standard is inapplicable in research. But the obligation of the investigator to answer any questions of the potential participant about the research allows for an appropriate individuation of information to the needs and concerns of individual persons in research, at least to the extent that they are or can be known.

This point illustrates the common mistake of confusing the consent form with the process of obtaining informed consent.²⁰ In medical therapy, an actual consent form is only sometimes required, and practice varies from institution to institution regarding when it is required, even though informed consent itself should always be obtained. In research with humans, on the other hand, a consent form is always required unless the institutional review board (IRB) has explicitly waived the requirement. The greater documentation and assurance that proper consent has taken place, which can be provided by a signed consent form, is justified by the conflict of goals that exists between investigator and participant in research that does not typically exist between physician and patient in medical therapy. However, a signed consent form is neither necessary nor sufficient for ethically valid consent. It is not necessary, as the practice of oral consent illustrates, so long as the appropriate process of obtaining consent has taken place; but a signed consent form is not sufficient if an appropriate informed consent process has not taken place, for example, because the form is not in a language or at a level that the person can understand. New information may be obtained after participants have enrolled in a research study, and the individuals' own preferences and values may evolve. Give these potential changes, informed consent

should be understood as an ongoing process, both in therapy and research, not as the single event of signing a consent form.^{21,22}

The practice and requirement of informed consent has come under considerable criticism, both in research and in other contexts, with most of the criticism focusing on whether participants can truly understand relevant information and make an informed choice whether to participate in the research.²³ For example, it has been argued that typical participants never have the scientific and medical training to understand the project as fully as the investigator who designed and is carrying out the research.²⁴ But this objection, like analogous objections to informed consent for medical treatment, misconstrues what people need to understand to make an informed decision. They do not need to understand the entire underlying scientific and medical basis of the research; rather, they need to know how their lives, and what is important to them in their lives, are likely to be affected, both positively and negatively, by participation in the research. If investigators carry out their responsibility to use their scientific and medical training and knowledge to convey this information to potential participants, then typical participants will be capable of understanding what they need to know to make an informed decision.

Other critics argue that participants can never be given complete information. Indeed, attempting to do so would result in information overload and confusion, not understanding. But we have already seen that appropriate standards for information to be provided do not require complete information in this sense. Under the reasonable person standard, for example, investigators should provide the information that reasonable people want to make the decision in question. The fact that provision of all information, even if possible in theory, would overwhelm individuals provides compelling reason to think that this is not the level of information desired by reasonable individuals.

Finally, critics point to studies showing a variety of significant misunderstandings that participants have about the research, such as the therapeutic misconception—failing to understand the difference between research and therapy—or the nature of randomization, and so forth.²⁵ These are serious concerns, and efforts should be made to reduce such misunderstandings, but comparable degrees of misunderstanding could probably be found in many decisions that individuals make in other areas of their lives, and those misunderstandings are not considered sufficient grounds for denying individuals the right to make those decisions for themselves.

Some have argued that although making relevant information available to participants may be necessary for valid consent, complete understanding of that information is not required.²⁶ They point to evidence of various limitations in both patients' and research participants' understanding, such as the therapeutic misconception about research, despite the consent having been accepted as valid.²²

A distinction should be made here between, on the one hand, making relevant information available to participants in understandable form together with a process that enables them to ask questions and to clarify information, and, on the other hand, requiring a particular level of understanding of the information. Ethically valid informed consent requires the former but not the latter. To require no relevant misunderstandings would simply be impractical and incompatible with practice in a wide variety of other circumstances in which important decisions are made. Moreover, some participants may not wish to understand all or even

much of the relevant information, for example, because they trust the researcher, or they may even waive their right to obtain the relevant information. This is compatible with ethically valid consent, even if for legal or policy reasons we may place limits on this kind of uninformed consent in research.

Voluntariness

A second condition for valid consent is that it be voluntary. This requirement places a responsibility on the investigator to ensure that participants' consent is in fact voluntary. Consent can be made involuntary in more than one way. The most obvious is when one is coerced to consent.²⁷ Coercion involves a threat that unless a person agrees to participate in the research, the coercer will make him or her worse off in some respect; a crude example would be a patient's physician threatening that unless the patient agrees to take part in a research project, the physician will not continue to provide therapeutic care. This kind of crude coercion from an investigator is no doubt rare. Nevertheless, patients may sometimes feel that their care will become worse if they do not accept their physician's invitation to participate in a research project, even if that is not true and their physician has done nothing to suggest it; physician-investigators need to make efforts to reassure patients that this is not the case in order to avoid inadvertent coercion. Coercion from family members is probably more common than from investigators and other health-care personnel, and can equally invalidate a person's consent.

In understanding coercion, it is important to distinguish it from warnings. A patient who has failed standard therapy may be told by his physician or others that his only chance of improvement is to participate in a clinical trial; if he does not do so, further decline or even death is likely. This does not constitute coercion to participate in the trial, but rather a warning of what can be expected if the patient does not participate. It is the disease that will make the patient's condition worse, not anything that the physician will do, which is why this is a warning and not a threat.

Some commentators consider it "coercion" if a patient is impelled by the disease to join a clinical trial, in particular when the intervention being studied has serious side effects but is the patient's only chance of preventing death or very serious harm.^{28,29} Both alternatives are in a sense very bad choices with very bad features; the patient would much prefer not to be in the position of having to make such a choice. But that is not enough to make the choice coerced and to invalidate the patient's choice about trial participation. The fact that individuals sometimes are forced by circumstance or nature to make choices that they would much prefer not to have to make is not grounds for failing to respect the choices they make in such unfortunate circumstances. Were this not the case, we would regard all patients with life-threatening illnesses as deciding under conditions of coercion, thereby freeing us to disregard their choices.

Although coercion involves threats that arise from other persons, rather than from circumstance or nature, it can also come from social institutions.³⁰ Prior to the mid-1970s it was common to do much drug testing with prison populations. They were in a controlled environment, and they could be motivated to participate with relatively little financial compensation, because of their limited opportunities to earn money, or from the hope of securing an earlier release or better treatment while in prison. Largely due to the work of the National Commission for the Protection of

Human Subjects of Biomedical and Behavioral Research, this practice was essentially stopped, in part on the ground that any choice prisoners made to participate in research was likely coerced because of the total control of the prison environment. The rationale was that prisoners were so completely under the control of prison authorities that they would feel pressured to comply with those authorities' desire that they participate in the research. This reasoning could apply to individuals confined to other so-called total institutions, such as involuntarily committed mental patients.³¹

Manipulation of the choice by others is perhaps a more common form of involuntariness than coercion in the research context.³² Yet it can sometimes be difficult to distinguish unethical manipulation from acceptable education or persuasion. Very roughly, manipulation means such practices as selective provision of information or playing on potential participants' fears. It is probably best understood as deliberately misinforming the potential participant (selective information) or as putting unwarranted pressure on the decision maker (playing on fears). In either case, it aims to have potential research participants make a choice they would not make if fully informed and choosing freely according to their own values. Like coercion, manipulation seeks to produce a choice that promotes the manipulator's good, or the manipulator's conception of the person's good, not the person's conception of his or her own good. In this respect, it is a clear violation of the person's autonomy.

There is controversy whether offers, not just threats, can sometimes be coercive.³³ Offers improve an individual's position by adding a new option that is better than the individual's existing options, while also leaving the previous options in place. Offers are generally not considered coercive or leading to involuntariness because they leave individuals with the option of remaining as they were before the offer. However, concerns arise when very substantial offers are made for research participation. Such offers may lead individuals, especially those in conditions of unjust deprivation, to accept excessive risks.^{34,35} Offers to very poor participants of very large financial compensation or of otherwise unavailable medical care for participation in research carrying substantial risks or burdens can be exploitative of the participants' disadvantaged position; they are morally objectionable as exploitation, even if they are not coercive. This can be an especially troubling issue in some research carried out in very poor developing countries (see Chapters 20, 64–67).

Competence

The third requirement for ethically valid informed consent is that the participant be competent to give his or her consent.^{36,37} Competence is a requirement for valid consent because without it, participants lack the reasoning capacities to arrive at a choice that fits their values and interests, even if relevant information has been made available and no involuntariness is present. Competence is part of what is necessary for autonomous choices. Strictly speaking, competence is a legal status, but it is also an ethical requirement and investigators, not the courts, make most determinations of competence for research participation, just as physicians do for therapy.³⁸ In general, adults are presumed to be competent to decide about participation in research unless determined otherwise. Children are presumed not to be competent to make that decision and so others, typically parents, must decide for them; in the case of older children, their assent to participation is typically required.³⁹

Sometimes decision-making competence or incompetence will be a global property of a person; a normal adult should be competent to make any decision about research participation, and an individual who is comatose or suffering from advanced dementia will not be competent to make any such decisions. In borderline cases, however, in which there is some but not complete impairment of an individual's decision-making capacities, the individual may be competent to make some research participation decisions but not others. That is because both the complexity of different decisions, as well as the risks associated with participation, can vary greatly across different research projects. Moreover, a potential participant's decision-making capacities can vary substantially over time from fluctuations in his or her medical condition, the effects of medications, and other factors such as being moved to an unfamiliar setting. Investigators are responsible for attempting to maximize the potential participant's decision-making capacities, for example, by tapering or temporarily stopping medications, particularly if there may be significant potential benefits to the person from enrolling in the research.

What decision-making capacities are needed for competence? First are capacities for understanding and communication. Capacities for understanding relevant information are needed to permit an informed choice, and capacities for communication are needed both for the process of becoming informed and to communicate a choice once it has been made. Second are capacities for reasoning and deliberation. This will most often be "if/then" reasoning; if I do this, then that will happen. A part of deliberation is the capacity to entertain alternative courses of action simultaneously so that they can be compared and a choice made. Third is the possession of aims and values that can be used as the basis for selecting from among alternative courses of action. Of course, whether to participate in a particular research project may not fit within the potential participant's past experience and so it may not be decided by reference to preexisting aims and values; then what is needed is the capacity to decide what weight to give to relatively new aims, outcomes, and values.

The competence evaluation should focus on the exercise of these various capacities in the person's reasoning about whether to participate in the research project at hand, not simply on the outcome of that decision process—whether consent is given or refused.^{40,41} That is, the competence evaluator should look for serious defects in the participant's decision-making process, not whether the participant has arrived at a decision that others consider correct, rational, or best. In the face of serious defects, of course, the first response should be to help the decision maker correct them; only if they prove uncorrectable can they serve as evidence for incompetence.

When there is some impairment of the person's decision-making capacities, but far from complete impairment, how should one determine whether the impairment is sufficient to render the individual incapable of making an informed choice?⁴² The function of the competence assessment in the therapeutic context is to determine whether the patient will retain decision-making authority or instead if that authority will be transferred to a surrogate to decide for the patient. There are two principal values at stake for the patient in that determination: on the one hand, the interest in making treatment decisions for oneself when one is sufficiently able, and, on the other hand, protecting one's well-being when seriously impaired decision-making capacities may result in a choice harmful to oneself. These two values must often be balanced

when a patient wishes to make the decision, but is making an apparently harmful choice. In particular, sometimes honoring an impaired refusal of consent for importantly beneficial treatment may be sufficiently harmful to the patient that he or she is correctly found incompetent to make the decision.

In the context of research participation, the interest in making the decision for oneself is essentially the same, but interest in the protection of well-being typically differs. In the case of research without benefit to the participant and with any significant risk, the interest in protection of well-being principally concerns not letting the individual participate in the research unless its risks are well understood. However, some medical conditions, such as some cancers, are often treated in a research context in which the patient's best hope of medical improvement lies in research participation. In this case, the patient may have a medical interest in participating in the trial, but refusal to participate does not necessarily demonstrate incompetence to decide, because the intervention being investigated is by definition of unproven medical benefit, with its potential risks also often not well established. In general, because benefits to the participant in research are either nonexistent or uncertain and unproven, there will rarely be a persuasive case for overriding a person's refusal to participate if that person is sufficiently able to understand the choice. Unlike in therapy, in which a patient's refusal of treatment may raise the question of competence to decide, in research the important competence evaluation will often be of a patient who consents to participate when there is significant or unknown risk in participation.

Conclusion

We are now in a better position to see how the specific requirements for informed consent for research participation spell out a conception of autonomous choice whether to do so. If the decision is not informed, the patient will be unable to reliably determine whether participating would serve his or her interests, aims, and values. If the choice is not voluntary, then the decision will serve someone else's interests, or someone else's conception of the patient's interests, not the patient's own conception of his or her interests. If the patient is not competent, he or she lacks the capacity to use the information to deliberate whether to participate in the research. Together, these three requirements provide reasonable assurance that the participant is exercising the capacity for autonomous choice and action when deciding whether to participate in research.

Legal and Regulatory Standards of Informed Consent in Research

Legal rules embodied in judicial decisions and in statutes and regulations are at the heart of modern bioethics, and nowhere more clearly than in research with humans. Of the basic ethical principles associated with clinical research, autonomy—in the guise of “informed consent”—is, in its origins as well as its content, the most legal. Whereas other aspects of bioethics, such as the principles of nonmaleficence and beneficence, can be traced to ancient medical texts as well as to the professional orientation of modern physicians, informed consent was first articulated in legal documents, and it has been further elaborated by judges, legislators, and regulators over many decades.

Besides being central, the law may also seem the most straightforward aspect of research ethics. Yet the role of law in research ethics is not simple, for several reasons. First, although the law has been a major stimulus for research ethics, in practice it does not always support the ethical norms it inspired. Second, the apparent primacy of autonomy and its legal handmaiden, informed consent, among bioethics principles is belied by the larger framework of ethics review of clinical research. Third, and most ironically, when applied with the greatest apparent rigor, the law—which can be a very blunt instrument—can impede the realization of the sorts of relationships and outcomes in clinical research most often endorsed by ethicists. In sum, the law of informed consent in research is a paradox enveloped in an enigma, though this reality is obscured by an outer wrapping of legal parchment.

This description could prompt several responses. The first might well be to give up on informed consent as a snare or a waste of effort. A better alternative, though one requiring greater effort and attention, would be to seek to recover what is valuable, indeed essential, in informed consent by recognizing the limitations of the

law and compensating for them. To illuminate the problems that need to be avoided, one must understand not only the current law of informed consent in research but also how it developed. This chapter therefore begins by examining the contribution various events and documents made to the contemporary legal regulation of research consent.

I. The Origins of the Law of Consent in Research

The roots of informed consent lie not in traditional medical ethics but in the law. To the extent that consent appeared in the norms laid down by medicine's early leaders, it was only by implication: Physicians needed the permission of sick persons to attend them in their homes. Yet, however willingly patients may have accepted their physicians' ministrations, this would not have been based on anything like what is now called informed consent. Even Plato, who favorably compared the doctors who cared for freemen with those who treated slaves without ever talking to their patients individually, still described the former as “instructing” the sick person, who was brought “under his persuasive influences.”¹ Rather than reveal the nature of ailments or the therapeutic options, Hippocratic physicians were schooled to withhold information and to soothe their patients by distracting their attention from their illness or the risks of treatment. After all, what would a patient, ignorant of medical art and perhaps anxious and confused, be able to contribute to a medical decision?

Although research in the current sense was not a part of medicine until well into the 19th century, nothing in the writing of Hippocrates or his professional descendants suggests that informed

consent was seen as any more necessary should a physician be performing an experiment rather than providing ordinary medical care. Physicians may have recognized that experiments are “perilous.” But because each new patient might react differently to a customary remedy and the therapeutic armamentarium was limited, experiments were inevitable, and a physician’s moral authority to proceed rested not on the patient’s consent but on the well-meaning exercise of medical art. Even when later medical moralists, such as Moses Mamonides or Claude Bernard, recognized the risks that inhere in treating patients as means to advance scientific knowledge, they counseled their fellow practitioners to avoid this practice rather than suggesting that physicians involve patients as knowing and voluntary partners in its undertaking.

For a long time, this combination of physicians’ beneficent intent and consent by implication (or lack of objection) was apparently accepted as the legal as well as the moral justification for both medical practice and experimentation. To appreciate the current law of consent for research, it is necessary to keep in mind not only the processes by which the law formally responded to research scandals and the claims of victims but also the development and limitations of the law of consent to treatment, which has shaped, and continues to shape, the assumptions of courts and regulators as well as the practices of physicians when they engage in research.

A. Battery

The law first began to move beyond its deference to physicians in the 18th century, in judicial decisions involving consent to surgery. Judges relied on ancient principles of battery law to hold that surgery, like any other “touching” of a person, could occur only with consent, the absence of which would render the intervention actionable at law despite the good intentions of the medical practitioner. By the beginning of the 20th century it was well established, as Judge Benjamin Cardozo memorably declared in *Schloendorff v. New York Hospital*, that “[e]very human being of adult years and sound mind has a right to determine what shall be done with his own body; and a surgeon who performs an operation without his patient’s consent commits an assault, for which he is liable in damages.”²

Applying the concepts emerging in contract law to the physician-patient relationship, courts also concluded that submitting to surgery could be presumed to signify agreement unless the patient, like any other party to a contract, “was the victim of false and fraudulent misrepresentation.”³ The result was a somewhat circumscribed affirmation of self-determination: Absent an emergency, surgery was battery if performed on a competent adult without consent, and consent would be invalid if obtained through misinformation or for an intervention other than the one performed. Plainly, this fell far short of requiring full disclosure of the information a patient would need to make an autonomous decision.

Although these rules about contractual breaches and battery arose in cases involving ordinary treatment, a third line of cases involving experimental treatment evolved (in line with the general movement of tort law) from strict liability to negligence. Judges initially took as self-evident that a doctor, no matter how skillful, who departs from “the known rule and usage” of his profession “to try an experiment” does so at his peril.⁴ In time, however, liability

was narrowed to cases in “which a system of treatment has been followed for a long time, [so that] there should be no departure from it, unless the surgeon who does it is prepared to take the risk of establishing, by his success, the propriety and safety of his experiment.” Otherwise, when “there is no established mode of treatment,” a patient “must trust to the skill and experience of the surgeon he calls” and not complain of novel interventions, providing the usual rules for consent to treatment were met.⁵

For most of the past century, consent developed along separate tracks for treatment and for research. On their face, the rules for research were more explicit and extensive than those for treatment. Yet the rules on consent for research frequently did not have their intended effect on physicians’ conduct, a failing that may be traced in part to the influence of physicians’ view of their ordinary consent obligations; indeed, this influence seemed to extend beyond physicians’ behavior to the formulation and application of the legal rules for medical research.

B. Government Regulation

Beginning in the middle of the 19th century, as physicians turned to scientific methods to develop their knowledge of disease, they increasingly used patients as subjects in studies unconnected with their medical conditions. A few researchers provided subjects formal contracts, most famously the board appointed in 1900 by the U.S. Army surgeon general to carry out studies on yellow fever in Cuba, under Major Walter Reed. The physicians on the board began by experimenting on themselves, but when one of them died, they decided to use U.S. servicemen and Hispanic laborers instead. To meet criticisms, especially in the Spanish-language press, Army officials drew up a formal contract (in Spanish and English versions), in which subjects agreed to allow themselves to be intentionally exposed to yellow fever, in exchange for gold worth the equivalent of six-months’ pay, to be doubled if they became infected. Each subject (apparently thinking in the third person) had to acknowledge that he understood “that in the case of the development of yellow fever in him, he endangers his life to a certain extent but it being entirely impossible for him to avoid the infection during his stay on this island he prefers to take the chance of contracting it intentionally in the belief that he will receive . . . the greatest care and most skillful medical service.”⁶

Most researchers in the second half of the 19th century and the early years of the 20th not only failed to describe risks accurately but engaged in experiments that fell into a category sometimes labeled *human vivisection*. Often using orphans, paupers, residents of mental institutions, or other marginalized persons as their subjects, these early researchers exposed them to a number of serious diseases, including gonorrhea and syphilis, resulting not merely in physical harm but sometimes in death. Although these shocking acts apparently did not lead to any disciplinary response in the medical community, they did prompt the first official regulation of research with human beings. In 1900, in response to reports in the general and medical press about such abuses, particularly in asylums and hospitals, the Prussian government issued a directive to the heads of clinics and similar establishments “absolutely prohibiting” medical interventions “for purposes other than diagnosis, therapy, and immunization” under any of the following conditions:

1. The person in question is a minor or is not fully competent on other grounds.
2. The person concerned has not declared unequivocally that he consents to the intervention.
3. The declaration has not been made on the basis of a proper explanation of the adverse consequences that may result from the intervention.⁷

In 1931, the German government expanded upon the Prussian regulations and even more clearly differentiated between “therapeutic experimentation and modes of treatment which serve the process of healing even though the effects and consequences cannot yet be adequately determined,” which were permitted, and “human experimentation” that consists of “operations and modes of treatment . . . carried out for research purposes which are not therapeutic” and that were not to be carried out on incompetent or uninformed persons.⁸

It is striking that these regulations embodied several features that continue through the present day in many legal regimes. First, they established a stricter set of requirements for experiments using “normal volunteers” than so-called therapeutic research with patients. Second, the Prussian rules included three of what are still regarded as the four essential elements of valid consent for research participants: that participation in research requires unambiguous agreement of the person prior to the start of the study; that the agreement be based upon a clear statement of the risks involved; and that the person must be legally competent. (The only element not addressed is the *voluntariness* of the consent.)

Regrettably, the 1931 German guidelines also serve as a sober reminder that the existence of legal rules is not enough to produce ethical research, for they proved to be wholly ineffectual in protecting the thousands of victims of the depraved physicians and their assistants who carried out lethal experiments in German concentration camps during World War II. This lack of effect might be ascribed to the 1931 rules being mere guidelines without legal force, as some authorities contend,⁹ though others maintain that the rules were German law with binding effect until the Third Reich’s fall in 1945.¹⁰ In any case, the rules were relied on by the prosecution’s expert witnesses at the trial of the Nazi concentration camp doctors after the war as one basis for concluding that the defendants had violated established standards of medical ethics¹¹ (see Chapters 2 and 12).

C. The Nuremberg Code

In the Doctors’ Trial, 23 Nazi experimenters were tried before a U.S. military tribunal sitting at Nuremberg in occupied Germany. In handing down judgment in August 1947, the court accepted the view of medical experts that “certain types of medical experiments on human beings, when kept within reasonably well-defined bounds, conform to the ethics of the medical profession generally” if “such experiments yield results for the good of society that are unprocurable by other methods or means of study.” The “well-defined bounds” were spelled out in 10 “basic principles” that “must be observed in order to satisfy moral, ethical, and legal concepts.”¹² The judges found that 16 defendants, having violated these principles, were guilty of war crimes and crimes against humanity. Although judicial holdings are usually known by the name of the case in which they appear, these 10 principles are

enshrined not as the ruling in *United States v. Karl Brandt* but as the Nuremberg Code. In addition to its historic origins, the Code’s broad influence on and frequent citation in laws, regulations, and court decisions for the past six decades has made it the cornerstone of the law of medical research and especially of informed consent. “[A]lthough the field of international research ethics has evolved greatly over the past 40 years, its origins can always be traced back to the 10 principles first enunciated at the trial of the Nazi physicians.”¹³

Several points in the Code concern what might be termed the scientific aspects of ethical research (a clear purpose, adequate preparation, qualified researchers), but “judicial concern” lay with those “so clearly related to matters legal that they assist . . . in determining criminal culpability.”¹² Thus, the court focused on the exposure of subjects to excessive risk of death or grave injury and on the absence of informed consent. Indeed, the Code’s first principle begins with the unequivocal declaration that “[t]he voluntary consent of the human subject is absolutely essential.”¹² The Nuremberg court elaborated two elements of valid consent in line with existing common law doctrine and the prewar German law: The subject must “have legal capacity to give consent” and “should have sufficient knowledge and comprehension of the elements of the subject matter involved as to enable him to make an understanding and enlightened decision.”¹² To this the court added that the subject must be “able to exercise free power of choice, without the intervention of any element of force, fraud, deceit, duress, over-reaching or other ulterior form of constraint or coercion.”¹² (By rejecting defense claims that some or all of the experimental subjects had implicitly agreed to participate, the Nuremberg tribunal implicitly endorsed a fourth requirement, namely that subjects must unequivocally indicate their agreement before the research may begin.) Principle 1 also makes clear that the person initiating and directing an experiment has a “personal duty and responsibility which may not be delegated to another with impunity” to ascertain the quality of consent. Finally, in light of the horrible suffering of many subjects in the Nazi experiments, the court in Principle 9 added a new requirement, the right to withdraw consent, which has become an essential part of subsequent regulations: “During the course of the experiment the human subject should be at liberty to bring the experiment to an end if he has reached the physical or mental state where continuation of the experiment seems to him to be impossible.”¹²

The Nuremberg Code moved the governance of research from domestic regulations to international human rights law. Article 5 of the Universal Declaration of Human Rights, adopted by the United Nations General Assembly in 1948 in the wake of the Nuremberg court’s judgment, states, “No one shall be subjected . . . to cruel, inhuman or degrading treatment or punishment.”¹⁴ In 1966, the International Covenant on Civil and Political Rights explicated that this means that “[i]n particular, no one shall be subjected without his free consent to medical or scientific experimentation.”¹⁵ Many countries have incorporated this provision or its equivalent into their constitution^{16–22} or public health legislation and regulation,^{23–25} and regional organizations have based their rules on the same premises.²⁶ The violation of international human rights principles, specifically as embodied in the Nuremberg Code, has also been alleged as a basis for liability in one case which involved a trial of an antibiotic during an outbreak of meningitis, measles, and cholera among children in Kano, Nigeria.²⁷

D. The Declaration of Helsinki

The Nuremberg Code is important as a legal and human rights document: “The Code remains a viable force. It squarely acknowledges the scientist’s responsibility for the respect of human rights.”²⁸ Yet despite its importance and its clear rules on subject’s consent, the Nuremberg Code has had only an indirect effect on medical research because physician-investigators regard it as relevant only to the barbaric acts of war criminals rather than to what they do with, and hence say to, their patient-subjects. The World Medical Association (WMA), formed by national medical bodies after World War II to reassert the ethical foundations of the profession, formulated in 1948 a new Hippocratic Oath that asserted that “the health and life of my patient will be my first consideration.” Shortly thereafter, the WMA began work on principles for medical research, but it was not until June 1964 in Helsinki, Finland, that it adopted its guide for physicians in clinical research. Although the Declaration of Helsinki reminded physicians that their acts must conform to the criminal, civil, and ethical rules of their own countries, it has itself assumed a large role in the legal regulation of research. This is the case where statutes or regulations explicitly incorporate or refer to the Declaration, as in the European Union (EU) clinical trials directive.²⁹ It is also true when research ethics committees use it as the standard to which researchers must adhere, with or without the expansion provided by the Council for International Organizations of Medical Sciences (CIOMS) in its *International Ethical Guidelines for Biomedical Research Involving Human Subjects*, first prepared in 1982 and revised in 1993 and 2002, to indicate how the ethical principles “set forth in the Declaration . . . could be effectively applied.”³⁰

Starting from the premise that “it is essential that the results of laboratory experiments be applied to human beings to further scientific knowledge and to help suffering humanity,” the 1964 Declaration of Helsinki drew a “fundamental distinction” between clinical research with and without a therapeutic aim.³¹ The second section, entitled “Clinical Research Combined With Professional Care,” makes clear that the WMA meant to spell out physicians’ responsibilities, not subjects’ rights. In Section II, Article I, it proclaims that physicians “must be free” to use new measures, and the duty to obtain consent receives only a brief and qualified mention:

If at all possible, consistent with patient psychology, the doctor should obtain the patient’s freely given consent after the patient has been given a full explanation. In case of legal incapacity consent should also be procured from the legal guardian; in case of physical incapacity the permission of the legal guardian replaces that of the patient.³¹

The Declaration’s treatment of research combined with clinical practice is a reminder of the significant influence that the often paternalistic norms of ordinary medical care have had on the legal regulation of consent in research. Frequently, no sharp line exists between research and clinical care; moreover, when research is conducted with patients, they remain in physicians’ eyes patients and not merely subjects. It is thus not surprising that the Declaration should reflect norms that doctors find appropriate to the physician-patient relationship, and that this in turn should have shaped the thinking of the framers of the legal rules for consent in research.

In addressing “Non-Therapeutic Clinical Research,” the Declaration followed both prewar law and the Nuremberg Code in mandating, in Sec. III, Arts. 3a and 2, that research “cannot be undertaken without [the subject’s] free consent, after he has been fully informed” of “the nature, the purpose, and the risk of clinical research.”³¹ The Declaration echoed the Nuremberg Code in stating that the subject “should be in such a mental, physical, and legal state as to be able to exercise fully his power of choice” (while also noting the difficulty of safeguarding “personal integrity, especially if the subject is in a dependent relationship to the investigator”) and “should be free to withdraw permission for research to continue”³¹ (Sec. III, Arts. 3a, 4a, 4b). The Declaration went beyond prior law in requiring that “[c]onsent should as a rule be obtained in writing” and in allowing research on a legally incompetent subject provided “the consent of the legal guardian [is] procured” (Sec. III, Arts. 3c, 3a), an extension it did not explain.³¹ These elements—competence; information about the nature, purpose, and risk of a study; voluntary consent in writing; the right to withdraw; and allowing guardians to consent to research on incompetent subjects—cover virtually all the important requirements found in contemporary law. One might say that in the years since, the law has merely elaborated the details.

Yet the Declaration has itself been revised five times since 1964 (most recently in 2000); these revisions reflect the influence of both critical analysis concerning the shortcomings of the original Declaration and the condemnation aimed at problematic research projects conducted despite the Declaration. For example, the document now requires disclosure of “sources of funding, any possible conflicts of interest, [and] institutional affiliations of the researcher.”³² Concern about subjects’ dependency on researchers has been made more specific by requiring subjects to be assured that they may “abstain from participating, or may withdraw, at any time without reprisal.” Moreover, according to paragraph 22, should the relationship of researcher and subject risk producing consent under duress, consent should be obtained instead “by a well-informed physician who is not engaged in the investigation and who is completely independent of this relationship.”³²

Most significantly, the latest revision of the Declaration turned the special treatment of “research combined with medical care” on its head: Rather than providing a license for physician-researchers to treat patient-subjects simply as patients—who could be enrolled in research based on no more disclosure than is “consistent with [their] psychology”—the Declaration now adds five special requirements for this category of research. (Two of these, which deal with placebo-controlled clinical trials and posttrial obligations to patients, have proven so controversial that the WMA has had to issue “notes of clarification” about them.) The evolution of the Declaration—which has become much longer and more detailed, and which now takes into account interests beyond those of practicing physicians—reflects the reality that in many parts of the world, this document, produced by a professional association, provides the de facto legal criteria for consent and other ethical requirements in research. Indeed, the U.S. Food and Drug Administration (FDA), which in 1975 first incorporated the original Declaration into its regulations for foreign clinical trials conducted without an investigational new drug application (IND), still relies on the Declaration’s 1989 version as the standard to which investigators are held.³³ The Declaration has ceased being simply a short statement of *principles* or moral aspirations for physicians engaged in research.³⁴ Yet, although it may appear more regulatory,

the Declaration still lacks the level of precision needed to guide investigators and research ethics committees.

II. The Procedural Aspects of Informed Consent Requirements

Greater specificity in the rules for research, including informed consent, is provided principally by national laws and regulations and related international documents such as the guideline on *good clinical practice* (GCP) issued by the major drug regulatory authorities through the International Conference on Harmonisation.³⁵ Even greater detail can be found in some of the rules adopted by research review bodies at an institutional (or regional or national) level; these rules take on the character of private law to the extent that these bodies have made commitments to regulators to follow them in reviewing research protocols submitted for their approval.

Among this welter of national and international regulations, two related sets of rules provide the basic legal framework for informed consent, the so-called Common Rule for research with human beings supported by most agencies of the U.S. federal government³⁶ and the research regulations of the U.S. FDA.³⁷ In what is surely the strangest example of global health governance, these rules, originating in a single country, have achieved influence worldwide because they encompass studies conducted or supported by the major research agencies of the U.S. government as well as those carried out with nonpublic funds (principally by biotech companies or drug or device manufacturers) with the intention of submitting the findings in an application for licensing approval by the FDA. The U.S. regulations achieve further reach because they have also directly influenced the law in other jurisdictions; for example, some provisions of the so-called Tri-Council Policy Statement, (TCPS) promulgated in 1998 by the three Canadian governmental agencies with primary responsibility for research with human beings, closely follow parts of the U.S. rules.³⁸

The comprehensive requirements for research projects set forth in these rules include many regarding informed consent. The consent-related rules fall into three groups: those that speak to the procedural aspects of informed consent (Who must do what when?), those that apply to the substantive aspects (What is the content of valid consent?), and those that involve the administrative aspects (How is consent reviewed and approved?). The procedural aspects are addressed in this section, followed by the substantive and administrative aspects in sections III and IV, respectively.

A. Activities Falling Outside the Rules

Before getting to the question of who has to obtain consent, one must know which activities are excluded, or may be exempted, from the Common Rule and related regulations. According to 45 CFR §46.116³⁶ and 21 CFR §50.20,³⁷ the basic procedural requirement for research consent is clear: With a few exceptions, “no investigator may involve a human being as a subject in research . . . unless the investigator has obtained the legally effective informed consent of the subject or the subject’s legally authorized representative.” The threshold question is thus whether a “human subject” is “involved” in “research.” When an ac-

tivity does not entail “systematic investigation, including research development, testing and evaluation, designed to develop or contribute to generalizable knowledge,” it is not considered research (45 CFR §46.102).³⁶ This does not mean that informed consent is not required (for example, when a patient receives an innovative treatment outside a research protocol), merely that the relevant legal rules would be those applicable in the jurisdiction to therapy rather than to research.

Likewise, the term *human being* erects a threshold because it limits application of the Common Rule to a *living individual* about whom an investigator obtains either “(1) [d]ata through intervention or interaction with the individual, or (2) [i]dentifiable private information” without interacting with the person (45 CFR §46.102).³⁶ The study of dead people or of information that is already available to an investigator and is not private does not qualify as research with human subjects under the Common Rule, though its use may be regulated in other ways.

In addition to these threshold exclusions, a broader exemption exists for six categories of research with human subjects (other than research on prisoners) that need not follow the federal requirements, including those on informed consent (45 CFR §46.101(b)).³⁶ Three exemptions are for studies involving education, one covers federal research and demonstration projects, and one is for food studies. Only one relates to health research:

(4) Research involving the collection or study of existing data, documents, records, pathological specimens, or diagnostic specimens, if these sources are publicly available or if the information is recorded by the investigator in such a manner that subjects cannot be identified, directly or through identifiers linked to the subjects.³⁶

For most medical outcomes or health systems research, or for studies using human biological specimens not collected for research purposes, the relevant material is unlikely to be *publicly available*. Therefore, for an investigation using existing private records or specimens to be exempt from federal research rules, an investigator would need to record the information derived in an unlinked anonymous fashion. Many activities involving monitoring and evaluation (of quality, safety, comparative outcomes, etc.) can adhere to this limitation, but many other research uses of existing records and specimen collections cannot and would therefore not be exempt from the rules. When an activity is neither excluded nor exempted, however, an institutional review board (IRB) may waive or alter the requirements for informed consent in various circumstances, as discussed in Section D below (“Waivers of Consent Requirements”).

The exclusion or exemption of an activity implies that the activity does not involve any action that, in the regulators’ view, could not ethically be performed without the consent of the people involved, because the effect of being excluded or exempted is to relieve the persons conducting the activity of the obligation to follow the rules, including the consent requirements. Nonetheless, the exemption of a project from federal review does not remove it from any other legal requirements in the jurisdiction, including review by an ethics committee or the obligation to obtain informed consent if specified by local law (45 CFR §46.101(b)).³⁶ Investigators and review committees must be familiar with those local rules, especially in collaborative research projects that will actually be carried out by researchers in other provinces or countries.

B. Form and Timing of Consent

The basic requirements of a “legally effective informed consent” for research are that it must be (a) prospective, (b) informed, and (c) voluntarily provided by (d) a person with the legal capacity to give it. Furthermore, the Canadian federal rules state a fifth requirement as typically do the statutes and regulations of other countries, namely, that (e) “evidence of free and informed consent . . . should ordinarily be obtained in writing,” as stated in Art. 2.1.b of the Canadian TCPS.³⁸ Although this may seem principally a procedural matter—consent formally exists when the subject signs the form—having a written consent also has administrative and substantive aspects. As to the former, a consent form can be reviewed in advance by an IRB, and the easiest way to demonstrate to research monitors that subjects have consented is with signed consent forms. As to the latter, the act of signing the form can impress on prospective subjects that they are making a serious decision and, indeed, manifest the essential fact that there is a choice to be made.

The procedural issues largely concern the first and last characteristics of consent, namely, that it be prospective and in writing; the other three characteristics (adequate disclosure, voluntariness, and legal capacity) are better regarded as substantive matters, though the requirement of legal capacity to consent raises an issue that it is convenient to frame in procedural terms in the section below on who must obtain consent from whom: When and how may consent be obtained from someone other than the subject him- or herself?

1. Signed, Written Form

It is frequently stated (yet all too often forgotten) that consent is a process not an event. When the consent form—a mere record of the understanding reached at a certain point between an investigator and a subject concerning the latter’s participation in a research project—is conflated with informed consent, the likelihood that genuine and legitimate consent has been given is greatly diminished. Yet it is understandable that this occurs for several reasons. First, those who are required to obtain “legally effective” consent typically have little orientation or training in their medical education to treat consent as a process. Second, the Common Rule, in line with other national regulations, requires at 45 CFR §46.117(a) that informed consent be documented “by the use of a written consent form approved by the IRB and signed by the subject” (or legal representative).³⁶ Such rules encourage the tendency of research ethics committees to focus on the consent form and related materials as the easiest means of satisfying themselves that a researcher will obtain valid consent; rarely do committees utilize any means of observing or evaluating the act of obtaining consent from prospective subjects. Third, this requirement simply reinforces the general sense among clinicians that the best protection against tort liability is a piece of paper that lists all possible risks and bears the future plaintiff’s signature. The rules are quite explicit at 45 CFR §46.117(b)(2) that the consent form must either contain all the required information or state that all necessary elements have been presented orally, in which case “there shall be a witness to the oral presentation” who, along with the person obtaining consent, must sign a written summary, approved by the IRB, of what is to be said to subjects.³⁶

The legal requirement that consent be documented on a form, or as a summary of material presented orally, has the beneficial

effect of generating a document, a copy of which can be given to subjects, as is indeed required by the regulations at §46.117 (a) and (b).³⁶ This enables subjects to review the information (either alone or with their own physician or family and others) and, if the circumstances allow, to return to the researcher with questions. Even when an investigator has followed the injunction to “give . . . the subject . . . adequate opportunity to read [the form] before it is signed” (§46.117 (b)(1)),³⁶ the added chance to review the information later may prove useful and reassuring. Consent to research is, after all, a continuous process, not an event.

According to the U.S. rules, an IRB may waive the requirement of a signed consent form under two circumstances. The first involves research in which “the principal risk would be the potential harm resulting from a breach of confidentiality” and the only record linking the subject to the research would be the form itself. If the IRB grants the waiver, each subject must be presented with the option whether to dispense with the documentation; the subject’s wishes govern. The second is research presenting “no more than minimal risk of harm to subjects” and involving only procedures for which written consent is not normally required outside of research (45 CFR §46.117(c)).³⁶ The latter standard is contextual, as it depends upon the expectations existing in ordinary care at that time and place. Such waivers apply only to the requirement of a signed consent document, not to the obligation to obtain consent; moreover, even when it grants a waiver, the IRB may still require that the investigator “provide subjects with a written statement regarding the research,” just as investigators must give to a person signing a consent form a copy of the document or of the summary of the information that has been provided. The Canadian TCPS adds a third category in Art. 2.1.b that is especially relevant in international research: Written consent is not required where it “is culturally unacceptable,”³⁸ as, for example, when written documents are only used as a means for people to forfeit rights (such as signing away a property claim) or when putting one’s signature on written document, rather than simply giving a handshake, implies distrust.

2. Prospective Consent

The origins of consent in tort law make clear the legal presumption that consent will be obtained in advance of an intervention, since any “touching” by a physician or scientist would be a battery had not the person already given permission. The presumption is also reflected in all contemporary regulations on consent. Sometimes it appears only indirectly, as in the Common Rule, which states that in order to approve research, an IRB must determine that (among other things) “informed consent will be sought from each *prospective* subject [emphasis added]” (§46.111 (4)).³⁶ Other times, as in §4.8.8 of the ICH-GCP guideline, the requirement is clear: “Prior to a subject’s participation in the trial, the written consent form should be signed and personally dated by the subject or by the subject’s legally acceptable representative, and by the person who conducted the informed consent discussion.”³⁵

One circumstance in which it is especially important to attend to the timing of consent is when researchers know that biological materials being taken for diagnostic or therapeutic purposes are going to be used (or stored for future use) in research. In such cases, according to Article 12 of the Council of Europe’s 2006 recommendations, whenever possible, informed consent for that use should be sought before the materials are removed.³⁹ Further-

more, the time between the intervention and the use may be quite long; when personal data and/or samples are maintained for years in *biobanks* or other collections, it will often be impossible to predict the nature or purpose of studies for which the material would later be useful. Although informed consent ought to “be as specific as possible with regard to any foreseen research uses and the choices available in that respect,” unless such consent is very broad (and hence of questionable ethical value), it will be necessary for researchers to make reasonable efforts to contact the person in order to obtain consent to use the materials beyond the scope of the original consent; failing that, according to the Council of Europe, research is limited to that which is essential or can be conducted with anonymized materials (Arts. 10, 22).³⁹

The two major situations in which the obligation to obtain prior consent may be waived are certain studies involving observation or deception, in which case subjects must be *debriefed* afterward and retrospective consent sought then, and research on treatments for emergency patients whose condition renders them unable to consent, in which case subjects must be informed “at the earliest feasible opportunity of the subject’s inclusion in the research, the details of the research and other information contained in the informed consent document” and “that he or she may discontinue . . . participation at any time without penalty or loss of benefits to which the subject is otherwise entitled” (21 CFR §50.24).³⁷ The requirements for waiving consent before commencing research in these circumstances, which vary among countries, are examined under “Waivers,” below.

C. Who Must Obtain Consent From Whom

The world of contemporary research, and particularly clinical trials of pharmaceutical and biological products, poses many challenges to the Nuremberg Code’s easy assumption that ethical research will involve an investigator personally obtaining consent from a person with the legal capacity to give it.

1. Person Obtaining Consent

Subsequent ethical and legal codes have accepted the position taken by the Nuremberg tribunal that the duty to obtain consent rests with the scientist conducting the study. The ICH-GCP Guideline even places the article “Informed Consent of Trial Subjects” in §4.8 of Section 4, which addresses the qualifications and conduct of the investigator.³⁵ Yet the Nuremberg Code’s classification of the duty as nondelegable does not mean that the task of informing the subject and obtaining his or her consent cannot be carried out by someone else; for example, Article 3.2(b) of the EU clinical trials directive states that information should be disclosed to subjects “in a prior interview with the investigator or a member of the investigating team.”²⁹ But being nondelegable, the obligation to ensure that the task is carried out correctly always remains the investigator’s, so if fault arises, responsibility rests with the investigator.

2. Person Giving Consent or Authorizing Participation

All adults are presumed to be capable of giving consent for medical procedures, including the choice to participate in a clinical trial. Most of the legal rules on informed consent do not dig below this presumption but simply acknowledge that some potential subjects, such as children, are legally incapable of giving valid

consent, and that, as the EU clinical trials directive states, “other persons [are] incapable of giving consent, such as persons with dementia, psychiatric patients, etc.” (Preamble, paras. 3, 4).²⁹ Although not well elaborated in most regulations, the question of potential subjects’ capacity deserves careful attention.

Capacity to consent is not simply a matter of cognitive ability, though the ability to understand that one is being asked to be a subject in research with certain obligations and potential risks and benefits is essential. Capacity also signifies that one is able to exercise free choice; hence, in certain circumstances, such as a prison, a person might be said to lack situational capacity. The contextual nature of the capacity to consent—that is, it is specific to a particular person facing a particular decision under particular circumstances—means that, just as in treatment decisions, a person may not be capable of making certain decision but can make others, or may lack the capacity at one point and then regain it, and vice versa. Blanket exceptions are particularly suspect when aimed at psychiatric patients, since even involuntary hospitalization for psychiatric treatment does not necessarily involve a finding of lack of capacity to make medical decisions.

Care in deciding which subjects are incapable of giving valid consent is especially important because research regulations now generally allow surrogate decision makers to act for such persons. Although limitations may be placed on trials in this situation (e.g., the same results should not be obtainable from a study with consenting subjects; the results of the study must be of value directly to the subjects or the group from which the subjects are drawn), recourse to the person’s *legal representative* underlines rather than removes the special vulnerability of those unable to consent for themselves. Whereas even a few decades ago, the legitimacy of any nonconsenting person being involved in a medical intervention not for his or her own direct benefit was strenuously debated, studies that entail “only minimal risk and minimal burden for the individual concerned” are now permitted, in accordance with Article 15.2.ii of the Council of Europe’s Additional Protocol, with subjects who are unable to consent for themselves.⁴⁰ Indeed, some rules, such as Guideline 9 of the CIOMS guidelines, go further, both in explaining that in the context of research interventions that do not hold out the prospect of direct benefit, minimal risk means “no more likely and not greater than the risk attached to routine medical or psychological examination of such persons” (who may be routinely exposed to burdensome examinations), and in allowing “[s]light or minor increases above such risk . . . when there is an overriding scientific or medical rationale for such increases and when an ethical review committee has approved them.”³⁰ Such an extension apparently rests on regarding such subjects as having an identity as members of a group (e.g., “the same age category or afflicted with the same disease or disorder or having the same condition,” as Art. 15.2.i of the Council of Europe’s Additional Protocol states),⁴⁰ and assuming that their identification with such a group justifies (to them, or at least to those making decisions on their behalf) the risks and burdens imposed on them.

It is common in the legal rules to describe legal representatives as giving “free and informed consent” for those incapable of consenting, as Art. 2.5 of Canada’s TCPS does.³⁸ However, it would be preferable to restrict the term *consent* to people deciding for themselves and to say instead that a legal representative provides “authorization” (Art. 15.1.iv of the Additional Protocol)⁴⁰ or “permission” (45 CFR §46.402(c))³⁶ for the subject. Whatever the

terminology, the rules consistently require that the legal representative be given the same information in the same (usually written) form that a consenting subject would receive, signify agreement in the same manner, and have the same authority over participation and withdrawal that a consenting subject would have. Finally, regulations commonly impose an obligation to make such disclosures to a subject incapable of giving consent as he or she would be able to understand. Some regulations, such as the U.S. Department of Health and Human Services' (DHHS') Additional Protections for Children Involved as Subjects in Research (known as Subpart D), specify that, in most cases, "adequate provisions" must be made for "soliciting the assent of . . . children" when "in the judgment of the IRB the children are capable of providing assent" (45 CFR §46.408(a)), "assent" being "a child's affirmative agreement to participate in research" (45 CFR §46.402).³⁶ Other legal provisions stipulate that persons without the capacity to consent may not be enrolled in research if they object, even with their legal representative's authorization (Additional Protocol, Art. 15.1.v).⁴⁰

D. Waivers of Consent Requirements

A number of grounds for waiving informed consent requirements are now recognized in regulations: the impracticability of obtaining consent, the need to study new treatments for emergency patients, and the need to test new interventions against chemical, biological, and nuclear weapons among members of the armed forces who may be exposed to them.

1. Omitting Consent When Obtaining It Is Not Practicable

Under the U.S. rules, an IRB may waive or alter informed consent requirements on grounds of "impracticability" in two situations. The first is for a governmentally approved study of a "public benefit or service program" that "could not practicably be carried out without the waiver" (45 CFR §46.116(c)).³⁶ The second occurs under the following conditions:

1. The research involves no more than minimal risk to the subjects;
2. The waiver or alteration will not adversely affect the rights and welfare of the subjects;
3. The research could not practicably be carried out without the waiver or alteration; and
4. Whenever appropriate, the subjects will be provided with additional pertinent information after participation (45 CFR §46.116(d)).³⁶

Although both of these exceptions start from the premise that research can be licit without informed consent when investigators would find it very difficult or unduly burdensome to obtain consent, the two exceptions differ in scope.

The first is narrow, being restricted to a type of research sometimes called a social policy experiment. The forgoing of informed consent here can be explained by the difference between the circumstances for which federal research rules were written—namely, biomedical experiments where drugs, surgery, or similar intervention could usually be used only with consent and where investigators enjoy no inherent privilege to enroll people in research absent their agreement—and social policy experiments where the approval of government officials serves a function simi-

lar to that of consent, since the interventions involved are usually ones that governments may alter without individuals' consent. Indeed, when approved by an appropriate federal official, studies of the latter sort are exempt not only from the consent rules but from all federal research review requirements (45 CFR §46.101(b)(5)).³⁶

Though it rests on a similar premise, the second exception is potentially much broader, taking in any study involving "no more than minimal risk" so long as the alteration of consent "will not adversely affect the rights and welfare of the subjects." The latter clause seems to underline that in addition to physical risks, subjects should not be exposed to other injuries to their "rights and welfare," but the protection provided is rather ephemeral because allowing researchers to omit the usual requirement to obtain informed consent in and of itself deprives subjects of the basic right not to be placed in research without their prior consent.

Paragraph (4) connects the exception to social and behavioral science studies in which the claim that prior informed consent would be impracticable to the design of the study, such as when results could be invalidated if subjects were forewarned that their behavior (or particular aspects thereof) was being studied. In such cases, Paragraph (4) states that subjects can be provided "pertinent information after participation," which would involve either taking the subjects through a complete consent process if none had occurred or providing them with those facts that had been omitted from the consent process to disguise the true purpose of the study to which they had "consented." As noted by the Canadian TCPS—which in Article 2.1(c) permits an exception to prospective consent under virtually identical rules (save that it adds a further limitation, disallowing waiver when a therapeutic intervention is involved)—this "debriefing" should be "proportionate to the sensitivity of the issue," in order to underline the importance of adequate counseling of subjects when the deception concerns matters such as relationships involving trust or revelations of a very personal nature.³⁸ Regardless of the sensitivity of the topic, research protocols should usually ensure that once the debriefing has occurred, subjects who object to having been involved without prior informed consent can have all information collected from or about them removed from the research records or database.

The scope of the second exception is, however, much broader than merely deception or behavioral studies involving after-the-fact debriefing and consent. An IRB may base its finding of impracticability on the character of the material (such as closed medical files or biological samples from a large group of patients who may be very difficult to contact), provided that the IRB also documents the absence of more than minimal risk and the investigator ensures that information from the records or specimens will not be used in a manner that adversely affects the subjects' welfare. Thus, consent requirements may be waived for studies that do not qualify for exemption from IRB review under §46.101(b)(4) because they involve data linked to an identifiable person that are derived from existing private records or specimens.³⁶

In exercising its authority to grant this exception, an IRB should be cautious about allowing consent to be waived in research that could lead to intellectual property (IP) rights involving findings based on the use of patients' records or specimens because the extent to which patients have any IP claim in such circumstances remains unsettled. In some recent cases, research review bodies have, for example, insisted that the holders of traditional knowledge used to produce a patentable invention must

share in the IP rights or should at least derive some benefit from the exploitation of those rights. Yet at least one court has held that a person whose biological material had certain unusual qualities that made it useful in producing a patentable product did not have a claim on the IP rights for that product. Nevertheless, the court in *Moore v. Regents of University of California* held that patients are owed a duty of full disclosure, including the intention of the physicians involved to make use of material taken from patients in a research project that could yield intellectual property.⁴¹ Therefore, in such circumstances, it would not seem possible for an IRB to certify that allowing research without prior informed consent would “not adversely affect the rights . . . of the subjects,” since in the absence of consent, the patients would not even know that their records or specimens might contribute to the physician-researchers’ IP claims.

2. Emergency Research Waiver

It is conventional law that consent is not needed to treat a patient who is unable to provide consent because of a medical condition that could cause death or grave impairment if not treated before the person regains the ability to consent and before authorization can be obtained from his or her surrogate decision maker. In such circumstances, an unproven treatment may be used if it offers the best potential outcome for the patient. For example, FDA rules at 21 CFR §50.23(a) allow the unconsented use of an investigational drug or device when a life-threatening situation necessitates the use and “no alternative method of approved or generally recognized therapy” is available “that provides an equal or greater likelihood of saving the life of the subject.” The rules specify that these conditions must be certified not only by the investigator but also by a second, independent physician.³⁷

The use of an intervention in a formal investigation of its efficacy for emergency patients (such as a randomized, placebo-controlled trial) is research, not treatment, and hence would not automatically qualify for the emergency exception. But, “in response to growing concerns that current regulations . . . are making high quality research in emergency circumstances difficult or impossible to carry out at a time when the need for such research is increasingly recognized,” the Secretary of Health and Human Services in 1996 created “a narrow exception” to the requirements of informed consent (which are grounded in statute) for “a limited class of research activities.”⁴² Thus, under U.S. rules and those since adopted in a number of other countries, a research ethics committee may allow such a trial (provided certain conditions have been met) even if neither the consent of the patient-subject nor the authorization of his or her legal representative can be obtained within a predetermined time period (termed the *therapeutic window*). The law in some jurisdictions explicitly allows the use of an advance directive for research,⁴³ and the FDA rules at 21 CFR §50.24(a)(2)(iii) seem to have such a research advance directive in mind in specifying that advance consent be sought when it is feasible “to identify prospectively the individuals likely to become eligible for participation in the clinical investigation.”³⁷ The most difficult cases arise when such prospective consent cannot be obtained.

The traditional ethical view, that physicians should intervene with nonconsenting patients only for therapeutic reasons, has eroded in recent decades. The most conservative view—that of the EU’s clinical trial directive, preamble para. 4—now seems to be

that patients should only be involved in research “when there are grounds for assuming that the direct benefit to the patient outweighs the risk,”²⁹ but in many cases, a more liberal exception is permitted, based on an essentially utilitarian justification. The FDA specifies at 21 CFR §50.24(a)(3) that such a trial may be approved when, based on “[a]ppropriate animal and other preclinical studies,” the research ethics committee finds that “[r]isks associated with the investigation are reasonable in relation to what is known about the medical condition of the potential class of subjects, the risks and benefits of standard therapy, if any, and what is known about the risks and benefits of the proposed intervention or activity.”³⁷ The Common Rule includes the same provisions for research not subject to FDA approval.

Given the inherently grave condition of emergency patients and the potential harm that could be caused by an experimental intervention, investigators and research ethics committees should be very wary about proceeding without consent. At least two conditions are essential. First, as the Council of Europe declared in Art.19.2.i of its additional protocol on biomedical research, a waiver is acceptable only when “research of comparable effectiveness cannot be carried out on persons in non-emergency situations.”⁴⁰ Second, as articulated in Article 2.8 of Canada’s TCPS, such research should be allowed only when it “addresses the emergency needs of [the] individuals involved.”³⁸ In other words, it is not permissible to conduct research under the waiver on a matter not related to the emergency (in contrast to a patient who could consent to being enrolled in a study unrelated to his or her disease or condition). Finally, when consent or legal authorization becomes feasible, it should be obtained. Under ICH-GCP provisions at §4.8.15, the subject or his or her legal representative “should be informed about the trial as soon as possible and consent to continue and other consent as appropriate should be requested.”³⁵ A similar provision exists in the FDA regulations at 21 CFR §50.24(b), which stipulates that the person deciding should be told that he or she may “discontinue the subject’s participation at any time without penalty or loss of benefits to which the subject is otherwise entitled.”³⁷

The leading regulatory systems respond in varied ways to the ethical dilemmas inherent in permitting research on emergency patients who cannot consent. The FDA rules require that an independent data monitoring committee be established to exercise oversight of the clinical investigation (21 CFR §50.24(a)(7)(v));³⁷ such a committee is supposed to have access to “unblinded” data on a regular basis, so that it can order a halt to any study whose continuation would be wrong. By contrast, the Council of Europe’s Additional Protocol restricts the permissible risk by relying on the method typically used for research on children. It specifies in Art. 19.2.iv that emergency research that offers no direct benefit to the person concerned, but that may produce knowledge that might benefit that person or others “in the same category or . . . having the same condition,” may be conducted without the subject’s consent if it entails “minimal risk and minimal burden.”⁴⁰

The U.S. rules (both FDA and the Common Rule as modified by the HHS secretary’s waiver) impose two “additional protections of [subjects’] rights and welfare,” whose intent and actual dictates are not entirely clear. First, when unable to contact the patient’s legally authorized representative, the investigator, in accordance with 21 CFR §50.24(a)(7)(v), must “commit” in the protocol, “if feasible, to attempting to contact within the therapeutic window the subject’s family member who is not a legally authorized

representative, and asking whether he or she objects to the subject's participation in the clinical investigation."³⁷ How a physician-investigator faced with an emergency would be able to track down family members who do not qualify as legal representatives is only the first problem with this requirement. Because the laws of most jurisdictions recognize a hierarchy of authority among next-of-kin, under which those lower down on the list gain authority only upon the unavailability of those more closely related to the individual, the basis for seeking out such a person is unclear. Why, for example, would it be appropriate to burden any relation of the patient that a researcher can find (the definition at 21 CFR §50.3(m) includes "any individual related by blood or affinity whose close association with the subject is the equivalent of a family relationship"³⁷), much less a child or a person with mental impairments, with this responsibility? And what if more than one such person were located or came forward, especially if they disagreed?

Even more problematic is what weight an objection voiced by such a person should have. This portion of the consent-exception rule does not actually require an investigator to exclude a subject on the basis of the family member's objection, merely to "summarize efforts made to contact family members and make this information available to the IRB at the time of continuing review." At 21 CFR §50.24(b), the rule provides that the IRB must "ensure that there is a procedure to inform the subject, or if the subject remains incapacitated, a legally authorized representative of the subject, or if such a representative is not reasonably available, a family member, that he or she may discontinue the subject's participation."³⁷ Assuming this applies as well to the decision to enroll a subject, it suggests that the family member's views would be controlling; however, such an interpretation would not be consistent with ordinary legal standards for medical decision making by third parties, under which a family member's objection to the research would not be dispositive unless it also represented the choice the emergency patient would have made.

The second requirement in the U.S. exception for research on emergency patients involves a process of "consultation . . . with representatives of the communities in which the clinical investigation will be conducted and from which the subjects will be drawn" and public disclosure to such communities "of plans for the investigation and its risks and expected benefits" prior to its initiation (21 CFR §50.24(a)(7)(i and ii)).³⁷ Although the regulation requires this process, it does not make clear what the investigator, or the IRB (if it carries out the consultation "where appropriate," as stated in the regulation), should do. Is the consultation intended to be a means simply for disclosure or is it also supposed to provide information to the investigator and IRB about the acceptability of the proposed trial to the community? If most people in the community find the study acceptable, should this be regarded as a form of proxy consent? Conversely, if most object, should the study be cancelled, or at least moved to another locale? The regulation does not answer such questions but hints that the regulators intend consultation primarily to serve a *disclosure* rather than *veto* function, because they also place a similar *disclosure* requirement on researchers when the trial has been completed "to apprise the community and researchers of the study, including the demographic characteristics of the research population, and its results" (21 CFR §50.24(a)(7)(iii)).³⁷ Why public disclosure would be needed to apprise the researchers of the study is opaque.

The regulation's uncertainties manifest that its authors realized that waiving consent in emergency research is problematic; these uncertainties also make it necessary for IRBs to be especially thoughtful in setting the conditions for research projects in this field. The regulation is also unusual in providing that if an IRB determines that it cannot approve a clinical investigation, the IRB must document its findings and provide them to the clinical investigator and the sponsor, who must promptly disclose this information not only to the FDA but also to other "clinical investigators who are participating or are asked to participate in this or a substantially equivalent clinical investigation of the sponsor, and to other IRB's [sic] that have been, or are, asked to review this or a substantially equivalent investigation by that sponsor" (21 CFR §50.24(e)).³⁷

3. Drug and Vaccine Research With Armed Forces Personnel

In response to fears about biological, chemical, and nuclear warfare attacks, the U.S. Food, Drug, and Cosmetic Act was amended several times in the 1990s to create a further exception, at 21 CFR §50.23(d)(1), to the usual informed consent requirements for "the administration of an investigational new drug to a member of the armed forces in connection with the member's participation in a particular military operation."³⁷ Under 10 U.S. Code §1107(f),⁴⁴ the president may waive the prior consent requirement (for a period up to one year) if the president determines in writing that obtaining consent is either not feasible or contrary to the best interests of the military member (in which case, the president must adhere to the usual FDA grounds for waiver in 21 USC §355(i)(4),⁴⁵ involving an immediate threat to the subject's life) or that obtaining consent would not be in the interests of national security.

In enacting the exception, Congress insisted on a high level of responsibility. The president's waiver must be initiated by a request from the secretary of defense that documents the substantial risk of an attack, the absence of a satisfactory medical alternative, the approval by a duly constituted IRB, the manner in which the intervention will take place, the ability of the Defense Department's record-keeping system to track the drug, its use and the medical follow-up, and that "conditioning use of the investigational new drug on the voluntary participation of each member could significantly risk the safety and health of any individual member who would decline its use, the safety of other military personnel, and the accomplishment of the military mission" (21 CFR §50.23(d)(1)(iv)).³⁷ Even when a waiver is granted and prior consent is not required, the disclosure requirements remain. Thus, according to 10 USC §1107(d), the armed forces member must still be provided with the following:

1. Clear notice that the drug being administered is an investigational new drug or a drug unapproved for its applied use.
2. The reasons why the investigational new drug or drug unapproved for its applied use is being administered.
3. Information regarding the possible side effects of the investigational new drug or drug unapproved for its applied use, including any known side effects possible as a result of the interaction of such drug with other drugs or treatments being administered to the members receiving such drug.⁴⁴

Furthermore, the statute specifies that the secretary of HHS may require additional information, and FDA regulations have

been issued, at 21 CFR §50.23(d)(1)(viii), which require that subjects be given “a specific written information sheet concerning the investigational new drug, the risks and benefits of its use, potential side effects, and other pertinent information about the appropriate use of the product.”³⁷ In addition, the Department of Defense must “provide public notice as soon as practicable” in the *Federal Register* “describing each waiver of informed consent determination, a summary of the most updated scientific information on the products used, and other pertinent information,” as required by 21 CFR §50.23(d)(1)(xvii).³⁷

Although the exception might be thought of principally as a military matter, its relationship to clinical research can be seen in the requirement that the Department of Defense must document that it “is pursuing drug development, including a time line, and marketing approval with due diligence” (21 CFR §50.23(d)(1)(xi)).³⁷ In effect, the Department is being treated as legally equivalent to any other clinical trial sponsor, which would mean, at least in theory, that its reason for administering the drug or vaccine to the armed forces members should be the same as that of any sponsor of a *therapeutic research* project: to produce information needed for licensing the product (and potentially to benefit the subjects). Given the open-ended nature of the “national security” justification for dispensing with consent, and the fact that, with advance planning, the other circumstances for an unconsented trial could usually be avoided, this exception, like the others, rests on a utilitarian justification for proceeding without prior informed consent. Moreover, dispensing with consent is grounded neither on the burden to the researcher in disclosing information prior to the trial nor on any potential risk to the subjects in doing so but rather on the Defense Department’s unwillingness to allow subjects to refuse to participate.

III. The Substantive Features of Valid Informed Consent

The essential requisites of a valid consent are that it be *informed* (which requires disclosure and comprehension) and *free* (which requires that the subject has acted voluntarily). The expectations for each aspect elaborated in the regulations are largely consistent between the Common Rule and the FDA, as well as the ICH-GCP guidelines and European regional requirements (see Table 57.1). These rules all pay much more attention to the disclosure requirements (which can more easily be enumerated and checked, at least on paper) than to the elements of comprehension and voluntariness.

A. Disclosure

Relevant U.S. regulations (namely, §46.116 of the Common Rule³⁶ and §50.20 of the FDA regulations³⁷) specify 13 mandatory elements that must be disclosed to prospective subjects (“shall be provided to each subject”) as well as six discretionary elements (“when appropriate . . . shall also be provided”); the elements of legally effective consent in the ICH-GCP guideline and the Canadian TCPS are substantially the same. The U.S. regulations permit an IRB to require that additional information “be given to subjects when in the IRB’s judgment the information would meaningfully add to the protection of the rights and welfare of

subjects” (45 CFR §46.109(b)).³⁶ The regulations also specify one item that must not be part of informed consent, whether written or oral, namely “any exculpatory language through which the subject or the representative is made to waive or appear to waive any of the subject’s legal rights, or releases or appears to release the investigator, the sponsor, the institution, or its agents for liability for negligence” (45 CFR §46.116),³⁶ and the ICH-GCP guideline contains nearly identical language in its section §4.8.4.³⁵

Several things are notable about these lists, which are at once incomplete and overlong. On the one hand, the lists omit important topics that appear elsewhere, such as among the 26 points specified in Guideline 5 of the International Ethical Guidelines produced by CIOMS³⁰ to elaborate the 2000 version of the Declaration of Helsinki (see Table 57.2). Also not mentioned is information about issues that have come to the fore since the Common Rule was issued in 1991, such as what will happen with biological specimens collected in the research, or subjects’ access to new medical products validated in the research, as well as other basic issues, such as the reasons the subject was selected to participate or potential conflicting interests of the investigator or institution. Some of these topics are covered in other guidance documents such as Article 2.4(e) of Canada’s TCPS, which requires disclosure of “the possibility of commercialization of research findings, and the presence of any apparent or actual or potential conflict of interest on the part of researchers, their institutions or sponsors.”³⁸ The importance of these topics can hardly be doubted, especially from the viewpoint of liability; allegations that undisclosed conflicting interests undermined the adequacy of informed consent have been made in several recent suits against research institutions, such as *Gelsinger v. University of Pennsylvania*, in which the family of an 18-year-old volunteer who died in a gene therapy study alleged lack of informed consent and misrepresentation⁴⁶ (see Chapter 10).

On the other hand, the Common Rule’s list is so lengthy that a consent form that complied with it risks not being the sort of succinct document that a person of ordinary intelligence with an elementary education would be likely to understand. Thus, the legal requirements for disclosure may interfere with expectations for comprehension and even voluntariness.

Unfortunately, investigators and IRBs that hope to achieve truly free and knowing consent while meeting the legal requirements receive scant help from the manner in which the elements are presented in the regulations. The points mix together factual statements (e.g., “an explanation of whom to contact in the event of a research-related injury” or “. . . [whom to contact] for answers to pertinent questions about the research”) with justifications (e.g., “an explanation of the purposes of the research”), and some things that are descriptions are called explanations (e.g., “an explanation of . . . the expected duration of the subject’s participation”).³⁶ Furthermore, the five points at 45 CFR §46.116(a)(1) that begin “a statement that . . .,” which would seem to amount to language prescribed for a consent form, are not presented separately nor are they all mandatory, including the statement that some risks may be unforeseeable, which pertains to all human actions.³⁶ (Similarly, another optional statement—that findings developed during the study will be provided to subjects if they might be relevant to the subjects’ decision to continue—ought always be included, except, of course, when the study is not expected to produce any findings until after all subjects have taken part in the research.)

Table 57.1**Requirements, Process, and Ethical Basis for Legally Valid Consent to Research in Leading Rules Having Legal Effect**

	<i>Nuremberg Code</i> ¹² (by numbered principle)	<i>Declaration of Helsinki</i> (revised, 2000) ³² (by paragraph)	<i>45 CFR Part 46</i> ³⁶ (by subsection number)	<i>ICH-GCP Guideline</i> ³⁵ (by subsection number, within §4.8)
<i>Norm for validity</i>	“voluntary consent” (1)	“freely-given informed consent” (22)	“legally effective informed consent” (116)	“informed consent” (1)
<i>Basis for norm</i>	Ethics of the medical profession and basic principles to satisfy moral, ethical, and legal concepts	Declaration of Geneva; International Code of Medical Ethics; legal requirement may not reduce or eliminate protections set forth (9)	Belmont Report; for foreign research, guidelines consistent with 1989 Declaration of Helsinki, if they afford “at least equivalent” protections (101(h))	“ethical principles that have their origin in the Declaration of Helsinki” (1)
<i>Use of subjects who lack capacity to consent (legally, physically, or mentally)</i>	Only subjects who are “able to exercise free power of choice” (1)	Allowed with consent of legally authorized representative if necessary to promote health of affected group and cannot be done otherwise (24)	Legally authorized representative may provide consent (111(a)(4)); for research involving children, special procedures in Subpart D, including children’s assent	Allowed with consent of legally acceptable representative if “therapeutic” or risks are low and objectives require using these subjects, who must be informed (12 and 14)
<i>Disclosure</i>	“sufficient knowledge and comprehension of the elements of the	“subjects must be . . . informed participants,” (20) “adequately informed [on 8 topics]” (22)	“in seeking informed consent the following information shall be provided [8 required and 6 optional topics]” (116 (a) & (b))	“should fully inform of all pertinent aspects of the trial” (5); written information must “include explanations of” 20 topics (10)
<i>Comprehension</i>	subject matter involved [nature, duration, and purpose; method and means; inconveniences and hazards] as to enable . . . an understanding and enlightened decision” (1)	Consent should be obtained “after ensuring that the subject has understood the information” (22)	“language understandable to the subject” and “sufficient opportunity to consider whether or not to participate” (116)	“language used should be as non-technical as practical and should be understandable to the subject” (4.8.6); “ample time and opportunity to inquire about details of the trial and to decide”; and all questions “should be answered to the satisfaction of the subject” (7)
<i>Voluntariness</i>	“able to exercise free power of choice, without the intervention of any element of force, fraud, deceit, duress, over-reaching or other ulterior form of constraint or coercion” (1)	“subjects must be volunteers” (20), may decline “without reprisal” (22), “if the subject is in a dependent relationship with the physician or may consent under duress” consent should “be obtained by a well-informed physician who is not engaged in the investigation and who is completely independent of this relationship” (23)	“circumstances . . . that minimize the possibility of coercion or undue influence” (116); tell subjects that participation is voluntary, with no penalty or loss of benefits for refusal (116(a)(8); added safeguards for “subjects likely to be vulnerable to coercion or undue influence, such as children, prisoners, pregnant women, mentally disabled persons, or economically or educationally disadvantaged persons” (111(b))	should not “coerce or unduly influence subject to participate or to continue” (3)
<i>Limitations on waiver of rights</i>	[not specified]	[not specified]	No exculpatory language to waive/appear to waive or to release negligence (116)	No language to waive/appear to waive any rights or to release negligence (4)
<i>Written vs. implicit consent</i>	“an affirmative decision”	in writing, or “formally documented and witnessed” (22)	Document by written consent, unless that risks breach of confidentiality or consent not usual for procedures used (117(c))	“written consent form should be signed and personally dated by the subject” and “by person who conducted consent” (8)
<i>Right to withdraw</i>	“at liberty to bring the experiment to an end” (9)	“Subject should be informed of the right . . . to withdraw consent to participate at any time without reprisal.” (22)	May “discontinue participation at any time without penalty or loss of benefits to which the subject is otherwise entitled” (116(a)(8))	May “withdraw from the trial, at any time, without penalty or loss of benefits to which the subject is otherwise entitled” (10(m))
<i>Role of the IRB/REC</i>	[no committee]	“consideration, comment, guidance, and where appropriate, approval” with “right to monitor ongoing trials” (13)	Require that information given to subjects meets regulations, plus any that would “meaningfully add” protection (109(b))	Prior to beginning trial, should have IRB’s “written approval/favorable opinion of written informed consent form” (1)

Table 57.2
“Essential Information for Prospective Research Subjects”
That Does Not Appear in 45 CFR Part 46

Before requesting an individual's consent to participate in research, the investigator must provide the following information, in language or another form of communication that the individual can understand:

3. . . . an explanation of how the research differs from routine medical care;
8. that subjects have the right of access to their data on demand, even if these data lack immediate clinical utility . . . ;
17. the sponsors of the research, the institutional affiliation of the investigators, and the nature and sources of funding for the research;
21. whether the investigator is serving only as an investigator or as both investigator and the subject's physician;
22. the extent of the investigator's responsibility to provide medical services to the participant;
26. that an ethical review committee has approved or cleared the research protocol.

From: Guideline 5, Council for International Organizations of Medical Sciences (2002)³⁰

Table 57.3 sorts the required elements into seven categories, keyed not only to the U.S. requirements but to the ICH-GCP guideline approved by the Committee for Proprietary Medical Products (CPMP) of the European Agency for the Evaluation of Medicinal Products (EMA), which provides the standard for clinical trials within, or whose data will be submitted to, the European Union. The purpose of the categorization in Table 57.3 is to encourage thoughtful and creative use of the legal requirements in the ethical review of research proposals and especially of the informed consent process.

The consent process should be focused on what is most important: that the potential subject is being invited to participate in a research project, the primary purpose of which is to produce new knowledge about a particular topic (as stated by the Declaration of Helsinki and built into the definition of *research* in the regulations); that this will involve being exposed to certain experimental interventions (including possible assignment to the control or placebo arm of the trial) and assuming certain responsibilities (that is, accepting burdens or limitations on one's life); that the person does not have to participate; and that failing to do so will not lead to loss of any existing alternative interventions the person would otherwise receive. These aspects are better conveyed when discussion of the first element under Orientation (“that the study involves research”) is used as an opportunity to explain what *research* means, and further when the elements gathered under Prediction do not lead to a mind-numbing recitation of remotely probable harms but instead produce an honest statement of the (small) likelihood of benefit and the existence of uncertainty.

Of course, for both ethical and liability reasons, it is important that all risks that could be material to a decision be conveyed; the suggestion in one Canadian judicial decision that all rare risks be listed has fortunately not been picked up by other courts.⁴⁷ The ICH-GCP guideline moves in the right direction by adding to the statement about reasonably expected benefits that “[w]hen there is no intended clinical benefit to the subject, the subject should be made aware of this” (§4.8.10(h)).³⁵ But to comply with the spirit

of this rule, investigators and research ethics committees will need to resist the temptation to omit this warning whenever even a small possibility of benefit can be hypothesized. The regulations should be read to avoid allowing the informed consent process to add to the already great risk that subjects will agree to participate under the influence of a *therapeutic misconception* (see Chapter 58). Bluntly put, subjects should be “asked if they are willing to be used as means to the ends of others.”⁴⁸

Several other points inherent in Table 57.3 bear mention. “The approximate number of subjects involved in the study,” which is optional under the U.S. rules (but required by the European), is placed under Orientation rather than Description because this fact can help to make clear to a potential subject what kind of a trial is being proposed. Will few people be involved because the intervention is at an early stage of investigation (such as a Phase I trial) in which *benefit* is not an endpoint? Conversely, are only very small effects expected at best, which requires a large number of participants in order to produce statistically significant results? Again, IRBs can use this element to stimulate those preparing informed consent materials to communicate what is truly involved in enrolling in a trial.

At the center of the seven categories is Options. The use of this term is intended to highlight that because the actual details of the intervention will be controlled by the protocol, the choices available to people participating in a clinical trial are very different from those available to patients in therapy. Thus, the two mandatory elements gathered here—a description of available alternatives, and assurance that no penalty will attach to declining to enroll or deciding to withdraw—represent a very modest version of *free choice*. Moreover, despite its inclusion in all sets of regulations, the right to withdraw is not without controversy.⁴⁸ Especially in situations far removed from the horrors of the Nazi camps that prompted the rule in the first place, a less absolute right may be appropriate. For example, in the context of stored specimens in research collections, the right to withdraw consent may mean that the biological materials should be rendered anonymous rather than removed from the repository, according to Article 15 of the Council of Europe's recent recommendations.³⁹ Perhaps the greatest value to the right is the reassurance it provides to subjects—even if few of them exercise it—that the choice to enroll in a research project is not irrevocable; of course, if this leads subjects not to weigh the choice carefully, that would, ironically, detract from the process of informed decision making.

B. Comprehension

As already suggested, the other two substantive attributes of legally valid consent, comprehension and voluntariness, are deeply dependent on what is disclosed to subjects and particularly on how well the basic choice whether or not to participate in the research project is presented. The other two elements are themselves important, however. Plainly, comprehension is essential for truly informed consent, for the act of disclosure would otherwise be pointless. As stated in the first principle of the Nuremberg Code, the subject “should have sufficient knowledge and comprehension of the elements of the subject matter involved as to enable him to make an understanding and enlightened decision.”¹²

At a minimum, then, “the language used should be as non-technical as practical and should be understandable to the subject,” in the language of the ICH-GCP (§4.8.6).³⁵ This also means

Table 57.3

Information to Be Disclosed to Research Subjects Under U.S. Federal Regulations and European Community Rules (ICH-GCP)

Category	U.S. Mandatory Elements (EC Elements are essentially similar except as indicated in boldface) <i>U.S. Discretionary Elements (EC Elements are essentially similar [but all are mandatory])</i>	45 CFR §46.166/ 21 CFR §50.25	ICH-GCP §4.8.10
Orientation	“a statement that the study involves research”	(a)(1)	A
	“an explanation of the purposes of the research”	(a)(1)	b
	“identification of any procedures which are experimental”	(a)(1)	f
	“the trial treatment(s) and the probability for random assignment to each treatment”		c
	<i>“the approximate number of subjects involved in the study”</i>	(b)(6)	t
Description	“an explanation of . . . the expected duration of the subject’s participation”	(a)(1)	S
	“a description of the procedures to be followed” “, including all invasive procedures”	(a)(1)	d
	“the subject’s responsibilities”		e
	“the anticipated prorated payment, if any, to the subject for participating”		k
	<i>“any additional costs to the subject that may result from participation in the research”</i>	(b)(3)	l
Prediction	“a description of any reasonably foreseeable risks or discomforts to the subject”	(a)(2)	
	“and, when applicable, to an embryo, fetus or nursing infant”		g
	“a description of any benefits to the subject or to others which may reasonably be expected from the research”	(a)(3)	h
	the reasonably expected benefits.” “When there is no intended clinical benefit to the subject, the subject should be made aware of this.”	(b)(1)	
	<i>“a statement that the particular treatment or procedure may involve risks to the subject (or to the embryo or fetus, if the subject is or may become pregnant) which are currently unforeseeable”</i>		
	<i>“anticipated circumstances under which the subject’s participation may be terminated by the investigator without regard to the subject’s consent”</i>	(b)(2)	r
Options	“a disclosure of appropriate alternative procedures or courses of treatment, if any, that might be advantageous to the subject”	(a)(4)	I
	“a statement that participation is voluntary, refusal to participate will involve no penalty or loss of benefits to which the subject is otherwise entitled, and the subject may discontinue participation at any time without penalty or loss of benefits to which the subject is otherwise entitled”	(a)(8)	m
	<i>“the consequences of a subject’s decision to withdraw from the research and procedures for orderly termination of participation by the subject”</i>	(b)(4)	
	<i>“a statement that significant new findings developed during the course of the research which may relate to the subject’s willingness to continue participation will be provided to the subject”</i>	(b)(5)	p
Identification	“a statement describing the extent, if any, to which confidentiality of records identifying the subject will be maintained” [FDA: “and that notes the possibility that the Food and Drug Administration may inspect the records”]	(a)(5)	o
	“records identifying the subject will be kept confidential and, to the extent permitted by applicable laws . . . , will not be made publicly available. If the results of the trial are published, the subject’s identity will remain confidential.”		n
	[Direct access to study records by monitors, auditors, IEC/IRB, and regulatory authorities is authorized]		
Remediation	“for research involving more than minimal risk, an explanation as to whether any compensation and an explanation as to whether any medical treatments are available if injury occurs and, if so, what they consist of, or where further information may be obtained”	(a)(6) (a)(7)	J
	“an explanation . . . of whom to contact in the event of a research-related injury to the subject”		q
	“an explanation of whom to contact for answers to pertinent questions about the research and research subjects’ rights”	(a)(7)	Q

that consent materials (including materials approved by the research ethics committee for soliciting subjects) need to be reliably translated into the language used by potential subjects when that differs from that of the investigator. (Back translation is a frequently used method for establishing reliability, but does not appear to be required in any statute or regulations.) More generally, in-

vestigators and research ethics committees should use some means to ensure that the reading level required to understand the consent form is appropriate for the group of potential subjects.

Section III (above) discussed the procedural requirement that consent must be sought from someone who has the capacity to give it; what is at issue now is whether that capacity has been used

to comprehend the information provided. Regrettably, the legal regulations on informed consent provide little guidance about how comprehension should be achieved or ascertained. The Common Rule, at §46.109(e), provides that an IRB “shall have authority to observe or have a third party observe the consent process and the research,” but this provision seems to be aimed at unusual research situations or at monitoring the conduct of researchers whose past conduct has raised questions about their reliability.³⁶ Given the burden that monitoring the process of obtaining consent would impose on IRB members or staff, it does not offer a routine means of ascertaining that subjects have understood the information provided.

Short of monitoring the consent process, the IRB can require that subjects be given an adequate opportunity to have any uncertainties cleared up. For example, §4.8.7 of the ICH-GCP guideline requires that before consent may be obtained, the investigator “should provide the subject or the subject’s legally acceptable representative ample time and opportunity to inquire about details of the trial and to decide whether or not to participate,” and all questions “should be answered to the satisfaction of the subject.”³⁵ Especially in settings in which those in power are not usually questioned, special effort may be needed to encourage subjects to ask for clarification or raise doubts. Furthermore, to fulfill the obligation stated in Paragraph 22 of the Declaration of Helsinki to ensure “that the subject has understood the information,” the person obtaining consent can be required to pose questions politely to prospective subjects about what they have been told and to exclude those whose answers indicate inadequate comprehension.³² The discretion accorded to ethics committees in all the regulations is broad enough to enable them to impose such requirements.

C. Voluntariness

As boldly declared in the Nuremberg Code’s opening words, “The voluntary consent of the human subject is absolutely essential.”¹² Yet this criterion for valid consent is the most difficult to implement in practice because voluntariness is a state of the mind, whereas the law, which deals with externalities, is dependent on discerning the state of mind from outward signs and circumstances. The elements in the Nuremberg tribunal’s litany—“force, fraud, deceit, duress, over-reaching or other ulterior form of constraint or coercion”—are not only inherently wrong as assaults on human dignity but are forbidden in the context of informed consent because they are used to produce a choice or action that their victim would otherwise not make. Yet, given the psychological overdetermination of most behavior, cases certainly arise, perhaps not infrequently, when the choice that a subject makes under pressure from someone else is nevertheless the same choice the person would have made absent that pressure. Nor is it always possible to use a choice itself to establish the voluntariness of an action because there is no one measure of which choices “make no sense” and hence hint at hidden coercion or undue inducement. For example, a choice that one person would reject as being insufficiently self-protective may represent another’s rational and voluntary embrace of an altruistic goal. Indeed, to the extent that the compulsion to act comes from inside, not out, what are investigators (much less IRBs) to do? A compulsion that is strong enough to be apparent—for example, a manifest desire to engage in risky behavior despite repeatedly injuries—might not render an

act involuntary, since the choice might reflect the person’s values and desires, though it could negate the presumption that the person has the capacity to make such decisions.

These difficulties do not mean that the legal rules on consent for research have ignored the requirement of voluntariness. In the main, besides repeating injunctions against investigators using coercion or undue influence (ICH-GCP §4.8.3),³⁵ the rules aim to protect persons who are vulnerable to having their free choice overridden. The problems in explaining when and why vulnerability arises are illustrated by the Common Rule’s requirement at 45 CFR §46.111(b) that “additional safeguards [be] included in the study to protect the rights and welfare” of “subjects likely to be vulnerable to coercion or undue influence, such as children, prisoners, pregnant women, mentally disabled persons, or economically or educationally disadvantaged persons.”³⁶ This lumping together of disparate groups does nothing to sort out the different meanings of vulnerability among them nor to help determine whether the circumstances of any particular person are inconsistent with the exercise of free choice about enrolling in a research project or what “additional safeguards” might thus be expected to be effective in restoring voluntariness.

Article 12 of the Council of Europe’s Additional Protocol obliges signatory countries to have regulations under which ethics committees are expected to give “particular attention” to “vulnerable or dependent persons” in making sure that “no undue influence . . . will be exerted on persons to participate in research.”⁴⁰ The accompanying Explanatory Report classifies subjects’ vulnerability due to cognitive, situational, institutional, deferential, medical, economic, and social factors (Para. 69) but offers no particular means of overcoming the resulting effects on voluntariness, which may be at odds with the assumption behind the disclosure rules.⁴⁰ For example, it is commonplace, in response to concerns about conflicts of interest, to insist that subjects be told about any incentives the enrolling physician is receiving from the trial sponsor. Such information would certainly be relevant in reaching an independent evaluation of the merits of participating in a study, but the disclosure would not in itself enable patients who feel dependent on the enrolling physician to exercise such independence. Paragraph 23 of the Declaration of Helsinki tells physician-investigators to “be particularly cautious” when obtaining consent “if the subject is in a dependent relationship with the physician or may consent under duress.”³² To increase the subject’s ability to exercise free choice, the ethics committee may insist that consent be obtained “by a well-informed physician who is not engaged in the investigation and who is completely independent of this relationship.”³²

Other legal rules exist to eliminate undue inducements and penalties as well as to overcome the effects of more subtle coercive forces. Policing the “rewards” given for trial participation poses a particularly difficult task. Cash payments are allowable; reimbursement of expenses and of direct losses (wages forgone or the like) being economically neutral are *prima facie* acceptable. Compensation for time or burden may, however, rise to a level at which, in the words of Paragraph 64 of the Additional Protocol’s Explanatory Report, subjects would “accept a higher level of risk than would otherwise be the case.”⁴⁰ This limit is, however, a matter of judgment and cannot be applied literally, because any payment—no matter how modest—may have the effect (and indeed the intent) of persuading some people to participate in

research when they otherwise would not; because the rule is clearly meant to exclude only certain inducements to accept “a higher level of risk,” ethics committees are left with the problematic task of applying their own sense of reasonableness (i.e., at what level a payment becomes an impermissible inducement to a subject to accept an unreasonable level of risk). Obviously, in judging inducements and penalties, familiarity with the circumstances of the potential subjects is necessary. Something as minor as bars of soap or transistor radio batteries might provide an undue inducement in a particular population, and the will of a feeble patient might be overcome by pressure to accept an experimental intervention where persons who are less weak would be able to refuse.

A circumstance that may involve both inducements and coercion is suggested by Subpart C of the U.S. DHHS research regulations (“Additional Protections Pertaining to Biomedical and Behavioral Research Involving Prisoners as Subjects”), which recognizes that “prisoners may be under constraints because of their incarceration which could affect their ability to make a truly voluntary and uncoerced decision whether or not to participate as subjects in research” (45 CFR §46.302).³⁶ Rather than focus principally on direct force, as might be expected in prisons, the regulation aims mostly at ensuring that the possible advantages to a prisoner from participating in research “compared to the general living conditions, medical care, quality of food, amenities and opportunity for earnings in prison” not be “of such a magnitude that his or her ability to weigh the risks of the research against the value of such advantages in the limited choice environment of the prison is impaired” (45 CFR §46.305(a)(2)).³⁶ The IRB has the burden of making sure that the advantages of participating in research are kept to a modest level.

The prospect that participation in research offers access to possible benefits (e.g., drugs or vaccines) not available outside the research setting is not unique to prisons, of course. In many clinical settings, either when no therapeutic alternatives exist or when those that do are unavailable to a prospective subject outside of a clinical trial, the notion of choice may seem rather hollow. Of course, the requirement, articulated in Paragraph 22 of the Declaration of Helsinki and repeated in many regulations, that subjects should be reassured that they may decline to participate in, or may withdraw from, a research project “without reprisal” is an essential ethical norm.³² Yet its legalistic formulation in the Common Rule (45 CFR §46.166(a)(8))—“refusal to participate will involve no penalty or loss of benefits to which the subject is otherwise entitled [emphasis added]”³⁶—which is echoed in the ICH-GCP guideline at §4.8.10(m),³⁵ is a reminder that the circumstances that make the offer of a place in a trial something that some subjects feel they cannot refuse often lie beyond a researcher’s direct control. Furthermore, physicians as well as patients are subject to the pressures created by constrained resources, and a physician in a low-resource setting may well decide to take part in research because the physician has nothing else to offer patients. “From that perspective,” as one such doctor has noted, “enrolling patients in a clinical trial will always look attractive, no matter how unethical that research may turn out to be.”⁴⁹ It is very difficult for IRBs to affect this barrier to voluntariness except by refusing to allow trials to be conducted among populations that have no alternative treatments or diagnostic regimens available; sometimes, however, these are the very settings in which research to develop new medical products is the most needed.

IV. The Administrative Aspects of Informed Consent Requirements

In light of the important rules governing the process and substance of obtaining valid consent, the administrative aspects may seem of only secondary importance. Yet the obligation of institutions to operate an IRB if their faculty or staff conduct federally sponsored and/or regulated research is the core legal requirement established by the National Research Act of 1974 (Public Law 93-348, codified at 42 U.S.C. 289(a)),⁵⁰ upon which the entire regulatory structure rests. The responsibility of such committees for the research process, including informed consent, is now a standard feature in research regulation globally. The administrative features of informed consent law take the form of rules on preparation, submission, review, implementation, and monitoring.

A. Preparation

Although the responsibility to obtain informed consent rests with investigators—indeed, in the ICH-GCP guideline, the provisions on informed consent appear in Section 4, “Investigator”³⁵—the rules describe consent forms in the passive voice, leaving unspoken who will prepare them. Whoever fulfills this role, the very formality of the requirements can stimulate careful reflection about what will occur in the research; the need to spell this out in the consent form and to be prepared to defend it before the ethics committee can generate self-reflection that benefits not only the consent process but even the design and execution of the research itself.⁵¹

In investigator-initiated research, it can be assumed that consent forms will be written by principal investigators and their associates, whereas in most clinical trials sponsors prepare them, along with the protocol and related materials. Sponsors’ greater familiarity with regulatory requirements makes it easier for them to write consent materials that cover all the requirements, but their financial interest in having trials executed quickly raises the danger that the consent document may be subtly slanted. The ICH-GCP guideline insists that the “investigator’s brochure” (a compilation of clinical and nonclinical data on the product being investigated, which is provided to researchers) present information “in a concise, simple, objective, balanced, and non-promotional form that enables a clinician, or potential investigator, to understand it and make his/her own unbiased risk-benefit assessment of the appropriateness of the proposed trial” (§7.1).³⁵ Although the research regulations all declare that consent forms must be nontechnical and understandable, none mandates objectivity and balance. (When reviewing consent forms, however, ethics committees should address potential bias and ensure that the forms are as evenhanded as possible; central to this is conveying that the activity involves an experiment, not a new treatment).

The person responsible for preparing the consent materials is also responsible for updating them. A promise to convey to subjects new findings from a trial that might affect their willingness to continue in the trial is a discretionary element in the federal rules (45 CFR §46.166(b)(5)).³⁶ By implication, the consent form for new subjects would need to be revised to reflect such information along with equally significant new information from other sources.

The ICH-GCP guideline, at §4.8.11, obliges investigators to provide existing subjects with such updated forms.³⁵

B. Submission

The Common Rule specifies that each IRB shall have written procedures for its work; the manner in which informed consent materials will be submitted is left to such local rules. Greater specificity appears in newer regulations, such as the guidance provided in February 2006 on the documentation needed under the EU clinical trials directive, which explains what information on recruitment arrangements (§6.1.2.4) and the informed consent procedure (§6.1.2.5) must be included in an application to an ethics committee before commencing a clinical trial.⁵² The application to the ethics committee must describe the procedure to provide information and obtain consent from the subjects—that is, who will give the information to potential subjects and when. The application also must provide the justification, and the procedures, for using legal representatives (such as for minors) and for relying on witnessed consent. The guidance document suggests the use of a “subject information leaflet,” which may go beyond the information in a typical consent form and may contain, for example, instructions on proper storage, handling, use, and disposal of the drug being studied. Pursuant to the EU clinical trials directive, the guidance also requires, at §6.1.2.5, the submission of an informed consent form that contains at least three elements:

- Consent to participate in the trial
- Consent to make confidential personal information available (direct access) for quality control and quality assurance by relevant personnel from the sponsor, a nominated research organization on behalf of the sponsor, and inspection by the competent authorities/institutions assigned this task in the Member State or, if applicable, the Ethics Committee
- Consent to archive coded information, and for its transmission outside the Community if applicable⁵²

C. Review

The central administrative procedure for informed consent is, of course, the research ethics committee’s review of relevant materials, especially the consent form. The committee is responsible for making sure that all required information will be provided to subjects and all procedural elements (such as needed documentation) will be satisfied, and it may add more requirements (such as means of measuring subjects’ comprehension) when doing so would, in the committee’s judgment, “meaningfully add to the protection of the rights and welfare of subjects” (45 CFR §46.109 (b)).³⁶ The committee’s authority to require modification in the informed consent materials or procedures is most frequently manifested in changes in the consent form (or leaflet). Once the committee is satisfied that the forms and process accord with the legal requirements, and it notifies the investigator that the proposed research has been approved, the research may commence. The investigator and the sponsor must retain documentation of this approval in their files.

The ethics committee has the responsibility to conduct continuing review of approved projects at appropriate intervals and

the authority to require modifications in the protocol and/or consent form as indicated.

D. Implementation and Monitoring

Investigators and sponsors are responsible for implementing research protocols (including consent procedures) as approved by the ethics committee, except that they may make any changes urgently needed “to protect the subjects . . . against any immediate hazard to their health or safety”⁵³ and may terminate the trial if the risk of harm from continuing is too great, without breaching any duty owed to subjects, provided due care is exercised and the consent form explains this possibility.⁵⁴ If an investigator or sponsor believes that significant changes in the protocol are necessary after a trial has commenced, then according to Article 10(a) of the EU’s clinical trial directive, the ethics committee must first be notified, must conduct a new review, and must decide whether to renew its approval, with such modifications in informed consent as are indicated under the circumstances.²⁹

In addition, the regulations give IRBs the authority to monitor research, including the consent process. The drug approval laws provide that clinical trial monitors should be appointed by sponsors to verify that the rights and well-being of subjects are protected, that the data reported are accurate and complete, and that the trial is being conducted in compliance with the approved protocol and applicable regulations. Monitoring, which typically involves on-site inspection, includes ascertaining that informed consent was obtained in the manner approved by the ethics committee, through review of the files that investigators are required to maintain. Monitors submit written reports to sponsors in which they summarize major findings, including any deviations and deficiencies regarding subjects’ consent and actions taken or needed. In addition to having monitors, sponsors are expected to conduct periodic independent audits of trials, which can also involve inspection of the records. When monitoring or auditing reveals problems, according to ICH-GCP the sponsor is responsible for ensuring compliance (§5.20.1) and, if necessary, for terminating an investigator’s participation in the study (§5.20.2).³⁵

V. Conclusion

The legal regulation of clinical research, including several essential elements of contemporary rules on informed consent, dates to the turn of the 20th century. The earliest legal standards arose in response to abuses of unconsenting subjects, just as the historic Nuremberg Code affirmed the basic rights of human beings in research in reaction to the Nazi concentration camp experiments. The formal protection of informed consent has waxed and waned over the six decades since Nuremberg. The text that gives the most limited scope to patient-subjects’ choices, the Declaration of Helsinki, is routinely invoked as the guiding document by research ethics committees around the world that are formally committed to protecting subjects.

In its first principle, the Nuremberg Code proclaims autonomy—the authority of each person to make his or her own choices about serving as a research subject—to be the core of research ethics: The prior, voluntary, informed consent of research subjects is “absolutely essential.” Yet, despite the apparent

incorporation of this principle into laws and regulations, utility and beneficence have emerged as the dominant values, though this has been disguised by the attention lavished on the rituals of “informed consent.” Given that the legal requirements that might actually ensure that people have made free and well-informed choices about whether to take part in research are quite weak, subjects remain relatively minor decision makers regarding the research enterprise, compared to sponsors, investigators, and review bodies.

If the principle of autonomy is imagined as a disk, it would be one that had been trimmed back substantially from the outer edge by regulations allowing research without the prior informed consent of many of the people being studied (see Figure 57.1). In some of these situations, such as research on minors or circumstances in which obtaining consent is not practicable, the IRB is supposed to ensure that research “involves no more than minimal risk to the subjects” (or a “minor increase” that is within the range experienced by the particular subjects in medical care). But other research studies—such as tests of emergency interventions, or clinical trials of drugs and vaccines on military personnel—are not limited to minimal risk, though the risks must be balanced by potential benefits. Equally important, though less obvious, the disk is also cut away from the center by the allocation to the IRB of the authority to decide which studies may be conducted on risk-benefit or other grounds. Such an exercise of judgment is not inherently problematic; indeed, it simply represents an independent body (the IRB) ensuring that investigators have fulfilled the long-recognized obligation of beneficence, itself a part of the

Nuremberg Code. But the result is to cut back the metaphorical disk to a relatively small ring around a large hole, because people other than the research subjects have weighed the potential harms and benefits and decided whether to proceed.

Subjects thus exercise their right of informed consent in only a limited range of remaining studies, in which their formal agreement is a necessary, albeit not sufficient, ground for the study to proceed. Prime among allowable studies are clinical trials in which the risk of the intervention is minimal, such as studies comparing standard therapy (or a placebo) to a minor variation on standard therapy or observational studies that produce data with personal identifiers. The ring also includes some studies that pose more than minimal risk, namely when seriously ill patients might derive a large benefit from the intervention being studied (though it excludes research that some potential subjects might be willing to undergo that in the judgment of an IRB would entail an unfavorable balance of risk and benefits).

To conclude that the legal rules on informed consent have, perhaps unintentionally, narrowed the range of research in which prior informed consent actually plays a role is not to deny the importance of autonomy as an ethical principle. Rather, to accept that consent operates in a narrow range of cases is to underline that an essential question needs always to be clearly posed to potential subjects: Do you understand what it means to participate in research and, if so, do you want to participate in this trial? If the needed attention to this question is absent—either because the decision to encounter a minor risk is treated as inconsequential or because the

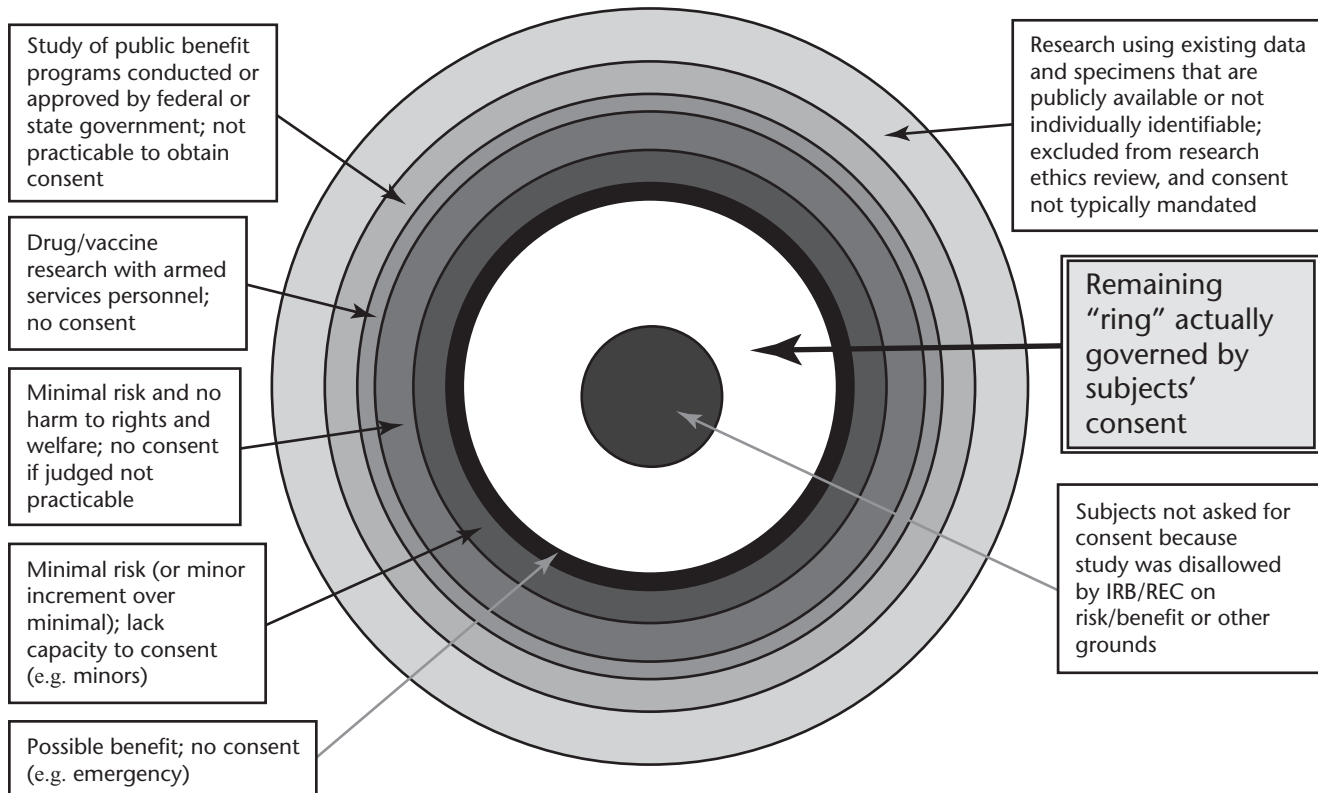

Figure 57.1. The Limited Scope for Informed Consent in Research: The “Autonomy Disk,” Diminished From Within and Without

possibility that subjects might benefit leads all concerned to treat the research as *therapy*—then the listing of many other factors, as required by informed consent regulations around the world, will be of little significance. This is the paradox at the heart of research regulation. A system erected on a deep commitment to autonomy has evolved such that the law of informed consent provides little protection for the vital choice it is intended to protect.

An enigma remains, beyond the scope of this chapter: Is this problem inherent or only a result of having lost sight of the ethical starting point as the legal standards have been formulated and applied? The original 1964 Declaration of Helsinki claimed that the “responsibility for clinical research always remains with the research worker; it never falls on the subject, even after consent is obtained.”³¹ Does this embody a preference for protection over autonomy, or merely an insistence that the consent form should not be seen as a contract that relieves the researcher of liability for proceeding with unjustified research? It may be that informed consent is freighted with expectations generated by its use in the therapeutic context in which it can be a vehicle for open discussion between physician and patient to arrive at choices that aim to align individual preferences and values with interventions and outcomes. Given the dictates of research protocols, such expectations are unrealistic; for subjects, the “choice” is often nothing more than *à prendre ou à laisser* (“take it or leave it”). Thus, perhaps the more modest version of informed consent that is found in the laws regarding research should come as no surprise. Yet the legal rules are a floor, not a ceiling. It thus remains for investigators, sponsors, and research ethics committees to execute their respective responsibilities in a fashion that gives subjects the opportunity to make choices in as voluntary and understanding a manner as they are individually able. In particular, the formal requirements to disclose information can open the door for the investigator to share further information honestly, “answering questions and identifying unanswerable questions, appreciating doubts and respecting fears.”⁵⁵

The Therapeutic Misconception

In the early 1980s, in the course of conducting a study of informed consent in psychiatric research, we noticed an interesting phenomenon exemplified by the following case example.

A 25-year-old woman, who was participating in a randomized, double-blind, placebo-controlled study of two medications for borderline personality disorder, was interviewed shortly after consenting to enter the project. At the time of the interview she displayed no apparent psychiatric symptoms, and her intellectual ability seemed consistent with her history of having completed three years of college. Her understanding of the research was generally excellent. She recognized that the purpose of the research project was to find out which treatment worked best for the class of patients of which she was a member. She spontaneously described the three groups, including the placebo group, and indicated that assignment would be random. She understood that dosages would be adjusted according to blood levels, not her level of symptomatology, and that a double-blind would be used. When she was asked directly, however, how her medication would be selected, she said that she had no idea. She then added, "I hope it isn't by chance," and suggested that each subject would probably receive the medication he or she needed. Given the conflict between her earlier use of the word "random" and her current explanation, the issue was pursued. She was asked what her understanding of "random" was. Her definition was entirely appropriate: "By lottery, by chance, one patient who comes in gets one thing and the next patient gets the next thing." She then began to wonder out loud if

this procedure were being used in the current study. Ultimately, she concluded that it was not.¹

What is going on here? This was a well-educated, intelligent, asymptomatic patient in a clinical research trial who seemed to have an excellent understanding of the project to which she had just consented. When it came to applying that knowledge to her own situation, however, she was unable to do so. That is, though she appeared to understand in the abstract that the methods of this clinical trial, specifically randomization, meant that decisions about participants' treatment would not be made on the basis of an individualized judgment as to what would be best for them, she seemed unable to appreciate that this would also be true in her own case. As a result, it appeared probable that she had consented to research participation with a false assumption about the consequences of becoming a subject in this study, including the possibility that she might receive a placebo.

We dubbed this phenomenon the *therapeutic misconception* (TM), and defined it as the mistaken belief that decisions about one's treatment while a research subject would be made solely based on one's individual condition and needs.¹ Since publication of our initial paper and later article with more detailed data from our study,² TM has been recognized as a major obstacle to obtaining ethically valid consent in clinical research.³⁻¹⁰ In this chapter, we review the tension between the ethics of clinical care and the ethics of research that lies at the core of TM, describe its probable origins among research subjects, provide an overview of TM's phenomenology, and suggest ways in which its prevalence might be reduced.

The Tension Between Clinical Ethics and Research Ethics

The ethics of clinical medicine are governed by what the legal philosopher Charles Fried referred to as the principle of *personal care*.¹¹ By this he meant that the dominant assumption among both physicians and their patients is that all decisions made by a physician will be intended to advance the patient's well-being. When a treatment is recommended for a patient, it will be chosen because the physician believes that it is the regimen most likely to cure the patient's illness or control the patient's symptoms, or because it is thought to offer the best available balance between the likelihood of effectiveness and magnitude and probability of side effects. In either event, it is the patient's interests that have primacy. There are some rare occasions, such as the imposition of quarantine, when physicians may make decisions that are contrary to their patients' interests or wishes; however, these are clearly departures from the norm and the long-standing debates about them are evidence of their exceptional nature.¹² Of course, there may be circumstances in which physicians fall short of fully embodying the ideal of personal care, as when treatment recommendations are made on the basis of the physician's financial interests or convenience, or as a manifestation of overt malevolence. That such situations occur, however, does not negate the normative force of the principle of personal care, on the basis of which these behaviors will be condemned as inappropriate deviations by both physicians and patients.

Note that adherence to the principle of personal care does not require that physicians be correct in their judgments as to how best to advance patients' interests. Their choices may be objectively wrong (i.e., existing data indicate another approach is more likely to be effective) or simply unsuccessful after the fact. Or, in the patient's particular situation, there may be no scientific reason to prefer one approach to another. In all of these cases, so long as the physician makes a decision based on what the physician reasonably believes is most likely to be in the patient's interests, the principle of personal care is vindicated.

As Fried points out, however, in a clinical research study "the care [participants] receive is not chosen exclusively on the basis of a concern for their individual well-being, but with regard to the success of the experimental design."¹¹ We have identified several aspects of research methodology that involve—to a greater or lesser extent—the sacrifice of personal care for the sake of protecting the integrity of the research data. These include randomization, double-blind procedures, placebos, protocols that restrict discretion in the administration of treatment, and limits on the use of adjunctive treatments.² We consider each in turn.

Randomized assignment to treatment conditions, common in research as a means of controlling bias in the allocation of subjects, undercuts the individualized determination of treatment needs that lies at the core of personal care. Some ethicists have argued that because randomization is used only when the treatment options are in clinical equipoise (i.e., there is no persuasive empirical evidence of an advantage for one over another in the patient population as a whole),¹³ there is no sacrifice of personal care in these situations. However, even in the absence of agreement in the medical community regarding general preferences for treatment of a given condition, there may be important reasons to favor one over another for particular patients.¹⁴ The treatments being com-

pared may have a differing range or likelihood of side effects, about which patients might have clear preferences because of the differing impacts on their lives. It will not be a matter of indifference, for example, to an architectural draftsman whether he receives a medication that induces a tremor or a likely equally effective one with a different side-effect profile. When new treatments are being compared with standard approaches, there may again be reasons for particular persons to have decided preferences among those choices. It is precisely because potential subjects may have failed to obtain acceptable results with "treatment as usual" that they may decide to enroll in research. Patients may also have individual characteristics that suggest a better response to one treatment than another (e.g., a sibling who successfully responded to one treatment, but not to another). Even if none of these situations obtains, it is clear that patient/participants who believe that individualized choices are being made about the treatments they receive—witness the case described at the beginning of this chapter—have badly misconstrued the situation into which they are entering.

Given that treatment will be assigned randomly, the use of double-blind procedures, in which neither the treating physician nor the patient/participant knows which treatment is being administered, may not seem to involve a further compromise of personal care. But in fact, when blind to the treatment, the ability of the physician to monitor and respond to unwanted effects of the treatment, or to instruct the patient/participant in self-monitoring, may be reduced. Not knowing whether the patient/participant is receiving a medication that induces nausea, for example, cannot help but complicate the task of trying to decide whether one is dealing with a medication side effect or the first sign of a recurrent gastric ulcer. Even mechanisms to flag subjects in some way as participants in a blinded trial, which may have value in emergency situations, do not entirely diminish this risk. Moreover, the failure to appreciate that a double-blind is being used often reinforces patient/participants' misconception that treatment is being selected based on their individual needs.

Use of placebos provides one of the most striking contrasts between ordinary clinical and research settings. Because placebos' use in the treatment context often involves deception of the patient, they are rarely employed for clinical purposes.¹⁵ However, they may have considerable utility in research as a means of establishing a baseline of spontaneous improvement or clarifying the impact of nonspecific factors, such as the increased attention that patient/participants may receive in a research clinic, against which the therapeutic effect of active treatments can be measured.¹⁶ Placebo use has become a matter of controversy when even partially effective treatments exist,¹⁷ although placebos may be scientifically appropriate depending on the circumstances of a particular clinical trial.¹⁸ In any event, it should be clear that when placebos are used, they violate the usual assumption of personal care that the physician will select an active treatment intended to alleviate the patient's symptoms.

More subtle, perhaps, is the impact of fixed protocols for the administration of treatment. Many studies, for example, specify the dosage of a medication to be administered, the intervals (if any) that must pass before adjustments can be made, and the magnitude of these alterations. The extent of such restrictions can vary substantially across studies. Unless treatment is standardized in some way, however—except for purely observational studies—it

will be difficult to know precisely which intervention has been tested or to replicate the research. In ordinary practice, of course, physicians routinely raise or lower the dose of a medication in response to side effects or to accelerate therapeutic response. When a physician loses the freedom to make such changes, the patient experiences the loss of some degree of personal care. Arguments that patients are often better treated by means of fixed protocols, because these eliminate the sometimes irrational variability in physicians' decision making, may be true on occasion, but in the context of research participation are largely beside the point. Whether such flexibility is ultimately to their benefit or not (and it is hard to see that it would not be beneficial whenever avoidance of side effects is the goal), patient/participants have lost the opportunity for an individualized decision to be made about whether and when to deviate from protocol-driven approaches to treatment.

Finally, when adjunctive treatments are limited or banned entirely, patient/participants lose another attribute of personal care that would ordinarily obtain in clinical settings. Such restrictions are not irrational from an investigator's perspective. Unless the treatment is limited to the intervention being tested, it will be impossible to know which aspect of care was responsible should a positive result be obtained. For example, although it is not uncommon for more than one antidepressant medication to be prescribed to a depressed patient who has not been responsive to a single treatment, allowing such concatenation of medications in a clinical trial of a new drug will preclude definitive assessment of that medication's effectiveness. Medications that alleviate side effects, or in some situations medications that treat other conditions, may be restricted because of the possibility that they will interfere with assessment of the therapeutic effect of the medication(s) being tested. For example, patient/participants in a clinical trial of a new sleep medication may not be allowed to take antihistamines for their allergies because of the possibility that the antihistamines will augment the sleep medication's effect. Once more, the difference between being in a research project and receiving ordinary clinical treatment may be significant.

To be clear, none of these approaches to research is necessarily illegitimate. Indeed, in many cases they will be critical to the conduct of a meaningful clinical trial. Designing a study without using methods that protect the integrity of the data may only serve to expose patient/participants to risk with no likelihood of a compensating incremental gain in knowledge. Any or all of the research methods that we have identified as diminishing personal care are acceptable when (1) they do not alter the risk/benefit ratio for patient/participants to a degree that makes experimentation with humans unacceptable, (2) they are scientifically necessary (or at least extremely helpful) to generate meaningful data, and (3) patient/participants have provided a valid informed consent for their use. It is the final condition of these three that is affected by the presence of TM. Whether TM by itself is sufficient to invalidate consent is considered below.

To summarize, the ethical tension inherent in most clinical trials arises from deviations from the principle of personal care that controls physicians' behavior in the ordinary clinical context. These practices should not be undertaken without the valid consent of patient/participants. When TM is present, however, such consent is impaired at best and may be effectively compromised. Hence, TM's importance as a major potential obstacle to informed consent in clinical research.

The Origins of the Therapeutic Misconception

Why might patient/participants manifest a TM? Although careful studies of the origins of the phenomenon remain to be performed, we believe two sets of causative factors play a role here. One reflects the preconceptions with which patients arrive in the clinical research setting, and the second results from the experiences they have in that setting itself.

Patient/participants bring concepts shaped by a lifetime of contact with medical professionals into the context in which they are asked to give consent for research participation. As a consequence of those interactions, they have learned that physicians are supposed to deliver personal care—though it is probable that they have never heard that term. Instead, they are likely to say, "My doctor will recommend whatever he or she thinks is best for me." Precisely that attitude is often carried into the setting of clinical research.

Although ethicists differentiate carefully between clinical and research settings, the differences may not be as clear to potential patient/participants. Referral to clinical trials often results from a visit to a physician (perhaps even one's personal physician) seeking help for a clinical problem, and the referral itself may be seen as a response to that request. When patient/participants meet the staff of a research project, they may find physicians and nurses in white coats or scrubs with stethoscopes slung around their necks—precisely the images they have always associated with ordinary treatment situations in which they have received personal care. Indeed, in some cases, it will be the patient/participants' own physicians who recruit them and carry out the research study. Far from being irrational for patient/participants to assume that their needs will have primacy in this new context, in many respects it would be rather odd if they did not.

Media coverage of the research enterprise may reinforce this tendency. News outlets often portray research efforts in terms that suggest research centers provide the best care—something that these institutions' own advertising frequently reinforces.¹⁹ Hence, the findings of the Advisory Committee on Human Radiation Experiments, based on interviews with more than 500 former research participants, seem entirely natural: "Patient-subjects frequently expressed the belief that an intervention [e.g., research participation] would not be offered if it did not carry some promise of benefit; many certainly assumed that the intervention would not be offered if it posed significant risks."⁴

Investigators' behavior may also contribute to the development of TM. Research projects are often denoted by titles or acronyms that suggest that patient/participants will receive optimal care, such as "BEST," "MAGIC," "MIRACL," or "PROVED."²⁰ Newspaper and website advertising aimed at recruiting participants may emphasize clinical benefits while underplaying the potential costs of enrolling in a clinical trial. Mark Hochhauser has assembled a telling collection of such promotional material, including the following from a press release posted on the website of a major academic medical center: "Chosen for their interdisciplinary nature and potential benefits to patients, these programs range from fundamental investigations of the origin of disease to advanced clinical trials in which patients have access to the latest and most promising treatments." As Hochhauser notes, "'Latest' and 'most promising' are not the same as effective," nor would potential patient/participants glean from this glowing description

that they may receive a placebo or an older comparison drug, and that they will otherwise sacrifice the personal care they are being led to expect.²⁰

Disclosures from research personnel themselves, whether written or verbal, may subtly or directly suggest to patient/participants an illusory adherence to personal care. Consent forms often avoid terms that directly indicate the experimental nature of the research endeavor, for example, referring to a “study medication” or a “new drug,” rather than an “experimental medication,” and avoiding “experiment” and even “research” in favor of “study,” “project,” or “clinical trial.”²⁰ Patient/participants may have very different associations to each of these terms.⁴ Consent forms may also be vague and misleading about the degree of likely benefit, as was the case in a recent large-scale study of gene-transfer research.²¹ Even a study that concluded that consent forms in Phase I oncology trials were generally unobjectionable found that the experimental agent was referred to as “treatment” or “therapy” on 260 of 272 forms that were examined.²² Verbal disclosures may fail to include discussion of those research methods that limit personal care, and may even underscore the therapeutic potential of a study in an overtly misleading way.^{23–26}

These behaviors may stem in part from a desire to be as persuasive as possible in recruiting patient/participants, as well as from investigators’ own reluctance to recognize the ways in which they are departing from clinical norms. One study of American oncologists who were queried about the purposes of clinical trials revealed that 13% to 38% of respondents in various oncologic subspecialties “believed that ensuring state-of-the-art therapy for trial participants, rather than improving the treatment of future cancer patients, is the main societal purpose of trials.”²⁷ Indeed, discomfort with deviating from the interests of their patients has sometimes led researchers to subvert their own studies, for example by tampering with randomization procedures to obtain the treatment they think will be most helpful for their patients,^{28,29} perhaps not a surprising phenomenon in a profession trained to place individual patients’ interests first.

Even when investigators do their best to disclose to patient/participants the nature of the research and the ways it may differ from ordinary clinical care, impediments to communication may limit their effectiveness. Research terminology is foreign to many patients. In a study of participants drawn from the general population, Waggoner and Mayo found that 25% did not know what a placebo was, 83% could not define a *double-blind*, and 78% did not know the meaning of *random*.³⁰ A striking example of how confused patient/participants can become from research jargon that is routinely used by investigators and their staff comes from an interview that our research staff performed with a cancer patient who was recruited for a cancer chemotherapy trial in which she was informed that she would be assigned to one of the treatment “arms” of the study:

INTERVIEWER: What does the project involve? The research study? What does your participation involve?

SUBJECT: Well, they choose an arm . . . one arm [subject points to her arm] . . . for an operation . . . the other one for the IV. If they choose the arm for the operation . . . I mean for the IV, there’s no operation involved.³¹

In fact, the patients in this study would in no case have received an operation, and would in either case have gotten intravenous chemotherapy. But the use of the term *arm* to mean treatment

group had left this patient totally confused as to the nature of the research project to which she had just consented.

It is worth noting that although the paradigmatic situation in which TM arises is a clinical trial—in which patient/participants have at least some opportunity to receive what may be effective treatment for their conditions—it may appear in even less probable venues. Wholly nontherapeutic research studies, such as investigations of pathophysiologic mechanisms underlying disease states, may be wrongly interpreted by participants as involving treatment and hence as holding the potential for therapeutic benefit. Somewhere along the lower end of the spectrum of potentially beneficial research are Phase I medication trials, which are intended to assess the tolerability and toxicity of experimental medications. Phase I trials of chemotherapeutics for cancer have been a particular focus of attention. Although the generally accepted data suggest that less than 5% of experimental cancer medications in Phase I trials are found to have any therapeutic benefits at all,³² an overwhelming proportion of participants in several studies—as will be discussed below—have attributed to them therapeutic intent.

Phenomenology of the Therapeutic Misconception

Defining the Therapeutic Misconception

Before considering how TM is typically manifested, we need to offer a more detailed definition of the phenomenon. We suggested above that at its core TM involves a patient/participant’s failure to recognize how personal care may be compromised by research procedures. Our research has led us to the conclusion that this core concept of TM can appear in two ways: (1) an incorrect belief that the patient/participant’s individualized needs will determine assignment to treatment conditions or lead to modifications of the treatment regime (TM1) or (2) an unreasonable appraisal of the nature or likelihood of medical benefit from participation in the study, due to misperception of the nature of the research enterprise (TM2). In the case of TM2, the misconception relates to aspects of research involvement other than individualization of care.

We have already examined some of the ways in which an incorrect belief that treatment decisions will be based on individual needs may be evident, such as when patient/participants fail to grasp that the treatment they receive will be chosen at random, rather than on the basis of what the physician believes is most likely to be of benefit to them—an example of TM1. But some patient/participants manifest a broader misconception about the nature of the research enterprise itself, as it relates specifically to the likelihood of benefit from participation—TM2. An obvious example is when a person misinterprets a research project that has no therapeutic intent—for example, a study of the pathophysiology of migraine—as holding the prospect of personal benefit. Even in research that tests clinical interventions, however, patient/participants may fail to recognize that the research is being done precisely because of uncertainty as to whether a new treatment is effective (or is more effective than existing treatments), and hence may believe that their involvement is highly likely to be beneficial. Often this belief is linked to the previously noted conviction that a physician would not suggest enrollment unless it was very likely to be of benefit to everyone in the study and very unlikely to present any substantial degree of risk. Here, the misconception in-

volves a misunderstanding of the very purpose of research rather than of a particular methodologic aspect precluding individualization of treatment.

Hornig and Grady have recently attempted to draw some finer distinctions, differentiating TM from what they refer to as *therapeutic misestimation*, which occurs when “[t]he research subject underestimates risk, overestimates benefit, or both.”³³ This category would appear to include both genuine manifestations of TM2 and misestimations that occur for other reasons, such as participants’ difficulty understanding probability statements or the failure of investigators to disclose risks. When misestimation occurs as a result of a misconception of the nature of the research itself, we would include it within the definition of TM2.

Prevalence of the Therapeutic Misconception

TM was initially described as part of a study (led by Loren Roth) of informed consent in four psychiatric research projects.^{1,2} Among the 88 patient/participants who were interviewed after consenting to participate in a clinical trial, 69% were unaware that their assignment to treatment interventions would be randomized and 40% explicitly said that treatment assignment would be made on the basis of their therapeutic needs. Forty-four percent of patient/participants failed to recognize that the use of placebos and nontreatment control groups meant that some who desired the experimental intervention would not receive it. And when explicitly asked, only 9% could identify a single way in which joining a protocol would restrict their options for treatment.

Some critics dismissed these data as displaying merely the expectable confusion that people with psychiatric disorders would naturally evidence. But they are consistent with data from a variety of areas of medicine suggesting that a desire for personal benefit is the major motive driving research participation, even in studies with little prospect of benefit.^{34–37} A typical survey in a combined sample of patients and nonpatients showed that when asked why people in general should participate in research, 69% of respondents cited benefit to society, and only 5% cited benefits for participants themselves. But when asked why they might participate in a research project, 52% said they would do it to get the best medical care, and only 23% responded that they would participate to contribute to scientific knowledge.³⁴ Although the desire for medical benefit is not in itself an indication of TM, when it is manifest as an unreasonable belief in the likelihood of benefit—for example, because the research is understood as offering the opportunity to receive the latest treatments of proven efficacy—it may reflect TM2.

Moreover, studies exploring the attitudes of patient/participants in nonpsychiatric research come up with findings at least as striking as those from the original TM study. In a study of 144 patient/participants in Phase II and III cancer chemotherapy trials, the authors reported that “[d]espite statements in most consent forms that benefits could not be guaranteed, 43% of patients stated that they had no doubts at all about benefits from the treatment,” a degree of certainty incompatible with the yet-to-be-demonstrated efficacy of the treatment being tested.³⁸ Even more remarkably, a study of 127 patients in four cancer chemotherapy protocols at the National Institutes of Health showed that despite being provided with contrary information, 100% of the patient/participants in Phase I studies described their protocols as having

both treatment and research aims.³⁷ Another study of 144 Phase I cancer chemotherapy patient/participants found that 88% of them said that the goals of their current treatment were no different than in prior noninvestigational treatments, and not a single person mentioned altruistic reasons for participation.³⁹ A final study of 207 cancer patient/participants showed that 74% did not recognize that they might receive a nonstandard treatment, 63% did not understand the potential for incremental risk, 70% failed to grasp the unproven nature of the experimental treatment, and only 29% thought that trials are done mainly to benefit future patients.⁴⁰

Nor are these kinds of findings limited to cancer chemotherapy trials. Researchers in England, looking at parental reactions to a randomized controlled trial of extracorporeal membrane oxygenation (ECMO) for severely ill neonates, found that in only 12 of 21 parent pairs was at least one parent aware of the randomization. Interestingly, after the fact, many of the parents explained their experiences in a way that resolved any cognitive dissonance, but without making reference to randomization. Parents of neonates who received the intervention tended to believe that all participants were treated with ECMO, whereas parents whose babies had not gotten ECMO explained that it turned out not to be indicated on clinical grounds.⁴¹ This development of post-hoc explanations has been observed in other randomized studies.⁴² One could summarize the literature as indicating that people frequently overestimate the benefits of entry into a study,^{37–39} underestimate the risks,⁴⁰ are confused about how treatments will be assigned,^{40,41,43,44} and generally tend to conflate research with ordinary treatment.^{4,39,45}

Recently, in the first attempt to identify the prevalence of TM across a range of patient/participants and research studies, we interviewed 225 patient/participants from 44 clinical research studies that spanned the medical spectrum from oncology to cardiology to rheumatology.³¹ Transcripts of interviews exploring participants’ understanding of the studies to which they had just consented were scored for the presence of TM. Thirty-one percent of participants expressed inaccurate beliefs about the degree of individualization of their treatment (TM1), whereas 51% manifested an unreasonable belief in the nature or likelihood of benefit, given the methods of the study in which they were enrolled (TM2). A total of 62% of participants were judged to have TM on one or both of these bases. This finding of a substantial prevalence of TM is echoed in a study of participants in gene transfer trials, 74% of whom scored 10 or higher on a 15-point composite scale largely focused on TM2,⁴⁶ and in a study of those with schizophrenia and schizoaffective disorder, approximately two-thirds of whom showed at least some evidence of TM1 on a 6-item scale.⁴⁷

Taken as a whole, then, the existing research indicates that TM is an extremely prevalent phenomenon among patient/participants.

Common Presentations of the Therapeutic Misconception

As suggested above, TM can be manifested in a number of ways. Some patient/participants evidence clear-cut beliefs that their treatment will be individualized for their particular needs (TM1). The examples we offer here are drawn from interviews with research participants in our previously mentioned study of TM.³¹

INTERVIEWER: Agree or disagree: Doctors are not allowed to choose the treatment I receive based on my needs?

PATIENT/PARTICIPANT: Um, disagree.

INTERVIEWER: So you think in the study they are allowed to pick which group you're going to be in?

PATIENT/PARTICIPANT: I think so.

Another example of TM1 is reflected in the response of a different patient/participant.

INTERVIEWER: [clarifying previous response] So [the choice of treatment] does depend on what each individual needs?

PATIENT/PARTICIPANT: I think so, yes. I think they do take into account what each person needs.

Unreasonable appraisal of benefit (TM2) can be seen in the following excerpt. In contrast to the examples above, which display the incorrect belief that treatment will be individualized for each person, this person's response reflects his apparent belief that there is a single "best" treatment, and that everyone in the study will be receiving it. Hence, although there is no individualization of treatment in the usual sense, this patient/participant believes that everyone who participates will end up with the best possible care.

INTERVIEWER: So do you think that they think that they are giving everyone the best treatment?

PATIENT/PARTICIPANT: I don't think they'd be in this if they didn't. You know it's just like being a doctor with a sign on the door. You know, they're healers.

The following person reflects not just a belief in her physician's therapeutic intentions, but firm certainty about her likelihood of benefiting from the study.

INTERVIEWER: Um, OK, what is the primary goal of the project, meaning is it gonna help people in the future or is it gonna help people in the project? Or a combination of both?

PATIENT/PARTICIPANT: Oh, I expect it to help me.

INTERVIEWER: Mhm.

PATIENT/PARTICIPANT: Um, I feel like I am already cured, but I expect it to make absolutely sure that I am.

In fact, the woman who gave this response had just entered a clinical trial comparing autologous peripheral stem cell transplantation with or without immunotherapy for Stage II–IV breast cancer. Defined as a "high risk" patient, not only was it unlikely that she was already cured, but there was no guarantee that she would even receive the experimental intervention (which, in any event, proved ineffective).

TM2 can also be seen when risks of participation apart from the risks of treatment per se are downplayed or discounted. In our study sample, we found that 24% of patient/participants reported no risks or disadvantages of any sort from participation in the trials to which they had consented; 3% reported disadvantages incidental to study participation such as having to drive further than they would if they were treated by their personal physicians; 14% noted the risks of treatment per se, which would have obtained even in non-research settings (e.g., the side effects associated with the control intervention); 46% cited risks of the experimental treatment (e.g., its side effects), but not risks or disadvantages associated with the study design; and only 13%

pointed to risks or disadvantages flowing from the design of the study itself (e.g., from randomization or a placebo arm).⁴⁸

Although it would be simple to say that all patient/participants either clearly manifest TM or appear to grasp fully the implications of research participation, the reality is more complicated than that. Some people seem at times to appreciate what they have gotten into in entering a clinical research project, but at other times to voice beliefs consistent with TM. Consider this example from three different points in an interview of the same person.

Excerpt 1:

INTERVIEWER: Do you think they are giving everyone in the study the best possible treatment?

PATIENT/PARTICIPANT: Well, no. Not if they're giving one a placebo.

Excerpt 2:

INTERVIEWER: Agree or disagree: This study has not been designed primarily to help the people who participate.

PATIENT/PARTICIPANT: To help everybody.

Excerpt 3:

INTERVIEWER: Are they allowed to choose [the treatment] on what best suits your needs?

PATIENT/PARTICIPANT: I would hope so.

Whereas the first of these excerpts appears to reflect a recognition that some participants will receive an inactive treatment that represents something less than optimal care, by the time of the second excerpt, the person appears to be suggesting that the study design is intended to benefit everyone who participates in the clinical trial. And in the third excerpt, when asked directly about his own treatment, he appears to have put the possibility that he will be randomly assigned to placebo entirely out of his mind. The "now you see it, now you don't" presentation in this case is consistent with what we know about people's beliefs in general. It is not uncommon for us to hold contradictory views simultaneously, never fully resolving the conflict, with the contingencies of the moment determining the perspective to which we give voice. Because the concepts related to clinical research so challenge our usual views of the roles of physicians and the purpose of medical care, it is not surprising to see recognition of those concepts alternate in the minds of patient/participants with efforts to make the research setting conform to the usual presumptions of clinical care.

To these varying presentations of TM must be appended the acknowledgment that it is not always easy to know to what extent—if at all—TM has affected a person's decision making. This is especially true when evidence both for and against TM is present, as in the last example, but it may be true in other cases as well. There is a large literature on why people decide to enter clinical research studies, or to enroll their children or others incapable of making decisions for themselves. The results of these studies are not always consistent, with some showing that most participants are interested in personal benefit³⁹ and others suggesting that altruism, reflecting a desire to advance knowledge and thereby help others, plays a substantial role.⁴⁹ But many participants and surrogate decision makers in these studies offer multiple reasons for participation, with belief in benefit for patient/participants very often playing some role.^{50,51} To the extent that this belief is unrealistic and reflective of TM, obvious concerns exist about the legitimacy of enrolling such patient/participants.

Studies of the prevalence of TM or certain aspects of it provide a rough upper limit for the percentage of research participants whose consent to enter the study may be problematic.

Characteristics Associated With the Presence of a Therapeutic Misconception

Prior to our recent study, there were only inferential data on those characteristics either of patient/participants or of the studies in which they were enrolled that may predispose to the development of TM. Our original TM study suggested that education and gender were related to understanding of disclosed information, although we did not determine their relationship to TM *per se*.² Roth and colleagues described a strong tendency for patient/participants to misinterpret research procedures as therapeutic, and found that overall understanding correlated with education and age; but they, too, did not explain the correlates of the misinterpretation they described.⁵² A large body of research data indicates—not surprisingly—that education, occupation, and age predict understanding of consent disclosures in both treatment and research settings.⁵³ Although poor understanding is not the same as TM, it would not be unreasonable to hypothesize that these variables would correlate with TM as well.

A number of studies have demonstrated that illness severity affects understanding of information, and moreover, that the most severely ill patient/participants are most likely to attribute therapeutic goals to research aimed at other ends and in which the prospect of benefit is extremely remote, such as Phase I trials.^{37,39,54} Of course, not every person who enters a Phase I trial because of hope of benefit is manifesting TM, which was not directly assessed in these studies; some subjects may realistically recognize a very low probability of positive impact but, having exhausted all other options, be willing to try a Phase I study as a last resort. But the attribution of therapeutic goals to the researchers creates a cognitive framework in which unreasonable assumptions about the likelihood of benefit (TM2) may flourish. Finally, researchers' disclosures to participants have been shown in several studies to be an important determinant of patient/participants' understanding, as well as of elements of TM.^{24,25,55}

Our research found a number of characteristics of patient/participants to be associated with TM, using a combined measure of TM1 and TM2.³¹ As in many studies of understanding of consent disclosures, these include lower levels of education and increased age. Greater pessimism about one's current health and more optimism about one's future health were also related to TM, as one might expect from studies suggesting that greater illness severity (here combined with hope for the future) makes people more likely to see research as designed to help them. Finally, based on data from the SF-36, a short questionnaire that measures health status, we showed that the worse one's self-described health and functional status, the greater one's likelihood of TM. However, we did not find a relationship between TM and race, gender, previous involvement in research, or having an occupation in higher education, health care, or research.

As far as study characteristics were concerned, higher rates of TM were observed in studies that exposed participants to the risk of death (as stated on their consent forms) and studies testing treatments (generally medications) for which alternatives approved by the Food and Drug Administration (FDA) were available outside the study. It is notable that none of the study methods that

most compromise personal care—randomization, blinding of treating physicians, placebo controls—was significantly associated with the presence of TM.

How does one put these data together? Based on one large-scale study, the only systematic data that now exist, vulnerability to TM seems to be associated with factors that may limit patient/participants' understanding of studies and heighten their need to believe that entering a research study will be beneficial for them. The data on study characteristics underscore the influence of desperation on the part of patient/participants; studies that present a risk of death ordinarily involve only patients who are severely ill and for whom there are no other available treatment options. When an FDA-approved alternative exists, that fact may lead many to believe that they would not be asked to enter a study unless it was likely to offer benefit at least equivalent to ordinary treatment. Of course, these hypotheses, based as they are on data from a single study, require further examination and verification.

Effects of the Therapeutic Misconception on Enrollment, Retention, and Satisfaction

No data exist on the impact of TM on enrollment of patient/participants, their retention in studies, or their satisfaction at the conclusion of their involvement in clinical research. But each of these issues has been the target of speculation that is worthy of mention here. As far as recruitment is concerned, it is widely assumed that those with TM are more likely to agree to participate in clinical trials. As a corollary, investigators often express discomfort with suggestions that potential research participants should be disabused of TM for fear that this will negatively impact their ability to recruit participants for their studies. To be sure, the data indicating that many patient/participants join clinical trials out of a desire for personal benefit lend credibility to these beliefs. But to date no one has compared the prevalence of TM among patients who consent and those who refuse to enter clinical research studies. Nor do we know whether altruistic motives might become more prominent if unrealistic beliefs about personal benefit were dispelled.

The relationship between TM and retention in studies that extend beyond a single contact is similarly unexplored. However, we speculate that patient/participants who discover that they are not as likely to benefit as they thought at the outset—perhaps because they begin to appreciate that placebos are being used, or that assignment to treatment is random—may be more likely to drop out than they would have been if, at the time of recruitment, they had had a good grasp of the impact of the study on personal care. If this is correct, it may be that the putative advantage in recruiting patient/participants as a result of TM is somewhat mitigated by a deleterious impact on retention in longer-term studies, a potentially serious problem because dropouts represent wasted resources from the investigator's perspective and needless exposure to risk from the participant's viewpoint.

Lastly, there is the relationship between TM and satisfaction with the research experience to consider. Anecdotal reports indicate that some former research participants later feel themselves to have been "deceived" or "used" by investigators.^{56–58} In part, this feeling appears to relate to their ultimate recognition that the personal care they expected to receive did not materialize. These feelings typically surface when the patient/participant experiences a poor outcome. One example comes from the case of a research

participant who later filed suit against the investigators and their university. He contrasted his disappointment at the adverse consequences of study participation with his initial willingness to enter the study, “because I thought I was going to get the premier treatment, while they did a little research on the side.”⁵⁶ Snowden and colleagues similarly found that many parents interviewed after a clinical trial involving their neonates who were critically ill expressed anger about the use of randomization, especially those parents who had not grasped at the outset of the study that decisions about treatment would not be made on an individualized basis.⁴¹ Feelings of anger at such treatment may generalize to the research enterprise as a whole and can fuel efforts to restrict research, limit research funding, or discourage enrollment in research projects.

Addressing the Therapeutic Misconception

Why Worry About the Therapeutic Misconception?

A necessary condition for deviating from medicine’s usual adherence to the principle of personal care is the informed consent of the patient/participant or, for those without the legal capacity to consent on their own behalf, of an appropriate surrogate decision maker. (Research in emergency settings may constitute an exception to this generalization; in the United States, federal rules allow some studies of emergency care to be conducted without consent in circumstances in which consent from either patients or surrogates cannot be obtained in a timely fashion (see Chapter 27). To the extent that patients decide to enter research projects in the belief that they will receive personal care, we believe that it cannot be said that they appreciate the implications of their decision, and the validity of their consent is in question. But not everyone agrees that even flagrant examples of TM invalidate consent to research, and the argument that TM does not negate informed consent is worth considering.

Some of those who make this argument look to the legal doctrine of informed consent for support.⁵⁹ As the doctrine of informed consent to treatment was shaped by the courts, there was often a lack of clarity regarding whether physicians were required merely to disclose material information or whether patients must comprehend such disclosure for the ensuing consent to be valid.⁶⁰ At times, courts have expressed concern that a requirement for actual understanding might have the unintended result of denying medical care to patients who, for whatever reason, were unable to comprehend even adequate disclosures, and concerns about evidentiary difficulties may have shaped this approach as well. Thus, legal standards for consent may be weaker than ethical doctrines may demand. Echoing such precedents, Gopal Sreenivasan maintains that an accurate comprehension of the risk/benefit ratio of participation in clinical research ought not to be required for consent to be considered acceptable.⁵⁹ He suggests that the well-being of research participants can be adequately protected, even in the face of TM, by an independent judgment of an institutional review board (IRB) that the study in question has a favorable risk/benefit ratio. Moreover, requiring good appreciation of the consequences of involvement in a study might restrict entry to a small group of patient/participants, thus impeding the conduct of important research.

In considering this approach, we note first that the assumption that comprehension by patients should not be required in the

treatment setting has been criticized as focusing unduly on ensuring decision making autonomy in a narrow sense (i.e., the right to say yes or no), while failing to protect a patient’s interests in informed choice—the true goal of informed consent.⁶⁰ Nor would a requirement for actual understanding by patients necessarily preclude needed treatment; patients who are unable to comprehend the essential elements of disclosure, despite efforts to help them do so, are not likely to be competent to make decisions for themselves, and substitute decision-making mechanisms can be provided. Transposed into the research realm, the argument against requiring comprehension seems even more problematic. Whereas the presumption that treatment recommendations are being made in a patient’s interests obtains in the treatment setting, no such blanket conclusion can be reached in clinical research. Thus, it seems even more important for consent to research to reflect an accurate assessment of the risks and benefits of participation by the prospective participant.

Sreenivasan’s retort is that an objective body, an IRB, will have determined that the research project has a favorable risk/benefit ratio before a patient is asked to participate. Hence an independent judgment by each patient/participant is unnecessary.⁵⁹ But this reflects confusion about the particular tasks of IRBs and potential patient/participants. The IRB’s role, in part, is to determine whether the net potential benefits exceed the potential risks. But the benefits that IRBs consider include societal benefits that may accrue as a result of the knowledge gained, thus allowing approval of projects in which there are likely to be little to no benefit for some or all of the participants. Each individual, in contrast, must decide whether the combination of possible personal benefit and altruistic contributions to the good of others warrants the risks associated with the research, including the risk, for those in a placebo-controlled study, of receiving no active treatment at all. Only the prospective participant can weight appropriately both the altruistic component of the benefit calculus and the salience of the potential risks to his or her unique situation. Moreover, because the inclination to self-sacrifice is not something that can be determined for others by a committee, prior IRB approval in no way removes the need for a meaningful judgment about participation by a potential participant. And the only way such a meaningful decision can be made is if the person is substantially free of the confusion embodied in TM.

It is of interest that both IRBs and investigators appear to be thinking increasingly along similar lines. In a growing number of higher risk protocols or studies involving populations with a greater prevalence of impaired decisional capacities, investigators are more frequently checking individuals’ understanding and appreciation of the implications of participation prior to accepting their consent. Whether this practice impedes recruitment or just encourages better and more creative disclosure practices remains to be determined. But we believe that there is a growing consensus that, given its apparent prevalence, TM constitutes a major obstacle to genuine informed consent in research, and efforts to diminish or eliminate TM are clearly warranted. How might such a task be undertaken?

The Inadequacies of the Current Consent Process

Current consent practices, driven by concerns about legal liability and the sometimes obsessive focus of IRBs on the precise wording of consent forms, have evolved in a direction that complicates the

task of neutralizing TM. Potential research participants are often given lengthy and highly detailed consent forms to read and assimilate. The forms, which in our experience can reach up to 20 single-spaced, typewritten pages and seem to get longer every year, recite with great precision the procedures to which patient/participants will be exposed, the risks they may face, and the possible benefits of participation, along with such items as whom to contact with questions and whether the costs of medical care will be covered should injuries occur. Risks are given particularly detailed exposition, even the minor risks of procedures such as drawing small amounts of blood or answering potentially embarrassing questionnaires. The dominant fear appears to be that some potential risk left unexplicated will materialize, leading to liability for the investigators, the institution, and perhaps for members of the IRB.⁶¹

As a result, patient/participants are often overloaded with information of varying degrees of importance. Frequently buried in this confusing mass of data is the very information that would help them grasp the substantial differences between clinical research and ordinary treatment. Somewhere in the midst of the form may appear an explanation of random assignment of treatment. Placebo use, double-blind procedures, and the limits placed on physicians' discretion by the protocol are also likely to be embedded in the depths of the form, but from a prospective participant's perspective, equally likely to be lost in the tangle of verbiage. Sometimes, of course, the information is framed so poorly or in such complex language that patient/participants are not likely to comprehend its significance even if they spot it. And sometimes the forms are subtly or overtly misleading, for example when experimental interventions or even placebos are referred to simply as *treatment*, or important risks of the study are omitted or downplayed. Even when investigators make a conscientious effort to explain these factors, however, the prevalent structure and length of consent forms greatly increase the risk that the information will go unnoticed or unappreciated.

Consent forms, of course, are not the only source of information for potential research participants. The recruitment process typically involves discussions with an investigator, research nurse, or research assistant who provides an overview of the study. This conversation may have a greater impact on the potential participant's understanding than anything written on the consent form. But the primary goal of these interactions is typically to persuade the patient to become a participant, and to the extent that focusing on the ways that research differs from ordinary clinical care is thought to dissuade patients from enrolling, there is an understandable tendency for research personnel not to emphasize these issues. Moreover, insofar as researchers themselves fail to recognize the ways in which research is not the same as clinical care, which appears to be surprisingly common,²⁷ they will be unable to discuss these matters clearly with potential participants,⁶² as preliminary evidence suggests they often are.⁶³

Dispelling the Therapeutic Misconception

Addressing TM in an effective way will require a multifaceted approach. The first step must involve the education of investigators and other research staff regarding the ethically significant differences between ordinary treatment and treatment in the context of clinical research. If this sounds simplistic or superfluous, our interactions with the clinical research community over

several decades suggest that it is neither. Perhaps because of physicians' habitual reliance on the ethical model in which they are trained—which emphasizes a dedication to patients' interests—it is extremely difficult for clinical investigators to see themselves as sacrificing those interests in any way for the sake of advancing scientific knowledge, no matter how important that knowledge may be. This tendency is reflected in the frequently heard assertion that clinical research is superior to ordinary treatment (despite data to the contrary),⁶⁴ because it provides closer monitoring by more experienced clinicians who are taking a more systematic approach to treatment. It may, in fact, be true that there are advantages to patients in participating in research projects, and those advantages are likely to be greater when the design of a project is less restrictive of physicians' discretion to act on patients' behalf. But to acknowledge this is in no way to diminish the ethically significant differences between the two situations. Unless researchers themselves recognize this discrepancy, they are likely to undercut through their communication with patient/participants whatever other efforts are made to dispel TM.

Investigators and others involved in recruiting participants can be trained to describe and underscore the differences between research and ordinary treatment in relatively simple ways. As we have suggested elsewhere,⁶⁰ unless patient/participants are educated about the reasons for deviations from personal care (e.g., the use of placebos), they are likely to reconstruct disclosures in a way that reinforces their preconceptions, such as the assumption that all participants will receive active treatment because no physician would permit a patient to go untreated. And data suggest that many lay people are unaware of the purpose of routine investigational procedures such as randomization.⁶⁵ Thus, as the investigator describes the purpose of the study and the procedures involved, he or she should emphasize the differences between research and clinical care and the reasons for them. For example, in describing placebo use, the investigator could say, "One-half of the people in this study will be selected by chance to receive sugar pills that are not intended to help the condition you have, in place of active medication. This is done so we can find out whether the medications are really effective, or if many people with your condition would get better even with no active medication at all." Once the differences are underscored, the remainder of the risks and benefits of participation can be disclosed.

Properly constructed consent forms have a role to play in this process as well. Consent forms ideally should be much shorter than they are today, because we have known for a long time that the more detail that is provided to potential participants, the less they assimilate.⁶⁶ Too many consent forms today spend pages detailing the intricacies of the study (for example, exactly what will happen at each visit over the next year, or precisely which blood tests will be drawn), when this level of minutiae is not likely to be meaningful to most patient/participants or material to their decisions whether to enter the study. This additional information could be offered in an informational pamphlet to those who enroll. A more effective consent form would again highlight the ways in which research diverges from the principles of personal care, emphasizing these items in bold print, or otherwise setting them off from the rest of the text. If multipage forms continue to be used—and we despair of persuading IRBs and investigators to abandon what we believe to be the illusory security of this approach—at the least they should be accompanied by one-page summaries that high-

light the major issues, including, of course, the departures from personal care.

Because we know that disabusing potential participants of their preconceptions about research will not be an easy task, it makes sense to quiz them routinely about their understanding of the disclosures and their appreciation of the implications of becoming involved in a research project. Such brief questionnaires—currently in use by some investigators⁶⁷—should include queries designed to probe for the presence of TM, in addition to ensuring that potential participants understand more basic issues such as the nature and purpose of the study, risks and benefits, and so forth. If a tendency toward viewing the project in therapeutic terms is detected, it should be addressed directly and effectively before the person is allowed to enter the study.

Higher risk studies, or studies that recruit particularly vulnerable groups, may call for additional measures to insure that TM has not compromised the consent of patient/participants. Our earlier work with Loren Roth demonstrated that an independent educator—in that study, a nurse not affiliated with any particular research project—could make a substantial difference in improving patient/participants' appreciation of TM-related issues, above and beyond the impact of disclosure by investigators.^{2,24} Some researchers may resist such proposals, fearful that an independent person educating potential participants will dissuade them from entering the studies. But in studies in which the quality of the consent is crucial, IRBs may want to look to this mechanism to ensure that patient/participants are protected from the consequences of decisions based on false premises.

A final consideration relates to the compensation that is sometimes given to participants in clinical research, although this occurs more commonly in studies that provide no treatment, such as studies that require participants to complete questionnaires or undergo tests that are unlikely to contribute in any way to their care. Such compensation is often an issue of contention because of concern that financial rewards may unduly influence people to enter projects, running risks that they otherwise would not have accepted. It has been suggested, however, that paying patient/participants for their participation might be an extremely effective way of dispelling TM.^{68,69} Payments are usually part of a two-way exchange of something of value. For patient/participants, who certainly are not paid by their physicians when they receive ordinary care, payments might have the salutary effect of concretizing the fact that they are surrendering something of worth—the wholly beneficent attention of their physicians—and are receiving compensation in return. Payments would have to be proportionate to the demands on patient/participants to reduce fears of undue influence,⁸ but it is the symbolic value that is of greatest significance here.

We should stress that—apart from the previously mentioned use of a neutral educator—there are no systematic data to indicate whether any of these approaches to the problem of TM are likely to be effective. Given the importance of the issue to the legitimacy of clinical research, however, investigations of how TM may be diminished should be a matter of the highest importance in research ethics.

The Consequences of Addressing the Therapeutic Misconception

Although there will be benefits to attacking TM at its roots, there will be costs as well. The most significant benefit, of course, will be

protection of the validity of informed consent in clinical research. It cannot seriously be maintained that patient/participants who view research merely as a form of “super” treatment have made a meaningful choice about participation. Yet, on their willingness to surrender the perquisites of ordinary care rests the legitimacy of the entire clinical research enterprise. If it is true that patient/participants and family members turn against the research enterprise as a whole when they discover after the fact the ways in which clinical research limits personal care, researchers' self-interest alone would seem to call for serious efforts to minimize the prevalence of TM.

In an intelligent discussion of what they refer to as “the therapeutic orientation to clinical research,” Miller and Rosenstein point to other salutary effects of addressing TM for the field of research.⁸ They contend that “the therapeutic orientation to research involving patients interferes with investigators' development of a sense of professional integrity.” To the extent that researchers tolerate or even encourage TM among their patient/participants, and then act toward them—as they must—in ways inconsistent with patient/participants' expectations, the researchers are fostering an ethical dissonance in their profession. Behavior of this kind borders on deception and exploitation. No self-aware group of professionals can long tolerate such a situation without further corruption of their integrity.

If there are potent reasons to combat TM, we ought not to lose sight of the probable costs as well. It has been argued that reducing TM will strip patient/participants of hope.⁷⁰ Although we do not know whether this is true, false hope that leads to unwise choices about research participation hardly seems a boon to patients. Moreover, it is widely believed—though unproven—that recruitment to clinical trials will be adversely affected if potential participants recognize the sacrifices they are being asked to make. If true, and it may be, this could increase the cost and slow the pace of clinical research, perhaps delaying the introduction of new treatments that could be helpful to many patients. Of course, it may be that the effect on patients' willingness to enter trials will not be as great as feared—that is, that altruistic motivations may be more powerful than is commonly accepted. Even if some patients decide not to participate in research, however, that may be a cost that we must accept, unless we are willing to exploit vulnerable persons for what is presumed to be the greater good.⁹ We suspect that most people, asked to make a choice, would favor a slower rate of medical progress in exchange for greater respect for the rights and interests of patients who may be asked to participate in clinical research.

Empirical Issues in Informed Consent for Research

In theory and practice, informed consent is considered a requirement of ethical clinical research. Since the late 19th century it has been a recognized ethical goal that people not only decide freely whether to participate in clinical research, but decide with an understanding of the relevant facts. This requirement helps to protect the autonomy of research participants and avert serious research abuses.

This simple doctrine—that consent should be not just voluntary but informed—has proven difficult to realize in practice. The data show that research participants can have significant misconceptions about the nature of research even when researchers diligently follow consent procedures required by regulation. Truly informing research participants is very hard, and therefore the goal of truly informed consent poses serious challenges in policy and ethics. To help to address these challenges, we consider three relevant empirical questions: How well do participants understand their research participation? Is there any way to predict who will have the most trouble understanding? And which interventions might improve participants' understanding?

Methodological Issues in Empirical Research on Informed Consent

Numerous studies have quantitatively measured participants' understanding using interviews and questionnaires. These studies tend to focus on how well participants understand the elements of informed consent as described in U.S. federal regulations. In particular, most studies have focused on how well participants grasp the purpose of research, their right to withdraw, the nature of study

procedures, the use of randomization, risks, and benefits. The accelerating pace of research on informed consent means that there is a great deal of work to draw on. Because new studies are being completed on a regular basis, even a comprehensive review will be outdated before it is complete.

Furthermore, the heterogeneity of the data that have already been collected poses a challenge for any review. The studies we examine take place in many different settings, from tests of new drugs on dying cancer patients in Chicago to studies of maternal iron supplementation in Bangladesh. Such diversity compels caution in comparing the results of different studies.

The studies also vary in methodology and quality. The studies use different questions to assess participants' understanding, making direct comparison of the results difficult. There is also little doubt that the quality of data collection varies from study to study: there are many methodological pitfalls in empirical informed consent research (see Table 59.1). In particular, some studies have less ambiguous, more carefully validated questions than do others.

Timing of data collection is also important. Some studies administer questions within a few hours after the informed consent process, whereas others wait days, weeks, or even months. Early data collection is preferable in this case because it captures understanding at the time participants are making their enrollment decision. Studies that wait longer end up measuring retention of information as much as understanding at the time of decision making.

Due to variability in setting, methodology, and quality, there is no way to integrate all of these data sources to create definitive, meta-analyzed conclusions. Nor is there any reason to assume that

Table 59.1
Common Problems in Empirical Studies of Informed Consent

	<i>Problem</i>	<i>Possible Solution</i>
<i>Timing:</i> Many studies use mailed questionnaires, so that participants don't have their understanding assessed until weeks after the consent process.	Delayed data collection makes it hard to distinguish understanding from retention.	Interview participants immediately after they give consent.
<i>Questions about purpose:</i> "Is the purpose of the study to determine which malaria drugs are most effective for children?"	This question doesn't show whether participants understand that a study could require extra risks and procedures that make it different from standard clinical care.	Additional question to resolve the ambiguity: "Will the study require that my child have more blood draws and other procedures than she would need just for her medical care?"
<i>Questions about voluntariness:</i> "Are you free to withdraw from the study at any time?"	This question doesn't clarify whether the participant needs a doctor's permission. This question also does not clarify whether there will be consequences if a participant withdraws. Nor does it clarify whether the participant feels constrained to stay in a study because of external circumstances, as opposed to coercion by researchers.	A change in wording and two additional questions: "Are you free to withdraw from the study whenever you want, even without a doctor's permission?" "If you withdraw from the study, will doctors still give you the same health care you had access to before the study started?" "If you were not in this study, would you be able to find and afford enough medical care?"
<i>Questions about prospect of benefit:</i> "How likely is it that you will receive medical benefit from participating in this trial?"	This question cannot distinguish optimism from mistaken beliefs about the chances of benefit.	Add a question that requests the objective assessment of chances, rather than a subjective (potentially hopeful) statement: "How many patients do the doctors expect to benefit from this experimental treatment? Fewer than 1 in 10, about half, or greater than 9 in 10?"

observations from one particular study generalize to different settings. Given this uncertainty, we proceed cautiously, focusing on observations that have been reproduced several times and in different settings.

Understanding the Purpose of Research

Empirical data on research participants' understanding of study purpose is typical of the data on participants' understanding in general (see Table 59.2). These data suggest that participants' understanding varies considerably from study to study but in general is relatively poor. At the encouraging end, a study of parents enrolling their children in a trial of malaria drugs in Uganda found that 80% of parents knew that the study purpose was "determining which malaria drugs are most effective for children."¹ In a rather different setting, a survey of people enrolled in oncology research in Boston found that 75% of participants agreed with the statement that "the main reason cancer clinical trials are done is to improve the treatment of future cancer patients."² But much of the data reflects poorer understanding. A study that focused on Phase I oncology research participants in Chicago found that only 27% could correctly describe the purpose of the research as dose finding/toxicity determination.³ In rural Bangladesh, half of the women in a study of iron supplements thought that participation in research was part of routine health care.⁴

These numbers, and similar data from other studies, provide a glimpse at the state of understanding in research studies across the world. Generalizing from data like this must be done cautiously, but we can at least note that the percentage of participants who

seem to understand the purpose of the studies in which they participate varies a great deal from study to study. It is rare for all participants to understand a study's purpose and common for fewer than 75% to understand it. In addition, there is no consistent evidence that people from poor nations understand less than those from affluent countries.⁵

But the data are more difficult to interpret than they at first appear. In most of the examples given above, there is a more complicated story to tell. In the Uganda study, most parents knew that the study was meant to answer a scientific question about which malaria drugs are most effective for children.¹ But in contrast to the high rate of correct responses to the purpose question, only 19% of these parents realized that different children in the study were being assigned to different treatments. Did these parents understand that the design of the study meant doctors would be unable to make treatment decisions based on what was deemed best for the child?

The Boston oncology study addressed this point more directly, asking whether participants agreed that the study was designed primarily to benefit future patients.² The statement that a study is designed primarily to benefit future patients is a truism of research ethics, and one's first reaction is concern about the 25% of participants who didn't agree with it. Yet that 25% were in good company: Only a minority of health-care providers (46%) agreed with this statement when they were given the same survey. Were providers more poorly informed than the participants they recruited? A more likely explanation is that in much of oncology research, the care participants receive on-protocol is arguably better than they would receive off-protocol, and it is reasonable to think of the protocol as partly or even primarily intended to benefit its

Table 59.2**Selected Studies Evaluating Understanding of Purpose**

<i>Study</i>	<i>Context</i>	<i>Measure of Understanding</i>	<i>Responding Correctly</i>	<i>Comments</i>
Pace (2005) ¹	A pediatric trial of malaria drugs in Uganda. Interviews with parents.	Chose “determining which malaria drugs are most effective for children” on a multiple-choice question.	80%	
Fitzgerald (2002) ⁴⁸	Study of HIV-1 transmission in Haiti. Questionnaires given to participants.	Correctly answered a true/false question on study purpose.	33%	
Joffe (2001) ²	Phases I, II, and III oncology studies in United States. Questionnaires mailed to participants.	Agreed with statement that “the main reason cancer clinical trials are done is to improve the treatment of future cancer patients.”	75%	46% of health-care providers also agreed with this statement. Questions were answered a median of 16 days after consent to trials.
		Disagreed with the statement “All treatments and procedures in my clinical trial are standard for my type of cancer.”	48%	
Lynoe (2001) ⁴	Study of maternal iron supplementation in Bangladesh. Interviews with participants.	Answered NO to the question “Did you get the impression that participation was only part of routine health care?”	47%	
Daugherty (2000) ³	Phase I oncology studies in United States. Interviews with participants.	Said that purpose of study was “dose finding/toxicity determination.”	27%	Subjects were interviewed within one week of beginning of oncology study. 61% stated erroneously that purpose of study was to determine the efficacy of the cancer drug; 8% agreed with both statements.
Van Stuijvenberg (1998) ²²	Pediatric study of ibuprofen to prevent febrile seizures, in Netherlands. Questionnaire mailed to parents.	Were able to correctly state the purpose of the study in their own words.	53% gave completely correct answer. 35% gave a partially correct answer.	Questionnaire sent to parents at home, so presumably some delay between consent and consent study.
Daugherty (1995) ¹⁵	Phase I oncology studies in Chicago. Interviews with participants.	In interview, described purpose as dealing with dose determination or tolerability.	33%	52% expressed the erroneous belief that the purpose was to determine response/benefit from treatment.
Howard (1981) ¹⁹	Study of beta-blockers in post-MI patients in the United States. Interviews with participants.	In interview, demonstrated knowledge that they were in research.	90%	Average delay of four months between consent and interview.
		In interview, demonstrated good understanding of study purpose.	80%	
Taub (1981) ²⁵	Study of comprehension and memory in the elderly, in the United States. Questionnaire given to participants.	Correctly identified purpose of study on multiple-choice question.	71%	Participants could refer to consent form while answering questions.

own participants. How is one to be sure that the remaining 25% of participants were really ill-informed about the study's purpose?

In the study of Phase I oncology research participants, researchers asked a more specific question about the scientific question addressed by the study. Only a third of participants correctly identified dose finding and toxicity as the purpose of this protocol; 61% of participants believed that the purpose of the study was to evaluate the efficacy of the cancer drug. How far wrong were these participants, and did their confusion make their consent invalid? Another way to view this data is to observe that nearly 90% of participants in this study realized they were in research: Is this good news, or should we focus on the bad news that most of them failed to make the further distinction between screening for safety and screening for efficacy?

The point of these examples is that the purpose of a research study is a surprisingly complex article of information. One can understand it at different levels, from the simple appreciation that a study is meant to create scientific knowledge to more detailed knowledge of the type of knowledge in question and the specific scientific issues involved. Even the most superficial levels of understanding can be murky with ambiguity. Although concern over the therapeutic misconception has led many theorists into the habit of thinking that studies are not meant to provide optimal medical care, the fact is that many studies have a dual effect, both generating scientific information and providing superior care for participants. This is especially true in settings in which individuals have little or no access to standard medical care.

Many questions about study purpose assume participants should recognize that the researchers' purpose is to create generalizable knowledge, and that anyone who fails to answer in this way fails to understand. But the fact that researchers' purpose is to create generalizable knowledge does not exclude the possibility that they also intend to benefit those who enroll in the research. Investigators at some sites may participate in the research with the primary purpose of helping their own patients. And, of course, many individuals enroll in research with the explicit purpose of receiving treatment. Therefore, questions about intentions and purpose can have more than one right answer.

Moreover, it is not always clear that understanding of the purpose of the research is necessary for a valid informed consent—at least, not for every study. Imagine participants who enroll in a Phase II treatment study of a new medication for a disease without any currently effective treatment. How important is it for participants to recognize that the purpose of the study is not to treat them per se, but to create generalizable knowledge on the efficacy of treating groups of patients?⁶

Understanding Voluntariness

Whereas study purpose is a complex topic, voluntariness stands out at first as simple. The topic has its complexities, but there is no fundamental ambiguity: Participants should be free to refuse research participation and to withdraw from research without pressure or coercion. This right to withdraw should be understood by 100% of participants. Against such simplicity, it is striking how many people do not fully appreciate that their participation in research is voluntary (see Table 59.3). In general, studies have shown that most but by no means all participants were aware that

they did not have to join a study and that they had the right to withdraw from it. In some cases, however, the percentage of participants aware of these rights was below 50%.⁴

Studies that delved deeper into the right to withdraw revealed that in many cases, participants' understanding is worse than it first appears. In one case, 65% of parents knew they had the right to withdraw their children from research, but only 17% knew they could exercise that right at any time. Essentially, they thought that they had the right to withdraw as long as investigators said that they could.¹ In another case, 91% of parents knew that they had the right to withdraw their children from research, but 25% of them still felt obligated to continue their participation.⁷ In a third case, although 93% of participants thought they were free to quit a perinatal HIV transmission study, only 2% believed that the hospital would allow them to quit. In addition, 32% felt their care would be compromised if they did not participate.⁸ In each of these cases, the initial impression that participants understood their rights is complicated by aspects of the responses that suggest participation may be less free than first appeared.

It is difficult to know for certain what these participants were thinking, but several possibilities present themselves. A relatively benign possibility is that participants were quite aware of the right to withdraw, yet felt they had to continue to participate because of external factors, as opposed to pressure from researchers. For example, they might feel that the study was the best or only way for them to get needed medical care.⁹ This possibility does not imply poor informed consent, coercion, or inappropriate pressure from researchers.

A second possibility is that participants thought the right-to-withdraw language is an empty promise. This is illustrated by those who thought they were free to quit at any time as long as investigators gave permission. A variation is illustrated by those who thought they were free to quit but that there would be adverse consequences to their medical care. This reveals confusion about the nature of the right to withdraw that has a parallel in everyday life: I have the right to say unflattering things about my boss; even so, there will be some unpleasant consequences if I exercise this right. Without specific information to the contrary, research participants may assume that the right to withdraw does not protect them from negative consequences if they exercise this right.

Thus it turns out that voluntariness is in its own way a complicated concept. There are different degrees of freedom. Research participants should have the highest degree of freedom, namely, the ability to refuse or quit a study whenever they want, with the knowledge that doing so will not compromise their routine medical care. Accordingly, investigators need to offer this freedom and should take care to communicate it fully. Investigators and regulators should also be careful not to mistake participants who feel obliged to participate by external circumstances, like the severity of their illness or limited options, for participants who feel that they are being coerced or inappropriately pressured by researchers. The fact that individuals feel compelled to enroll in research due to the severity of their illness, and the absence of alternative treatments, does not necessarily undermine the validity of their informed consent, any more than patients' experiencing respiratory distress undermines the validity of their consent to intubation.^{10,11} The data do not always clearly distinguish pressure from one's illness from more ethically worrisome pressure, especially pressure from the research investigators.

Table 59.3
Selected Studies Evaluating Understanding of Voluntariness

<i>Study</i>	<i>Context</i>	<i>Measure of Understanding</i>	<i>Responding Correctly</i>	<i>Comments</i>
Pace (2005) ¹	A pediatric trial of malaria drugs in Uganda. Interviews with parents.	Understood right to withdraw. Understood could withdraw at any time. Understood that could have refused to enroll.	65% 17% 41%	
Fitzgerald (2002) ⁴⁸	Study of HIV-1 transmission in Haiti. Questionnaires given to participants.	Correctly answered two true/false questions on voluntariness.	47%	
Joffe (2001) ²	Phases I, II, and III oncology studies in United States. Questionnaires mailed to participants.	Understood right to decline enrollment. Understood right to withdraw.	99% 90%	Questions were asked a median of 16 days after consent to trials.
Lynoe (2001) ⁴	Study of maternal iron supplementation in Bangladesh. Interviews with participants.	Answered YES to the question "Did you know that after giving consent you were free to withdraw from participation at any point in time?" Answered YES to the question "Did you know that you were free to abstain from participation?"	48% 65%	87% of women answered YES to the question "Did you get the impression that participation might mean such great advantages that it was difficult to say no?"
Hietanen (2000) ¹⁶	Study of adjuvant therapy for breast cancer in Finland. Questionnaires mailed to participants.	Reported feeling free to decide about their participation independently.	85%	11-month delay between consent and informed consent study.
Abdool Karim (1998) ⁸	Study of perinatal HIV transmission in South Africa. Questionnaires given to participants.	Understood were free to quit. Understood hospital would allow them to quit.	93% 2%	32% believed their care would be compromised if they quit the study.
Van Stuijvenberg (1998) ²²	Pediatric study of ibuprofen to prevent febrile seizures, in the Netherlands. Questionnaire mailed to parents.	Parents understood right to withdraw.	91%	25% of parents felt obliged to participate.
Schaeffer (1996) ¹⁸	Various studies at the NIH, in the United States. Questionnaires given to patients.	Understood right to withdraw.	Variable: over 90%	
Taub (1981) ²⁵	Study of comprehension and memory in the elderly, in the United States. Questionnaires given to patients.	Correctly answered multiple-choice question about freedom to withdraw.	76%	Participants could refer to consent form while answering questions.
Bergler (1980) ²⁰	Study comparing hypertension medications, in the United States. Questionnaires given to patients.	Understood were free to withdraw at any time and still receive best available treatment.	77%	Study was done within two hours of consent procedure. At three months, retention of this information was 61%.

Understanding Protocol Design and Randomization

Research on how well participants understand protocol design almost invariably focuses on randomization and placebo control (see Table 59.4). Although there are exceptions, the majority of studies show that fewer than half of participants understand these

issues. There is far less evidence on how well participants understand prosaic but important details like whether a study drug is oral or injected, or the length and frequency of clinic visits they need to make as part of their participation. The limited available data suggest that investigators may do a good job communicating this information, yet still fail to get the concept of randomization across to participants.

Table 59.4
Selected Studies Evaluating Understanding of Protocol Design and Randomization

Study	Context	Measure of Understanding	Responding Correctly	Comments
Pace (2005) ¹	A pediatric trial of malaria drugs in Uganda. Interviews with parents.	Understood there would be 7 clinic visits.	78%	
		Understood children would be taking oral drugs.	79%	
		Understood children would be assigned to different treatments.	19%	
		Understood children would be assigned treatment at random.	7%	
		Understood that blood samples would be taken.	98%	
		Could name one or more side effects of study drugs.	18%	
		Understood biological samples could be used for future research.	52%	
Kodish (2004) ¹²	Pediatric leukemia trials in the United States. Interviews with parents.	In interview, expressed understanding of randomization.	50%	Parents were interviewed within 48 hours of consent meeting.
Appelbaum (2004) ¹⁴	Variety of clinical studies at academic medical centers in the United States. Interviews with participants.	Did NOT express inaccurate beliefs in individualization of their treatment.	69%	
Hietanen (2000) ¹⁶	Study of adjuvant therapy for breast cancer in Finland. Questionnaires mailed to participants.	Understood that they would be randomized.	23%	11-month delay between informed consent and interview.
Van Stuijvenberg (1998) ²²	Pediatric study of ibuprofen to prevent febrile seizures, in the Netherlands. Questionnaire mailed to parents.	Understood the child had a 50% chance of being assigned to placebo.	88%	
		Understood that treatment would be allocated randomly.	50%	
Howard (1981) ¹⁹	Study of beta-blockers in post-MI patients in the United States. Interviews with participants.	Demonstrated understanding of placebo control.	89%	Average delay of four months between consent and interview.
		Demonstrated understanding of randomization.	72%	
Taub (1981) ²⁵	Study of comprehension and memory in the elderly, in the United States. Questionnaires given to patients.	Correctly identified length of session.	78%	Participants could refer to consent form while answering questions.
		Correctly identified the type of tests being used.	40%	
Bergler (1980) ²⁰	Study comparing hypertension medications, in the United States. Questionnaires given to patients.	Understood that trial would last one year.	64%	Two hours after consent procedure; at three months, understanding was unchanged. At three months, understanding had fallen to 46%.
		Understood that trial was double-blind.	64%	

The malaria study in Uganda offers a detailed example of this point.¹ Of those participating, 78% knew that they would have to make seven clinic visits in the course of the study, 79% knew their children would be taking drugs orally, and 98% knew that the study involved blood samples. Only 19% knew that children were being assigned to different treatments, and only 7% went further to understand that assignment would be random.

What is one to make of such a striking shift, from the majority of patients understanding practical details of the protocol to a tiny minority understanding randomization? There are several possible explanations. First, randomization may simply be a hard concept

to understand. Few studies assess whether most people fail to grasp randomization due to the therapeutic misconception, as opposed to simple confusion about a complicated concept. Another possibility might be that participants must understand practical details in order to comply with the protocol, so investigators and participants find it easier to focus on them. Finally, investigators might gloss over the subject of randomization. Against this possibility, one study in which consent procedures were videotaped and compared against participants' later understanding found that understanding of randomization continued to be poor even when investigators devoted significant time to explaining it.¹²

Table 59.5
Selected Studies Evaluating Understanding of Risks and Benefits

<i>Study</i>	<i>Context</i>	<i>Measure of Understanding</i>	<i>Responding Correctly</i>	<i>Comments</i>
Appelbaum (2004) ¹⁴	Variety of clinical studies at academic medical centers in the United States. Interviews with participants.	Did NOT express an unreasonable belief in nature of likelihood of benefit.	49%	
Joffe (2001) ²	Phases I, II, and III oncology studies in United States. Questionnaires mailed to participants.	Disagreed with statement that "the treatment being researched in my clinical trial has been proven to be the best treatment for my type of cancer." Disagreed with statement that "all the treatments and procedures in my clinical trial are standard for my type of cancer."	30% 26%	Questions were asked a median of 16 days after consent to trials.
Daugherty (2000) ³	Phase I oncology studies in United States. Interviews with participants.	Knew fatigue and GI symptoms possible side effect. Knew hair loss possible side effect. Knew neutropenia possible side effect.	71% 48% 29%	Subjects were interviewed within one week of beginning of oncology study. 90% of participants expected medical benefit.
Daugherty (1995) ¹⁵	Phase I oncology studies in Chicago. Interviews with participants.	22% of participants expected to receive treatment benefit; 70% expected to receive psychological benefit.		
Van Stuijvenberg (1998) ²²	Pediatric study of ibuprofen to prevent febrile seizures, in the Netherlands. Questionnaire mailed to parents.	Awareness of possible negative side effects.	40%	
Miller (1994) ²¹	Trial of analgesics in United States. Interviews with participants.	Could recall any of the 12 potential side effects.	52%	Interview within 60 days of consent.
Penman (1984) ¹³	Phases II and III oncology studies in United States. Interviews with participants.	Were able to list more than 3 side effects. Knew nausea was a side effect. Knew hair loss was a side effect. Knew risk of decreased WBC and infection.	31% 99% 65% 23%	43% of participants agreed with the statement that they had no doubts at all about benefits from the trial. One- to three-week delay between consent and informed consent study.
Bergler (1980) ²⁰	Study comparing hypertension medications, in the United States. Questionnaires given to patients.	Aware of both side effects. Aware of 1 side effect.	28% 44%	After three months, only one participant (4%) recalled both side effects, whereas an additional 70% could recall 1.

Understanding of Risks and Benefits

The literature approaches understanding of risks and benefits in two ways (see Table 59.5). The broad approach asks research participants how much they expect to benefit from or be harmed by their study participation. Here, the literature suggests that research participants tend to be quite optimistic, possibly unreasonably so, about their potential to benefit from research participation. The narrow approach assesses how well participants remember specific details about the risks and benefits of their trial. The data here show that participants have difficulty absorbing and retaining lists of potential adverse events, but occasionally have good retention of particular facts.^{2,3,13-22}

There are several examples of what seems to be excessive optimism. In one survey, 43% of patients stated that they had no

doubts at all about benefits from a treatment even though most of their consent forms stated that no benefit could be assured.¹³ A study specifically designed to identify the prevalence of unreasonable optimism reported that 51 percent of participants expressed an unreasonable belief in the likelihood of benefit.¹⁴ It seems reasonable to expect that many research participants will tend to overestimate the likelihood that they will benefit. In spite of these results, it is hard to determine whether this is a widespread problem or not. At least in oncology, it is clear that some participants can be realistic. In one example, only 22% of participants thought they would receive benefit in a Phase I trial.¹⁵ The rest of the participants appeared to have faced up to a difficult reality. It is hard to be sure whether understanding was a problem among the 22% who thought they would benefit. A key issue in communication of risk and benefit is the difficulty of

distinguishing a patient who is mistaken about the prospect of benefit from one who is simply hopeful and prefers to make positive statements about the future.¹⁷ Confusion implies inadequate informed consent; hope does not.

Given this ambiguity about the meaning of broad expressions of optimism or pessimism, the narrow approach of seeing how many facts about risks and benefits participants are able to absorb has obvious appeal. Studies taking this approach make it clear that retaining long lists of possible adverse events is difficult for participants.^{13,15,20,21} In one oncology study, only a minority of participants were able to remember three side effects within one to three weeks of receiving that information. Although most participants were aware of the risk of vomiting or nausea, only 20% to 30% were aware of more abstract risks, like lowered white cell counts.¹³ In another study looking at retention of information for up to 60 days after informed consent, only about half of participants could recall even 1 of 12 side effects. In a study looking at recall of two side effects from heart-failure drugs, only 28% of participants could name both side effects shortly after the study was explained to them, although an additional 44% could name one.²⁰

These data raise a question as to whether it is reasonable to expect research participants to benefit from long lists of potential adverse events, when it is clearly difficult to remember more than a few side effects. A telling example from the literature is a study of hospital employees who were asked to consider joining a sham protocol in which they would take an experimental drug. Employees were randomized to one of three consent forms for this trial. Each consent form described the side effect profile of the sham experimental drug in a different level of detail, and in each case the profile was an accurate description of the potential side effects of aspirin. Employees given the most detailed description grossly overestimated the risk of taking the drug; those given the brief description formed a much more accurate conception of the drug's risk even though they had less raw information to work with.²³

These data suggest investigators should be careful about encouraging too much optimism in research participants. They also indicate that expecting participants to recall a laundry list of risks is unrealistic, and they cast doubt on the utility of loading consent forms with long lists of side effects.

The Effect of Demographics on Understanding

Several demographic factors have been shown to be associated with better understanding in informed consent. The literature offers strong evidence that better education is associated with better understanding. A more limited evidence base indicates that advancing age (over 50) and mental illness are risk factors for low understanding. Other basic demographic characteristics, including sex, minority status, and income, have not been consistently linked with poor understanding. Importantly, there is no evidence that participants from poor countries understand less well than participants from industrialized nations.

At least 13 studies have showed that higher education and reading levels are significantly associated with increased overall understanding scores.^{12,15,24-35} Frequently these differences are striking. In a study of parents who were considering pediatric leukemia trials for their children, 7% of parents with less than a

high school education understood randomization, whereas 78% of parents who were college graduates understood it ($p < .001$).¹² Another study of advanced cancer patients enrolling in Phase I trials found that 69% of college graduates correctly stated the purpose of Phase I trials as a determination of dose toxicity, whereas only 26% of noncollege graduates were right about this ($p = .002$).¹⁵ The relationship between education and understanding is robust across many settings and studies, and it is strong enough to be of major practical significance.

Increased age was associated with significantly lower understanding in five studies that enrolled participants with mean age older than 50 years (all $p < .05$).^{24,27,28,32,33} However, two other studies have reported no association between understanding and age.^{34,35} In addition, mental illness, particularly schizophrenia, has been associated with lower understanding in four studies that compared mentally ill research participants with healthy or medically ill volunteers (all $p < .05$).^{31,35-37}

A review article comparing informed consent in research in poor countries to that in affluent democracies found no evidence that participants from the poor countries understood less.⁵ In light of generally lower levels of education in poorer countries, this is a surprising finding. One possibility is that international studies might have more heavily monitored and effective consent processes than is the norm in industrialized countries. It is worth noting that saying understanding in poor countries is as good as it is in developed countries is not the same as saying it is good on an absolute scale.

Interventions to Improve Understanding

Helping research participants understand better is a challenge. An extensive and growing literature has tested diverse approaches. At least 42 trials have compared the understanding of research participants who had undergone a standard informed consent process with the understanding of those who had received an intervention to improve their understanding. Unfortunately, no clearly effective solutions have emerged.

Interventions that have been tested can be categorized into five groups: (1) multimedia, including computer-based informed consent; (2) enhanced consent form; (3) extended discussion; (4) test/feedback; and (5) miscellaneous. Overall, 12 trials tested multimedia interventions, using computer or video technology in place of,^{35,38-40} or in addition to,^{31,40-42} the usual written informed consent form. A further 15 trials evaluated consent forms with modified content, writing style, format, or length.^{23,24,27-29,33,37,39,40,43-47} Five trials of extended discussion evaluated interventions in which a member of the study team or a neutral educator scheduled additional time to discuss the disclosed information with research participants.^{30-32,34,48} These interventions ranged from a 30-minute telephone conversation with a nurse³² to multiple counseling sessions lasting up to 2 hours.⁴⁸ Another five trials evaluated test/feedback interventions, in which research participants were quizzed about the information disclosed to them and were given a review of questions that they answered incorrectly.^{25,26,37,49,50} Five trials of miscellaneous interventions were not readily comparable with any of the other interventions that were tested.^{36-37,40,50,51} For example, one trial put research participants through a weeklong tryout period for the procedures in the protocol before asking for consent.⁵¹

The studies can be compared on the basis of whether a trial employed randomization, whether the trial evaluated real or simulated informed consent processes, the number of participants in the trial, and whether the trial was published in a peer-reviewed journal. Simulated trials, which asked volunteers to consider a hypothetical or sham decision to enroll in research, were less realistic, hence potentially less relevant to actual clinical trials, than those comparing two real informed consent processes. Overall, peer-reviewed randomized trials in a real setting with relatively large enrollment have the greatest validity but are rare: Only eight trials met this standard and had enrollment of over 100 people.^{30,32,33,39,43,49}

A minority of studies attempted to assess the effect of interventions on research participants' satisfaction and accrual. Studies that assessed satisfaction simply asked participants to rate their satisfaction. Studies in a real setting measured accrual directly; studies of simulated consent processes asked participants either to make a hypothetical decision or to rate their willingness to enroll.

The Effectiveness of Interventions

Overall, 12 trials of multimedia interventions revealed that such interventions often failed to improve research participants' understanding^{31,35,38–42} (see Table 59.6). One published trial showed a statistically significant improvement in understanding using a computerized presentation of information.³⁵ The population for this trial was primarily patients with mental illness, with a few healthy volunteers. In addition, two unpublished trials reportedly produced increases in understanding, one from a video presentation and the other from a computerized presentation;⁴⁰ but the significance of these results is difficult to assess prior to complete analysis, peer review, and publication of the data. None of the other nine trials reported a significant improvement in understanding, although two trials of video interventions that showed no increase in understanding immediately after disclosure did show improved retention of information weeks later.^{41,42}

Of the 15 trials with enhanced consent forms, 6 studies showed significant gains in understanding^{23,29,44–47} whereas 9 did not.^{24,27,28,37,39,40,43,45} (see Table 59.7). The nine negative studies included four of five more rigorous randomized controlled trials of real consent processes.^{27,28,33,39} Of the 6 studies that showed significant gains, 5 evaluated simulated consent processes with no discussion of the information in the consent form; the consent form was the only means used to disclose information to participants.^{23,29,45–47} Because in most real consent processes research participants receive some information through discussion, the effect of improvements to the consent form is likely to be larger in such a hypothetical scenario than in a real research context.

When modifying consent forms, investigators used four basic strategies: reducing the length of the form; revising the content of the form to make it more comprehensible and readable; improving formatting through the use of techniques like larger font size and italics; and adding graphics. The data do not indicate that any of these approaches is more successful than the other approaches. But the one randomized controlled trial in a real setting to show a significant improvement used a dramatically shortened form, from four pages to two.⁴⁴ This reduction in length was accomplished by removing standard but irrelevant information on risk.

Extended discussion between study staff and research participants resulted in statistically significant increases in understanding in three of five trials^{32,34,48} (see Table 59.8). Both negative trials showed trends toward improved understanding ($p = .054$ and $p = .08$, respectively).^{30,31} Three of the trials in this category have questionable validity due to their small sample sizes and nonrandomized designs.^{31,34,48}

The test/feedback approach, in which participants were evaluated for understanding and then given additional explanation if their understanding was inadequate, had significant impact (all $p < .05$) in all five trials that evaluated this approach^{25,26,37,49,50} (see Table 59.9). But each study in this category measured the outcome using the same questionnaire that was used in the test/feedback intervention itself. This is a serious methodological flaw because any improvement in the test score could reflect rote memorization of the answers to questions rather than increases in real understanding.

Among the five miscellaneous interventions, two were combinations of more common approaches (see Table 59.10). One trial compared a standard consent process with a process enhanced by a combination of extended discussion time, additional written information, and simple teaching aids.⁵⁰ A second trial used extended discussion time and teaching aids that included computerized presentation.³⁶ Both trials simulated a consent process and resulted in significant gains to understanding. A one-week tryout period in which research participants underwent some protocol procedures before deciding whether to give consent was also associated with a significant improvement in understanding.⁵¹ Two other trials did not show a significant increase in understanding.^{37,40}

Actual accrual to real protocols, or stated willingness to join simulated protocols, were secondary outcomes for 12 trials. Two multimedia trials^{38,42} and one enhanced consent form trial²³ noted significantly higher willingness to join for the intervention group, although the other trials noted no statistically significant difference.^{29,32,41,44,45,50} No trial documented statistically significant reduction in accrual or willingness to join due to an intervention.

Two enhanced consent form trials that asked research participants to rate their satisfaction with the disclosure processes found that participants were more satisfied with the enhanced form than with the control form.^{33,43} Two more trials, which had an enhanced consent form and a computerized presentation, found that the intervention and control groups reported comparable satisfaction.^{38,44} The only other trial to measure satisfaction found that an extended discussion intervention was viewed as "worthwhile" or "very worthwhile" by 89% of patients.³²

Overall, these data indicate that multimedia and enhanced consent form interventions do not consistently improve research participants' understanding. Person-to-person interactions, especially the extended discussion interventions, may be more effective in improving understanding.

This review suggests several conclusions and recommendations for policy and future research. First, although multimedia interventions may have the potential to improve understanding, this potential has not been realized in practice. Of 12 trials, only 1 published and 2 unpublished trials of such interventions have documented an improvement in understanding among research participants.^{35,40} Most participants in the published trial were mentally ill, suggesting that multimedia intervention might be helpful for that population. In addition, two trials that used video

Table 59.6
Results of Trials of Video and Computer Multimedia Interventions

Coyne (2003) ³³	Readability improved from college to 7th grade level, less technical language, simpler paragraphs, question–and–answer format, treatment calendar, larger font, more white space	Oncology patients	Real	Randomized	207	69	72	.21
Campbell (unpublished) ⁴⁰	More white space, bold headings, photographs, figures	Parents of pediatric participants	Simulated	Randomized	No significant improvement reported			

*This trial tested three consent forms; the longest consent form yielded the lowest understanding, but was so verbose as to be unrealistic for a control and is not shown here; § understanding was measured two to three weeks after information disclosure.

Table 59.8
Results of Trials of Extended Informed Consent Discussion Interventions

Author	Intervention	Population	Scenario	Methodology	Sample Size	Understanding Scores		P value
						Control	Intervention	
Aaronson (1996) ³²	Semistructured phone conversation with oncology nurse, lasting about 30 minutes	Oncology patients	Real	Randomized	180	66	83	.001
Kucia (2000) ³⁴	Detailed repetition of clinical trial information	Cardiac patients	Real	Longitudinal	20	52	68	.0005
Fitzgerald (2002) ⁴⁸	Three meetings with a counselor, lasting up to 40 minutes each	Haitians at risk for HIV	Real	Nonrandom	45	73	93	.0001
Benson (1988) ³¹	Extra meeting with independent educator	Psychiatric patients	Real	Nonrandom	43	51	67	.054
Tindall (1994) ³⁰	Extra meeting to discuss trial with research participant's enrolling physician	HIV patients	Real	Randomized	113	60	63	.079*

*This trial was designed with a significance threshold of $p = .1$ to avoid a risk of false-negative results. Therefore by the standards of this trial, the results were positive; but by the standards applied to other trials in this review, the results are nonsignificant.

Table 59.9
Results of Trials of Test/Feedback Interventions

Author	Intervention	Population	Scenario	Methodology	Sample Size	Understanding Scores		P value
						Control	Intervention	
Taub (1981) ²⁵	Research participants were given an 8-question test and received brief feedback on incorrect answers. Total time for intervention was 15 minutes or less.	Elderly volunteers	Real	Randomized	87	37	52	.01*
Taub (1983) ²⁶	Research participants were given an 11-question test up to 3 times, and received brief feedback on incorrect answers.	Elderly volunteers	Real	Longitudinal	100	69	89	.01
Wirshing (1998) ⁴⁹	Research participants were tested and received brief feedback on incorrect answers until they were able to score 100%, then reevaluated for understanding 7 days later.	Psychiatric patients	Real	Longitudinal	49	Significant improvement reported [¥]		.02
Stiles (2001) ³⁷	Research participants were tested up to 3 times with a quiz and received brief feedback on incorrect answers.	Mentally ill and normal volunteers	Simulated	Randomized	111	82	97	.001
Coletti (2003) ⁵⁰	Deficiencies in participant knowledge identified with questionnaires and discussed with research participants. Three such meetings occurred at 6-month intervals.	At risk for HIV	Simulated	Longitudinal	3908	55	69 [§]	.05

*Understanding was measured two to three weeks after information disclosure; ¥ significance based on evaluation seven days after test/feedback intervention compared to initial evaluation; § final understanding score is after two sessions of feedback with 12 months between control and intervention values.

Table 59.10
Results of Trials of Miscellaneous Interventions

Author	Intervention	Population	Scenario	Methodology	Sample Size	Understanding Scores		P value
						Control	Intervention	
Rikkert (1997) ⁵¹	Week long tryout before consent	Elderly patients	Real	Longitudinal	50	55	70	.001
Carpenter (2000) ³⁶	Extended discussion, computerized presentation, and other simple teaching aids such as a flip chart	Mentally ill	Simulated	Longitudinal	20	32	71	.001
Coletti (2003) ⁵⁰	Extended discussion, additional pamphlet, and other teaching aids	At-risk for HIV	Simulated	Randomized	4,572	55	70	.05
Stiles (2001) ³⁷	Neutral facilitator present at research participant's meeting with investigator	Mentally ill and normal volunteers	Simulated	Randomized	227	82	81	NS
Merz (unpublished) ⁴⁰	Educational vignettes included with consent information	Apheresis patients	Simulated	Randomized	206	Unpublished: no increase in understanding reported		

technology, which did not find an increase in understanding, did establish an increase in retention of disclosed information.^{41,42} If this result were further verified, video technology might be useful as a tool for improving retention of information.

The lack of consistent improvement in understanding due to video and computer technology may seem surprising, partly because previous studies have suggested that multimedia interventions increase patients' understanding in routine medical care.^{52,53} This disparity may result from the fact that in research, the informed consent process is already formalized through federal regulations that require a written consent form. Video-based and computer-based interventions may not add much to this relatively thorough disclosure process. Indeed, in previous studies, when a decision aid was compared with standard medical care, increases in understanding were quite large; but when a more elaborate decision aid was compared with a simple one, increases were small.⁵⁴ In the same way, multimedia interventions could be much better than nothing but not necessarily better than the disclosure processes already common in clinical research.

Second, the data indicate that enhanced consent forms do not typically yield significant increases in understanding. Although enhanced consent forms seemed to have a significant effect in several trials, most of these trials simulated the consent process unrealistically; they included no discussion, only a reading of the form. In such a setting, the form becomes the participant's only source of information and this exaggerates the impact of changes in the form. The one realistic trial that showed an effect suggests that shortening forms by removing unnecessary standardized content appears to improve understanding.⁴⁴

Third, limited evidence suggests that more person-to-person contact, rather than videos or paper forms, may be the best way to improve understanding. The most promising model is that advanced by Neil Aaronson and his colleagues, in which a nurse made 30-minute phone calls to participants at home and went through a semiscripted conversation with them.³² One purpose of this conversation was to ask questions to find out how much

participants understood and to review key topics with them. The 10 trials of extended discussion and test/feedback interventions provide preliminary support for a hypothesis that in-person human contact tends to be more successful in improving understanding than relying on tools like consent forms and multimedia interventions.^{25,26,30–32,34,37,48–50} Extended one-on-one interaction with another person may offer more opportunity for active engagement and responsiveness to the individual needs of the research participant. This hypothesis would support the idea that informed consent is more than just the action of reading a form and signing it. It is better thought of as a process, ideally a dialogue, that takes place over time and largely depends on interactions between humans.

Fourth, lower educational attainment, mental illness, and perhaps advanced age are associated with lower understanding. Indeed, the differences in understanding between well-educated and less well-educated individuals outweigh any improvement in understanding from the various interventions. These results may reflect poorer test-taking skills among less educated research participants, causing them to score lower on tests of understanding even when their understanding is actually adequate. It may also indicate that these interventions are still not effective for individuals with less education and that disclosure processes need to be more appropriate for individuals with lower cognitive skills.

Recommendations for Improving Informed Consent

For clinical investigators who seek to better inform participants in their clinical trials, these data support several conclusions.

Using a standard consent process and adding an extra meeting with a qualified person has the best evidential support. There is no evidence that this person needs to be an investigating physician; it might be ideal to use a nurse or outside educator to reduce the risk that a physician with vested interest in the study might unduly

influence the research participant's decision. If resources are limited, researchers should consider targeting interventions to at-risk groups: Less well-educated, mentally ill, and possibly elderly populations. Further studies of extended discussion would be useful, particularly if they collected data to define how much extra time is helpful and what aspects of the interaction are most effective at improving understanding.

Multimedia interventions are not a reliably good investment for improving understanding, being expensive and time-consuming to produce without dependable positive effect. There may be effective ways of using multimedia interventions, but the burden is on investigators to show that this approach really helps research participants. Investigators who invest in multimedia should do research to confirm that its use is actually improving understanding.

Investing additional effort in consent forms is unlikely to have a large effect on understanding, although some evidence suggests that brevity and the elimination of irrelevant boilerplate information improves research participants' understanding.

A randomized controlled trial is needed to determine the effectiveness of test/feedback interventions that avoid the rote-memorization methodological problem. The test/feedback approach is intriguing, but research on it must be rigorous in order to show that it is really enhancing understanding, not just improving the participants' ability to parrot the correct answers to standard questions.

Future studies should avoid simulated consent processes because such simulations are often unrealistic. For instance, in evaluating improved consent forms, research results would be much more persuasive if they came from a real consent process in which the form assumed its usual role as only part of the consent process.

Finally, there is no reason to think that research participants will be dissatisfied with interventions to improve understanding or that interventions will diminish accrual.

Conclusion

This chapter synthesizes the empirical literature on informed consent to answer the following questions: How much do research participants understand? Do some participants understand more than others? How can understanding be improved?

The reason for asking these relatively simple questions is to help answer more complicated ethical and policy questions. Were this not primarily an empirical review, we might dwell further on questions such as the following: Are research participants well enough informed that their participation is ethical? What should investigators do to improve understanding? Hopefully the evidence accumulated here will be useful to anyone who wants to explore these questions in greater depth.

These are important questions for anyone involved in research, partly because researchers are as tightly bound by regulations as they are by financial and technical concerns. Research must have a satisfactory consent process for a conscientious institutional review board (IRB) to approve it. But nobody knows for certain what is and is not a satisfactory consent process. There is no evidence on what steps are necessary to achieve a given level of understanding in a given population. There is no way to show whether an IRB's demands are reasonable; there is no way to show whether an investigator's efforts to inform potential participants are adequate.

IRBs lack consistent standards to apply, investigators have no reliable tools to achieve informed consent, and it is not clear that participants are adequately protected by a system of informed consent that is flying blind.

This situation is dangerous. It retards valuable research and consumes the time of IRB members and investigators in unproductive debates lacking valid answers. Particularly in international research, in which everyone struggles with the challenge of communicating information to people from a different culture, this process can be a major logistical barrier. Meanwhile, inadequately informed research participants are less able to protect themselves either from exploitation or from the inherent risks of research.

We propose that participants will be safer and regulatory processes will run more smoothly if informed consent can become an evidence-based discipline. At this point, it is essentially never evidence-based. The information summarized here is still insufficient to design a consent process to achieve any given goal. But we now have testable hypotheses, and we can identify the further research needed to develop a reliable set of ways to help research participants understand. If this research is conducted, we can hope that the demands of IRBs and the capabilities of investigators will become closely matched, and that the volunteers who make research possible will more often be well enough informed to be true partners, rather than passive subjects.

The Assent Requirement in Pediatric Research

Jimmy, a bright, energetic, and confident 8-year-old, suffered from a serious inborn immune deficiency characterized by a disorder in white cell function. Jimmy spent a significant percentage of his life in the hospital, fighting off obscure infections. Given the rarity of his disease, Jimmy also spent a good deal of time enrolled in clinical research aimed at understanding his condition and immune function in general.

In the spring of 1999, investigators developed a protocol to obtain white cells from individuals with Jimmy's disease. The investigators believed that studying the cells in the laboratory might provide information about the specific white cell deficiency that characterizes the disease and, perhaps, might yield important insights into immune function in general. Several factors made Jimmy an especially good candidate for the procedure. He had undergone similar procedures in the past and had never experienced any ill effects. In addition, Jimmy had a rare genetic variant of the disease that was little understood.

Jimmy's parents strongly supported his participation in the study. They had already lost one child to the disease and were committed to understanding it better. Because the study investigator did not want to pressure Jimmy into agreeing, she asked a bioethics consultant to explain the procedure to Jimmy and solicit his agreement. The consultant met with Jimmy, accompanied by his primary nurse. The consultant explained that the procedure would involve placing two needles in Jimmy's arms and would require that he sit relatively still, in a reclining chair, for approximately 30 minutes.

The consultant also explained that the procedure posed very low risks to Jimmy, apart from a remote possibility of some blood loss if the tubing became clogged. The investigators proposed to

use a topical anesthetic, which would reduce and might fully eliminate the pain associated with the initial needle sticks. Jimmy related that he remembered undergoing a similar procedure, and stated that the procedure had not bothered him and had caused him no anxiety. Indeed, Jimmy explained that he enjoyed the time he spent undergoing the procedure because the nurses had brought in a television and played one of Jimmy's favorite videos.

By the end of the 45-minute discussion, it was clear to both the consultant and the nurse that Jimmy understood the procedure and was not afraid or made anxious by the prospect of undergoing it. Based on several years of caring for Jimmy, the nurse assured the consultant that Jimmy made his views clear when he did not want to undergo a particular procedure. Indeed, after Jimmy was told that the procedure would not help him, and that he could refuse to undergo it, he quickly refused. To explain his refusal, he pointed out that the procedure would not help him and said he would rather spend the 30 minutes required to undergo the procedure playing basketball in the hospital hallway.

Two days later, Jimmy's mother asked the bioethics consultant to meet with him again regarding the procedure. The previous day, Jimmy's 14-year-old sister, who suffered from the same disease, had undergone the procedure and told Jimmy that it was easy, and that he should do it. The sister explained that the procedure was not painful or difficult, that Jimmy could watch videos while undergoing it, and that his participation would help the doctors learn more about their terrible disease.

Jimmy worshiped his sister, and his mother assumed that the sister's report was likely to influence him. The consultant agreed, and met with Jimmy alone in his room. The consultant again explained the procedure, and again explained that the doctors

thought Jimmy's participation would be helpful to the study. The consultant also again explained that the decision was up to Jimmy and that he could refuse, even though his parents and sister supported his participation. With very little hesitation, Jimmy again declined, explaining that the procedure would not help him. He stated his second refusal in almost identical terms, expressing surprise that the consultant seemed unable to understand that playing basketball is more fun than sitting in a chair with needles in one's arms. Based on Jimmy's refusal, the procedure was not performed.

Everyone agrees that, with some exceptions, parents or legal guardians should give permission for their children to be involved in research. The question of assent for pediatric research participation asks whether children's prospective agreement should be solicited in addition to their parents' permission. In requiring Jimmy's assent, were the investigators showing appropriate respect for him, or inappropriately treating a child as if he were an adult? Does appropriate respect imply that children should be asked to provide prospective assent? If so, should all children be asked to give assent, or only some subset of children? At a practical level, how should the assent requirement be implemented? And what is the appropriate approach for children who are not being asked to assent?

The Regulatory Landscape

Most research ethics guidelines allow children to be enrolled in research studies that do not offer them a prospect of direct benefit only when their parents or legal guardians give permission. Many guidelines, including those from the Council for International Organizations of Medical Sciences (CIOMS),¹ South Africa,² and the United States,³ also require the assent—defined as “positive agreement”—of children who are capable of providing it. Specifically, most regulations require the assent of children when the research does not offer them a compensating potential for clinical benefit. Most regulations either do not require children's assent when research does offer a compensating potential for clinical benefit or allow the reviewing IRB to waive the requirement when the research offers such potential for clinical benefit. The Ugandan guidelines, for example, allow children to be enrolled in non-beneficial research only when “adequate provisions have been made for the solicitation of the children's assent.”⁴ Similarly, the Indian Council on Medical Research guidelines require that the “assent of the child should be obtained to the extent of the child's capabilities.”⁵ The U.S. regulations require the assent of children capable of providing it in all cases. However, the U.S. regulations, at 45 CFR 46.408, allow IRBs to waive this requirement when the research offers the “prospect of direct benefit that is important to the health or well-being of the children and is available only in the context of the research.”³ These regulations also allow IRBs to waive the requirement for assent in cases that qualify for waiver of informed consent, such as minimal risk research when obtaining consent is not practicable.³

Most commentators regard the assent requirement as an important protection for children in the context of clinical research that does not offer them a compensating potential for clinical benefit.⁶ But it is unclear *which* children are capable of assent, and research ethics guidelines provide little guidance in this regard. The U.S. federal regulations, for example, specify only that the

determination of which children are capable of assent should take into account the children's “ages, maturity, and psychological state.”³ This guidance leaves many questions unanswered. Which aspects of children's age, maturity, and psychological state should investigators take into account when determining whether they are capable of assent? Is the ability to nod one's head sufficient? Must children understand certain aspects of their research participation? And, if so, which ones?

Several commentators argue that, as a general rule that admits of exceptions, children become capable of assent at the age of 7. The American Academy of Pediatrics and the U.S. National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (hereafter, National Commission) have taken a similar stance.^{7,8} This view traces to the centuries-old “Rule of Sevens.”⁹

The Rule of Sevens states roughly that children under the age of 7 do not have the capacity necessary to make their own decisions; children 7–14 years of age are presumed not to have this capacity until proven otherwise in individual cases; and children over age 14 are presumed to have the capacity to make their own decisions and lead their own lives, unless proven otherwise. The fact that age 7 has been regarded, for hundreds of years at least, as an important threshold for the purposes of making decisions may explain why a number of commentators have endorsed it as the age of assent. That is, historic precedent may have been viewed by commentators, either consciously or not, as an additional argument in favor of adopting this threshold, providing reason to prefer age 7 over, say, age 6 or age 10. Alternatively, one may argue that the prior acceptance of the Rule of Sevens had a more pernicious effect, biasing commentators in favor of this age threshold to the extent that it was endorsed without sufficient analysis.

It is worth noting, however, that the assumption that children are capable of assenting to research participation by age 7 is inconsistent with the Rule of Sevens. Strict application of the Rule of Sevens would classify children between ages 7–14 as incapable of providing assent, unless proven otherwise. In addition, a 2004 survey of the chairpersons of 188 IRBs revealed great variation in practice in the United States. Specifically, only 20% of U.S. IRBs used the age 7 cutoff, 9% used age 5 or 6, and 18% used an age between 8 and 12.¹⁰ In addition, 54% of U.S. IRBs left the decision of which children are capable of assent to the judgment of the investigators in charge of a given study.

These data on implementation point to the need for systematic analysis of the rationale for the assent requirement. Is such variation appropriate? Should individual IRBs, or even individual investigators, make their own decisions about which children are capable of assent? Or should there be a consistent threshold across IRBs and across studies?

Appealing to Family Practice to Set a Threshold

Some commentators argue that the debate over the appropriate age threshold for assent should be informed by data on how families engage their children in decision making outside the research context.¹¹ Specifically, at what age do parents allow their children to make various decisions? Gathering this information would provide background on the types of decisions that children are allowed to make in their daily lives. This information would

have important practical implications, clarifying the ages at which children make decisions in other contexts and thereby revealing how familiar children and families might be with different age thresholds for assent, and how they might react to these thresholds. Similarly, it would be useful to gather data on the ages at which children's agreement is required for decisions outside of the research context. Is children's assent required for them to serve as a bone marrow donor for a sibling, for instance? At what age are children allowed to decide they no longer want to go to school, or to go on family vacations?

Families presumably involve their children in decision making to different degrees, and the extent to which they do so varies by the decision in question and diverse cultural and social norms. Hence, without further argument, this view seems to imply that no substantive regulatory stance should be adopted. Instead, the regulations should state simply that the research should be presented to the family and that the family should be asked to decide whether the child will be enrolled, using whatever decision-making process the family relies on outside of the research context. Under this approach, parents who do not involve their children in day-to-day decisions would decide on their own; families that decide together would do so in the research setting as well; and any parents who defer completely to their children would also be able to do so in the research setting.

In contrast, one might endorse the view that there should be no assent requirement at all. First, one might argue that, by definition, children are individuals who are legally not able to make their own decisions. Therefore, children should not be asked to make their own decisions regarding research participation. This view might be supported by the claim that it is consistent with respect for families.¹² Children are dependent on their parents, and parents are responsible for their children. In general, society allows parents to decide how to involve their own children in decision making. We allow parents to determine whether their children get to decide when they go to bed, or what they wear to school. On these issues, we do not legislate standards for all families to follow.

It is true that there is value to allowing families to decide how to run their respective lives and society should interfere with families only when there is good reason to do so. However, the policy of granting families a sphere within which they are allowed to make their own decisions without societal interference does not imply that whatever families do, and however they decide to engage their children in the decision-making process, is acceptable. Rather, it reflects the fact that unless the matter is sufficiently important, interfering is not justified, even when families may be treating their children inappropriately.

Furthermore, the practice of allowing families wide discretion in choosing their own decision-making styles does not apply directly to the research setting. Research involves exposing children to risks for the benefit of society at large. Thus, in this setting, society has a greater responsibility to ensure the proper treatment of children. In this setting, society cannot grant that some families may be making mistakes in whether and when they allow their child a say, but justify noninterference on the ground that noninterference promotes other goods that are not outweighed by minor mistakes. In the research setting, society is already involved and already responsible for ensuring that proper practices are followed. The practices that society allows families to pursue in their private sphere apply to research only if there is independent

reason to think that they are appropriate to that setting; the fact that families rely on these practices in their own lives does not settle the matter. Instead, we need to determine what constitutes an appropriate practice in the research setting. We need to figure out why requiring assent is important, and how important it is compared to other values, such as allowing families to make their own decisions. And we need to determine how assent practice is relevant to the nature of the research context. The fact that parents are allowed to disrespect their own children in their own homes does not imply that I am obliged to allow the same parents to disrespect their children in my home. At that point, others become involved and their interests and obligations become relevant to the moral calculation. The fact that the ethical concerns of the research team often get short shrift in research ethic literature does not make them less important or relevant. For example, the fact that parents treat their children one way at home does not necessarily entail that research nurses should be party to such treatment in the research setting.

Arguments for Assent

The U.S. federal regulations governing research with humans are based on the recommendations of the National Commission in the late 1970s. Therefore, to identify the rationale behind the assent requirement as it is expressed in the U.S. regulations, the National Commission's recommendations provide a good starting place. The National Commission's consideration of pediatric assent began with the principle of respect for subject autonomy: Individuals who can understand and shape their lives should be allowed to decide whether to enroll in research based on their own conception of a flourishing life. Conversely, individuals who cannot understand the proposed research cannot make an autonomous decision. They cannot decide whether research enrollment, or one of the available alternatives, would further their conception of a flourishing life.

The autonomy rationale implies that the threshold for assent should be fixed at the age at which most children become capable of making their own research decisions. Although one often thinks of respect for autonomy as applying to adults only, the National Commission recognized that individuals do not suddenly develop the capacity to make their own decisions at age 18. An individual's capacity develops over time, and many children are able to make their own decisions before they reach the legal age of adulthood.¹³

To make an autonomous decision regarding research enrollment, potential research participants must be able to understand the study in question and their own medical and personal situations, and to make a voluntary decision whether to participate on this basis. To understand the study in question, potential participants must understand the "elements of informed consent": the study's purpose, risks, potential benefits, requirements, procedures, and alternatives.¹⁴ Potential participants must also appreciate how the elements of informed consent pertain to their own circumstances. Recognition that the capacity to make research decisions requires individuals to understand and appreciate all the elements of informed consent suggests one way to identify the age at which children develop this capacity, namely, identify the age at which children come to understand and appreciate the *final*—that is to say, the last to develop—element of informed consent.

Appreciation and the Purpose of Nonbeneficial Research

Children first understand concrete facts about the world and later come to understand more abstract facts. This suggests that the age at which children understand and appreciate the more abstract elements of informed consent provides an approximation of the age at which they should be able to make their own research decisions. Perhaps the most abstract element of informed consent is the *purpose* of research for which children's assent is required, namely, nonbeneficial research that is intended to develop generalizable knowledge that might help future patients.

The capacity to decide whether to enroll in nonbeneficial research requires children to understand and appreciate the potential to be altruistic, that is, the possibility of taking on risks and burdens to help others. Again, children do not have to be motivated to help others; they need only to understand this possibility. Children who do not understand the concept of altruism cannot decide for themselves whether helping others by enrolling in nonbeneficial research would further their conception of a flourishing life. They cannot decide whether the moral reasons to help others outweigh the risks of the research. Therefore, the autonomy rationale suggests that the assent threshold should be fixed at the age when (most) children develop the concept of altruism.

The Concept of Altruism

The term *altruism* is often used to describe those who are motivated to help others. Empirical studies of altruism tend to focus on helping behavior, often labeled *pro-social* behavior, independent of why individuals behave in this way.¹⁵ Because these studies do not assess individuals' motivations for acting, they provide only limited evidence regarding when children develop the concept of altruism. The fact that children behave in a helping way at this or that age does not establish that they possess the concept of altruism at that age; it depends on why they act in this way.

The current data on prosocial behavior describe a roughly U-shaped function between age and altruistic behavior.^{16–18} Starting at approximately age 2, many children will help others who are present and experiencing visible distress—for instance, offering a toy to a crying baby.^{19–21} By age 5, most children will respond to the needs of individuals who are not within the child's circle of intimates. For example, a number of studies have found that many 5-year-olds will contribute to charity.²² Finally, children's helping behavior appears to drop off after age 5, before increasing linearly starting around age 10.

Because of the inherent difficulties in assessing the motivations underlying individual behavior, it is not surprising that very few studies have assessed why children help others at various ages. Given this paucity of data, any recommendations must be tentative and subject to revision in light of future data. With this caveat in mind, the existing data suggest that most children younger than 10–12 years old behave altruistically for nonaltruistic reasons. They help others because they expect to be rewarded, to comply with the request of an adult, or because they feel bound by unwritten social rules.^{23,24} These data suggest that most children under age 10 do not possess the concept of altruism.

At some point after age 10, most children begin to understand that there are moral reasons to help others, independent of the

possibility of reward or punishment.²⁵ For example, in a longitudinal study of children 5–16 years of age, Eisenberg and colleagues found that adolescents begin to understand and develop the ability to act from moral motivations at 11–12 years of age.²⁶ That is, they begin to understand that there are moral reasons to help others, even when doing so is not required and may place burdens on them.

It is important to distinguish this argument from the claim that potential research participants must be *motivated* to help others. The difference here is roughly the difference between acting altruistically versus understanding the concept of altruism. The claim that people must understand the concept of altruism in order to understand the purpose of nonbeneficial research, and hence to give informed consent, does not imply that they must be motivated to help others. Similarly, the claim that participants must understand the potential benefits of the research does not imply that they must enroll because they want access to those benefits.

These data suggest that most children cannot appreciate that the potential to help others provides a reason to enroll in nonbeneficial research until 10–14 years of age. Therefore, to the extent that the assent requirement is based on the principle of respect for autonomy, the age threshold for assent should be fixed somewhere in the range of 10–14 years. Before endorsing an age threshold within this range, however, one should consider whether there are any nonautonomy based reasons to support an earlier threshold. Are there reasons to require children's assent for nonbeneficial research before they develop the capacity to make their own enrollment decisions?

Other Arguments

The National Commission argued that investigators should obtain children's assent at age 7, not out of respect for their autonomy, but to help teach them to become autonomous. Effectively teaching children to become responsible and autonomous adults involves asking them to make decisions they are capable of making. For this reason, parents typically begin with fairly minor decisions and proceed, as children mature, to more important decisions. For instance, parents often begin by allowing children 5–8 years of age to help decide what to wear, or how to decorate their bedrooms. At what age should the decision to participate in nonbeneficial research be added to this teaching process?

Asking children to decide whether to enroll in research before they can understand and appreciate the elements of informed consent is ill-suited to teaching them to become good decision makers. For instance, a child who can understand the risks or potential benefits of research, but not both, is unlikely to make a decision that promotes their interests. Similar concerns arise when investigators ask for children's assent for nonbeneficial research before they can recognize that there are moral reasons to help others. From the child's perspective, asking children whether they want to enroll in nonbeneficial research before they have developed the concept of altruism amounts to asking them to accept burdens and risks for no reason. To the extent the children respond in a rational way, they will refuse, simply because they do not understand that there are reasons to agree.

Of course, parents and investigators may encourage reluctant children, and such encouragement may influence children to agree to enroll in nonbeneficial research. Nonetheless, this approach is

unlikely to teach children to make decisions that promote their interests. It is more likely to teach them to doubt the judgment of adults, or simply to follow the advice of others, even when the advice makes no sense from their point of view. This analysis suggests that the importance of teaching children to become effective decision makers supports the proposal to fix the assent threshold at the age when (most) children are able to understand and appreciate the elements of informed consent.

In some places, the National Commission argued that assent should be required as a way to respect the ability of children 7 years of age or older to make “decisions concerning their activities.” Does the ability to understand *some* aspects of research participation, and to make a decision on that basis, provide an independent reason to require children’s assent for nonbeneficial research?

One might argue that the principle of respect implies that we should obtain children’s assent even before they are able to make autonomous decisions. It is not clear, however, whether the principle of respect alone has substantive implications. Respect for persons tells one, roughly, to treat others in the way they deserve or ought to be treated. The principle of respect for persons itself does not tell one specifically how to treat them. To determine how one ought to treat a given individual—which is a necessary prelude to determining whether a particular behavior toward the individual is consistent with respect—one needs to know more about the individual in question. To take an example from the research ethics literature, there is ongoing debate about the conditions under which it is ethically appropriate to conduct research on the dead. Everyone agrees that we should respect the dead, yet appeal to a principle of respect does not settle the issue. We need to know whether research on the dead is consistent with appropriate respect. We cannot answer that question by analyzing the principle of respect. We need to understand something about corpses, including the relationship that the corpse bears to the previously living person.

Similarly, the principle of respect for persons tells us to treat children as they ought to be treated. Whether asking children to make research decisions is integral to respecting them is a further question. Should investigators solicit children’s assent at the point at which they can nod their heads? when they can understand at least one aspect of research participation? when they can understand several aspects of research participation? If so, which ones? when they can understand all the elements of informed consent? or only when they become emancipated from their parents? The principle of respect for persons, although obviously relevant and important, does not answer this question. Rather, the principle of respect for persons implies only that investigators should solicit children’s assent at the ages at which it is appropriate to do so, and not before. But this is the very question that the appeal to the principle of respect for persons is intended to answer in the first place.

The Existing Data

It is important to emphasize that the existing data are scanty with respect to those aspects of human development that are relevant to assent for research. Thus, only tentative conclusions will be possible, and these conclusions will be subject to revision as further data appear.

With that caveat in mind, the existing data suggest that children cannot understand many aspects of research participation until at least age 10. For instance, Ondrusek and colleagues found that children under age 9 do not understand most aspects of research participation.²⁷ At the same time, children over age 7 can understand some elements of informed consent.^{28,29} For instance, Susman, Dorn, and Fletcher found that a majority of children involved in research understand the research’s potential benefits and duration, what participation requires of them, and that they have an option to ask questions.³⁰

The ability to understand and make decisions develops gradually, and children as young as 2 years old can understand some rudimentary aspects of research participation, such as the fact that it requires them to leave home, or allow strangers to touch them. Hence, the claim that children’s assent should be required once they can understand any aspect of research participation, and express a choice on that basis, implies that the threshold for assent should be lowered to the age at which most children first understand at least one aspect of research participation, likely around 2 years of age.

What reason might justify requiring investigators to obtain the affirmative agreement of children as young as 2 years old? We have seen that respect for persons implies that investigators should obtain children’s assent starting sometime in the range of age 10–14. Of course, respect for persons is not the only reason why it might be important for investigators to obtain children’s assent. In particular, it is also important to consider the relevance of the principle of nonmaleficence to this issue.

The Role of Nonmaleficence

The principle of nonmaleficence applies to individuals of all ages, whether they are autonomous or not. This principle implies that children should not be required to participate in nonbeneficial research that is more than minimally distressing. In many cases, children will not know whether research participation will be distressing until they experience it. Thus, requiring children to make a prospective decision whether to enroll does not offer an effective mechanism to protect them from harm, particularly because children may be reluctant to go back on agreements with, or promises to, doctors. Children may also find it positively distressing to be asked to make decisions about research they cannot understand. Hence, the principle of nonmaleficence does not seem to support, and in some cases may conflict with, a requirement to ask children to decide whether to enroll in nonbeneficial research before they are able to understand the research in question.

Supporters may respond that the principle of beneficence, as distinct from the principle of nonmaleficence, implies that investigators should obtain children’s assent at the point that they understand some aspects of the research in question. More research is needed to assess what impact asking young children to make research decisions has on them. In principle, however, there is no reason to think that asking individuals who cannot fully understand to make their own decisions will further their welfare. This is supported by the fact that children may find it distressing to have to make prospective enrollment decisions, especially for research their parents support, but for which they can find no reasons to enroll. Furthermore, asking children to make decisions

they cannot understand conflicts with teaching them to become good decision makers.

Once children are enrolled in research, they will be in a good position to assess whether it is causing them distress. And because most children who experience distress will communicate this verbally or through body movements, the principle of nonmaleficence supports adoption of a dissent requirement: The dissent of all children should be respected in the context of research that does not offer them a compensating potential for clinical benefit.^{31–33} Although this dissent requirement is not explicit in many regulations, including the U.S. federal regulations, it is included in some national regulations. For example, the Tanzania guidelines for research with humans stipulate that researchers “must recognize when a child is very upset by a procedure and accept that as genuine dissent from their being involved.”³⁴

Although the importance of a dissent requirement seems clear, it may not always be clear in practice, because a child’s statements and behavior do not always reflect actual distress. For instance, an infant may cry in the absence of distressing stimuli. Nevertheless, children’s participation in nonbeneficial research should be halted and reassessed at any indication that the child is experiencing more than minimal distress. The first question to ask is whether the signals from the child reflect actual distress. With respect to very young children, this judgment may require input from parents who are familiar with the behavior of their children. To err on the side of protecting children, unclear signals should always be regarded as reflecting underlying distress.

Because children’s distress may be the result of nonessential aspects of their research participation, a dissent requirement need not stipulate that children must be removed from research at the first sign of dissent or distress. Instead, investigators and parents should attempt to identify and address the source of distress. Simple reassurance, a short pause, or a minor modification in the procedure may be sufficient to eliminate the distress. However, indications of more than minimal distress that cannot be alleviated should always be respected in nonbeneficial research.

Although some children may express apparent dissent in the absence of underlying distress, others may experience significant distress without expressing dissent. To address this concern, children participating in nonbeneficial research should be explicitly told to inform the investigators or nurses if they experience any distress. In addition, everyone involved in pediatric research should be trained to monitor children for signs of distress the children cannot or are unwilling to communicate.⁷

Setting an Age Threshold

The present analysis suggests that children should be asked to provide assent at the age at which they have the capacity to understand the nature of the research study in question. Because human development occurs at different rates, there will no single age at which all children develop the ability to understand. Some children will develop this ability at a relatively young age, whereas others will not develop this ability until much later. Thus, one possibility would be to require investigators to assess individual children to determine whether they have the capacity necessary to give assent. Investigators could then solicit assent on an individual basis, from the time that specific individuals develop the necessary capacities.

This approach has obvious virtues in terms of tailoring one’s practice to the abilities of individual children, thereby ensuring sufficient respect for all children in this regard. At the same time, assessing each child’s capacity is likely to require a good deal of resources for any study that involves more than just a few children. This is especially true given the fact that no one has developed an instrument that would allow such an assessment. Some instruments have been developed for the purposes of assessing adults’ capacity to give consent, but these would have to be modified for evaluating children. In particular, these instruments typically assume that adults are able to understand the purpose of nonbeneficial research and do not assess this understanding directly. Adapting the instruments for this purpose would likely be difficult in practice. Further research is needed. In particular, it will be important to develop ways to assess understanding and determine how much time and resources they require.

At least until such research has been conducted, investigators will have to rely on more general thresholds. The use of general thresholds in the face of a continuum of age development and the absence of assessment tools is common in other areas. No one thinks that all people suddenly become capable of drinking alcohol responsibly at age 21 and that all adolescents suddenly develop the abilities necessary to vote responsibly at age 18. We recognize that children develop these abilities at different ages. Nonetheless, as opposed to theorizing about particular individuals, society endorses a general threshold, recognizing that whatever threshold is chosen will be too low for some and too high for others.

Current data suggest that most children come to appreciate what is likely the *final* element of informed consent—the ability to understand the possibility that nonbeneficial research may help others—sometime between ages 10 and 14. A plausible decision procedure in the face of insufficient data is to select the option that minimizes the potential resulting harms. The primary risk of choosing the lowest age in the range for the assent threshold is that children who are not autonomous will be asked to make their own research enrollment decisions. Conversely, the primary risk of choosing the highest age in the range is that investigators will fail to respect the autonomy of those children who develop the ability to make their own research decisions at an earlier age. Choosing intermediate ages involves balancing these two risks to varying degrees. How should we choose among these options?

It is important to improve medical treatments for children. Requiring the assent of children who are incapable of understanding the moral importance of helping others may carry significant costs if many children decline to participate based on a failure to appreciate these reasons. On the other hand, failing to allow children to make their own research decisions, if they are capable of doing so, carries the moral harm of failing to respect their autonomy. This is also an important concern: It would deny some children the chance to make a fully informed, altruistic decision to participate in the research. It would deny some other children the right to make a fully informed decision not to participate. However, to the extent that this failure is limited to the research context, it will be a relatively isolated event. Moreover, adoption of a dissent requirement will ensure that children who are upset at being enrolled will be able to control their fate by dissenting. The addition of this protection, together with the importance of improving medical treatments for children, supports choosing age 14, the highest age in the range, as the threshold.

To implement the dissent requirement with children who are unable to provide assent, investigators should explain what they are proposing to do, emphasize that the child's parents gave their permission, and tell the child to inform the investigator if he or she has any questions or experiences any distress. Under a dissent requirement, the investigators would then proceed with the research procedure without asking for the child's positive agreement, while carefully monitoring him or her for any signs of dissent or distress.

IRBs often mandate that researchers inform children about their prospective research participation by means of an assent form. Given this practice, fixing the assent threshold at age 14 may inadvertently result in younger children not receiving any information about their research participation. Yet very young children often want to know what is going to happen to them, and they find it reassuring to know how long their participation will last and where they will stay. To address this concern, IRBs might develop information sheets for children who are not able to give assent.

The fact that some children are not able to provide assent to research enrollment does not imply that they should be left out of all research decisions. Research participation often involves many small decisions—when to get medications, what clothes to wear, which elevator to take—that children can make and often enjoy making. The principle of beneficence suggests that children should be allowed to make these decisions when possible. The principle of beneficence also implies that investigators and IRBs should work to make research participation as enjoyable and beneficial for children as possible. To take one example, children may benefit from age-appropriate explanations of the science behind the research and the procedures it involves.

Some might argue that the present proposal that children become capable of assent at the point at which they are able to understand this decision confuses assent with consent. This issue is an important one, but deserves its own treatment. The fact that children can understand as well as adults at age 14, say, does not immediately imply that they should be able to make their own research decisions without parental input. Specifically, future research should consider whether being a dependent member of a family implies that parents should still have a say in their children's participation in research, especially nonbeneficial research, even when the children are capable of making an autonomous decision.

Practical Implications

Given that a dissent requirement allows children to veto their parents' decision to enroll them in nonbeneficial research, what is the difference between requiring children to make an affirmative decision versus respecting their dissent? The possibly subtle difference between these two requirements may explain why the drafters of the federal regulations adopted the National Commission's proposed assent requirement, but not its proposed dissent requirement. The drafters of the federal regulations may have assumed that adoption of the assent requirement was tantamount to requiring investigators to respect children's dissent.

In practice, there are three important differences between requiring assent and respecting dissent. First, respect for dissent does not imply that investigators should ask children to make a prospective decision on whether to participate in a given research study. A dissent requirement allows children to stop their research

participation; it does not allow them to prevent their initial enrollment. An assent requirement, in contrast, requires that children make a prospective decision and lets children block their research enrollment. Second, an assent requirement alone does not require investigators to respect the dissent of children who are unable to provide assent. For this reason, it is important to adopt a dissent requirement in addition to an assent requirement. Third, asking children to make their own affirmative decisions puts them in the position of having to assess the options and prospectively choose the best course of action for themselves. When they cannot understand the research in question, requiring children to make this decision puts them in the position of having to choose (or reject) a course that their parents endorse but they cannot understand.

A dissent requirement places children who cannot understand the elements of informed consent in a very different position. Under a dissent requirement, children are not required to understand the research and make their own prospective decisions. Instead, they simply react to how the research is affecting them and indicate any distress they experience.

Assent and the Necessity Requirement

It is widely agreed that investigators should not enroll individuals who are unable to consent in research that could just as well be carried out by enrolling individuals who are able to consent. Should a similar *necessity* requirement be applied to research with children who are able to assent? That is, should investigators be allowed to conduct research with children who are unable to assent only when they cannot conduct the research equally well with children who are able to consent? The National Commission endorsed a variation of this requirement, stating that investigators should always enroll older children in research before enrolling younger children. This suggests, for instance, that in the process of testing drugs on children, investigators should first assess drugs in older children and only then move on to testing them in younger children.

The relevance of a necessity requirement for research with children seems to depend in large part on the basis one uses for determining which children are capable of assent. For example, if one simply uses the age of 7 as the threshold for assent, it is not clear what reason there might be to prefer the enrollment of children just under this threshold to children who have recently turned 8. To be sure, any requirement that prefers the enrollment of older children over younger children makes sense in that such a requirement generally will favor children who are more mature and better able to understand. Although this seems an important result, the inclusion of the age of assent does not seem to be doing any independent work here. Instead, this threshold simply forces investigators to prefer older children, a preference which could be stated equally well without any mention of the age of assent.

In contrast, with a threshold of age 14, the age of assent gets set at the age at which most children are able to understand the essential elements of informed consent. This threshold provides a clear reason to prefer the enrollment of children who are capable of assent to the enrollment of children who are not so capable. As with the necessity requirement as it is applied to adults, there are good reasons to prefer the enrollment of those who are able to understand over those who are not able to understand.

Conclusion

What, then, is the most appropriate way for investigators and IRBs to handle cases like that of Jimmy, described at the beginning of this chapter? Some commentators who emphasize the importance of respect for persons seem to assume that respect requires that individuals be asked to make their own decisions in all cases. Endorsement of such a view suggests that Jimmy's case was handled appropriately, even though he was not able to understand crucial elements of the decision in question. Indeed, this view seems to imply that children should be treated as competent and autonomous decision makers from the time they are able to make any decisions at all. Most commentators, however, do not take the principle of respect for persons so far that they argue that children should be able to veto their enrollment in research that offers them a prospect of direct benefit. We do allow competent adults to veto such participation. Those who appeal to the principle of respect for persons need to explain why, if that principle requires children as young as 3 or 4 to give assent to nonbeneficial research, it does not have the same implications for beneficial research.

Other commentators suggest that assent requirements should be patterned on the ways in which families engage their children in decision making outside of the research context. Although these data seem relevant, it is not clear that families' current practices are necessarily the appropriate ones. It may rather be that society simply tolerates the practices of some families on the ground that interference would be too costly, not on the ground that the practice is appropriate. In addition, I have argued that the context of research is fundamentally different. Research with humans involves exposing some individuals to risks for the benefit of society. For this reason, society needs to identify the correct policy in the context of research.

I have argued that children should be required to provide their assent at the point at which they are capable of understanding the research in question. Given the paucity of current data on the development of human understanding, any recommendations in this regard must be considered very tentative and subject to future modification. Accepting that caveat, the existing data suggest that children should be asked for their assent at the age of 14.

Importantly, this proposal does not confuse the child's assent with informed consent that is necessary for the research to proceed. The fact that individuals can understand the essential elements of consent at age 14 implies, on the current view, that their assent should be solicited. However, one might further argue that at that point, children should be able to provide their own consent, independent of their parents, rendering the question of assent moot. Although this view sounds plausible, and may be correct in many cases, it does not immediately follow. The fact that children continue to live in families may provide sufficient reason to require the parents' permission, in some cases at least, even after the children have adequate understanding. At any rate, that is a distinct issue that requires its own consideration.

Finally, the view endorsed here implies that the treatment of Jimmy, although consistent with U.S. regulations and a good deal of the existing literature on pediatric assent, was mistaken. The approach inappropriately treated Jimmy as being able to make his own decisions. Instead, after obtaining the parents' permission, the investigators should have explained the procedure to Jimmy and answered any questions he might have had. The investigators should then have gone ahead while monitoring him for any signs

of distress or dissent. If this procedure turned out like his previous ones, the investigators would have obtained the cells for their studies and Jimmy would have lost only some free time. If the procedure had caused any more than minimal distress to Jimmy, it could have been stopped at that point. If the source of the distress could not be eliminated, the procedure should have been terminated at that point.

Respect for Human Research Participants

This page intentionally left blank

Confidentiality

Protecting the confidentiality of individually identifiable health information that is acquired, used, disclosed, or stored in the design, performance, or analysis of human subjects research is essential to respecting the dignity and privacy of human subjects participating in clinical research. Theories of confidentiality and privacy of identifiable health data are featured in the earliest conceptions of medical ethics. These theories are replicated in research ethics that evolved in the latter half of the twentieth century. Research ethics have consistently reflected a strong respect for the autonomy of individuals participating in research studies by protecting identifiable health data used in conducting research studies. Legal requirements at the international, federal, and state levels specifically address confidentiality protections in human subjects research and other settings.

These protections are not only theoretically, legally, and ethically grounded, they are critically important for practical reasons. Without adherence to principles of confidentiality, researchers may engage in, and individuals may fear, misuses of health data. Breaches of confidentiality involving human subjects in clinical research can lead individuals to avoid future participation in research studies. Unwarranted disclosures of identifiable health data can cause direct and indirect harm to individuals who are the subjects of such data, or to vulnerable groups of which they are members. Protecting data confidentiality, in sum, is essential to conducting human subjects research.

Most researchers understand the principle of confidentiality protections in human subjects research. They agree with the need to respect the private nature of research participants' health and other data, to avoid disclosures of such data without individual authorization, and to safeguard data to avoid unintended releases

or nonapproved uses. Yet, what does it really mean to respect the confidentiality of human research subjects' health data? Protecting confidentiality, in theory, is easy; in practice, however, it is complex and fraught with essential trade-offs. Modern principles—grounded in law, such as the U.S. Common Rule; in international agreements on human rights, such as the United Nations Universal Declaration of Human Rights; and in biomedical ethics—seek to clarify the scope of confidentiality and its applications in human subjects research. These principles provide a collective series of guideposts and norms that set formal, structural requirements for protecting individual (and group) confidentiality. This chapter seeks to explain the historical and modern understandings of confidentiality protections through an assessment of the ethical, legal, and policy issues, as well as their implications for the design and performance of clinical research involving humans.

History

The history of confidentiality is intrinsically tied to the history of medical ethics. "Requirements of confidentiality appear as early as the Hippocratic Oath,"¹ and are featured in virtually every code of medical ethics since. An adherent to the Hippocratic oath vows, "What I may see or hear in the course of the treatment or even outside of the treatment in regard to the life of men, which on no account one must spread abroad, I will keep to myself, holding such things shameful to be spoken about."² Early origins of medical confidentiality demonstrated the dual needs of medical practitioners to promote the welfare of their patients and to sanctify the role of physicians through ethical and increasingly legal

practices that sought to restrict uses of identifiable data.³ Restricting physicians' use and disclosure of patient health data, though unpopular as applied to some research and public health uses, was justified as protecting patients from unwarranted, and potentially damaging, exchanges of health data. Nineteenth-century codes of medical ethics articulated this theme of self-restriction by medical practitioners. The American Medical Association Code of 1847, based on Percival's code from Britain, followed the tradition of the Hippocratic oath and imposed on physicians an "obligation of secrecy," which required that physicians should divulge "no infirmity or disposition or flaw of character observed during professional attendance . . . except when he is imperatively required to do so."⁴

Even these early, basic statements of medical confidentiality, however, were qualified by the fundamental premise that individual privacy is not absolute. Confidentiality protections of individually identifiable health data must be balanced with communal or other needs for disclosure. Government may need routine access to identifiable health data to promote the public's health, prevent emergencies, investigate criminal actors, or protect individuals from known harms. Justifications for breaching individual expectations of confidentiality have also traditionally included disclosures to researchers. Public and private sector entities have asserted strong claims to identifiable health data to perform clinical and health services research. The need to balance individual and communal interests in health data, explained further below, is one of the key challenges in health information privacy.

By the beginning of the 20th century, ethical conceptions of medical confidentiality were featured more prominently in laws of medicine and practice. One of the primary tenets of individual autonomy in research with humans, informed consent, found meaning beyond consenting to the risks and benefits of the research itself. Informed consent also came to be applied to research participants' authorization to acquire, use, and disclose their identifiable health data as part of research activities.⁵ This application of informed consent has been clarified through legal principles. Courts have imposed legal duties of medical confidentiality for decades. After Warren and Brandeis persuasively articulated individual rights to privacy in their famous article *The Right to Privacy*,⁶ lawmakers and policy makers focused on privacy as a legal and ethical norm worthy of significant additional protections. Ethicists justified strong respect for data confidentiality through utilitarian and normative principles. Utilitarian arguments centered on the value of confidentiality in facilitating honest communication between doctor and patient, or health researcher and subject. Expectations of privacy allow patients to feel comfortable in divulging personal information that is often needed for accurate diagnosis and treatment. Unauthorized uses or disclosures may subject individuals to embarrassment, social stigma, and discrimination, which consequently impact their health and interfere with the physician's ability to render effective medical care.

The principle of respect for autonomy, a foundational norm in bioethical discourse, contributed to a restructured conception of privacy and its incumbent rights, especially in research settings. Addressing the horrors of medical experimentation during World War II, the Nuremberg Code affirmatively stated the preconditions for, and the condition of, autonomy in the context of medical research⁷ (see Chapter 12). In the United States, the Belmont Report, addressing ethical requirements for human subjects re-

search, clarified principles of autonomy: "To respect autonomy is to give weight to autonomous persons' considered opinions and choices, while refraining from obstructing their actions, unless they are clearly detrimental to others"⁸ (see Chapter 14). Modern bioethicists defend health information privacy on grounds of respect for persons. According to this reasoning, competent adults have full moral authority to make their own decisions about their physical and mental well-being.¹ Informational privacy enhances individual autonomy by allowing individuals control over identifiable health information. By exercising control, individuals can limit disclosures to persons of their choosing, deciding in effect which disclosures are worth the potential risk of having sensitive information in the possession of various actors.

As they were formalized in ethical and legal discourse, principles of confidentiality evolved to reflect changing conceptions on the proper balance between individual privacy and communal needs for health data. A model social welfare act devised by the U.S. National Social Welfare Assembly in 1958, for example, proposed a balance favoring access to confidential data for research purposes:

Research by its very nature, often must have access to original material. . . . [Consequently,] undisguised case records may be made available for studies and research activities which seek to advance social work objectives if they are carried out under direction that assures protection of case information.⁹

Over the latter half of the century, however, the powerful rise of autonomy and its concurrent tenet of informed consent reshaped this balance between individual privacy and communal uses of health data for research uses. The World Medical Association's Declaration of Helsinki, which has provided international ethical guidance for human subjects research since 1964, specifically mentions the need to respect subjects' privacy through data confidentiality protections (paragraphs 10 and 21¹⁰; see Chapter 13). In 2002, the Council for International Organizations of Medical Sciences (CIOMS), in collaboration with the World Health Organization (WHO), noted in its International Ethical Guidelines for Biomedical Research Involving Human Subjects that researchers "must establish secure safeguards of the confidentiality of subjects' research data. Subjects should be told the limits, legal or other, to the investigators' ability to safeguard confidentiality and the possible consequences of breaches of confidentiality"¹¹ (see Chapter 16). The increasing development of longitudinal electronic health records and their prospective linkage through a national electronic health information infrastructure have heightened individual concerns about the potential for widespread data sharing and unwarranted uses, including unauthorized research. The result is broader requirements for individual authorization for all acquisitions, uses, and disclosures of identifiable health data for research purposes, except in specific circumstances, as noted in sections below.

Core Concepts

Confidentiality, as an ethical and legal principle, is often bundled with conceptions of privacy and security. People tend to think of these concepts interchangeably. They are, however, ethically and legally distinct. *Privacy*, in the context of health care and research,

refers broadly to an individual's right to control identifiable health information. (This conception may be contrasted with U.S. constitutional notions of privacy that protect an individual's bodily integrity or interest in making certain types of intimate decisions.) Legal privacy interests, such as those provided in the U.S. Privacy Rule issued under the 1996 Health Insurance Portability and Accountability Act (HIPAA),^{12,13} support individual rights to inspect, copy, and amend health data, to limit the acquisitions and uses of health data, and to demand an accounting of disclosures. Additional fair information practices expressed through legal and ethical norms also stem from broad conceptions of privacy. Whereas privacy represents an individual right, confidentiality is the corresponding duty to protect this right. *Confidentiality* comprises those legal and ethical duties that arise in specific relationships, such as doctor/patient or researcher/subject. A physician or researcher's duty to maintain confidentiality, which invokes the "secrecy" aspect of privacy, is one mechanism to protect the individual's broader privacy interests, which also include the individual's right to access or correct his or her own information. *Security* refers to technological or administrative safeguards or tools to protect identifiable health information from unwarranted access or disclosure. Although researchers may work hard to keep confidential the data that they acquire, use, and disclose, privacy breaches can occur if they fail to maintain adequate security protections. These distinct terms are accurately linked in the following statement: "If the *security* safeguards in an automated system fail or are compromised, a breach of *confidentiality* can occur and the *privacy* of data subjects can be invaded [emphasis added]."¹⁴

Ethical and legal norms of privacy and confidentiality impose standards on the relationship between researchers and their subjects and set requirements for the acquisition, use, and disclosure of identifiable health data for clinical research purposes. In the United States, human subjects research that is conducted or supported by a federal department or agency must comply with a set of regulations designed to protect human subjects—the Federal Policy for the Protection of Human Subjects, known as the "Common Rule"¹⁵ (see Chapter 15). Among other requirements, one of the conditions for approval of research proposals by institutional review boards (IRBs) is that "[w]hen appropriate, there are adequate provisions to protect the privacy of subjects and to maintain the confidentiality of data" (§46.111(a)(7)).¹⁵ Furthermore, the Common Rule requires, in most cases, that investigators obtain the informed consent of research participants, which must include "[a] statement describing the extent, if any, to which confidentiality of records identifying the subject will be maintained" (§46.116(a)(5)).¹⁵

Federal and state research protections like the Common Rule stipulate the need to protect privacy and confidentiality, but significant gaps in the protection of data of research subjects remain. These laws typically only apply to research conducted or funded by the government, and not to private sector research, although the Common Rule has been widely adopted by private research entities in the United States.¹⁶ The Common Rule also has gaps. It exempts from complying with the full requirements of the regulations several categories of research, including the collection or study of existing data, documents, records, pathological specimens, or diagnostic specimens, if these sources are publicly available or if the data are not individually identifiable (§46.102(b)(4)).¹⁵ Genetic databases are especially problematic because they may be deemed

nonidentifiable even though technological methods can increasingly link genomic data to individuals. Moreover, the Common Rule (1) does not require confidentiality protections in all cases, (2) allows investigators to dispense with protections so long as subjects provide informed consent, (3) fails to explicate further uses of research data, and (4) allows for expedited reviews of several types of research proposals.¹⁶ As a result, considerable variation in IRB reviews leads to inconsistent protection of research participants' privacy.

For example, an investigator may disclose personal data to other researchers for related or nonrelated purposes without violating the Common Rule. If the data are in a format that cannot reasonably identify or be matched with other available information to identify an individual, such disclosures are completely exempt from the Common Rule and the HIPAA Privacy Rule. As a policy matter, the Common Rule allows data to be exchanged like a commodity, without limits, provided they are nonidentifiable. But research participants still may feel that their privacy has been infringed, even if they cannot be personally identified. By itself, the Common Rule thus provides minimal and insufficient protections for the privacy of research subjects' information.¹⁷

Myriad additional protections are found in U.S. federal and state health information privacy laws, although many commentators view these protections as insufficient to fully protect the privacy of digitized health data within an ever-growing national electronic health information infrastructure. Under Section 242m(d)—a.k.a. section 308(d)—of the U.S. Public Health Service Act,¹⁸ identifiable health information collected by federal public health agencies cannot be used for any purpose other than that for which it was supplied, unless the agency or person has consented. However, under Section 241(d) of the same Act,¹⁸ the Department of Health and Human Services (DHHS) can issue Certificates of Confidentiality that protect research participants from legally compelled, nonconsensual disclosures of any identifiable information, including health data, to persons not connected with the research. This protection is generally sought by researchers for sensitive health data, such as genetic information or data related to sexual practices, to encourage subjects to participate or to provide accurate or complete data. This protection is not limited to federally supported research.¹⁹ IRBs reviewing research proposals regularly recommend that the researcher obtain a Certificate of Confidentiality as part of the IRB approval for the study.

Informed consent requirements, assurances, and Certificates of Confidentiality offer opportunities for respecting the private nature of health data, but collectively lack clarity as to what is ethically and legally required to protect individual privacy. Protecting data privacy is more than an aspirational goal. Fundamental principles of privacy require that responsible persons take action, or avoid mistakes, to ensure that data are kept confidential. The HIPAA Privacy Rule seeks to specify these requirements. Promulgated by DHHS in 2002 and codified at 45 CFR 160¹² and 164,¹³ the Privacy Rule provides the first systematic national health information privacy protections in the United States. It governs "covered entities," which include health insurers and health plans, health-care clearinghouses, and health-care providers that conduct transactions electronically, as well as their business associates (§160.103).¹² Notably, covered entities do not include clinical researchers unless they are performing "covered functions" while conducting research. Covered functions are

services that assimilate the functions of covered entities. Thus, if a researcher provides clinical care to humans during the course of a study, and bills or conducts other standard transactions electronically for these services, the researcher may be required to adhere to the Privacy Rule. Even if a researcher is not performing covered functions, the Privacy Rule may still affect clinical research activities by limiting the flow of health data from covered entities to researchers.

The Privacy Rule protects most individually identifiable health information created or received in any form by covered entities (§160.103).¹² Protected health information includes individually identifiable data that relate to the past, present, or future physical or mental health or condition of a person, or the provision or payment of health care to a person (§164.501).¹³ But protected health information does not include nonidentifiable health information or de-identified data—health statistics or other aggregate data that do not or cannot identify individuals (§164.514(a)(b)).¹³ Covered entities, their business associates, and those providing covered functions are responsible for establishing and adhering to a series of privacy protections related to protected health information that reflect modern ethical norms. These include (1) providing notice to individuals regarding their privacy rights and how their protected health information is used or disclosed (§164.520),¹³ (2) adopting and implementing internal privacy policies and procedures (§164.530),¹³ (3) training employees to understand privacy policies and procedures (§164.530(b)(1)),¹³ (4) designating persons who are internally responsible for implementing privacy policies and procedures (§164.530(a)(1)),¹³ (5) establishing appropriate administrative, technical, and physical safeguards to protect the privacy of protected health information (§164.530(c)(1)),¹³ and (6) helping patients exercise their rights under the Privacy Rule to inspect and request corrections or amendments to their protected health information, or to seek an accounting of certain disclosures (§§164.524, 164.526).¹³

As with any privacy law or policy, the Privacy Rule balances individual and communal interests, most notably through its disclosure provisions. In general, a covered entity may not disclose protected health information without individual written authorization, subject to a series of exceptions (§164.508(a)(1)).¹³ Among these exceptions are some disclosures for research. Both the Privacy Rule and the Common Rule define research as “a systematic investigation, including research development, testing, and evaluation, designed to develop or contribute to generalizable knowledge.”^{13,15} Covered entities can disclose protected health information to others for research without individual authorization, but only under certain limited instances.^{13,20} These are the following:

1. *IRB or Privacy Board Approval of Waiver of Written Authorization.* A covered entity may disclose protected health information for research purposes without written authorization if an IRB or a privacy board (a specialized institutional board authorized by the Privacy Rule and constituted of noninterested members with the professional competency to review the effects of research on individual privacy interests, including at least one person who is not affiliated with the covered entity) waives the requirement, based on three criteria: (1) The use or disclosure of protected health information must involve no more than a minimal risk to individual privacy, based on the existence of an adequate plan to protect identifiers from improper use and to destroy the identifiers

at the earliest opportunity, along with written assurances that the data will not be reused or disclosed to any other nonauthorized person or entity; (2) the research could not practicably be conducted without the waiver; and (3) the research could not practicably be conducted without access to and use of protected health information (§164.512(i)(1)(i)).¹³ These criteria are very similar to the requirements for waiving informed consent under the Common Rule.²¹

2. *Preparatory to Research.* A researcher can review protected information to design a research study or assess its feasibility without written authorizations, if the researcher represents to the covered entity that the disclosure is needed to prepare a research protocol or for similar purposes preparatory to research, that the protected health information will not be removed from the covered entity, and that the protected health information is necessary for the research (§164.512(i)(1)(ii)).¹³

3. *Research Using Decedents’ Protected Health Information.* A researcher may acquire protected information about deceased individuals if the researcher represents to the covered entity that the disclosure is solely for research on decedents’ information, that the information is necessary for the research, and, if requested, provides documentation of the death of the individuals about whom information is being sought (§164.512(i)(1)(iii)).¹³

4. *Limited Data Sets With a Data Use Agreement.* A covered entity may disclose a limited data set of protected health information if it obtains a data use agreement from the researcher assuring that the data will only be used or disclosed for the limited purposes authorized by the agreement (§164.514(e)).¹³ Limited data sets exclude specified individual identifiers from the health data disclosed. Data use agreements establish permitted uses and disclosures of the limited data set by the recipient consistent with the purposes of the research.

Thus, the Privacy Rule typically requires advance, written authorization of each individual whose identifiable health data are acquired or used in research, unless a researcher can obtain a waiver of authorization, is performing activities preparatory to research, is using decedents’ health information, is willing to work with stripped data in a limited data set, or uses nonidentifiable data. Though similar requirements may arise under the Common Rule, the Privacy Rule’s protections extend farther. The Privacy Rule applies to virtually all producers of identifiable health data in public or private sectors. Its ability to impose disclosure restrictions on covered entities for research purposes may enhance individual privacy interests, but it has also led to some deleterious results. Covered entities complain that the Privacy Rule’s requirements place financial, time, and human resources burdens on them. Facing the costly need to secure specific written authorization for many acquisitions of health data, some researchers have abandoned or curtailed their research plans.²² Some types of research may be particularly hampered by Privacy Rule requirements because they cannot utilize nonidentifiable data. For example, a study to assess determinants of cancer or other chronic diseases may collect a wide array of information from the review of hospital records including other diagnoses, birth dates, place of residence, family history, DNA, and environmental or behavioral factors over several years. Identifiers are essential to follow-up with participants throughout the study.

To circumvent the Privacy Rule in other cases, activities that have previously been considered human subjects research may

increasingly be categorized by investigators and IRBs as public health practice activities. For example, if research is classified as a program evaluation, a quality improvement exercise, public health surveillance, or an epidemiological investigation, disclosures may be allowed under Privacy Rule without written authorization, and the Common Rule would not apply. Although it is difficult to disguise a clinical trial involving living human subjects as one of these public health activities, some research activities involving only data or biological samples can more closely resemble nonresearch public health activities. The Privacy Rule allows more liberal data exchanges for public health purposes, therefore providing incentives for classifying data uses as public health activities.²³

Ethical Issues

Despite its risks, there is little doubt as to the importance of clinical research in the modern health and public health systems. Biomedical research on the determinants, prevalence, prevention, and treatment of diseases and injuries advances clinical care and the public's health.²⁴ Expansive electronic health care databases can facilitate research studies.²⁵ Small- and large-scale clinical trials offer opportunities to uncover promising new treatments, to study the safety and efficacy of pharmaceuticals and vaccines, or to improve the quality of health-care services. These studies, however, require the exchange of enormous amounts of health information related to health outcomes, existing conditions, and individual behaviors and characteristics.

The quintessential ethical question bridging historic and current confidentiality protections is how to properly balance individual privacy interests and communal research needs.³ It is a debate that requires difficult choices and trade-offs. If societal restrictions on the use of identifiable health data are too severe, research may be curtailed. If sensitive health data are too easily acquired, used, or disclosed, individual privacy is threatened. People will then avoid some clinical care and research studies, again hampering research.

Some commentators believe that modern privacy protections go too far in protecting data confidentiality, threatening the accuracy and use of health information for medical research. Privacy protections that allow consumers to restrict the flow of their data through requirements for informed consent or advance authorization may hinder the collection of comprehensive and accurate information that may benefit health consumers.²⁶ Congress and some state legislatures, for example, have attempted to protect the privacy of genetic information by giving individuals proprietary interests in their genetic information.²⁷ Vested with property rights, individuals could seek even greater control over how these data are used, including for clinical research.

Other privacy laws that require specific written authorization of research subjects in many cases, such as the HIPAA Privacy Rule, can stymie clinical research while offering few benefits for research participants.²⁸ Responding to public pressure for rigorous privacy protection, Minnesota enacted legislation in the late 1990s that restricts access to medical records for research purposes. The law requires advance, written informed consent of patients for health records to be used for medical research. After the law was implemented, the Mayo Clinic in Minneapolis reported that 96% of patients contacted for the purposes of ob-

taining informed consent agreed to allow their medical information to be released to researchers. This response rate suggests that most people receiving medical care are willing to allow their information to be used for medical research and that the Minnesota provisions are unnecessary.²⁹

Policy Implications

The ethical and legal debate concerning appropriate acquisition, use, and disclosure of identifiable health data for clinical research is not over. Significant policy choices must still be made as the environment for information practices continues to evolve from paper-based records to electronic, from mostly local sources of data to regional, national, and international health databases, and from societal perspectives that focus on the autonomy of the individual to a focus on the protection of communal health. We suggest that rules for balancing private and public interests in identifiable health data should go beyond the conception of individual autonomy as a dominating factor.³⁰ Privacy interests should be maximized when they matter most to the individual. Communal interests in the exchange of identifiable health data should be maximized when they are likely to achieve the greatest public good. For example, population-based registries of genetic data are critical to assessing the clinical validity and usefulness of new genetic tests.³¹ Thus, where the potential for public benefit is high and the risk of harm to individuals is low, health data should be usable for communal purposes. Privacy rules should not be so arduous and inflexible that they significantly impede, for example, clinical research or public health surveillance that is necessary to promote the community's health. Provided that the data are used only for the public good and that the potential for harmful disclosures is negligible—because researchers respect the confidentiality of the data in their possession—there are ethically sound and practical reasons for permitting data sharing.

If, however, identifiable data are used or disclosed in ways that are unlikely to achieve a strong public benefit (such as testing a protocol that has already been shown to be ineffective), or if the personal risks are high (if, for example, the data may be used to discriminate against high-risk individuals in employment or insurance), individual interests in autonomy should prevail. Disclosure of identifiable health data to family, friends, neighbors, employers, insurers, or others can cause stigma, embarrassment, and discrimination. Such unauthorized disclosures can lead to a loss of patient trust in health care and research professionals, as well as other potential harms. Consequently, when the public benefits are negligible and individual privacy risks are high, release of information without the patient's consent should be prohibited.

Like the Privacy Rule, this framework rejects the use of enhanced legal or ethical protections for exceptional or sensitive health data. Absent an overriding public benefit, all individually identifiable health data warrant privacy protections. Correspondingly, acquisition, use, or disclosure of health information for important public purposes would be permitted without specific informed consent provided that (1) uses are restricted to the purposes for which the data are collected, and (2) subsequent disclosures for other purposes are prohibited without authorization by the individual involved. Acquisition, use, or disclosure of

health information that can lead to harm would be subject to strict privacy protections. Although adherence to this balancing test may entail some diminution in current conceptions of autonomy, it offers individuals greater benefits from the communal goods offered by clinical research, public health, and other enterprises.

Study Design Implications

The modern ethical and legal frameworks for protecting confidentiality in the performance of clinical research have several implications for the ethical design of research studies. Investigators may have to adhere to national privacy standards in the performance of clinical care activities as part of the study itself if they are a covered entity or otherwise performing covered functions. For any study involving the acquisition, use, or disclosure of identifiable health data, investigators must be able to build confidentiality protections into their study design. These protections include sufficient language within informed consent documents to specify the nature of confidentiality protections. Alternatively, investigators may seek to acquire health data without either informed consent under the Common Rule or written authorization under the Privacy Rule, pursuant to a waiver under these laws and similar state protections. To do so, however, they generally must demonstrate that the use or disclosure of protected health information involves no more than a minimal risk to individuals or their privacy, consistent with suitable, written plans for protecting data confidentiality, and that the research could not practicably be conducted without the waiver or access to identifiable health data. Other exceptions apply as discussed above.

Collectively, these exceptions are meant to set a high standard for the unauthorized access, use, or disclosure of identifiable health data. By default, investigators must be cognizant of the need to seek full informed consent and written authorization from research participants prior to the use of their identifiable health data for research purposes. This requires development of sound, IRB-approved consent documents that spell out in detail the confidentiality protections inherent in the study design and implementation.

Of course, investigators can always use nonidentifiable health information for any research purpose without advance consent or authorization. Ethical and legal norms almost universally allow researchers, or anyone for that matter, to exchange nonidentifiable health data. Under existing standards of what constitutes non-identifiable health data within the Privacy Rule and the Common Rule, however, these data may be so stripped of helpful information as to be unusable. Nonidentifiable data under the Privacy Rule, for example, are aggregate health statistics or any other collection of health information that does not—or cannot when coupled with other accessible information—identify the individuals to whom it pertains. Realistically, researchers need identifiable data to perform meaningful research, and thus must be prepared to adhere to ethical, legal, and societal expectations of confidentiality that accompany these data.

Unresolved Ethical Issues and Data Requirements

Considerable ethical debate remains over several important questions, including the scope of confidentiality protections, the

treatment of group privacy interests, and the difference between research and public health activities.

The Scope of Confidentiality Protections

At the macro level, the proper balance between individual privacy interests and communal needs for data is still unresolved. Uncertainty also exists on a micro level as to the extent of privacy protections needed for research data. Current legal frameworks give investigators substantial discretion to design appropriate protections, allow individuals to dispense with these protections through informed consent, and limit the responsibility of those supplying health data, such as covered entities under HIPAA, to assessing the legality and ethicality of the initial disclosure of data to researchers. There is still no uniform approach as to how to protect the privacy of health data used by clinical researchers. What has yet to be proposed is a data use policy that attaches privacy protections to health data no matter what its use, disclosure, or setting. The Privacy Rule goes far in applying legal and ethical privacy standards to most entities that produce or transmit identifiable health data, but its protections do not fully carry over to research settings. Covered entities are not responsible per se for what happens to health data in the possession of researchers. Researchers who are not performing covered functions do not have to adhere to the Privacy Rule.

Perhaps some flexibility in data confidentiality practices is necessary, given the breadth of clinical research applications and significant variance in health data. Do we as a society need to protect the confidentiality of mental health records or genetic data used in research to the same extent as clinical indicators of heart disease? Many may respond, “No,” although the trend in privacy discourse is to attempt to protect all health data in particular settings uniformly. Participants in nonexempted research studies have the ability to determine their comfort level with confidentiality protections through informed consent requirements. Still, a vast amount of research does not require specific informed consent, nor does everyone who participates in research studies know or understand the nature of confidentiality protections. Principles of justice suggest a need to equalize privacy protections across the spectrum of research data uses.

Group Privacy Interests

Justice also requires an examination of privacy interests of individuals in clinical research, not merely as research participants, but also as members of vulnerable groups whose interests may be affected by the results of the study. Since the early 1990s, public and private researchers have increasingly targeted communities or other definable groups for clinical research into the etiology, especially genetic factors, of multiple diseases and conditions.^{32,33} Communities selected for genetic research include specific ethnic groups such as the Kahnawake Mohawks in Canada,³⁴ religious groups such as the Amish, disease groups such as people with Huntington’s disease or diabetes, and even entire nations with homogeneous populations, such as Iceland.³⁵ Genetic research among targeted groups offers significant individual (clinical) and societal (public health) benefits by revealing propensities for genetic diseases among segments of the population. For example, particular genetic mutations predisposing to breast or ovarian

cancer have been identified through studies involving Ashkenazi Jews.³⁶ With knowledge of these propensities, members of this group may seek individualized genetic testing, and, if positive, utilize environmental or clinical interventions to potentially avoid the onset of disease.

The proliferation of group genetic research, however, raises questions as to whether other members of identifiable groups, in addition to those who choose to participate in group research studies, are entitled to some level of control over research activities to protect themselves from stigmatization, discrimination, or other negative consequences. Nonparticipatory group members may have ethical claims, similar to privacy interests that might justify requiring informed consent. Some scholars suggest that these interests are more appropriately framed in terms of justice;³⁷ others disagree on the need for group protections through consent.³⁸ The fundamental interests of nonparticipating community members regarding information produced through group research studies may lie in control over how information is used or disclosed through group research.

Acknowledging the need for group privacy protections is simple; protecting nonparticipatory members of groups without significantly infringing on the rights of others is complicated. What level of control should group members have over potential or actual information produced from genetic studies? Who should speak for identifiable groups—group leaders, activists, experts, or laypersons? For that matter, who constitutes an identifiable group entitled to privacy protections? Although some legal and ethical scholars, researchers, and human rights committees have proposed that group privacy protections are based on a principle of “respect for communities,”³⁹ formal protections are largely nonexistent. Additional discussions are needed to determine when, or whether, investigators have an ethical or legal obligation to respect group privacy interests in the performance of some clinical studies.

Distinguishing Research and Public Health Practice

One of the core premises of confidentiality protections under any standard of law or ethics is that disclosures or uses for research purposes should be made under clearly defined standards. Practical application of this premise, however, is seriously flawed due to the absence of specific legal distinctions and uncertainty over how to distinguish research and nonresearch. The Common Rule and the Privacy Rule systematically require investigators and data handlers to distinguish human subjects research activities from clinical care and public health practice. Yet, neither rule provides meaningful guidance on what distinguishes research from other activities, particularly public health practice, that often resemble research. Legislators, policy makers, scholars, ethicists, researchers, IRB members, and public health practitioners struggle to draw these distinctions, resulting in confusion, inconsistent applications, and potential breaches of confidentiality arising from poor, improper, and even unethical decisions. It is unethical, for example, to systematically collect identifiable health data under the guise of a public health purpose, only to use the data for human subjects research. Yet, this scenario is entirely possible under the Privacy Rule, as discussed above.

Other scenarios may not be unethical, but may still pose challenges to practitioners assessing the legal requirements for their

activity. For example, an acute epidemiological investigation of airline passengers possibly exposed to the SARS virus may be viewed as a quintessential public health activity necessary to protect their and their contacts' health. Yet if the investigation continues to collect data from asymptomatic passengers after incubation periods have expired, the data collection serves no health purpose for those individuals, though it may help public health officials assess important characteristics about the disease. Public health practitioners at the federal, state, and local levels have struggled with these and other examples to determine whether their activities are public health practice or research (see Chapter 31).

We and others have attempted to provide improved guidance on the need to make clearer distinctions between human subjects research and public health practice activities.²³ Researchers, practitioners, IRB board members, and others, for example, may confuse public health surveillance activities and human subjects research in which both activities involve the systematic acquisition and use of identifiable health data for laudable communal purposes. We propose a two-stage framework for classifying these activities. The first stage draws on key assumptions and foundations of public health practice and research to distinguish these activities in relatively easy cases by reviewing those parameters that are exclusive to each activity. Eliciting essential characteristics, or foundations, of public health practice and research helps separate the easy and hard cases, and eliminates some cases altogether from further need for classification. Essential characteristics of public health practice (i.e., the collection and analysis of identifiable health data by a public health authority for the purpose of protecting the health of a particular community, in which the benefits and risks are primarily designed to accrue to the participating community), include the following:

- Specific legal authorization for conducting the activity as public health practice at the federal, state, or local level.
- A governmental duty to perform the activity to protect the public's health.
- Direct performance or oversight by a governmental public health authority (or its authorized partner) and accountability to the public for its performance.
- Involvement of people who did not specifically volunteer to participate (i.e., they did not provide informed consent).
- Adherence to principles of public health ethics that focus on populations while respecting the dignity and rights of individuals.

Essential characteristics of human subjects research (i.e., the collection and analysis of identifiable health data for the purpose of generating knowledge that will benefit those beyond the participating community who bear the risks of participation) include the following:

- The subjects of the research are living individuals.
- Identifiable private health information is gathered and produced.
- Research subjects participate voluntarily, or participate with the consent of a guardian, absent a waiver of informed consent.
- The researchers adhere to principles of bioethics that focus on the interests of individuals while balancing the communal value of research.

These characteristics help distinguish public health practice from research in many of the easy cases. For example, a public health reporting requirement may be specifically authorized via legislation or administrative regulation. Laws may require the public health agency to perform the activity to protect the public's health. Some states, like New York, clarify by statute that epidemiological investigations or other common public health practices are not human subjects research.⁴⁰ These activities are public health practice so long as their design and implementation do not cross over to the realm of research. As well, if an activity may lawfully require the nonvoluntary compliance of autonomous individuals, it is likely not classifiable as research because voluntary consent is a foundation of research. Only through the waiver of the consent requirement—which requires regulatory approval—may persons participate in human subject research without providing specific informed consent. Furthermore, if an activity is designed as research but does not involve identifiable health data about living individuals, it should not be included in this analysis because it does not implicate the Privacy Rule.

The second stage of analysis introduces and explains enhanced principles of guidance to draw distinctions in more difficult cases. These principles include the following:

1. *General Legal Authority.* Public health authorities may conduct activities pursuant to general legal authorization, which may justify classifying an activity as public health practice subject to additional analysis.
2. *Specific Intent.* The intent of human subjects research is to test a hypothesis and generalize findings or acquired knowledge beyond the activity's participants. Conversely, the intent underlying public health practice is to assure the conditions in which people can be healthy through public health efforts that are primarily aimed at preventing known or suspected injuries and diseases or promoting the health of a particular community.
3. *Responsibility.* Responsibility for the health, safety, and welfare of human participants in research falls upon a specific individual, typically the principal investigator. Public health practice, however, does not always vest responsibility for participants' welfare in individuals, but rather in government agencies or authorized partner entities.
4. *Participant Benefits.* Public health practice should contribute to improving the health of participants and populations. In contrast, research may, but does not necessarily, provide benefits to participants. Such is the nature of risk in research studies.
5. *Experimentation.* Research may involve introducing something nonstandard or experimental to human subjects or their identifiable health data. Public health practice is dominated by the use of standard, accepted, and proven interventions to address known or suspected public health problems.
6. *Participant Selection.* To reduce the possibility of bias in their studies, and to generalize their results, researchers may select humans for research at random. Participants in public health practice activities are self-selected persons with, or at risk of, an affected disease or condition who can benefit from the activity.

No set of principles will completely distinguish between human subjects research, public health practice, or other related activities. There will always be difficult examples of activities that

do not fit neatly into either category. However, these principles may help resolve a majority of cases, provide consistency in decision making on a national basis, and help shape the level of confidentiality protections in research settings. It will remain important for public health authorities to follow ethical guidelines for data uses that do not fall within the Common Rule. The Centers for Disease Control and Prevention (CDC) is preparing additional ethical guidance for public health data uses outside of the research context.⁴¹

Conclusion

Health information privacy and confidentiality are vital to the legal and ethical performance of human subjects research. Research subjects expect that their identifiable health data will be kept confidential and that their use or disclosure will be limited to the purpose of the research. Theories of confidentiality and privacy are pervasive throughout the histories of medical ethics, human rights, and law. Modern conceptions of privacy support strong respect for the autonomy of individuals participating in research studies, offering significant protections for identifiable health data used in research studies and other settings. These protections, which continue to evolve, impact the design and performance of research studies by limiting some access to existing health databases, requiring specific written authorization (in many cases) of subjects to use their data for research purposes, and necessitating secure information practices to prevent breaches of confidentiality. Although modern protections clarify the privacy of research participants' data, additional challenges remain. Existing privacy laws do not protect research data uniformly. The focus of protections on individuals, but not the groups of which they are members, leads to infringements of group privacy. Conceptual difficulty in distinguishing research from public health activities creates significant potential for privacy violations. Addressing these and other challenges is essential to the performance of clinical research under ethical and legal norms that reflect responsible and dignified research data uses.

Liability and Compensation for Injury of Research Subjects

Most clinical research with human subjects takes place out of public view without complaint or controversy. Yet the legal history of biomedical research highlights the occasional shocking catastrophe.^{1,2} Scandals in particular periodically rouse public outrage, recommendations for law reform, and lawsuits, which refine the legal principles governing research. More than 30 years ago, revelations of the Tuskegee Syphilis study led to the adoption of federal regulations to protect research subjects in federally funded research.³ More recently, the deaths of research subjects at renowned academic research institutions,^{4,5} most famously that of 18-year-old Jesse Gelsinger at the University of Pennsylvania in 1999,⁶ revived calls for reform.^{7–11} So far, neither the legislation nor regulations governing research with human subjects has changed significantly, perhaps because public attention was diverted in the aftermath of September 11, 2001. However, lawsuits against researchers may have gained more visibility, both applying and refining fundamental legal principles.¹²

This chapter describes the major laws that define researchers' liability for harm to research subjects. Section 1 offers a thumbnail description of the sources of law governing clinical research. Sections 2 and 3 summarize the most important rights of research subjects and duties of investigators and the types of cases that have been adjudicated, noting areas of uncertainty that may encourage future legal claims and possible evolution in the law. Section 2 focuses on the subject's consent to participate in research and research with individuals who cannot or do not consent. Section 3 examines issues in the conduct of clinical trials. Section 4 notes the difficulty of determining the number and proportion of injuries experienced by research subjects, practical obstacles and defenses

to legal claims, and alternative ways to redress harm and compensate injured research subjects.

1. The Development and Sources of Law

All researchers are legally responsible to those enrolled in their clinical trials, just as physicians have been legally responsible to patients under their care for centuries.¹³ Physicians have a duty to provide their patients with reasonable care in almost every type of legal system.¹⁴ The Code of Hammurabi imposed penalties on physicians who failed to cure their patients 4,000 years ago, with the penalty increasing with the patient's status.¹⁵ The American colonies brought English common law from England,¹⁶ where court decisions finding that a physician could be liable for negligent harm to a patient were reported as early as 1374.¹⁷ Historically, physicians who used experimental procedures were subject to malpractice liability for failing to employ accepted medical therapy.¹⁸ Researchers have somewhat different duties than physicians, because research is not considered part of patient care, and researchers expose humans to investigational therapies and interventions that have not yet proved to be effective.

In the United States, the legal principles governing the rights of research subjects and the duties of physicians and researchers to research subjects are grounded primarily in the common law, or case law—the statements of rights and duties expressed in judicial opinions deciding specific lawsuits.¹³ Legislation and regulations rarely addressed research until after World War II, when pharmacology and clinical trial methods began their mod-

ern development, and even then did not grant remedies to subjects.

The Nuremberg Code, which set forth 10 principles for research with humans, was the first international declaration of research ethics.¹⁹ It qualifies as precedent under international common law, because it was part of the 1947 judgment issued by American judges in the tribunal established by the United States Military Government for Germany after World War II.²⁰ The Nazi physicians were convicted of crimes against humanity, including murder and torture, accomplished in the guise of medical experiments.^{21–22} In the 1987 U.S. Supreme Court decision in *Stanley v. United States*, Justices William J. Brennan Jr. and Sandra Day O'Connor argued in dissenting opinions that subjecting people to experimentation without their knowledge or consent may violate a constitutional right to human dignity like that expressed in the Nuremberg Code.²³ Courts in the United States have not yet recognized such a specific constitutional right to human dignity and only recently have any courts applied the Nuremberg Code as precedent in American law.^{24–26} The substance of the Code's principles, however, have been incorporated into statutes, regulations, and common law.²⁷ More recently, plaintiffs have used the Code's principles to support their claims, and some courts, even when declining to use the Code as precedent, have acknowledged its influence in what may be a harbinger of future application.^{28–35}

The Declaration of Helsinki prescribes more detailed ethical standards for clinical research, and specifies in Article 5 that “[i]n medical research on human subjects, considerations related to the well-being of the human subject should take precedence over the interests of science and society.”³⁶ Article 15 states, “The responsibility for the human subject must always rest with a medically qualified person and never rest on the subject of the research, even though the subject has given consent.” The Declaration does not impose legal obligations, because it was adopted not by a legislature or court of law but by a private association of physicians as a statement of professional ethics.³⁷ Still, it may serve as evidence of minimum professional standards in legal determinations of the applicable standard of care. The same is true of the International Ethical Guidelines for Biomedical Research Involving Human Subjects, issued by the Council for International Organizations of Medical Sciences (CIOMS) in collaboration with the World Health Organization (WHO).³⁸ Despite physicians' widespread acceptance of both documents as more modern statements of research ethics, they are likely to remain a floor, not a ceiling, for legal duties, because courts are free to find that a professional standard is too low. Judge Learned Hand gave the classic statement of that principle in 1932, saying that

in most cases reasonable prudence is in fact common prudence; but strictly it is never its measure; a whole calling may have unduly lagged in the adoption of new and available devices. It may never set its own tests, however persuasive be its usages. Courts must in the end say what is required; there are precautions so imperative that even their universal disregard will not excuse their omission.³⁹

The Universal Declaration of Human Rights, adopted by the General Assembly of the United Nations in 1948, contains very general principles prohibiting “torture and cruel, inhuman or degrading treatment or punishment.”⁴⁰ The International Covenant on Civil and Political Rights, adopted in 1966, contains a similar prohibition in Article 7, which also adds, “In particular, no one shall be

subjected without his free consent to medical or scientific experimentation.”⁴¹ The United States is a signatory to both documents. U.S. companies sponsoring pharmaceutical research with humans may need to comply with international and regional conventions and guidelines on clinical research to obtain licensure of their products in signatory countries. For example, the Note for Guidelines on Good Clinical Practice (ICH/GCP Guidelines), issued following the International Conference on Harmonisation of Technical Requirements for the Registration of Pharmaceuticals for Human Use (ICH), requires that research sponsors provide insurance or indemnify investigators against claims arising from clinical trials.⁴²

In the United States, formal regulations to supplement the common law were not adopted until the late 1970s after revelations of research with humans without their consent,⁴³ specifically the Tuskegee Syphilis Study,^{3,44} which first prompted the study of ethical conduct of research by the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research.⁴⁵ The National Commission's 1978 *Belmont Report* and recommendations⁴⁶ led to the promulgation of federal regulations, currently harmonized in the Common Rule, which apply to research with humans funded by or submitted to more than 20 federal departments and agencies, including, most recently the Department of Homeland Security.⁴⁷ Additional regulations followed from the work of the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research.⁴⁸

The Common Rule requires an institution conducting research with humans to enter into an assurance agreement with the federal agency that it will comply with the regulations, including maintaining an institutional review board (IRB) to review and approve its research.⁴⁹ Although the Common Rule incorporates some basic common law requirements, such as informed consent to research, it does not preempt state, federal, or constitutional law.⁵⁰ Moreover, it does not grant individuals a personal remedy, such as compensation for injury, against researchers who violate the regulations.^{51–52} Instead, the Office for Human Research Protections (OHRP) in the Department of Health and Human Services enforces compliance by suspending or terminating federal funding for an institution that fails to comply with the regulations. Courts have rejected a claim by research subjects that they were third party beneficiaries of an institution's general assurance and found that the regulations do not specifically authorize research subjects to enforce the contract.^{53–54} Research subjects who seek a personal remedy must qualify under an independent common law or statutory rule. Some states have legislation regulating specific types of research, such as laws limiting research with fetuses, stem cells, or hazardous materials.^{55–56} Such laws typically vest enforcement with a state agency and rarely grant a private right of action. In some cases, however, one who is injured may use the statute as evidence of the standard of care that an investigator should have followed.⁵⁷

Despite periodic calls for reform, the law governing research with humans has changed little since the Common Rule regulations were first adopted almost 30 years ago. In contrast, the common law continues to evolve in response to new cases. Like state statutes, the Common Rule can be used as evidence of the standard of care accepted by investigators, but it does not exhaust the duties of researchers nor define the rights of research subjects themselves. Indeed, the Common Rule applies to institutions, not individual researchers, and does not apply to all research. Thus, the common law remains the primary source of rights and remedies for individuals who are injured while participating in research.¹³

2. Rights and Remedies for Research Subjects in the United States: Voluntary and Informed Consent

Unlike the Common Rule, which was adopted specifically to regulate certain research with humans, liability for injury is governed by generally applicable legal principles that apply to all individuals and organizations. The common law of torts is the primary source of researcher's duties, although the common law of contracts may apply in rare circumstances, and constitutional law may protect important liberty rights of research subjects.

Researchers who conduct clinical trials have three general types of duties to subjects: the duty to ensure that the trial itself is justified; the duty to ensure that the person participates voluntarily; and the duty to carry out the trial with reasonable care.¹³ More specifically, under common law, researchers have the following duties:

- Determine that the research question to be answered is sufficiently important to justify the use of humans as research subjects.
- Properly design the clinical trial to ensure that it does not pose unnecessary, avoidable, or unreasonable risks to subjects.
- Ensure that the individuals invited to enroll as subjects are appropriate.
- Ensure that all subjects who enroll voluntarily agree to participate with full knowledge of the trial procedures and potential risks of participation.
- Ensure that all investigators are qualified to carry out their study functions.
- Conduct the trial with reasonable care so as to maximize the safety and welfare of subjects and minimize risks, including removing individuals from the trial or halting the trial when it endangers subjects.
- Provide appropriate information to subjects after the trial if necessary to protect their safety, health, or welfare.

Investigators are subject to liability to subjects who are injured as a result of their violation of any of these duties. Table 62.1 lists the possible legal claims (causes of action) for research subjects. In practice, lawsuits claiming research injuries typically assert all causes of action that fit the factual circumstances in order to avoid missing any potentially valid legal claim against a responsible party. A typical lawsuit today might include one or more claims of fraud, misrepresentation, negligence, assault, battery, intentional or negligent infliction of emotional distress, and possibly products liability, breach of contract, or violation of constitutional rights.⁵⁸ Each cause of action has somewhat different standards and possible remedies. A plaintiff may not recover more than the total amount of damages incurred for the same injury, regardless of the number of successful claims.

Historically, the majority of litigated cases arose from using people in research without their knowledge or consent.¹³ Notorious examples of such research in the United States include the U.S. Public Health Service's Tuskegee Study of syphilis in poor, African American men,⁴⁴ the Willowbrook study of hepatitis B in mentally disabled children,¹ and the injection of cancer cells in patients at the Jewish Chronic Disease Hospital in 1963.^{59–60} Yet none of those cases resulted in litigation. During the Cold War, the federal government exposed military personnel and civilians to

radiation exposure without their knowledge,^{26,61–64} and the Central Intelligence Agency gave LSD to unsuspecting personnel to study its effects.^{23,65–66} Few of the Cold War experiments resulted in successful lawsuits, often because servicemen were precluded from suing the federal government.⁶⁷

Battery

Using people in research without their consent violates fundamental principles of autonomy and self-determination, grounded in ancient English common law.^{68–69} In 1891, the U.S. Supreme Court said that “no right is held more sacred, or is more carefully guarded, by the common law, than the right of every individual to the possession and control of his own person, free from all restraint or interference of others, unless by clear and unquestionable authority of law.”⁷⁰ (More recently, the Supreme Court has suggested that this right is also part of individual liberty protected by the U.S. Constitution.^{71–73}) Anyone who touches or causes an offensive or harmful contact with another person without the latter's consent commits a battery at common law, regardless of whether any injury results.^{74,75} Individuals are entitled to recover at least nominal damages in battery—for the dignitary harm of invading the person's bodily integrity or inviolability of the person.⁷⁶ Substantial damages may be warranted when physical injury results.

Battery includes giving investigational drugs and devices to patients without disclosing the investigational nature of the intervention, as was the case with pregnant women who were given diethylstilbestrol (DES) to see whether it prevented miscarriage without telling them it was not part of the regular prenatal care they sought.⁷⁷ The use of an investigational drug or medical device without telling the patient that it was experimental continues to give rise to lawsuits.^{78–84} For example, about 400 mostly indigent women with high-risk pregnancies at Tampa General Hospital were enrolled in a clinical trial beginning in 1986 to compare drug regimens for fetal respiratory distress syndrome.³¹ Most signed consent forms while in pain or medicated with morphine because they were told the medicine was needed to save the baby's life. A class action on behalf of the women was settled in 2000 for \$3.8 million.⁸⁵ In all these cases, the central violation was that people were involuntarily subjected to research.

Fraud and Misrepresentation

When an experiment is concealed entirely from those who are used as subjects, researchers can be liable for fraudulent concealment.^{86–88} Several university studies of the effects of radiation exposure in the 1940s and 1950s hid the experiment from the subjects. For example, 829 pregnant women were given the radioactive isotope Iron 59 but told it was a vitamin or “sweet.”⁸⁹ Their class action was settled in 1998 for \$10.3 million.⁹⁰ Developmentally disabled children institutionalized at the Fernald School were fed Quaker Oats cereal with radioactive isotopes in the 1950s. A class action on behalf of the children was partially settled for \$1.85 million in 1999.⁹¹ The Human Radiation Experiments with cancer patients in the 1960s resulted in a class action settlement of \$5.4 million in 1999.^{26,92}

Research misrepresented as standard medical care may be actionable as fraud or misrepresentation, depending upon the investigator's intent. Negligent misrepresentation can occur when

*Note: Defenses are listed as an undifferentiated group and may apply to more than one cause of action.

an investigator fails to exercise reasonable care in communicating information or in ascertaining the accuracy of the information.⁹³ It is specifically applicable to professionals, like physicians and investigators, who have a duty to furnish information to patients and research subjects respectively. Fraud is more difficult to prove, because it requires evidence of false statements (written or oral) intended to induce a person to take action (or refrain from taking action), and proof that the plaintiff justifiably relied on such falsehoods and suffered injury as a result of such reliance.^{94–95} The defendant must know or believe that his representation is false or at least that he does not have sufficient knowledge to make the representation.^{95–96} Fraud may include the omission of information that one has a duty to disclose.⁹⁶ Researchers have a duty to

disclose any material information that might affect a person's decision about whether to enroll in a study.

Patients receiving medical care who are asked to participate in research may be especially susceptible to the therapeutic misconception—mistaking the research intervention for accepted medical therapy.^{97–98} Both patients and researchers may hope that something “new” or “cutting edge” will turn out to help the patients. Physician-investigators are subject to an inherent conflict of interest between their patients' welfare and the trial protocol, and may experience psychological resistance to the idea that no benefit to the individual can be expected.⁹⁷ The opportunities for conflating research with therapy are growing with the number of clinical trials that enroll patients with medical conditions that have

not responded satisfactorily to standard therapies, such as trials of devices like an artificial heart, gene transfer research, or cancer chemotherapy.^{99,100} At least one study found that consent forms for Phase I cancer chemotherapy trials did not make clear that the trials were not designed for patient therapy.¹⁰¹ Foremost among the problems that led the study coordinator for the University of Oklahoma's melanoma vaccine trials to seek assistance from the OHRP was her concern "that it had been coercive to promise subjects that the melanoma vaccine offered hope of a cure."¹⁰² Those enrolled in that vaccine trial brought a lawsuit claiming that the investigational vaccine was misrepresented as a cure for cancer.²⁵ The university reached a settlement with some of the subjects in 2002.¹⁰³

Those who believe they were misled may be more inclined to seek legal redress than those with a more informed and dispassionate view of research. Of course, disappointment, by itself, does not give rise to a cause of action for misrepresentation. However, investigators who mislead subjects, or encourage subjects to believe that an investigational intervention is standard therapy, or fail to correct a mistaken statement may be liable for misrepresentation.

Informed Consent

Today, clinical trials rarely hide their experimental purpose or proceed without seeking consent from subjects. The real question is whether the consent was informed, that is, meaningful enough to be valid and enforceable at law. The doctrine of informed consent, also required for medical treatment, requires investigators to provide prospective subjects with sufficient information about the proposed research to permit a knowledgeable decision about participation.^{104–106} This includes the following:

- The fact that the person is being asked to participate in a research study, not medical treatment
- The purpose of the study, what will happen, and why
- What the subject will be asked to do and not do, where, and when
- The nature and potential risks of any investigational intervention, drug, or device
- The potential risks to the person of participation in the study
- The fact that participation is voluntary and that the person is free to withdraw from the study at any time
- What standard therapy exists for those who need therapy and choose not to participate

Beyond the minimum legal requirements, ethical guidelines and the Common Rule require telling prospective subjects about whether and what kind of compensation is available in case of injury.^{36,38,107} In addition, the National Bioethics Advisory Commission and others recommend telling subjects whether they will have access to successful therapies after the trial.^{108,109}

Detailed information about clinical trials became necessary when the risks of an intervention were no longer self-evident to the average person.¹¹⁰ A person's consent to participate in research is meaningless, and of no legal effect, if that person does not understand what he or she is getting into. Thus, the law requires the party most knowledgeable about the trial—the researcher—to provide information that a person having only general knowledge would not ordinarily know. An investigator who fails to tell a prospective subject about facets of the trial that are material to that

person's decision breaches the duty of disclosure. This includes the foreseeable risks of harm, as well as the uncertainties inherent in the research, but does not include particular risks that are not foreseeable.¹¹¹ The breach is typically actionable as negligence—a failure to exercise reasonable care.

A cause of action in negligence requires the plaintiff to prove the following: the researcher had a duty (to disclose material information); the researcher breached the duty (by failing to disclose that information); the person was injured; and the breach of duty proximately caused that harm.^{95,112} Proximate causation ordinarily requires proof that a reasonable person would not have enrolled (or continued) in the trial if the information had been disclosed. If the information is withheld in order to induce the person to enroll in the trial, it may be actionable as misrepresentation or even fraudulent concealment. Unlike battery, a negligence cause of action is not available unless the person has suffered cognizable physical injury.

The doctrine of informed consent allows written consent forms to be used as evidence of what subjects were told and what they agreed to, but consent documents are not conclusive.¹¹³ Although federal regulations and some state statutes require consent to be documented in writing, common law principles are directed at the content of oral communications.¹¹⁴

Several recent cases have claimed that researchers failed to obtain the subjects' informed consent.^{31,115,116} For example, subjects in the University of Oklahoma melanoma vaccine trial claimed that no one was told that the investigational vaccine posed a risk of infection because it had not been manufactured in a sterile environment or tested for safety in animals.²⁵ The U.S. General Accounting Office (GAO, now the Government Accountability Office) found many instances of failure to obtain informed consent, as well as other problems, in the Department of Veterans Affairs (VA) research centers around the country, although few resulted in lawsuits.^{117,118} Although individual investigators have the common law duty to obtain informed consent, a few courts have found that hospitals also assumed this duty by agreeing to comply with regulations governing research promulgated by the Food and Drug Administration (FDA) or the DHHS.^{119–120}

The doctrine of informed consent was developed for individuals who are legally competent to make decisions; that is, free from coercion and capable of understanding and evaluating relevant information and making a voluntary decision.¹¹⁴ All adults are presumed to be competent unless a court adjudicates them incompetent, either permanently (because of developmental disability, for example) or temporarily (as from medication, pain, or unconsciousness). Informed consent, then, requires the voluntary, informed and understanding decision of a competent adult.

Exceptions to the general rule have been made in practice. For example, the Common Rule permits an IRB to approve a study without all elements of informed consent (or waiving consent) when the "research could not practicably be carried out without the waiver or alteration" as long as the subjects will be informed after the study.¹²¹ This waiver or alteration has been used in deception studies in psychology and behavioral research, when knowledge of the study's purpose or procedures would bias the responses and produce invalid results. Some deception studies can be controversial, but they rarely pose a risk of physical injury.^{122–123} In addition, after the Gulf War, FDA regulations were amended to permit the president to authorize the use of investigational drugs and vaccines in armed forces personnel without consent for certain

military operations.^{124–125} Federal regulations have also adopted exceptions to the requirement for informed consent to permit research in life-threatening emergencies. However, the regulations do not trump state statutory or common law requiring informed consent. Clinical trials that study interventions intended to help people other than competent adults often raise questions about how to reconcile the need for scientific evidence with basic legal principles governing participation in research. These issues are discussed in the following section.

Research With Legally Incompetent Subjects

Clinical trials and other research studies sometimes use people who are not legally competent to consent to participate in research.^{1,61,68,126} The law has not entirely confronted practice on this point. Questions about whether incompetent persons lawfully can be used in research, and, if so, in what circumstances, whether any form of surrogate authorization is necessary or sufficient to permit it, and the weight, if any, to be accorded federal regulations permitting such research, remain unsettled. Ethical principles may justify the use of incompetent persons in research when the goal of research is to discover the etiology or find a therapy for a disease or condition that affects only people who are not competent.^{127–128} The need for research to help these groups, however, conflicts with the general principle prohibiting the use of individuals in research without their voluntary, competent, and informed consent.¹²⁹

The doctrine of informed consent has been consistently applied to preserve the right of incompetent adults to refuse medical treatment.^{71–72,130} Based on this reasoning, legal scholars and courts generally agree that incompetent adults also have the legal right to refuse to participate in research, and that their guardians can refuse on their behalf if that is what they would want or if the research would not be in their best interests.¹³¹

It is less clear whether the reverse is true. Few courts have considered whether a legal representative has the lawful authority to enroll an incompetent adult or child in a clinical trial. Several early reported decisions permitted an experimental procedure as part of treatment for a patient when no standard therapy was available, but did not address participation in a clinical trial.¹³ The FDA adopted a similar exception by regulation allowing the immediate use of an investigational drug or device on a case-by-case basis in a life-threatening situation without the person's consent if that person cannot communicate or is otherwise not legally competent.¹³² This exception allows the use of an investigational product not approved by the FDA for medical treatment, which otherwise would be prohibited by the Food, Drug and Cosmetic Act. The exception is not intended to set general standards for clinical trials. It applies only when the investigational product is immediately required to save the person's life, no alternative approved or generally recognized therapy offers an equal or better chance of saving the person's life, and there is no time to seek surrogate consent from the person's legal representative.

Federal Common Rule regulations governing research with mentally disabled adults have never been adopted.^{126,129} Some states have statutes or regulations that prohibit research with residents of mental health institutions. Others permit research with incompetent adults in specific circumstances, including clinical trials.¹³³ In 1996, in response to concerns that therapies to save the lives of people in a life-threatening medical emergency could not be systematically evaluated because the patients' medical condition

precluded them from giving consent to enroll in a clinical trial, the FDA adopted a rule authorizing certain types of emergency medical research without the consent of subjects.¹³⁴ This rule allows clinical trials of investigational emergency life-saving measures when "subjects are in a life-threatening situation, available treatments are unproven or unsatisfactory, and the collection of valid scientific evidence [including randomized placebo-controlled trials], is necessary to determine the safety and effectiveness of particular interventions;" and the intervention must be administered before any legal representative can make a decision.¹³⁴ Individual consent is not required for those who are unable "to give their informed consent as a result of their medical condition."¹³⁴ Those who are in a condition to make their own decision may not be enrolled without their informed consent. The rule itself does not expressly address whether individuals who lack competence when not in a medical emergency can be included in research.¹³⁵ In practice, it is unlikely that investigators in an emergency department will know who is or is not otherwise unable to consent solely because of their current medical emergency condition.

The emergency research rule contains additional conditions, including IRB review and approval and a somewhat ambiguous requirement for "consultation" with "representatives of the communities in which the clinical investigation will be conducted and from which the subjects will draw."¹³⁴ Public education about research has value in its own right. Community consultation, however, should not be confused with legal authorization of the research itself. A draft Guidance by the FDA confirms that the exception does not permit enrolling people without consent if state law precludes such research without consent.¹³⁶ Courts have never considered the decision to participate in research as belonging to anyone except the individual. In the absence of any court decision on the merits of the rule, it remains uncertain whether it would be upheld as a reasonable means of identifying effective emergency procedures or struck down as a violation of individual autonomy.

Two recent court decisions suggest that research with incompetent individuals may not be permitted unless it poses no more than minimal risk. A New York court struck down the state Office of Mental Health's regulations permitting research with mental health patients who were incapable of giving informed consent, because the regulations were not approved by the Commissioner of Health.¹³⁷ In part of its opinion that was considered advisory, because it was not necessary to decide the case, the court also noted, "It may well be that for some categories of greater than minimal risk nontherapeutic experiments, devised to achieve a future benefit, there is at present no constitutionally acceptable protocol for obtaining the participation of incapable individuals who have not, when previously competent, either given specific consent or designated a suitable surrogate from whom such consent may be obtained. The alternative of allowing such experiments to continue, without proper consent and in violation of the rights of the incapable individuals who participate, is clearly unacceptable."¹³⁷

Although federal regulations and some state laws permit the use of children under certain conditions,^{138–139} common law decisions concerning research with children have not yet reached consensus about whether parents or guardians have the legal authority to allow their children to participate in research.¹³⁹ Parents have a legal duty to safeguard their children and provide them with life-saving or essential medical care.^{140–141} Parents have been permitted to consent to an individual experimental procedure when it offered a substantial probability of success and posed only

minimal risks to the child.¹³⁹ Clinical trials may not be deemed to be in the best interest of the child, however, unless perhaps there is no standard medical therapy available for a life-threatening or very serious condition and the trial poses relatively minor risks. In 2001, Maryland's highest court found that parents and surrogate decision makers "cannot consent to the participation of a child or other person under legal disability in nontherapeutic research or studies in which there is any risk of injury or damage to the health of the subject."³² Although the decision disconcerted some, it is a reminder that even practices that are presumed legitimate by many investigators and IRBs may not be found lawful when tested in court.¹⁴² In a 2004 speech, Judge Dale R. Cathell, who issued the Maryland decision, warned investigators against assuming that the beneficial goals of research or compliance with federal regulations would protect them from liability for breaches of other legal duties: "In the tort litigation context, good intentions do not, even in the smallest degree, normally define duty and the breach of duty."¹⁴³

Future studies of new ways to treat people in life-threatening circumstances could be challenged in litigation to resolve the question whether or when individuals can be used in research without their consent. Competent adults who have specific opinions about whether they wish to participate in research are free to execute powers of attorney authorizing a surrogate decision maker to consent or refuse on their behalf when they are not able to make their own decisions. Such documents may be analogous to health care proxies, but their legal validity has not yet been tested. One could reasonably argue that legal representatives and researchers who comply with a "research proxy's" instructions protect the person's rights by carrying out the person's wishes. It is possible, however, that such research proxies could be found to have no binding effect or perhaps not to apply with respect to research that poses significant risk.¹⁴⁴ Moreover, they would not resolve questions about children or adults who have never been competent.

The state has the power (*parens patriae*) to protect the safety and welfare of children and incompetent adults and could challenge their participation in research if parents or legal representatives fail to act in the best interests of their wards. Despite the need for clinical trials to evaluate interventions unique to children and incompetent adults, as well as federal regulations allowing such research in certain circumstances, the law governing their participation in research remains patchy and unsettled.

3. Rights and Remedies for Research Subjects in the United States: The Conduct of Research

Beyond ensuring that subjects are properly enrolled in a trial, investigators must carry out the research study in accordance with the protocol agreed to by the subjects. As with almost any endeavor, investigators have common law duties to prevent unlawful injury to subjects and to keep any promises made to subjects. The most relevant are summarized in this section.

Tort Claims

Although competent subjects who agree to participate in a clinical trial may assume the inherent risk of unexpected injury from an investigational intervention like a drug, they do not assume the risk

of the researcher's own negligence or other wrongdoing in conducting the study. Here again, the general principles of law that require everyone to act with reasonable care to avoid foreseeable injury to others also apply to researchers. Investigators who violate their duties to design and carry out research properly and to protect subjects against foreseeable harms can be liable for injuries they cause.^{13,145} Moreover, investigators, especially physician-investigators, are held to the standard of an expert in the field and must exercise the same degree of knowledge and skill that a similarly situated, qualified professional would exercise.

Examples of problems in carrying out clinical trials that have been cited in lawsuits include failing to seek IRB approval,¹⁰² letting IRB approval lapse,¹⁴⁶ negligently or fraudulently enrolling ineligible persons in a trial,^{25,102,117–118,147–149} using unapproved consent forms,^{25,102,119} administering an incorrect dosage of an investigational drug contrary to the trial protocol,¹⁵⁰ performing other research interventions improperly or contrary to the trial protocol,^{54,102,146} failing to stop a trial intervention that harms a subject,¹⁴⁵ failing to provide appropriate medical care to a person having an adverse reaction to a trial intervention,^{97,120,145,150–152} and failing to tell subjects about risks discovered during or after the trial.^{32,77,120,153–154} It should be noted that the federal regulations forbid researchers from requiring subjects to waive any of their legal rights or to release any responsible party from liability for negligence.¹⁵⁵

Tort law holds employers vicariously liable (under the doctrine of *respondeat superior*) for the negligence of their employees in order to encourage employers to ensure that their employees act with reasonable care in performing their jobs.¹⁵⁶ Thus, universities, hospitals, and other organizations that carry out research may be vicariously liable for the unlawful acts and omissions of their employees and agents, regardless of the employer's own conduct.^{25–26,32,77,157} Plaintiffs sometimes elect to sue the university or hospital if the individual researcher does not have sufficient assets to compensate the harm. This requires the plaintiff to prove not only that the individual researcher breached a duty of care to the research subject that was the proximate cause of injury, but also that the researcher was the employee or (actual or ostensible) agent of the organization.

Research organizations themselves may also act unlawfully and become liable for their own corporate (or direct) breaches of duty.¹⁵⁶ Organizations have a duty to use reasonable care in hiring, supervising, and terminating their research staff, just as hospitals have a duty to use care in granting and renewing physician privileges.¹⁵⁸ For example, an Illinois appellate court held that when the University of Chicago and Eli Lilly & Company learned that the children of women who were given DES had an increased risk of cancer, the corporation could be liable for failing to notify the former research subjects that they had been part of a DES experiment.⁷⁷

Until recently, lawsuits have rarely targeted an IRB, even when subjects suspected that an IRB wrongfully approved a study, because most IRBs are an organizational component of a university or medical center, which would be the responsible legal entity. Members of IRBs have been named as defendants in a few cases in recent years, but no reported decision has even considered the possibility of IRB or IRB member liability, and there is no evidence that IRBs or IRB members have paid any damages to a plaintiff. In theory, perhaps, independently incorporated review organizations might be liable for their own unlawful actions.¹⁴⁹ However, it is

doubtful that they would have any responsibility for injuries because IRBs do not control the conduct of research.

The Stratton Veterans Affairs Medical Center in Albany, N.Y., was recently accused of violating multiple duties to research subjects, including fraud, patient abuse, and carelessness, for a decade.¹⁵⁹ One researcher, Paul Kornak, pleaded guilty to criminal charges of making false statements, mail fraud, and criminally negligent homicide and was sentenced to 71 months in prison and payment of almost \$640,000 in restitution to the VA and the drug companies.¹⁶⁰ Mr. Kornak reportedly changed medical records to enroll ineligible veterans in a clinical trial of cancer drugs, misrepresented himself as a physician, and continued to administer to subjects drugs with adverse reactions including premature death. Families of veterans also commenced a class action against the Department of Veterans Affairs and the individual researchers.¹⁵⁹

Major research universities and medical centers have experienced similar problems of more or less severity, including the deaths of subjects in clinical trials. In 2003, a Detroit Veterans Affairs center administered a fatal overdose of drugs to a research subject.¹⁵⁹ In 1999, the Office for Protections from Research Risks (OPRR, now OHRP) suspended research at the West Los Angeles Veterans Affairs medical center for its history of failing to obtain informed consent and its careless conduct of research. The GAO found "a disturbing pattern of noncompliance" with regulations for the protection of human research subjects in eight Veterans Affairs centers.¹⁶¹ A second GAO report several years later found little change.¹¹⁸ OPRR found sufficient deficiencies in subject protection procedures to suspend federal funding at several medical centers, including Johns Hopkins University, Duke University, the University of Illinois at Chicago, Virginia Commonwealth University, and the University of Oklahoma.¹⁶² In a few cases, the subjects' families commenced lawsuits against the institutions on multiple causes of action, ranging from negligence to intentional infliction of emotional distress and fraud.

Publicity about research scandals may increase public awareness of the risks and uncertainties inherent in research. It may also encourage injured research subjects and their families to bring claims for redress against researchers and their institutions. Jesse Gelsinger's father expressed surprise and anger at learning that James Wilson, who enrolled Jesse Gelsinger in a study, had founded a company to sell the rights to the vector for gene delivery that was tested in Jesse Gelsinger.¹⁶³ His lawsuit against the University of Pennsylvania and the investigators was settled within a month.¹⁶⁴ The fact that several recent lawsuits have targeted researchers who failed to disclose their financial connection with the studies they conducted suggests that research subjects are paying closer attention to researchers' financial ties. One study found that a majority of people surveyed believed that investigators and hospitals conduct clinical trials to make money and don't tell subjects all the risks involved.¹⁶⁵

Some conflicts of interest may be inherent in research, but financial conflicts raise particular concerns.¹⁶⁶⁻¹⁷⁰ Conflicts of interest may lead investigators to enroll ineligible subjects, resist finding that a trial intervention has harmed a subject, or to interpret, or even manipulate, data to support desired outcomes.^{171,172} As universities rely on research funding for a growing proportion of their revenues, financial conflicts of interest can spread throughout the institution.¹⁷³ The DHHS issued new (interim) regulations on Feb. 3, 2005, to prevent possible conflicts of interest among research scientists at the National Institutes of Health (NIH).¹⁷⁴

The final regulations apply only to senior employees and prohibit ownership of more than \$15,000 of stock in any pharmaceutical, biotechnology, or medical device company (or \$50,000 in the aggregate).¹⁷⁵ Senior NIH researchers also may not be employed by or receive compensation from such companies or health-care providers or insurers without prior NIH approval. Public opposition to such payments suggests that research conducted with conflicts of interest is peculiarly vulnerable to legal challenge.¹⁷⁶⁻¹⁷⁸ Conflicts of interest may trigger legal claims against investigators and research institutions by injured research subjects or their representatives that might not otherwise have been brought. Financial conflicts of interest also may provide evidence for some claims if they influenced investigators to act in ways that injure a subject. If the research is viewed as a business operation, wrongdoing might even be analogized to business fraud, when punitive damages might be allowed.¹⁷⁹

Lawsuits sometimes function as the last resort for those who fail to achieve reform via the legislative or regulatory process. Thus, if research subjects or the general public believe that federal agencies, universities, or hospitals are not adequately investigating or penalizing research violations, those institutions may become the target of personal injury or even whistle-blower lawsuits.¹⁸⁰⁻¹⁸¹

Studies using individually identifiable information qualify as research with humans, and investigators who collect such information have a duty to keep the information confidential and use it only as authorized by the subject.¹¹⁴ Obtaining such private information without consent would ordinarily qualify as an invasion of privacy.^{95,182} Misuse of confidential information in research is rare, and lawsuits based on such tort claims are virtually unheard of. The major risks to subjects from an invasion of privacy or breach of confidentiality are damage to reputation and economic costs, such as loss of insurance, employment, or housing, which are often too speculative to warrant legal action.¹⁸³ Research subjects concerned about privacy may seek new ways to control access to their information, such as contractually limiting information disclosure or even asserting a property interest in their information. Information technology has made it possible to link and manipulate large data sets, increasing both the value of information and the risk of unauthorized access.¹⁸⁴ The DHHS Privacy Rule, commonly known as the HIPAA (Health Insurance Portability and Accountability Act) Privacy Rule, has focused renewed attention on how medical information is used and disclosed.¹⁸⁵ Yet the Privacy Rule does not apply to researchers unless they are also considered to be a covered entity such as a physician or hospital employee who maintains regular records of medical care, and it does not preempt state privacy laws. A rash of reports about the loss of financial records may encourage public debate about medical as well as financial information, such as what types of studies count as research with humans and whether information collected for one purpose, such as cancer registries or public health surveillance, can be disclosed to others for research purposes without the individual's consent.¹⁸⁶

Contract and Property Claims

Although most lawsuits claiming research harm have been based in tort law, the law of contract, property, or even intellectual property may be applied to certain research relationships in the future. The Maryland Court of Appeals has suggested that the consent form

may be considered a contract between investigator and subject, which would permit a subject to recover damages for breach of contract in the event that an investigator failed to adhere to the terms of the agreement.³²

Contract principles appear to be better suited to research with tissue samples, DNA, and other genetic material and information. Courts have generally accepted the presumption, which is consistent with general practice in the research community, that “donors” of such material relinquish any property interest in tissue (and related information) collected for a research study and that the material becomes the property of the investigator.¹⁸⁷ The only state supreme court decision on the issue of ownership dealt with a physician-patient relationship, not a research relationship. The Supreme Court of California found only that a physician had a duty to inform his patient, Moore, that he intended to develop and patent a cell line from Moore’s tissue—Moore’s spleen was removed as standard therapy for hairy cell leukemia.¹⁸⁸ Moore sued for conversion, arguing that the physician took (converted) his property (the spleen) without his knowledge or consent for the physician’s own profitable use. The court denied Moore a share of the cell-line profits, finding that Moore had not expected to retain ownership of his spleen after its removal.

Although courts have not yet held that subjects have a property interest in tissue or DNA donated in research, there may be pressure to do so as genetic and genomic research increases and, with it, the promise of beneficial and commercially profitable results.^{189–190} Two recent cases offer possible glimpses of the future. In the first, a group of parents of children with Canavan disease organized a foundation, recruited an investigator, and provided the tissue samples and genetic and pedigree information that made it possible to identify the gene and develop a test to detect it. When the discovery was patented and the foundation was asked to pay royalties for using the test, they sued the investigator and university for unjust enrichment, conversion, lack of informed consent, fraudulent concealment, breach of fiduciary duty, and misappropriation of trade secrets for failing to make the genetic test widely available, inexpensively or free.¹⁹¹ A Florida court followed the reasoning in Moore, rejecting all but the unjust enrichment claim and found that the foundation and the research subjects did not retain any property interest in their tissue samples or genetic information. Before the last claim went to trial, the university holding the patent reached a settlement with the plaintiffs that allows certain research institutes and laboratories to use the test without a licensing fee.¹⁹²

Parents of children with PXE (pseudoxanthoma elasticum) took a different approach to ensure their control over a genetic test for the disease. They, too, organized a foundation to collect tissue samples and genetic information. In addition, the foundation’s founder participated directly in the research itself and was named as a coinventor on a successful patent application.¹⁹³ This approach allows the research subjects a measure of ongoing control over the use of the test.

The lesson of these cases may be that in the future, as a condition of participating in a study, subjects may insist on retaining ownership of any tissue or information used for commercial purposes or receiving a share of any profits from the research. Few subjects would qualify as an inventor for purposes of a patent application, but they may use contracts to require researchers to assign some or all resulting patent rights to them or to a representative organization. A contractual approach might also

be applied in the future to enable subjects to control the use of personally identifiable genetic or medical information, with or without related tissue samples.

Research subjects recently attempted to use contract principles to assert entitlement to products tested in clinical trials. Subjects in clinical trials of glial-derived neurotrophic factor (GDNF) for Parkinson’s disease brought a lawsuit against the trial sponsor, Amgen Inc., seeking to compel Amgen to provide them with GDNF because they believed that it had helped them.¹⁹⁴ Amgen terminated the trials before their scheduled completion after finding cerebellar toxicity among primates and neutralizing antibodies in humans. The trial court found that the plaintiffs were not entitled to a preliminary injunction granting them access to GDNF because they had virtually no likelihood of succeeding on their claims: Their participation in the clinical trial did not create any contractual obligation on the sponsor’s part to continue the trial or to provide GDNF, the sponsor had no fiduciary duty to the subjects, and the investigator had no authority to require the sponsor to provide GDNF. The court’s legal analysis is consistent with current law. Investigators and sponsors of research generally retain the prerogative to terminate a study and to decline to distribute any investigational product. The case is notable because it demonstrates an attempt (albeit unsuccessful) to use litigation to obtain access to investigational products and perhaps a misunderstanding of clinical trials. Research is not a substitute for medical care, and researchers should not be put in the position of trying to compensate for the unavailability of health care elsewhere.

A related problem arises when people enroll in a clinical trial in order to obtain basic medical care that they cannot otherwise afford or which is not otherwise available.¹⁹⁵ AIDS research was pushed forward by advocates arguing that, in the absence of any proven therapy, clinical trials were the only treatment available to people with HIV infection.^{196–198} However, if not carefully informed of the nature of the research, individuals under such pressures may enroll in inappropriate studies and experience harmful consequences. Many people enrolled in schizophrenia studies at more than a dozen medical schools in the 1980s and 1990s as a means to get basic health care.^{97,199} Some became ill after being taken off their medication and brought legal claims against the investigators for failing to monitor their condition. These issues arise with particular sensitivity in clinical trials conducted by U.S. researchers in foreign countries, where an increasing proportion of clinical trials are conducted.^{200–202} Those from other countries who believe that they have suffered harm while participating in research may be able to sue investigators in U.S. courts.^{35,203} Although there is no legal obligation to provide the successful results of clinical trials to the study population or others, ethical principles increasingly recognize the need to do so.^{36,199}

4. Estimating Research Injuries and Obtaining Redress

Millions of individuals are believed to have participated in clinical trials, but there is little comprehensive data on either the number of people or the number of injuries in research.^{204,205} A 1996 U.S. GAO report found that the DHHS, which includes the NIH, spent about \$5 billion to fund 16,000 studies involving humans each year.²⁰⁶ OHRP data indicates that about 70 million people par-

anticipated in research between 1990 and 2000, whereas institutions reported 8 deaths and fewer than 400 adverse events, suggesting to some that reporting may not be a reliable indicator of research injuries.²⁰⁷ The increased number of trials and, presumably, research subjects may expand opportunities for error and injury, but the absence of empirical data makes estimating actual injuries speculative.

Despite the large number of clinical trials involving humans and the wide range of general laws that might apply to clinical trials, there have been few reported lawsuits on behalf of injured subjects.¹³ It is often difficult to distinguish harms caused by the research from complications of illness or risks accepted as part of the study. Few attorneys are willing to take on personal injury cases that are difficult to prove or would recover damages less than the cost of litigation. In recent years, lawsuits may have become more visible because they can involve more parties on both sides. If there is a common problem in a large clinical trial, such as a systematic failure to advise subjects of risks or to perform research tasks properly, class action suits on behalf of all those harmed in the trial may be the most efficient form of lawsuit. By bringing together many people with a similar experience, class actions make litigation possible for individuals who could not otherwise afford it. They also put significant pressure on defendants to settle claims. Recent federal legislation places new restrictions on federal class actions, but state class actions remain possible.²⁰⁸

Alternative Remedies

Some commentators hope that litigation will improve the way research is conducted, as well as increase accountability on the part of investigators.²⁰⁹ Although some lawsuits and publicity about claims, whether litigated to conclusion or not, have prompted institutions to improve their protections of research subjects, the common law has had less influence on the conduct of research than the Common Rule so far. Yet litigation may offer leverage for changing behavior in the future. Jesse Gelsinger's father, Paul, planned to use the settlement funds from the University of Pennsylvania to improve protections for research subjects.¹⁶⁴ Other litigants have used settlement agreements to forge new policies at research institutions. After the quiet settlement of a lawsuit by the family of Betsy Lehman, the *Boston Globe* reporter who died from an overdose of chemotherapy in a breast cancer trial at Dana-Farber Cancer Institute in Boston, the hospital created a new patient safety program to prevent medication and other errors, and the state created a broader program in her name.²¹⁰ In 2002, the University of South Florida Health Sciences Center and Tampa General Hospital agreed to new practices and procedures for research, including developing readable consent forms and training researchers in designing readable documents and tracking study subjects, as part of its settlement of a class action on behalf of indigent pregnant women who claimed they were enrolled in a clinical trial to compare drug regimens for fetal respiratory distress syndrome without their informed consent.⁸⁵

If research subjects are unable to obtain equitable redress through litigation, their advocates may press for more stringent legislative penalties for researchers who violate the law. Paul Gelsinger was reportedly very disappointed in the Justice Department's settlement with the researchers, because it only forbade Wilson from leading research with humans until 2010, and fined

the University of Pennsylvania \$517,496 and Children's National Medical Center \$514,622.²¹¹

Defenses

Plaintiffs who have legitimate complaints may be precluded from bringing a lawsuit for several reasons. Statutes of limitations or repose limit the time in which a lawsuit may be commenced to several years after the injury occurred or should have been discovered. Time limits for negligence claims are typically three years, whereas fraud claims usually must be brought within six years. The vagaries of litigation are illustrated by *Heinrich v. Sweet*.²¹² In 1997, the families of research subjects sued the Massachusetts Institute of Technology, the Massachusetts General Hospital, a New York association of universities, and the federal government, as well as the individual investigators, for conspiracy to conduct a boron neutron capture therapy experiment without their consent in the 1950s and 1960s. The study was to determine whether a boron compound injected into an artery would collect in a brain tumor and selectively attract radiation to eliminate the tumor without injuring other brain tissue. The subjects were patients with brain cancer. But the compound allegedly caused severe illness and premature death in many. The claims based on New York law were dismissed because they were brought after statutes of limitations had expired. The fraud claim under Massachusetts law was allowed to proceed, and the plaintiffs were awarded \$13 million dollars, including \$5 million in punitive damages, in 1999.²¹³ On appeal by defendants, however, the appeals court found that the doctrine of informed consent was not sufficiently established before 1970 to permit the plaintiff's claims, and vacated the judgment in 2002.²¹⁴ There is some irony in the ruling, because Massachusetts has had a law requiring consent to medical care since 1649.²¹⁵

Sovereign immunity—based on the ancient notion that the king can do no wrong—can be a defense to tort claims brought against officials, employees, and agents of state and federal governmental institutions, such as state universities and city hospitals. Governments cannot be sued unless they waive sovereign immunity. The Federal Tort Claims Act waives federal sovereign immunity and permits tort suits against federal government agencies, like the NIH, in some circumstances.^{216,217} Federal officials are also protected by qualified immunity from suit if they perform discretionary functions in their official capacity, unless they violate established constitutional rights.²¹⁸ States typically have similar statutes that waive sovereign immunity and permit tort claims against state entities, although the law often limits the dollar amount of liability to a maximum (\$100,000 in Massachusetts).²¹⁹ Research subjects who are injured by government entities cannot sue the state unless their injuries fit the narrow causes of actions covered by a tort claims statute. Moreover, the U.S. Supreme Court has interpreted the 11th Amendment to forbid suits based on federal law to be brought in federal court against state government entities.^{220–222} For nongovernment entities, some states continue to grant charitable immunity to nonprofit hospitals and educational institutions, limiting their tort liability for personal injury to a dollar amount (\$20,000 in Massachusetts), although most states have abandoned such protection.

Products liability, a set of common law principles derived from both tort and contract law, is normally applicable to commercially marketed products, not investigational products still in

clinical trials.²²³ However, approved products being studied in postmarket trials may be subject to product liability claims based on a product defect. Some states grant manufacturers immunity from liability for personal injury caused by defective drugs if the FDA has approved the product at issue and the manufacturer has complied with FDA standards, unless it has withheld information from the FDA or acted fraudulently.

Compensation for Research Injuries

Compensation for research injuries is not systematically available in the United States outside the litigation system. Several national commissions and panels have given favorable consideration to or recommended compensating subjects for research injuries, but no formal, national mechanism has yet been adopted.^{44,46,61,209,224–225} So far, compensation for injury remains voluntary, and institutions that provide it often limit it to providing remedial medical care.²⁰³ Some hospitals and research institutes purchase liability insurance (products liability and clinical trials liability) to cover their payments to research subjects. However, these policies are typically limited to the cost of medical care and do not cover lost income or pain and suffering.²²⁶

International guidelines stop short of requiring compensation. The Council of Europe's Convention for the Protection of Human Rights and Dignity of the Human Being with regard to the application of Biology and Medicine has a chapter of general principles for the protection of subjects in scientific research.²²⁷ Article 24 requires that "fair compensation" be provided to any subject who has suffered undue damage, by act or omission, but leaves the procedures and amounts to national law. The Council of Europe's recent additions to this Convention are virtually identical on the issue of fair compensation for research injuries (Article 31).²²⁸

Conclusion

The fundamental legal principles governing research with humans have changed little in the past half century. Although the Common Rule sets institutional standards for a substantial proportion of clinical trials, the common law remains the source of redress for injuries to subjects in research. Augmented by a growing body of statutory and constitutional jurisprudence, these general common law principles offer a comprehensive, but still evolving, description of the rights of research subjects and the obligations of investigators. As clinical trials increase in number and complexity, these principles will be applied and adapted to answer new research questions. Some causes of action little used in the past may become more prominent, such as dignitary harms inferred from constitutional provisions and international covenants. Lack of informed consent, the most prevalent complaint in published decisions, may center on the failure to disclose conflicts of interest or a research component of health care. Litigation is sometimes used to obtain or encourage changes that neither private industry nor the legislature has yet adopted, as was the case with the tobacco litigation. If litigation fails to resolve disputes, people may be discouraged from participating in research unless they are made financial partners. If those enrolled in research are to be true *research participants*—the terminology that patient advocates now prefer—they may demand participation in the financial rewards as well as

the risks of research, as in the PXE case. Finally, it should be noted that criminal prosecution remains available for conduct that rises to the level of a criminal offense. Although criminal punishment does not compensate those who are injured, it often has a broader effect on national standards of conduct than civil law cases.

The relatively small number of published court decisions involving injuries to research subjects may be viewed either as reassuring evidence that research poses little serious risk to subjects or as a lack of adequate legal redress for hidden harms. More public attention to both the importance and uncertainties of research may encourage better protection against injuries and more public support for research.

The Obligation to Ensure Access to Beneficial Treatments for Research Participants at the Conclusion of Clinical Trials

The conclusion of a clinical trial triggers a new set of ethical obligations to research participants. The way these obligations are conceptualized and fulfilled, particularly in clinical drug and device trials, can have a profound influence on the way research participants benefit from their participation in clinical research. In particular, the central question in many clinical trials is whether, at the conclusion of the trial, individual research participants should continue to be provided with drugs and devices that have benefited them during the trial. Although a solid consensus about this and related posttrial obligations has not yet emerged in the literature, several key ideas have been prominent and are beginning to influence research ethics guidelines and the practices of researchers and sponsors. Posttrial obligations can arise in any clinical research setting, but the ethical issues they raise have been particularly salient in research conducted in low- and middle-income countries by researchers and sponsors from high-income countries. As a result, analysis of international collaborative research has contributed a great deal to current thinking about these questions.

Posttrial obligations to research participants can be described under three broad headings: first, the obligation to avoid the exploitation of research participants by ensuring that they receive a fair distribution of research benefits along with the sponsors and investigators; second, the obligation to recognize the contribution of research participants, and third, the obligation to minimize the likelihood of feelings of loss or abandonment on the part of research participants whose continued access to a beneficial intervention might require special provisions beyond the planned clinical trial. Each of these obligations reflects a different ethical rationale, and these are discussed in greater detail below. Other

more controversial proposals have been made about posttrial obligations. For example, some commentators have argued that investigators also have an obligation to serve as advocates for therapies growing out of their research findings, particularly in some low- and middle-income countries in which bureaucrats and politicians may lack the knowledge and/or political will to utilize research findings in ways that may improve the health of their citizens.¹ Some of the implications of this type of expansion of the customary roles and responsibilities of investigators have also been explored.²

In this chapter, I describe the current thinking about obligations to research participants at the conclusion of a clinical trial, focusing on the three main obligations described above and emphasizing the issue of continued provision of beneficial drugs and devices. The chapter begins with a brief review of the current guidelines on posttrial obligations and then describes some of the current thinking about the ethical rationale and appropriate scope of posttrial obligations. It then explains what I call the “mechanics” of posttrial obligations, including specific mechanisms by which the obligations may be met. The chapter ends with three brief case examples of posttrial obligations in international research, the first of a successful funding partnership to ensure continued access to antiretroviral drugs for participants in HIV clinical trials in Thailand, the second of intermittent presumptive treatment (IPT) for malaria in a trial of infants in Kamasi, Ghana, and the third of a public-private partnership to develop a new antimalarial drug between the Medicines for Malaria Venture (MMV) and Bayer, which includes a comprehensive agreement about posttrial obligations for research.

Current Guidelines on Posttrial Obligations

A great deal of the recent debate about international research ethics has focused on how ethical obligations about highly complex matters should be articulated in international codes and guidelines. As with many other issues, the available guidance with respect to posttrial obligations is both limited and varied in ways that impede consensus, rather than promote it.

Declaration of Helsinki

One of the most controversial guidance statements related to posttrial obligations has been Paragraph 30 of the 2000 version of the World Medical Association's Declaration of Helsinki, which reads, "At the conclusion of the study, every patient entered into the study should be assured of access to the best proven prophylactic, diagnostic and therapeutic methods identified by the study."³ Paragraph 30 has given rise to enormous controversy, although it has also played a formative role in laying out the contentious parameters of the posttrial obligations debate.

The first point is that posttrial obligations kick in "at the conclusion of the study." This seemingly simple observation has itself provoked considerable discussion. At issue is how to determine, for the purposes of posttrial obligations, when a trial has actually concluded. Historically, a great deal of international research—particularly drug trials—limited the amount of time spent in the host country. Once data collection has ended and appropriate procedures have been put in place for necessary follow-up, the investigators often return to their home countries, ending the effective presence of the trial in the host country. From the perspective of the host communities, then, this point might reasonably be thought to mark the conclusion of the trial. In fact, it is precisely this type of rapid departure that has fuelled sentiments of abandonment, which I discuss in greater detail below. But because Paragraph 30 goes on to emphasize interventions that have been "identified by the study" as satisfying (or not) the "best proven" criterion, the departure of the research team cannot serve as a reliable measure of a trial's conclusion.

A more promising, but still controversial, account of a study's conclusion is when the data analyses necessary to answer the primary research question(s) have been completed. But other problems quickly become apparent. How long does it take to prepare and analyze study data? What are the necessary analyses? Who should determine these? Taking this point even further, it can be argued that the conclusion of a trial follows the successful publication of the trial results, in other words, the point at which the trial has met the scientific requirement of peer review and the fair conclusions have been clarified and agreed upon by the study's investigators. But even this seemingly "hard" endpoint is now well known to be subject to gaming and manipulation by research sponsors and investigators. Depending on the favorability of the findings for their personal or corporate ends, sponsors and investigators may delay, or avoid completely, the responsibility of publishing their results, or may publish findings selectively.^{4,5} In international collaborative studies, host country governments may also be reluctant to declare a specific trial (or necessary program of research) finished if the findings might suggest costly changes, such as the wholesale revision of a national malaria treatment and prevention program.⁶ And yet, without a reliable marker of the

conclusion of a trial, the remaining requirements of Paragraph 30 lack coherence.

Although the World Medical Association has long resisted calls for clarification of the intended meaning of the "best proven" requirement,⁷ it remains a highly controversial standard in its own right.⁸ All the more controversial, then, is Paragraph 30's implication that an individual study can provide definitive clarification of the status of the interventions it aims to compare. A cynical reading of this requirement is that it is simply impossible for an individual trial to clarify whether any given intervention is the "best proven," whatever the precise definition of that standard. A more forgiving reading would limit the scope of the claim to the results of the trial itself. If drug B proved to be better than drug A in a comparative trial, then it might be considered the "best proven" in the trial. If the trial met the ethical requirement of clinical equipoise, itself a highly controversial notion in the context of international research,⁹ this would provide some indication that some judgment had been made about the adequacy of the care provided to participants in the trial. Although it may not clarify whether the selected standard of care is truly the *best proven* for the population and context of the trial,¹⁰ it would at least offer some assurance that the appropriateness of the interventions being compared in the trial for the study population had been considered.

Paragraph 30 explicitly limits the applicability of posttrial obligations to "patients entered into the study." Although this approach is consistent with some of the justifications of posttrial obligations that I describe in more detail below, it also differs from other guidelines, such as those of the Council of International Organizations of Medical Sciences (CIOMS), which extend the obligation to communities and populations.

One of the most important of Paragraph 30's clauses is that patients should be "assured of access" to the best proven intervention. This requirement has also given rise to a great deal of debate and disagreement. Briefly, the debate relates primarily to the scope of the posttrial obligations, in other words, whether investigators and sponsors are required to assume the full responsibility for all aspects of the financing, procurement, approval, delivery, and oversight of the relevant interventions, or whether it is sufficient that they arrive at an appropriate agreement with other parties, including host country governments, about how these will be handled. These issues are also explored in greater detail below.

CIOMS

The other main driver for the debate about posttrial obligations has been the well-known "reasonable availability" clause of the 2002 version of the CIOMS International Ethical Guidelines for Biomedical Research Involving Human Subjects.¹¹ CIOMS Guideline 10 (Research in populations and communities with limited resources) states that "before undertaking research in a population or community with limited resources, the sponsor and the investigator must make every effort to ensure that the research is responsive to the health needs and the priorities of the population or community in which it is to be carried out, and any intervention or product developed, or knowledge generated, will be made reasonably available for the benefit of that population or community."¹¹

As with the Declaration of Helsinki, the controversy surrounding the CIOMS guideline turns on several key points. First,

the guideline makes explicit that plans to ensure the successful execution of posttrial obligations must be in place before researchers undertake the research, including means of ensuring that the research is responsive to the health needs and priorities of the population or community. In effect, this requires investigators, and other interested parties, to engage in planning and relationship-building activities that they might have little familiarity with, training for, or dedicated funding to support.² Second, the guideline implicates sponsors as well as researchers. Third, the guideline focuses on “ensuring” benefits, raising the same set of concerns as the “assured access” requirement of the Declaration of Helsinki.

The main thrust of the CIOMS guideline, however, is the “reasonable availability” requirement, which is meant to ensure that research avoids the exploitation of participants and communities by providing a mechanism for transferring benefits—when they are demonstrated in a clinical trial—to participants and populations. Because the reasonable availability requirement has played such a central role in the debate about exploitation in research,¹² I deal with it separately, and in more detail, below.

The 2002 revision of the CIOMS guidelines also includes an explicit statement about the ethical obligation of external sponsors to provide health-care services. Guideline 21 states that external sponsors should ensure the availability of “healthcare services that are essential to the safe conduct of the research . . . treatment for subjects who suffer injury as a consequence of research interventions . . . and healthcare services that are a necessary part of the commitment of a sponsor to make a beneficial intervention or product developed as a result of the research reasonably available to the population or community concerned.”¹¹ This final requirement, though consistent with the intent of Guideline 10, reaches far beyond the idea of reasonable availability of products and/or knowledge. Like the “assured of access” statement in Paragraph 30 of the Declaration of Helsinki, Guideline 21 explicitly tags sponsors with the responsibility for ensuring that the entire health care infrastructure necessary to deliver a given intervention effectively, and safely, is put in place, along with the intervention itself.

There are two main complaints about this provision. First, Guideline 21 explicitly states that the products, knowledge, and necessary infrastructure must be provided “to the population or community concerned,”¹¹ as opposed to “every patient entered into the study,” as specified in Paragraph 30 of the Declaration of Helsinki. The implications are obvious. First, there is the thorny problem of determining who the “population or community concerned” is in any given study.¹³ An expansive interpretation of “population” or “community” could impose an enormous financial burden on research sponsors (public as well as private) that could have serious implications for their willingness and ability to fund international research. Although this might serve one interest of limiting “parachute” research by high-income country research sponsors that has limited value to low- and middle-income countries hosting the research, it might equally limit the feasibility, or desirability among sponsors, of funding and conducting research that is “responsive to the health needs and priorities of the population or community in which it is to be carried out,” as required by Guideline 10.¹¹ Perhaps more to the point, it is not clear how such a standing obligation on the part of investigators and sponsors to ensure access to health care—even in a limited form—to all members of a community or population could be justified.

UNAIDS

One of the most challenging contexts for posttrial obligations has been preventive vaccine research, and the main focus of this type of research in recent years has been on the development of an effective vaccine for HIV/AIDS.¹⁴ The UNAIDS Ethical Considerations in HIV Preventive Vaccine Research is similar in structure to the reasonable availability approach of the CIOMS guidelines.¹⁵ UNAIDS Guidance Point 2 (Vaccine availability) states that “(a)ny HIV preventive vaccine demonstrated to be safe and effective, as well as other knowledge and benefits resulting from the HIV vaccine research, should be made available as soon as possible to all participants in the trials in which it was tested, as well as to other populations at high risk of HIV infection.”¹⁵

The clause raises the now familiar litany of problems. What is a safe and effective vaccine? Is a 25% to 30% efficacy sufficient to trigger this obligation? What about a vaccine for rotavirus that causes a small number of serious side effects in children in the United States, but which is otherwise highly effective and could save millions of lives in low- and middle-income countries? Should it be considered safe?¹⁶ Is the standard “as soon as possible” meant to take into account the real-world challenges of securing financing and political will for the administration of a vaccine to the target population? And how should “populations at high risk of HIV infection” be understood in vaccine trials in countries with huge populations, such as India and China?

Nuffield Council on Bioethics

The United Kingdom’s Nuffield Council on Bioethics has issued two influential reports related to the ethics of research in developing countries: The first provided a rich overview of key issues,¹ and the second provided a report of a follow-up conference at which the initial report, and subsequent developments in the field, were considered.¹⁷ Both reports addressed the issue of posttrial obligations to ensure continued provision of beneficial treatments to research participants at the conclusion of a clinical trial. The Council’s recommendations direct researchers, sponsors, national health-care authorities, international agencies, and research ethics committees, prior to the initiation of a trial, to “clearly consider” provisions for monitoring possible long-term deleterious outcomes for an agreed period of time beyond the completion of the research. In addition, the Nuffield Council calls on these authorities to consider “the possibility of providing participants with the intervention shown to be best (if they are still able to benefit from it), for an agreed period of time.”¹ The Council also endorses the position of the U.S. National Bioethics Advisory Commission¹⁸ that proposals submitted for research ethics review should include an explanation of how proven interventions will be made available to research participants and an explicit justification if this is not seen to be feasible or relevant.

Wellcome Trust Position Statement

In light of sustained controversy in international research ethics, the Wellcome Trust issued a position statement and guidance notes for applicants to its research funding schemes for research involving people living in low- and middle-income countries.¹⁹ Although it does not constitute a formal requirement for the receipt

of funding from the Trust, the statement provides guidance to prospective investigators, including setting out “roles and responsibilities of the various parties involved.” The Wellcome Trust position statement (Section 7) divides the issue of posttrial obligations into two separate categories, one for individual research participants and the other for the host country, region, and locality.¹⁹ The statement makes clear that the Trust “may consider it an ethical requirement to guarantee post-research access to treatments to participants involved in research investigating chronic or progressive conditions.”¹⁹ It also cautions prospective applicants that the way in which they propose to handle these issues may affect the funding decision. Importantly, Section 11, on roles and responsibility, identifies both the investigator and her/his employing institution as sharing the responsibility for “engaging, where appropriate, in processes with relevant stakeholders (for example government ministries or pharmaceutical companies) to try and ensure post-research access to interventions demonstrated to be effective to host communities or populations.”¹⁹ Presumably, these obligations would apply as well to ongoing access for individual participants.

European Group on Ethics in Science and New Technologies

The European Group on Ethics in Science and New Technologies, an advisory body to the European Commission, issued an opinion on posttrial obligations in 2003: Opinion No. 17. Ethical Aspects of Clinical Research in Developing Countries.²⁰ Under Section 2.3 (Inequality), the opinion recognizes that scientific research alone cannot solve global inequalities, but it goes on to say that “[t]he public or private investigators who do their research in low- and middle-income countries have a moral duty to make a concrete contribution to overcome inequalities.”²⁰ In this respect, the European Group directive is the most forceful of all the relevant guidance documents in stating the moral character of posttrial obligations.

Section 2.13 of the document begins with an important reference to practices in industrialized countries, in which the “free supply of a proven beneficial new drug to all participants of a trial after the trial is ended is the rule as long as it is not yet available through the normal health care system.”²⁰ Section 2.13 continues, “In developing countries, the same rule must be applicable even if this implies supplying the drug for a lifetime if necessary. Moreover, there should be an obligation that the clinical trial benefits the community that contributed to the development of the drug. This can be e.g. to guarantee a supply of the drug at an affordable price for the community or under the form of capacity building.”²⁰ The European Group guidelines avoid the CIOMS strategy of ambiguous language (“reasonable availability”), which was intended to facilitate deliberation and judgment in research ethics review rather than to prescribe a rigid position.

The European Group also directly challenges patent restrictions on publicly funded research. Its opinion states, “In order to avoid limitations due to patent rights when the research is carried out mainly with public funding, the results produced should be regarded as falling within the public domain, or else a system of compulsory licences for applications in developing countries should be considered.”²⁰ This goes further than the other guidelines to throw down the gauntlet for research sponsors, which may

diminish their appetite for funding research in some circumstances that might ultimately have been of value to low- and middle-income countries. Whereas the Declaration of Helsinki, CIOMS, and UNAIDS guidelines are essentially voluntary standards,²¹ the European Group directive could have a more direct influence because it may prove to be influential in terms of shaping the requirements for European Union funding schemes, including the EU transnational science and technology “Framework” funding initiatives.

Other Guidelines

Other influential guidelines, such as the World Health Organization (WHO) Good Clinical Practice Guidelines,²² are widely used in clinical research, particularly by scientists in low- and middle-income countries, and address obligations to ensure continued provision of beneficial drugs at the conclusion of clinical trials. In 2005, UNESCO produced a Universal Declaration on Bioethics and Human Rights²³ that supports the basic moral thrust of posttrial obligations, namely that science and technology should improve the access of the world’s poor “to quality health care and essential medicines, to adequate nutrition and water, improvements of living conditions and environment.”²⁴ However, this effort has encountered severe criticism,²⁵ and it remains to be seen whether the UNESCO Declaration can exert any real influence on governments—particularly in low- and middle-income countries—to enhance their interest and participation in science funding, policy development, and health systems improvement. Increased attention to these issues in the laws and guidelines emanating from other countries, such as Brazil²⁶ and Uganda,²⁷ have helped to keep the issue high on the global health research policy agenda.

The Ethical Rationale for Posttrial Obligations

What is the ethical justification for obligations to provide medical care to research participants at the conclusion of a clinical trial? What principles provide the basis for policy and action on these issues? As noted above, the three broad ethical rationales for posttrial obligations are (1) avoiding exploitation in research, (2) recognizing the contribution of research participants, and (3) minimizing feelings of loss or abandonment on the part of research participants. Although avoiding exploitation and minimizing feelings of loss and abandonment can also be applied at the level of communities, in the sections below I will briefly outline the ethical rationale for these obligations for individual research participants, and the implications for research practice and policy.

The Obligation to Avoid Exploitation in Research

Posttrial obligations to ensure continued access to beneficial treatments for participants in clinical trials are now widely viewed as mechanisms for averting the exploitation of research participants. However, what constitutes exploitation in international research has proved to be surprisingly difficult to pin down. As a result, the topic has been the subject of sustained debate. Although most of the controversy has focused on what standard of care should be employed in clinical trials in resource-poor settings,¹⁰ a recent

account of exploitation in research has been targeted directly at deficiencies in the “reasonable availability” standard of the CIOMS guidelines.²⁸ Guidelines 10 and 21 of the 2002 CIOMS Guidelines lay out a framework for ensuring that the products and knowledge generated from the research become available for the benefit of participants and host country communities. But it has been argued recently that it is not the assurance of access to these *specific* benefits, so much as a fair distribution of the wider range of relevant benefits from research, including those that accrue to the investigators, that is the appropriate way to avoid exploitation in research. Several specific concerns with the CIOMS reasonable availability requirement have been noted in this regard.¹² Perhaps the most important of these is that limiting the eligible benefits to those specified in the reasonable availability clause can be viewed as inappropriately paternalistic, in that it privileges the views of the experts who drafted the CIOMS guidelines over the views of the host country participants as to what constitutes an appropriate benefit to warrant their participation in research.¹²

One rebuttal to this criticism of the reasonable availability approach is that it makes the determination of appropriate benefits a matter of negotiation. The worry is that existing differentials in power, influence, and resources between host country communities and organizations and the foreign researchers and sponsors might confer an unfair bargaining advantage to the foreign investigators, and that this might be manipulated to include inappropriate enticements to participate in research, rather than more meaningful contributions to the health of research participants.¹⁰ The fair benefits model assumes that exploitation results from unfair distribution of benefits within particular agreements. Critics of the model dispute the claim that the terms of these agreements can be considered independent of the background economic conditions in the low- and middle-income countries hosting the research, which are widely perceived to be unjust.²⁹

But given the poor record to date of transferring research-related benefits to communities in low- and middle-income countries, just how compelling these objections are, or how influential they should be in the posttrial obligations debate, is not clear. It is clear, however, that the skills and experience required to negotiate fair benefits effectively are not part of the typical training program for health researchers,² nor have these negotiations been deemed worthy of dedicated funding from research sponsors.

The Obligation to Recognize the Contribution of Research Subjects

Clinical trials, and the resulting gains for all interested parties, would simply not be possible without the willing participation of human subjects. Yet the formal recognition of the importance of their contribution is among the most poorly developed aspects of research and research ethics. The decision to participate in research, and to assume the associated risks, inconvenience, and inherent uncertainties, requires a commitment of trust on the part of research subjects. This feature of the relationship among the research subject, investigators, and research staff entails its own unique set of responsibilities, including the requisite trustworthiness of the investigators. What happens to research subjects once the trial is over can affect this relationship of trust between individual participants and investigators, and by extension, the overall level of trust in the research enterprise. There is a growing

recognition of the importance of respecting and protecting this public trust in the research enterprise.³⁰

In light of these concerns the U.S. National Bioethics Advisory Commission (NBAC) in 2001 proposed an ethical justification for posttrial obligations in clinical research that it called “justice as reciprocity.”¹⁸ According to this model, justice or fairness requires some formal recognition of the essential contribution of research subjects to the research enterprise. In particular, some meaningful reciprocity is required of investigators and sponsors in return for research subjects’ investment of time and energy, assuming personal risk—when it exists—in research, and in recognition of the fact that research subjects have ongoing interests in the findings, procedures, and impact of the research after their direct participation has ended.¹⁸

Justice as reciprocity goes beyond the basic ethical requirement that there be a favorable balance between the risks and potential benefits for research participants in a given trial—which some view as a sufficient guarantee of benefit. It involves a more holistic recognition that research participants represent a *sine qua non* of clinical research, and that the essential nature of their contribution warrants some special gratitude or recognition, over and above the potential benefits inherent in a given research design.

The Obligation to Minimize Feelings of Loss or Abandonment

Another contribution to thinking about posttrial obligations emanating from NBAC was the idea that the failure to recognize and implement posttrial obligations to research participants could result in a harmful loss for them.¹⁸ For example, a research participant in a clinical drug trial is randomized to receive the experimental intervention, which turns out to have a beneficial clinical effect. If, at the conclusion of the trial, the sponsors and investigators were under no obligation to continue to provide this research participant with the experimental drug, or to take appropriate steps to ensure ongoing access to it—and if no other provisions for access have been made, such as approval and adoption within the public health system—then it is clear that the research participants would experience a significant loss and possibly a setback in health status. The psychology of this loss is also important ethically. When a research participant’s involvement in a study ends abruptly, without any plan for continued communication or provision of information, and usually without any explicit show of gratitude, a range of dignitary harms become likely, including grief, frustration, and disappointment. As well, the experience could shake the participant’s confidence in a fundamental aspect of personal security, in other words, the ability to count on the willing assistance of others in time of need. The obligation to avoid feelings of loss or abandonment among research participants might be thought of as a specific formulation of the principle of respect for persons in research. But given the background concerns about unfair distribution of the benefits of research, there is a strong rationale for treating this obligation as a special instance of this principle, deserving independent articulation.

In clinical research, a sense of loss is likely to be enhanced or exaggerated for research participants who mistakenly believe that a central aim of research is to serve their personal therapeutic goals, as opposed to the broader societal goal of knowledge-generation to improve treatment modalities. If, for whatever reason, research participants are operating on the assumption that their participation

in a given research trial will result in improvements in their personal health—the “therapeutic misconception”³¹—without a deeper appreciation of the less predictable course of research, then the failure to provide mechanisms for some reasonable form of ongoing access to care at the conclusion of the trial is all the more likely to result in feelings of loss for these research participants, perhaps especially for those in low- and middle-income countries who may be less familiar with the aims and conventions of research.

Without fair and accurate accounts of what research participants should expect at the conclusion of a clinical trial, there are likely to be few justifications for the withdrawal of beneficial care by investigators or sponsors, especially when there are no other means to access the care. A more difficult question is whether disclosing to prospective participants that they can expect continued access to a beneficial therapy only for a specified period, or in a limited form, at the end of the trial is sufficient justification for discontinuing care after the trial. This question introduces the challenge of delineating the scope of posttrial obligations.

The Scope of Posttrial Obligations

Richard Ashcroft has outlined three possible positions on the scope of posttrial obligations: the *minimal* obligation position, the *maximal* obligation position, and a *more nuanced* approach.³²

The Minimal Obligation Position

The minimal obligation position does not, under normal circumstances, require investigators to ensure research participants continued access to treatments from which they have benefited during the course of the clinical trial. This applies when the investigators have satisfied the usual requirements of ethical research,³³ including an honest account of what prospective participants can expect to happen to them during and after the trial and a favorable balance between risks and potential benefits. In this sense, the minimal obligation position might be viewed simply as a rejection of any posttrial obligations. It holds that as long as investigators and sponsors don’t “withhold any normally available effective treatment,”³² their actions can be considered fair, even in the absence of specific posttrial commitments. Ashcroft also emphasizes an economic reality to research funding and posttrial responsibilities that figures prominently in the minimal obligation position. In essence, research sponsors have a specific mandate that does not include paying for people’s medical care outside the context of a specific trial. If funding agencies had limitless wealth, then clinical obligations to people who have previously participated in a clinical trial could be absorbed with no negative impact on the research mission. However, quite aside from the amount of available resources, many research funders, such as the U.S. National Institutes of Health, are prohibited by statute, or similar authority, from purchasing health-care services outside the normal confines of a clinical trial. The minimalist position, in essence, is a defense of the status quo and its clear demarcations between research and clinical care.

The Maximal Obligation Position

Economics figures prominently in the maximal obligation position as well. In this case, Ashcroft emphasizes the fact that research

sponsors often derive enormous economic benefit from research, because the results of clinical trials can serve as the basis for regulatory approval of new drugs and devices that can then be sold within lucrative markets for enormous profits. This is an issue almost exclusively for private, for-profit, research sponsors, but because private sector research funding is now estimated at \$30 billion a year globally (approximately 40% of global research funding),³⁴ and the profitability of the research-based pharmaceutical industry is well known,³⁵ it effectively applies to about half of the health research being conducted annually around the world.

The maximal position reflects key aspects of the “justice as reciprocity” rationale, described above. It is rooted in the simple observation that, although there could be no profits for new drugs without the voluntary participation of human subjects in research, these participants seldom even receive sufficient gratitude for their contributions, let alone a fair share of the gains. As well, research participants often assume some personal risks while making their contribution to research and this, too, deserves some appropriate recognition. Finally, in contrast to the minimal obligation position, which emphasizes clear boundaries between research and clinical care, the maximal obligation position recognizes that investigators do assume a duty of care for participants in a trial,^{32,36} and that such a duty cannot simply be set aside because the data collection phase of a clinical trial has come to an end. Although it does not follow automatically from the maximal obligation position that research sponsors must provide treatment to participants following a clinical trial for the rest of their lives, it does not permit this conclusion to be dismissed out of hand.

A More Nuanced Approach

In recognition of the complex issues occupying the space between the minimal and maximal obligation positions, Ashcroft has proposed what he calls a “more nuanced position.”³² This approach incorporates features of the minimal and maximal positions with three main constraints: rationality, limited responsibility, and nonexploitation. These constraints dictate that posttrial obligations must not be arbitrary, but instead must take into account the prevailing circumstances in the countries and communities in which the trials take place, such as access to care and the research opportunity costs associated with various funding strategies for ongoing clinical care. As well, the more nuanced position recognizes that individual actors in these complex scenarios—sponsors and investigators—are limited in their ability to address these complex challenges, and it encourages an increased reliance on effective institutions and democratic process to achieve viable and ethically praiseworthy solutions. Finally, the more nuanced position requires that all of these other considerations must be met without falling back into the patterns of exploitation of communities in research that gave rise to these debates in the first place.³²

Obligations to Research Participants in the Control Group of a Clinical Trial

The Nuffield Council report discusses some of the challenges related to ensuring ongoing access to beneficial treatments to members of the control group in a clinical trial, who might have received another, inferior, treatment or a placebo during the trial, depending on the study design.¹ Although there is little dis-

agreement in principle that control group members should be provided with treatments demonstrated during the trial to be effective—in other words, either more effective than the treatment received by the control group or placebo, depending on the design of the trial—the Council's report highlights several circumstances that might justify exceptions. First, there may be circumstances, particularly in trials of longer duration, such as vaccine trials, in which some or all of the control group members are no longer at an age, or stage in disease progression, to benefit from the effective therapy. This situation may arise, for example, in vaccine trials involving children.

A critical issue in vaccine research is the duration and strength of protection from vaccination. The intensity of the immune response to the target disease pathogens often declines over time following vaccination, and generating a clear understanding of this attenuation requires a stable control group. Because the bulk of the attenuation occurs after the conclusion of a trial, a potential conflict arises between the obligation to provide effective treatments to the control group at the conclusion of the trial, and the obligation to maximize the scientific value of the trial by generating clear answers to questions such as the effective duration of the vaccine, which may be critical to the overall assessment of the vaccine's efficacy.¹ The Nuffield Council recommends that members of the control group should receive the vaccine at the conclusion of the trial, if it is deemed to be effective and if the group is still at risk of the disease against which the vaccine is targeted, but the Council recognizes that different conclusions may also be warranted, depending on the specific circumstances of the trial.¹ Another approach to this problem has been to provide the control group with an unrelated, though relevant, vaccine to ensure a benefit for the control group without undermining the overall integrity of the trial—for example, giving the control group in a malaria prevention trial a rabies vaccine instead of the experimental malaria vaccine.³⁷

A closely related issue, which applies equally to members of the control group and the intervention group, is the responsibility to ensure that there is sufficient posttrial surveillance to detect treatment-related harms that might arise in the posttrial period, even if short-term testing suggests the treatment is safe. The Nuffield Council report describes the case of a high-titer measles vaccine trial in Guinea-Bissau and Senegal, in which children were provided high-titer vaccine at a younger age than the conventional measles vaccine. The children receiving the vaccine produced higher level of antibodies against measles than children receiving conventional measles vaccine, but long-term surveillance detected an increase in mortality among girls in the trial compared to girls receiving the conventional measles vaccine, several years after the end of the trial.¹ These examples help to illustrate the importance of long-term surveillance following clinical trials and the related challenge of ensuring fair provision of effective treatment for all trial participants.

Circumstances in Which Provision of Effective Treatment May Not Be Obligatory

The presumption underlying the obligation to ensure ongoing provision of treatment at the conclusion of a clinical trial is that the effective treatment will be beneficial to the research participants. Although this is a reasonable presumption, there are some cir-

cumstances in which this might not be the case. The clearest examples arise in clinical trials of chronic diseases, and malaria provides an excellent illustration of the problem in clinical trials in malaria-endemic countries. Acute, severe malaria kills more than 1 million children in low- and middle-income countries every year and now accounts for more than 10% of all childhood deaths in these countries.³⁸ Despite the high death rates from malaria, multiple infections with malaria parasites in childhood are also well known to confer protective immunity into adulthood. As a result, providing prophylaxis or treatments that might disrupt children's normal acquisition of immunity to malaria parasites beyond the conclusion of a clinical trial could have a detrimental effect on their later immunity and may increase their risk of illness or death in later life. This issue is discussed in more detail below.

The Mechanics of Posttrial Obligations

Mechanisms

To date, the principal mechanism for addressing posttrial obligations has been to capture the relevant interests and commitments of the various parties (e.g., sponsors, investigators, communities, governments) in a formal agreement that is finalized before the research is initiated. These *prior agreements*, as they have come to be known, reflect the constraints of Ashcroft's more nuanced position in that they treat the interests at stake as negotiable, which recognizes that the responsibilities of sponsors and investigators are limited, rather than absolute, and rational deliberations are required to achieve successful outcomes. Prior agreements also provide an avenue for the inclusion of other interests and responsibilities, such as the responsibilities of host country governments, which are often neglected in discussions of research ethics.

Alice Page has reviewed the use of prior agreements and has advocated their use in international research as a means of ensuring that benefits accrue to host country participants in research.³⁹ Page tackles six main criticisms that have been leveled against the use of prior agreements, ultimately concluding that none of these criticisms is sufficiently strong to warrant the abandonment of prior agreements. These criticisms reflect many of the same concerns that occupy the space between Ashcroft's minimal and maximal positions.

The first criticism is that prior agreements delay or prevent research. Page concedes that, even though this might be true in some circumstances, it is equally true that the benefits to host countries from their participation in international collaborative health research have been modest, making it difficult to gauge what is lost if research is delayed or prevented. Prior agreements, according to Page, open up space for innovative discussion about financing, underwriting, and delivering care posttrial, some of which has already given rise to benefits for host countries.³⁹

The second criticism is that there are significant financial, logistical, and other practical obstacles to prior agreements. Again, Page argues that successful solutions and workable strategies will not be discovered without attempting some of these negotiations in practice, and she reemphasizes that these are surely worthy efforts if the central aim of prior agreements is sound.

The third criticism against requiring prior agreements is that it is not the prevailing international standard. As I have done, above,

Page reviews some of the ways that current international guidance documents deal with posttrial obligations and finds not only a general consistency with the main ethical thrust of prior agreements, but in some cases, such as in the UNAIDS guidance document and CIOMS Guideline 10, recognition of affirmative obligations. Similar affirmations of such obligations are present in the Human Genome Organization's Ethics Committee Statement on Benefit Sharing,⁴⁰ the WHO Operational Guidelines for Committees that Review the Ethics of Biomedical Research,⁴¹ and numerous national guidelines issued by low- and middle-income countries.^{26,27,42}

The fourth criticism is that researchers cannot realistically influence health policy. This criticism spans two related issues. The first, outlined briefly above, is that individual studies seldom provide clear direction for widespread policy adoption. The path is usually circuitous and prolonged. Although this may be a good reason to clarify the scope of obligations in international guidelines, it seems insufficient on its own to undermine the entire justification for posttrial obligations or the more specific emphasis on prior agreements.

The fifth criticism is that prior agreements would create a double standard with regard to clinical research conducted in the United States and other industrialized countries. This criticism seems flawed for two main reasons. First, prior agreements are already used to extend access to unapproved drugs and devices for research participants at the conclusion of clinical trials in high-income countries. These agreements are generally made among the regulatory authority, the drug or device manufacturer, and the trial sponsor(s), and provide limited access under clearly specified terms. These agreements may also extend to people who have not been participants in clinical trials, usually on compassionate grounds.^{43,44} Second, rather than giving low- and middle income countries an unfair advantage, posttrial obligations and prior agreements actually aim to level the playing field by filling gaps in access to medical care that are, for the most part, better handled in high income countries.

The sixth, and final, criticism of prior agreements is that they can always be breached. This line of reasoning pays insufficient attention to the value of prior agreements as a way of structuring a negotiation about a complex set of interests, which might also serve as an important process for establishing the understanding and commitments that might make compliance with the terms of the prior agreements more likely than they would have been under a more informal agreement.

Sponsor Policies and Practices

The emphasis on posttrial obligations tends to obscure some important practical constraints on research sponsors. For example, the U.S. National Institutes of Health (NIH), the world's largest public funder of biomedical research, has a specific mission: to encourage and support research.⁴⁵ This mandate does not include the authority to purchase drugs or devices as health-care services, even as a continuation of the treatment tested in a clinical trial. In response to increasing pressure to ensure the continued provision of antiretroviral drugs at the conclusion of HIV/AIDS clinical trials, the NIH issued a guidance statement that clarified its mission and which recommended that "NIH-funded investigators work with host countries' authorities and other stakeholders to

identify sources available, if any, in the country for the provision of antiretroviral treatment to antiretroviral treatment trial participants following their completion of the trial."⁴⁶ The NIH policy serves as an excellent illustration of how the policies and practices adopted by research sponsors—particularly the large, influential ones—can have a profound effect on the status of posttrial obligations.

A similar example comes from the United Kingdom's Wellcome Trust, another influential funder of global health research. Its position statement for research applicants establishes several important limits with respect to posttrial obligations. For example, Section 7 (Post-research access to interventions demonstrated to be effective), makes clear that "[t]he Wellcome Trust does not fund healthcare per se and considers the financial responsibility of providing successful interventions after research is over to fall outside its remit. It does, however, encourage grant applicants to consider how post-research access could be ensured."¹⁹ Later in the same section, three main reasons are offered for these limits on the Trust's obligations for funding posttrial access: (1) that it "does not fall within the Wellcome Trust's remit and area of expertise," (2) that it "could divert funds away from supporting valuable research," and (3) that it "could render research prohibitively expensive for the Wellcome Trust."¹⁹

It is important to emphasize that these statements from health research funders do not indicate a lack of support for the notion of ensuring posttrial access to beneficial interventions. Instead, they illustrate the complexity and potential hazards associated with seemingly simple statements about the moral obligations of research sponsors in international guidelines. Posttrial obligations may serve as a useful illustration of the hazards of an overreliance on aspirational statements in international guidelines, which, although they may serve the intended purpose of establishing international expectations of ethical conduct, also may inadvertently impose complex requirements without offering further guidance about how these requirements might be applied. Although the stakes may be high for the research sponsors, investigators, and research participants alike, it is clear that we need more examples of workable posttrial agreements, and more innovation, in order to gain more confidence that declarations of posttrial obligations will produce the desired ethical results.

Public-Private Partnerships

The Nuffield Council on Bioethics recognized public-private partnerships (PPP) as an innovative and potentially powerful mechanism for addressing posttrial obligations in clinical research. PPPs are collaborative arrangements between public agencies and private entities to tackle problems related to global health. There is enormous diversity in the goals of PPPs, including distributing donated or subsidized products to control a specific disease, strengthening health services, educating the public, improving product quality or regulation, and new product development.^{47,48} PPPs have been growing in importance in global health, including in the field of drugs and health products development. Although they are not mechanisms for posttrial obligations, per se, PPPs have several features that make them ideal contexts for exploring and implementing posttrial obligations. First, they allow public agencies to overcome constraints and limitations on their roles, authority, and resources. Second, they

broaden the available sets of skills and experience that can be brought to bear on a problem, for example, by providing managers, administrators, and lawyers with extensive negotiating experience to assist investigators who may be inexperienced in these matters. And third, they can drastically expand the available pool of resources, or mechanisms for underwriting or financing complex initiatives, which can result in opportunities that would otherwise not be available to parties pursuing effective mechanisms for satisfying posttrial obligations. To date, most of the experiences with prior agreements and mechanisms for posttrial obligations have come from PPPs, and some of these are discussed in greater detail below.

Examples and Lessons

A great many factors influence the existence, nature, and success of posttrial obligations in research, beyond the nature of the research itself and the potential benefits to research participants. Not least among these factors are the prevailing economic and political forces globally, and their specific effects on research in low- and middle-income countries.⁴⁹ A recent example involved the antiretroviral drug Nevirapine, which is used to prevent mother-to-child transmission of HIV-1 and was tested in clinical trials on South African women, but whose distribution was severely limited by the South African government. A ruling by the South African Constitutional Court was required to establish that the restrictions constituted a barrier to the exercise of the right to health by South African women.⁵⁰ This ruling also removed a critical restriction that complicated posttrial agreements involving Nevirapine research in that country.

Support for posttrial obligations is not universal, as Ashcroft's minimal obligation position illustrates. Although most would agree that research is necessary to generate knowledge to address health problems in low- and middle-income countries, it is unrealistic and inappropriate for research to be viewed as a corrective for the widespread social injustice that characterizes most of the low- and middle-income world. Posttrial obligations arise at the murky interface between research and humanitarian assistance, a position that is best occupied with some trepidation. For example, Article 1.14 of the Canadian Tri-Council Policy Statement, the main national research ethics guidelines in Canada, states explicitly about research conducted outside Canada that "since researchers are not aid agencies, REBs [research ethics boards] should not try to force them to undertake aid work."⁵¹ Similarly, the conscious negotiation for, and distribution of, benefits to research participants in clinical research that is required by posttrial agreements also holds enormous potential to create tension and unrest within communities.

Despite these challenges, posttrial obligations have been implemented successfully, and examples and lessons are beginning to emerge. In her review of prior agreements, Page describes several examples of how posttrial obligations have been approached in practice. These include prior agreements employed by the WHO with its industrial partners for new product development, by the International AIDS Vaccine Initiative (IAVI) with industry partners for vaccine development and with organizations such as the World Bank and low- and middle-income country governments to establish purchasing funds for vaccines, and in agreements negotiated around the first VaxGen Phase III HIV

vaccine efficacy trial in Thailand.³⁹ Here I will focus on three additional examples: first, the HIV Netherlands Australia Thailand Research Collaboration (HIV-NAT); second, a trial of intermittent presumptive treatment of infants for malaria in Kamasi, Ghana; and third, an industry partnership with a nongovernment organization (NGO) for the development of a new antimalarial drug.

The HIV Netherlands Australia Thailand Research Collaboration (HIV-NAT)

HIV-NAT was formed in 1996 as a partnership among the Thai Red Cross AIDS Research Centre, the Australian National Centre in HIV Epidemiology and Clinical Research, and the International Antiviral Therapy Evaluation Centre in Amsterdam. Its mandate was to undertake clinical trials of antiretroviral drugs and to ensure that participants in these trials continued to have access to the medications following the conclusion of the trials.⁵² Initially, HIV-NAT negotiated access to antiretroviral drugs with drug companies in the context of "rollover protocols," in other words, studies that permit research participants to move directly from one study into an extension trial, either for different clinical trial phases or different outcome measures. But this practice became unsustainable as the population of trial participants in Thailand gained more and more experience with various antiretroviral drugs in clinical trials, which made it difficult to meet inclusion and exclusion criteria for the subsequent trials. Another HIV-NAT approach has been to negotiate with pharmaceutical companies that sponsor clinical trials either fixed-fund contributions to pay for, or commitments to provide, antiretroviral drugs for research participants.

Despite these mechanisms, in 2001 HIV-NAT anticipated a shortfall in antiretroviral drug supply for research participants completing clinical trials, and launched the HIV-NAT drug fund. About 85% of this fund is covered by overhead costs from running clinical trials, and about 15% from other revenues such as symposia and training programs. Since 2001, approximately 20% of research participants who have been unable to pay for their antiretroviral drugs, or who have been ineligible for other government-funded antiretroviral programs, have received support from the drug fund. The fund requires a monthly copayment from research participants, the amount of which is determined by a means test on admission to the fund. The fund has provided an important bridging mechanism during a period when the Thai government has been expanding its antiretroviral access program.⁵²

Trials of Intermittent Presumptive Treatment of Malaria in Infancy

Intermittent presumptive treatment (IPT) of malaria involves the provision of an antimalarial drug or drugs during peak periods of vulnerability to infection in an effort to reduce morbidity and mortality from severe acute malaria. Because infants between 6 and 23 months of age represent a major component of the disease burden from malaria, IPT has been targeted primarily at pregnant women and infants.⁵³ For IPT of infants, the goal is to provide effective control of parasitemia and clinical episodes of malaria in children who are already infected, during the period when passive immunity acquired from the mother has declined, but before the immune advantages of acquired immunity to malaria parasites has had sufficient time to develop.⁵⁴ The rapid emergence of

resistance to drugs used for IPT and the enormous scale of the disease burden from malaria globally have made the testing of different drugs and strategies for IPT a priority in malaria treatment, in both pregnant women and infants.

In several early clinical trials, IPT demonstrated improvements in morbidity and mortality in infants in the first year of life.⁵⁴ However, rapidly acquired resistance to preferred drugs for IPT, such as sulphadoxine-pyrimethamine (S-P), as demonstrated in a recent trial from Kamasi, Ghana,⁵⁵ has increased the urgency for further clinical trials to ensure that appropriate timing and duration of effective drug combinations are used in IPT to maximize its clinical benefits in both high- and low-transmission areas.⁵⁴

Although IPT has been endorsed by WHO as part of the available arsenal of clinical tools to combat malaria,⁵⁶ recent findings about the rapid acquisition of S-P-resistant parasites, even after single dose administration of S-P, raised concerns about the long-term viability of S-P-based IPT programs. Yet the only way to determine effective solutions to these problems is through continued clinical testing of alternative IPT strategies.

In the Kamasi trial involving SP-resistance after a single dose administration of S-P, the placebo control group had fewer infections, fewer cases of parasitemia, and fewer cases of mild malaria than the S-P group.⁵⁵ The children enrolled in the trial had a mean age of 9 months at the beginning of the trial. Previous evidence had suggested that a course of S-P treatments at 2, 3, and 9 months, and amodiaquine treatments at 3, 5, and 7 months, reduce the incidence of malaria episodes and anemia.^{57,58} Furthermore, there is concern that any additional treatment of asymptomatic children will lead to further selection of drug-resistant parasites that can result in increased morbidity and mortality by decreasing acquired immunity (the rebound effect).⁵³

These IPT in infancy trials raise significant challenges for posttrial obligations to research participants. As described above, based on existing data, it may be that the children in both the placebo and control groups in the Kamasi trial have passed the critical window of opportunity for any further benefit from drug administration following the completion of the 26-week trial period. This might make continued provision of treatment of the infants at the conclusion of the trial impossible, or clinically inadvisable, given the serious nature of the associated risks. Similarly, given the rapid development of drug resistance to the frontline therapies used in IPT, fulfilling the obligation to ensure access to beneficial treatment for the infants in the Kamasi, and similar, trials also conflicts with the obligation not to contribute to increased drug-resistant strains of malaria parasites, which represent an enormous global health threat. In these circumstances, it is reasonable to conclude that the investigators still have an obligation to the infants in the trial, but that the obligation may best be met by careful clinical monitoring, as opposed to the administration of any specific treatment.

Bayer–Medicines for Malaria Venture Artemisone Deal

In their review of public-private partnerships for health, Kettler and White describe several case studies, including an agreement between Bayer Pharmaceuticals and the Medicines for Malaria Venture (MMV), for the development of a new malaria drug using Artemisone, a substance for which Bayer holds the patent.⁴⁸ This

case serves as a useful example of how posttrial obligations can be addressed in the context of PPPs, an increasingly common approach to drug development, and therefore also an important context in which to consider posttrial obligations.⁵⁹ It also highlights efforts by MMV, a WHO initiative funded largely by the World Bank and private foundations, primarily the Bill and Melinda Gates Foundation, and a recognized global leader in PPP-driven drug discovery and development.⁶⁰

There are four main players with recognized responsibilities in the Bayer–MMV deal, Bayer, MMV, WHO, and the host country health systems and patient groups. Under the terms of the agreement, Bayer has agreed to manufacture the Artemisone product for clinical trials and to fund the remaining preclinical and clinical studies. Later stage clinical development will receive guidance from WHO country teams and local health systems and patient groups. This is also the stage at which the details of ongoing access to Artemisone will be determined, if it proves to be beneficial for participants in current clinical trials. Bayer has agreed to make any beneficial product available at an “affordable price” to the partners of this agreement, to ensure ongoing access for all who need it.⁴⁸

Summary

Posttrial obligations to research participants are intended to avoid the exploitation of research participants, to recognize the value of their contribution to the research enterprise, and to minimize the likelihood of feelings of loss or abandonment among research participants whose continued access to a beneficial intervention might require special provisions beyond the planned clinical trial. Major international research ethics guidelines, including the World Medical Association’s Declaration of Helsinki and the Council of International Organizations of Medical Sciences guidelines, have offered controversial guidance on posttrial obligations, but the ensuing debate has been extremely influential in the development of current thinking about posttrial obligations.

Several positions have been proposed on the appropriate scope of posttrial obligations of researchers and sponsors, ranging from rejection of any specific posttrial obligations, beyond the usual demands of ethical research, to full responsibility to ensure access to needed interventions and even advocacy on behalf of research participants and their communities, especially in low- and middle-income countries.

Some special considerations are required in terms of ensuring access to effective treatment for members of the control group in clinical trials. There also are instances, such as some trials involving malaria and other chronic diseases, in which it may be impossible, or clinically inappropriate, to provide continued treatment, due to interference with the acquisition of natural immunity or contribution to the development of drug-resistant disease. These issues are illustrated by the Kamasi trial of intermittent presumptive treatment of malaria in infants.

The principal mechanism for addressing posttrial obligations to date has been *prior agreements* that reflect the key negotiated interests of sponsors, researchers, and research participants for a given clinical trial. Despite some important criticism, prior agreements remain the most common approach to ensuring that posttrial obligations are satisfied in practice.

Research sponsors have also been instrumental in the development of approaches to posttrial obligations. Private sponsors of

research, including pharmaceutical companies and private foundations, are free to purchase and provide beneficial interventions to research participants at the conclusion of clinical trials, if the economic and humanitarian incentives are appropriate, but public research funding agencies are usually constrained from doing so by their mandates. Many sponsors, including the U.S. NIH and the U.K. Wellcome Trust, have established clear policies to reflect these constraints and have encouraged investigators to pursue posttrial obligations in their individual research activities. These policies do not indicate a lack of support for the notion of ensuring posttrial access to beneficial interventions. Instead, they illustrate the hazards and logistical challenges that posttrial obligations represent for research funders.

One innovative and powerful mechanism for addressing posttrial obligations is the public-private partnership, a collaborative arrangement between public agencies and private entities. Public-private partnerships allow public agencies to overcome constraints and limitations on their roles, authority, and resources; they broaden the available sets of skills and experience that can be brought to bear on a problem; and they can drastically expand the available pool of resources or mechanisms of underwriting or financing complex initiatives, which can result in opportunities that would otherwise not be available to parties pursuing effective mechanisms for satisfying posttrial obligations. The HIV Netherlands Australia Thailand Research Collaboration (HIV-NAT) and the Bayer–MMV deal to develop Artemisone are examples of how creative partnerships can ensure that posttrial obligations are satisfied in clinical trials.

Multinational Research

This page intentionally left blank

Appropriate Ethical Standards

Wherever research involving human beings may be conducted, it must adhere to appropriate ethical standards. Yet despite universal agreement on this fundamental requirement, interpreting and applying the concept of ethical standards has produced a surprising amount of vagueness, ambiguity, and even disagreement. Even more vexing is the need to determine the appropriate ethical standards for multinational research.

A thorough analysis of this topic requires examination of conceptual as well as ethical issues. At least the following questions must be addressed: Are all ethical aspects of research with human subjects properly considered *standards*? Should standards be universally applicable or are variations permissible according to economic, political, or cultural differences among nations? When different ethical standards are potentially applicable, to which ones should researchers adhere? How should disagreements about ethical standards in research be adjudicated or resolved?

In multinational research, these questions have given rise to debates over so-called double standards. Are double standards acceptable in multinational research, or should researchers adhere to a single ethical standard, regardless of differences among nations or cultural groups? It is impossible to assess opposing positions in this debate without clarifying just what counts as an ethical standard, and what are the criteria for determining when standards are appropriate.

History and Current Guidelines

The first known regulations governing research involving human beings were promulgated in 1900 in Prussia, addressed to the

directors of clinics, polyclinics, and similar establishments. A somewhat later code in Germany was the Circular of February 28, 1931, of the Reich Minister of the Interior, about two years before the start of the Nazi era.¹ Under a more informal policy of disclosure to the subjects and their consent to participate, the U.S. Army carried out experiments on healthy subjects for decades, beginning with Walter Reed's yellow fever experiments in the early 1900s.

However, scholars have concluded that the 1947 Nuremberg Code is almost certainly the first *international* code.² Therefore, the history of ethical standards for research in the international context can be said to begin with the Nuremberg Code and to proceed through the Declaration of Helsinki in 1964, revisions in the Helsinki Declaration from 1975 to 2000, and International Ethical Guidelines issued by the Council for International Organizations of Medical Sciences (CIOMS), culminating in the 2002 revision. (See Part 2 of this volume for discussion of these and other codes, declarations, and guidelines.)

However, the term *standards* appears only in rare instances in these documents, and when it does appear, there is no explanation of precisely what the term means. The 1964 Declaration of Helsinki said, "It must be stressed that the standards as drafted are only a guide to physicians all over the world. Doctors are not relieved from criminal, civil, and ethical responsibilities under the laws of their own countries."³ These same sentences appear, with no other explicit references to ethical standards, in amended versions of the Declaration in 1975, 1983, 1989, and 1996. The substantially revised version of the Declaration in 2000 includes the following sentence: "Medical research is subject to ethical standards that promote respect for all human beings and protect their

health and rights.”⁴ These brief mentions of standards in the Declaration of Helsinki could refer to some or all of the provisions in the document.

The CIOMS International Ethical Guidelines make explicit reference to standards in both the 1993 version and the 2002 revision. Guideline 15 of the 1993 version is entitled “Externally Sponsored Research” and includes the following provision: “An external sponsoring agency should submit the research protocol to ethical and scientific review according to the standards of the country of the sponsoring agency, and the ethical standards applied should be no less exacting than they would be in the case of research carried out in that country.”⁵

Guideline 3 of the 2002 version has only a slight change in wording and includes an additional requirement, but the reference to standards is the same: “An external sponsoring organization and individual investigators should submit the research protocol for ethical and scientific review in the country of the sponsoring organization, and the ethical standards applied should be no less stringent than they would be for research carried out in that country. The health authorities of the host country, as well as a national or local ethical review committee, should ensure that the proposed research is responsive to the health needs and priorities of the host country and meets the requisite ethical standards.”⁶

The concept of ethical standards remains unanalyzed. This vagueness in the concept gives rise to two problems. The first is failure to distinguish between principled ethical standards, on the one hand, and ethically necessary procedural mechanisms, which are sometimes referred to as standards, on the other. The second problem is uncertainty whether ethical standards for research should be universally applicable or whether they may be relative to cultural norms and other differences among countries. The answer to both questions depends on what counts as an *ethical standard*. Does the level of treatment provided to research participants who acquire a disease in the course of a trial constitute an ethical standard? Does the clinical treatment provided to a control group in randomized, controlled trials—often referred to as *standard of care*—count as a standard? (See Chapter 66.) Are the requirements for the manner in which informed consent is obtained and documented ethical standards? Or are they procedures, to be properly distinguished from standards?

Ethical Standards: Universal or Relative?

It is difficult to find a clear statement of a universal standard for research ethics. One candidate might be the following: *If it is unethical to carry out a particular research project in a developed country, it is unethical to do that same research in a developing country.* However, this formulation is flawed because it fails to recognize that particular circumstances can be so different that some research that could not be conducted in a developed country could still be ethically acceptable in a developing country.

Another flawed statement of a universal view, which its authors call the “Uniform Care Requirement,” states that all participants in research “should receive the level of care they would receive in a developed country.”⁷ Adherence to this requirement would make it impossible to do research designed to develop treatments for tropical diseases in remote, rural areas of developing countries, which lack the facilities of tertiary care hospitals in industrialized countries. However, most proponents of a uni-

versal standard would not claim that such research is ethically unacceptable.

The Uniform Care Requirement seeks to protect vulnerable populations from exploitation, implying that decision makers in those countries might agree to research that would be rejected in industrialized countries because of high risk to participants or other ethical concerns. An expression of this position is an opinion issued by the European Group on Ethics in Science and New Technologies (EGE) in 2003. The opinion, entitled “Ethical Aspects of Clinical Research in Developing Countries,” states the following:

[R]esearch activities involving human subjects cannot exclusively be assimilated to an economic activity subject to market rules. On the contrary, in the context of solidarity, regarding health as a public good, rather than a commodity, it needs to be regulated according to fundamental principles. The general approach chosen within this Opinion is that fundamental ethical rules applied to clinical trials in industrialized countries are to be applicable everywhere. Even if some difficulties may arise in their implementation, a weakening of the standards would be in contradiction to the fundamental principles of human rights and dignity and their universal guarantee and protection.⁸

A different view—in effect, a form of ethical relativism—holds that rules governing research practices may vary according to the cultural norms accepted in the country in which the research is carried out. Respect for diversity underlies this form of ethical relativism, which rejects the notion that a single set of ethical standards for research should prevail in our culturally diverse world. Still another consideration, different from cultural variation, is the economic disparity between industrialized countries and resource-poor countries. This disparity has been used to justify some research in developing countries that could not be conducted in industrialized countries, based not on cultural factors but rather on different needs in resource-poor and wealthier countries.

One proposed analysis intends to show the possibility of accepting universal ethical standards for research while permitting differences in what is provided to research subjects in developed and developing countries.⁹ The key to this analysis lies in distinguishing the ethical *principles* that apply to particular research endeavors from other aspects, such as the research design. The relevant ethical principles embody the well-known and widely accepted requirements of informed consent, reasonable risks in light of potential benefits and minimization of risk. As long as these universal ethical principles are fulfilled, according to this argument, the research can be judged ethically acceptable. What permits a research design to be different in an industrialized country and a resource-poor country is the difference in local circumstances—in particular, in economic resources. According to Orentlicher, “It does not follow that, if a research study is unethical in the United States, it is also unethical in Kenya.” Under this approach, the determination of whether a double standard exists depends on whether research in different countries adheres to the same ethical principles, not whether a particular study could be conducted in one country but not in another.

This analysis has a certain appeal. The key to accepting it, however, lies in whether the economic circumstances of industrialized and resource-poor countries should count as a morally relevant factor in assessing the ethics of a particular research de-

sign. If a study is designed and conducted by Kenyan researchers, funded only by Kenyan resources, with no collaboration or sponsorship by the pharmaceutical industry or an industrialized country, then a good case can be made for accepting the moral relevance of the local economic circumstances. If the Kenyan researchers *cannot* provide expensive drugs or laboratory equipment to carry out a particular study design, then it makes no sense to say they *ought* to do so. However, in the type of research most commonly carried out in developing countries, there is an external sponsor or an industrialized country collaborator. These external sponsors or collaborators could afford to supply the same costly drugs that they would provide for participants if similar research were conducted in the industrialized country.

Some people reject the idea that different economic conditions in rich and poor countries can justify conducting research in the poor country that could not be ethically conducted in the rich country. Greco contends that “It is clear that the pressures to lower the ethical standards set by the DoH [Declaration of Helsinki] are primarily economic—it costs less to run a trial where you do not have to provide for medical care. . . . So let us push to keep the highest ethical standards applied everywhere.”¹⁰

Other commentators maintain that economic factors do constitute a relevant difference between industrialized and resource-poor countries, and that this difference can justify the use of different standards. For example, Resnik contends:

We . . . should not expect a single standard of research to govern all study designs. There are a variety of ethical principles that apply to research on human subjects, and they sometimes conflict. . . . In order to achieve an optimal balance of these different ethical standards, we need to take into account various social, cultural economic, political, as well as scientific factors. . . . One might even argue that it is unjust, unfair, and insensitive to demand that the exact same standards of research that govern study designs in developed nations should also be implemented in developing countries.¹¹

Countries in Europe and North America have for many years had detailed laws and regulations governing research involving human subjects. More recently, developing countries such as Brazil, South Africa, and India have introduced laws or policies with requirements that are equally stringent. However, many countries still have the only barest minimum of such controls or none at all. Conflicts are bound to arise when a country in which research is being carried out lacks norms or mechanisms that have become accepted standards in the sponsoring country or agency. If researchers in developing countries must adhere to regulations promulgated by industrial countries, this is sometimes characterized as ethical imperialism. But if researchers in some countries can ignore ethical standards widely accepted elsewhere, the door would be open to a regime of ethical relativism allowing virtually any standard a country desired. The key to resolving this apparent dilemma lies in distinguishing between ethical principles and procedural mechanisms.

Distinguishing Ethical Standards From Procedures

The 2000 report of the U.S. National Bioethics Advisory Commission (NBAC) on international research makes a useful dis-

inction between substantive and procedural ethical requirements.¹² Substantive ethical requirements, the NBAC says, are those embodied in the fundamental principles of bioethics stated in the *Belmont Report*: respect for persons, beneficence, and justice¹³ (see Chapter 14). These substantive principles constitute ethical *standards*, and should be applied universally. They give rise to such requirements as obtaining informed consent individually from each adult participant, disclosing adequate information about the research maneuvers to be performed, and fully informing participants of the risks and anticipated benefits of those interventions. Procedural requirements, on the other hand, may vary according to cultural and other differences in multinational research. For example, the requirement that informed consent documents be signed can hardly be applied in a country with low literacy rates, and the composition of ethical review committees in urbanized communities may not be appropriate in a heavily rural society. Distinguishing between substantive and procedural ethical requirements can make it possible to apply the same ethical standards across national borders, while permitting differences in specific procedures to respect cultural variations. On the other hand, failure to distinguish between substantive standards and procedures may give rise to a perception of ethical conflicts when none really exist.

In order to determine whose ethical standards should be adopted when there is an appearance of conflict, it is necessary to agree on what constitutes ethical *standards*. For example, the 1993 CIOMS Guidelines included a provision intended to prevent exploitation of host countries in externally sponsored research. This guideline required scientific and ethical review of proposed research to be carried out “according to the standards of the country of the sponsoring agency, and the ethical standards applied should be no less exacting than they would be in the case of research carried out in that country.” This provision prompted the criticism by Christakis and Levine that the guidelines reflected a “Western bias” because of “the assumption that the circumstances . . . in the developed world are the norm. Thus, the developed world is envisioned as more advanced, not only technologically but also morally.”¹⁴

This criticism is not shared by any of the developing countries that by 2005 had enacted laws or adopted ethical guidelines governing research. Most provisions in these regulations and guidelines replicate the CIOMS guidelines and the Declaration of Helsinki. In particular, all adhere to the ethical *standard* that informed consent be obtained from each individual research participant, yet they permit certain *procedures* in obtaining consent to diverge from the U.S. requirement for written, signed, informed consent forms.

Informed Consent: Standards Versus Procedures

Confusion between ethical standards and procedures has even given rise to debates over the necessity of obtaining individual informed consent from research participants. Differences among cultures—especially with regard to the primacy of the individual—have prompted some to argue that the concept of informed consent is understandable and applicable in the West but is irrelevant to social and cultural norms in Africa and Asia. For example, when the CIOMS first presented its Proposed International Ethical Guidelines for Human Experimentation at a

conference sponsored by the World Health Organization in December 1980, Emily Miller, a U.S. participant, described the guidelines as “essentially based on American standards of ethical review as well as on the international codes”—the Nuremberg Code and the Declaration of Helsinki.¹⁵ This concern was also voiced by some participants from developing countries, who objected to elements of the proposed guidelines on grounds of ethical imperialism. As Miller reported, “How far, they wondered, can Western countries impose a certain concept of human rights? In countries where the common law heritage of individuality, freedom of choice, and human rights do not exist, the . . . guidelines may seem entirely inappropriate.”¹⁵

The idea that respect for human rights applies only to Western countries is surely peculiar, in light of the numerous United Nations treaties and covenants ratified by almost all countries, including those in Africa, Asia, and the Middle East. However, the only direct reference to human rights in the context of research is Article 7 of the International Covenant on Civil and Political Rights: “No one shall be subjected to torture or to cruel, inhuman or degrading treatment or punishment. In particular, no one shall be subjected without his free consent to medical or scientific experimentation.” Although this passage may at first appear to equate research involving human beings with “inhuman or degrading treatment,” it is not medical or scientific experimentation itself but rather the absence of voluntary, informed consent that constitutes inhuman or degrading treatment.

The requirement for individual, informed consent is by now enshrined in laws and guidelines of many non-Western countries. The South African guidelines state two rules regarding informed consent: “i. research subjects should know that they are taking part in research; ii. research involving subjects should only be carried out with their consent.” Yet these guidelines also say, “It can be proper for research involving less than minimal risk and which is easily comprehended to proceed on the basis of oral consent given after an oral description of what is involved.”¹⁶ Similarly, the guidelines issued by the Indian Council of Medical Research require that informed consent be obtained from each individual subject. But the guidelines also say that the nature and form of the consent may depend on a number of different factors.¹⁷

In some developing countries, a substantial proportion of the population is illiterate or semilliterate. Requiring written, signed consent documents when the research participants are illiterate is clearly inappropriate. For semilliterate participants, a written consent document may be appropriate, especially because family members whom the participant may wish to involve in the consent process may be literate.

It is important to distinguish between the requirement that a written document be provided to a prospective participant and the requirement that the participant sign the document. In some countries, the meaning of signing a document is quite different from what it is in North America or Western Europe. Even when the need for individual, informed consent is fully acceptable, it would be ethically appropriate to waive the requirement of a signature on a consent document if the country has a history of oppressive regimes or if people are fearful, based on their experience, that a signed document might be used against them in some manner. This can pose a problem for multinational research involving drugs for which approval will be sought from the U.S. Food and Drug Administration (FDA). FDA regulations require written, signed informed consent documents in research that in-

volves more than minimal risk. All clinical trials testing investigational new drugs are likely to be categorized as involving more than minimal risk.

In addition, researchers who conduct clinical trials in developing countries often confront practices that depart from the requirements of informed consent in the United States and other industrialized countries. For example, in many developing countries, physicians routinely withhold information from patients with certain diseases. Even if this custom might be defended in ordinary medical practice, it poses a severe challenge to the disclosure required for research involving human participants. Adherence to local practices could require withholding diagnoses from patients who become research participants and concealing key elements of the research design, such as the use of placebo controls, the process of randomizing subjects into different groups in a clinical trial and the expected efficacy (or lack of efficacy) of a method being tested.^{18,19} Withholding information also might promote the mistaken assumption—known as the therapeutic misconception—that the purpose of research is to benefit participants by providing them with a known, effective treatment for their medical condition (see Chapter 58).

Potential participants cannot make an informed decision without knowing that they may not receive a proven treatment that will benefit them. To enroll individuals who are not provided with such key items of information would deviate from the substantive ethical standard of disclosure required for adequate informed consent.

In a randomized clinical trial of adjuvant treatment for breast cancer conducted in Vietnam, the principal investigator, Richard R. Love, “found himself uncertain about the application of American standards of informed consent in the Vietnamese setting,” according to an article he coauthored in the *Journal of Investigative Medicine*.²⁰ After consultation with Vietnamese immigrants in the United States (including physicians, a sociologist, and several women), Love concluded that “American standards would not be acceptable to Vietnamese physicians, political leaders in Vietnam, or the vast majority of Vietnamese patients.”²⁰

The researcher told the institutional review board (IRB) at his U.S. medical school that in Vietnam, patients do not participate in medical decision making, but look to their physicians to tell them the appropriate treatment. As a result, he contended that he needed to withhold any elements of the consent process that would suggest uncertainty on the part of the treating doctor. Specifically, he wanted to avoid discussion of alternative therapies, and he did not want to reveal that the proposed treatment had been determined by randomization. After many months of deliberation and considerable negotiation, the IRB approved a consent form that did include the key elements of informed consent, “though with somewhat less detail than is typical in a U.S. consent form,” Love and his coauthor reported. Love and Fost stated that it is unclear whether the women in the study understood that their treatment was determined by randomization. However, a small survey of the participants in the study suggested that the women actually did understand randomization to a degree comparable with studies in industrialized countries.

Multinational research requires adherence to internationally accepted standards, one of which is disclosure to research participants—even if similar disclosure to patients is not the norm in a host country’s practice of medicine. Reluctance to disclose a physician’s uncertainty about the best treatment rests on custom-

any medical practice in such countries. The authors of the article describing the breast cancer study in Vietnam argued that “trying to force [the U.S. mode of] consent on the physicians [in Vietnam] risked losing their cooperation with the project because of the tone of cultural imperialism that it would convey.”

During its study of international research, the NBAC heard evidence confirming that in many cultures, a diagnosis of cancer is made not to the patient but instead to the patient’s family. The question is whether practices common in the clinical setting should be acceptable in the research setting, especially when local or national cultural practices depart significantly from international standards of informed consent in research.

The NBAC report contains two recommendations that address this issue:

- Recommendation 3.1: Research should not deviate from the substantive ethical standard of voluntary informed consent. Researchers should not propose, sponsors should not support, and ethics review committees should not approve research that deviates from this substantive ethical standard.¹²
- Recommendation 3.2: Researchers should develop culturally appropriate ways to disclose information that is necessary for adherence to the substantive ethical standard of informed consent, with particular attention to disclosures relating to diagnosis and risk, research design, and possible post-trial benefits.¹²

A report by the United Kingdom’s Nuffield Council on Bioethics essentially agrees with the NBAC recommendations, affirming that “obtaining genuine consent to research from participants is vital in ensuring that respect for persons is promoted.”²¹

A different problem arises when research participants are unacquainted with the concepts and methods of modern science or biomedical research. In this situation, the NBAC urges researchers to seek creative ways of presenting information, such as by analogies readily understood by the local population. It is not sufficient simply to present the information. An important component of the process is determining whether the prospective subjects adequately understand what they have been told. To this end, the NBAC recommends the following:

- Recommendation 3.4: Researchers should develop procedures to ensure that potential participants do, in fact, understand the information provided in the consent process and should describe those procedures in their research protocols.¹²
- Recommendation 3.5: Researchers should consult with community representatives to develop innovative and effective means to communicate all necessary information in a manner that is understandable to potential participants. When community representatives will not be involved, the protocol presented to the ethics review committee should justify why such involvement is not possible or relevant.¹²

In cross-cultural contexts, some commentators consider it problematic to require that informed consent be obtained from each individual recruited as a research participant. Christakis and Levine claim that to do so is “philosophically and practically difficult.”¹⁴ Some Asian and African cultures lack the individualistic concept of a person to which the Western world adheres, so how to apply the principle of respect for the person becomes problematic.

Some ethicists hold that researchers should adhere to local customs and traditions, and that insisting on Western requirements for individual informed consent in other cultures is ethical imperialism.²² Others maintain that individual informed consent should not be eliminated or altered. “We see no convincing arguments for a general policy of dispensing with, or substantially modifying, the researcher’s obligation to obtain first-person consent in biomedical research conducted in Africa,” said Ijsselmuiden and Faden.²³

The 2002 Nuffield Council report calls for requiring informed consent:

[W]e cannot avoid the responsibility of taking a view when the two aspects of respect—respect for culture and respect for persons—come into conflict with one another. We are of the view that the fundamental principle of respect for persons requires that participants who have the capacity to consent to research should never be subjected to research without such consent.²¹

Those who would subordinate the principle of respect for persons to other considerations have not identified a competing ethical principle that deserves a higher ranking. The unstated assumption that culture outranks respect for persons places respect for cultural tradition on a par with the three most widely acknowledged principles of ethical research: respect for persons, beneficence, and justice. No one argues against the ethical requirement that researchers should be culturally sensitive. But a limit is reached when a cultural practice violates an internationally accepted principle of research ethics.

A different sort of problem arises when it is necessary to obtain permission from a community leader or tribal chief in order to enter the community to embark on research. That requirement has to be respected, but it is no different in principle from the need in Western culture to obtain permission to enter the premises from the head of a workplace or a school principal. Permission from a tribal chief or village leader may be required, but should not serve as a substitute for individual informed consent obtained from each potential participant. The NBAC report contains the following recommendation:

- Recommendation 3.6: Where culture or custom requires that permission of a community representative be granted before researchers may approach potential research participants, researchers should be sensitive to such local requirements. However, in no case may permission from a community representative or council replace the requirement of a competent individual’s voluntary informed consent.¹²

Considerably more problematic is the need to obtain individual informed consent from women in cultures in which the husband or father of an adult woman normally grants permission for her participation in activities outside the home. The NBAC’s recommendation on this point calls for a presumption that men and women should be treated equally in the informed consent process, but it would give men the power to say “No” in cultures in which that seems necessary.

- Recommendation 3.9: Researchers should use the same procedures in the informed consent process for women and men. However, ethics review committees may accept a consent process in which a woman’s individual consent to participate

in research is supplemented by permission from a man if all of the following conditions are met:

- a. it would be impossible to conduct the research without obtaining such supplemental permission; and
- b. failure to conduct this research could deny its potential benefits to women in the host country; and
- c. measures to respect the woman's autonomy to consent to research are undertaken to the greatest extent possible.

In no case may a competent adult woman be enrolled in research solely upon the consent of another person; her individual consent is always required.¹²

Here, as in other recommendations, the NBAC leaves the ultimate decision on controversial matters to the discretion of an ethics review committee.

Unlike the NBAC recommendation, the CIOMS 2002 Guidelines do not permit a departure from the need to obtain individual informed consent only from the woman. The commentary under CIOMS' Guideline 16 states the following:

[Only] the informed consent of the woman herself is required for her participation. In no case should the permission of a spouse or partner replace the requirement of individual informed consent. If women wish to consult with their husbands or partners or seek voluntarily to obtain their permission before deciding to enroll in research, that is not only ethically permissible but in some contexts highly desirable. A strict requirement of authorization of spouse or partner, however, violates the substantive principle of respect for persons.⁶

In this, as in other areas of multinational research, what some people take to be ethical imperialism, others consider proper adherence to universally applicable ethical standards.

Adherence to U.S. Rules: Appropriate Standards or Ethical Imperialism

U.S. federal regulations require that research using federal funds conducted outside the United States must be reviewed by an IRB that has been approved by the U.S. Office for Human Research Protections (OHRP). The CIOMS International Ethical Guidelines require scientific and ethical review in both the sponsoring and the host country. Some commentators contend that this is precisely the right mechanism for adequate protection of human participants. Others argue that approval of proposed research by a U.S. IRB should be sufficient, and still others argue that a research ethics committee in the developing country should suffice. Between these positions are a variety of views about how flexible a sponsoring country's regulations should be when research is conducted elsewhere, and whether requiring strict adherence to the sponsoring country's rules is another instance of ethical imperialism or "colonialism" in the conduct of research. In a study commissioned by the NBAC, 77 percent of U.S. and 85 percent of developing country researchers surveyed recommended the use of international guidelines instead of U.S. regulations to cover joint projects.¹²

In 2002, OHRP issued new rules for non-U.S. institutions seeking authorization as sites for research by U.S. investigators or

others using U.S. funds. The technical name for this authorization is Federalwide Assurance for International (non-U.S.) Institutions. The foreign institution must indicate on the application whether the Declaration of Helsinki or some other statement of ethical principles governs it in protecting the rights and welfare of human participants in research. If the box marked "Other" is checked and other principles are named, a copy of those principles must be submitted with the application.

Adherence to a statement of ethical principles is not sufficient, however. The institution applying for this authorization also must comply with U.S. regulations or with alternative regulatory standards that are considered to be generally consistent with the U.S. Common Rule—the U.S. policy for the protection of human subjects in federally sponsored research (see Chapter 15). In addition, the international institution must obey any additional regulations that may be imposed by a federal agency involved in or funding the research. OHRP listed the following as acceptable international regulations:

- a. The U.S. Federal Policy for the Protection of Human Subjects, known as the Common Rule (e.g., Subpart A) or the U.S. Department of Health and Human Services (DHHS) regulations at 45 CFR 46 and its Subparts A, B, C, and D;
- b. The May 1, 1996, International Conference on Harmonization E-6 Guidelines for Good Clinical Practice (ICH-GCP-E6), Sections 1 through 4;
- c. The 1993 Council for International Organizations of Medical Sciences (CIOMS) International Ethical Guidelines for Biomedical Research Involving Human Subjects;
- d. The 1998 Medical Research Council of Canada Tri-Council Policy Statement on Ethical Conduct for Research Involving Humans;
- e. The 2000 Indian Council of Medical Research Ethical Guidelines for Biomedical Research on Human Subjects; or
- f. Other standard(s) for the protection of human subjects recognized by U.S. Federal Departments and Agencies which have adopted the U.S. Federal Policy for the Protection of Human Subjects.²⁴

It is much easier to agree to comply with ethical principles than to succeed in conforming to detailed regulations governing research. Ethical principles are stated in general terms and often require interpretation for each situation to which they are applied; regulations are normally quite specific and cover a wealth of topics in minute detail.

There is, however, a gray area in which procedures become so important that they shade into ethical principles. An example is the requirement for due process in legal or ethical proceedings, in which the rights of accused individuals are protected by procedural safeguards. If the procedural mechanisms for protecting the rights and welfare of human subjects of research in developing countries are equivalent to the protections in place in the United States and other industrialized countries, then it would surely be paternalistic to insist on ethical review of proposed research by a committee sitting in the United States. Nevertheless, it may be difficult to ascertain that procedural mechanisms are equivalent simply by examining rules of procedure, such as the rules governing an IRB in a developing country. If the members of the IRB are inexperienced, if they have not been educated in research ethics, or if members have serious conflicts of interest, these shortcomings will not be reflected in the committee's procedural rules.

Additional questions surround the mechanism of committee review, including at least the following: Must ethics committees in developing countries have the same composition and rules of procedure as U.S. IRBs? When research proposals are reviewed by an IRB in both countries, how should any disagreements between the two committees be resolved?

Available evidence suggests that, at least in the United States, IRBs rarely if ever try to communicate with host country ethics review committees. United States IRBs do not seek pertinent information from the developing country committee, nor even ascertain whether a qualified committee exists. In a 2003 review of international clinical research, Fitzgerald, Wasunna, and Pape proposed the following:

IRBs from a wealthy sponsor country should ensure that a viable local ethics committee in the proposed host country will review the protocol. . . . A viable local IRB should be viewed as a critical resource for IRBs in sponsor countries. . . . Better communication between the sponsor country IRB and the local IRB could help resolve [any] disagreements. . . . Further, the sponsor country IRB and the local IRB may possess complementary expertise and may be able to carry out a better review working together than either could working alone.²⁵

If U.S. IRBs were to adopt this novel recommendation, they would raise the review of multinational research to a new level, improving both the quality of the review process and the protection of the rights and welfare of research participants in developing countries.

The Debate Over Double Standards

Some commentators have maintained that identical standards should be employed the world over, whereas others contend that different standards are required because different circumstances obtain. But does *different* necessarily mean *lower*?

Rothman argues that “there are strong practical as well as principled reasons for Americans to follow American ethical standards when they do research abroad.”²⁶ He contends that U.S. IRBs have “too little familiarity with developing countries to set different standards.” Angell agrees that ethical standards should not depend on where the research is performed. “The nature of investigators’ responsibility for the welfare of their subjects should not be influenced by the political and economic conditions of the region” she writes. “. . . [A]ny other position could lead to the exploitation of people in developing countries, in order to conduct research that could not be performed in the sponsoring countries.”²⁷

Resnik, however, contends that we “should not expect a single standard of research to govern all study designs. There are a variety of ethical principles that apply to research on human subjects, and they sometimes conflict.”¹¹ And Mbidde, a Uganda Cancer Institute researcher, strongly defends research in his country that could not have been conducted in the United States or Western Europe:

Ugandan studies are responsive to the health needs and the priorities of the nation. . . . [T]he appropriate authorities, including the national ethics review committee, have satisfied

themselves that the research meets their own ethical requirements. With these requirements met, if Ugandans cannot carry out research on their people for the good of their nation, applying ethical standards in their local circumstances, then who will?²⁸

This consideration puts a different twist on the matter. In the absence of research conducted in developing countries, the inhabitants are denied the potential benefits that may result. In many such countries, a majority lacks access to treatments available in industrialized countries or, for that matter, any treatment at all. If research is not conducted in developing countries, the public health benefits that could result may never be available to the population. Still, the Ugandan researcher’s comments hark back to the concern about the quality of protection of research participants in developing countries. Are the procedural mechanisms for protecting the rights and welfare of human subjects adequate in those countries?

If there is something inherently unjust about allowing a double standard of ethics in research—one for industrialized countries, another for resource-poor countries—what are the options for arriving at a single standard, applicable wherever human beings are enrolled as research participants? Some commentators justify a double standard because of the undeniable differences in wealth and other resources that exist in the world. Those who hold this view point to the vast array of activities, outside the sphere of human subject research, in which inequalities exist. Further, they contend, rectifying inequalities among nations, or even among subpopulations within nations, will not be accomplished by imposing obligations on the sponsors of biomedical research.

This argument rests on the view that different economic conditions can justify different standards for providing care and treatment to research participants. The argument begins with the premise (1) that the world is filled with inequalities in resources, which is true; adds a second premise, also true (2) that striving for a single standard in research will do nothing to rectify the larger number of existing inequalities; inserts an implicit premise (3) that research involving human subjects should be treated no differently from other international endeavors; and concludes (4) that double standards in research are ethically acceptable.

The validity of this argument turns on premise (3), which is not a factual statement but an *ought* statement. To accept it is to consider biomedical research and health care as just another commodity in a market-driven world. However, if one views health care, medical benefits, and the research that yields these services as a special sort of social good, it is possible to reject the idea that research involving human subjects should be treated no differently from other activities driven by market forces.⁸

Opponents of the single-standard position might argue that they start from a quite different set of premises. They contend that insisting on one standard in research will not reduce inequalities among rich and poor nations, but that adjusting ethical standards to reflect differing real-world conditions will, in fact, reduce these inequalities. They conclude, therefore, that there is an obligation to insist on different standards of research. The plausibility of this argument depends on empirical facts and circumstances in specific cases. There is probably no way to adjudicate the general arguments in defense of single or double standards without the factual details necessary for reaching sound conclusions.

International ethical codes and guidelines will not resolve all questions or conflicts that may arise in the design and conduct of multinational research. Any differences in judgments made by two or more committees that review a research protocol will have to be negotiated. On some points, codes and guidelines may be insufficiently specific. On other issues, provisions in codes or guidelines that address the same point may vary in minor or even major respects. For example, existing guidelines differ over the use of placebo controls and the level of care and treatment to be provided to research subjects during and after a clinical trial (see Chapters 25, 65, and 66). As long as unresolved differences remain among parties committed to conducting research according to the highest ethical standards, it is open to question whether ethical codes or guidelines should attempt to settle the conflict by imposing an unequivocal rule.

Benefits to Host Countries

One of the major ethical issues in biomedical research relates to access to drugs and other interventions after a trial has been completed. If the ultimate purpose of research studies is to improve health, then somehow ensuring access to interventions proven safe and effective would seem to be a necessary step. Yet, as is well documented, adoption of any new intervention or technology is haphazard at best.¹ In part this is because after research studies, the drugs or devices might not be submitted for regulatory approval or, if submitted, might not be approved. In addition, health-care providers might not implement the interventions because of inertia or lack of training. And, in both developing and developed countries, the high cost of the interventions might preclude access to these interventions. Historically, a commonly identified problem—which may or may not have been common—has been so-called helicopter or “briefcase” research. The researchers, concerned about the data and publication, came, conducted their study, obtained the relevant data, and left the research area, unconcerned about what subsequently transpired for the research participants and their community.

Beginning in the early 1990s, concern about such helicopter research led to the articulation of a new ethical principle to ensure that the community in which the research was conducted benefited from the research. This became known as the *reasonable availability* requirement. It is important to understand the fundamental purpose of this requirement, the nature of the requirement, criticisms of the requirement, and three different alternatives.

Benefits of Biomedical Research

Although biomedical research may have intrinsic merit in expanding understanding of human biological systems, it is fundamentally a practice with instrumental value. The ultimate aim of biomedical research is not just to increase knowledge but to improve human health and well-being.^{2–4} The fundamental ethical challenge is that the people and communities that participate in research are assuming risks and burdens, whereas the benefits of the knowledge gained from research can extend to many other people who have not assumed any risks or burdens. That some might benefit because others are exposed to risks raises the specter of exploitation⁵ (see Chapter 20).

This risk of exploitation is inherent in all biomedical research that might benefit people beyond those actually enrolled in the research study.^{6,7} It is particularly worrisome in situations in which those who participate as subjects in the research are less likely to actually benefit from the research itself or the results of the research. They might not benefit because they are poor and cannot afford the intervention, because they live in communities that lack the infrastructure or health-care personnel to deliver the intervention, or because their community is poor and the companies marketing the intervention might not deem it financially worthwhile to have the intervention licensed and distributed there. These are conditions that are more frequent in developing countries.⁸ Consequently, the concern about ensuring that participants and communities benefit from research has arisen most

forcefully and consistently in relationship to research conducted in developing countries.⁹

In order to avoid or minimize the possibility of exploitation, those who assume the risks and burdens of research should be assured of receiving fair benefits from the research.^{5,7} This notion is embedded in the ethical requirement that biomedical research has social value. The challenge is how to fulfill this requirement of ensuring that the research participants and community who bear the burdens and risks actually benefit. In what follows, I will present and critically assess the reasonable availability requirement and three alternate accounts.

Reasonable Availability

The most influential attempt at ensuring that participants and communities, especially those in developing countries, benefit from participating in biomedical research has been the reasonable availability requirement.¹⁰ The Council for International Organizations of Medical Sciences (CIOMS) proposed this requirement in its 1993 *International Ethical Guidelines for Biomedical Research Involving Human Subjects*. In the commentary to Guideline 8, "Research involving subjects in underdeveloped communities," CIOMS argued the following:

As a general rule, the sponsoring agency should ensure that, at the completion of successful testing, any product developed will be made reasonably available to inhabitants of the underdeveloped community in which the research was carried out; exceptions to this general requirement should be justified, and agreed to by all concerned parties before the research is begun.¹⁰

This requirement was reemphasized in the commentary to Guideline 15, "Obligations of sponsoring and host countries," which stated,

As a general rule, the sponsoring agency should agree in advance of the research that any product developed through such research will be made reasonably available to the inhabitants of the host community or country at the completion of successful testing.¹⁰

Furthermore, the 2002 revision of the CIOMS Guidelines reemphasized this requirement. Reasonable availability was not just included in a commentary but made part of Guideline 10 which requires that

[b]efore undertaking research in a population or community with limited resources, the sponsor and the investigator must make every effort to ensure that . . . any intervention or product developed, or knowledge generated, will be made reasonably available for the benefit of that population or community.¹¹

In the commentary on this Guideline, CIOMS justified this requirement by stating that it was necessary to avoid exploitation:

If the knowledge gained from the research in such a country is used primarily for the benefit of populations that can afford the tested product, the research may rightly be characterized as *exploitative* and, therefore, unethical. . . . In general, if

there is good reason to believe that a product developed or knowledge generated by research is unlikely to be reasonably available to, or applied to the benefit of, the population of a proposed host country or community after the conclusion of the research, it is unethical to conduct the research in that country or community [emphasis added].¹¹

In the years since its original formulation, many individuals and groups have supported the reasonable availability requirement as necessary for ethical research in developing countries. For instance, Crouch and Arras:

agree with the Council for International Organizations of Medical Sciences (CIOMS) guidelines and with many observers that in order to be judged ethical and non-exploitative in the final analysis, such research must not only address local problems, but the results must also be made reasonably available to local populations.¹²

The chair and executive director of the National Bioethics Advisory Commission (NBAC) in the United States argued that

[i]f the intervention being tested is not likely to be affordable in the host country or if the health care infrastructure cannot support its proper distribution and use, it is unethical to ask persons in that country to participate in research, since they will not enjoy any of its potential benefits.¹³

And NBAC argued in its report on the topic, *Ethical and Policy Issues in International Research: Clinical Trials in Developing Countries*,

NBAC concludes that at the end of a clinical trial that results in an effective intervention, research participants should be provided with this intervention. In addition, NBAC concludes that before initiation of a research project, researchers or sponsors should consider how they might make benefits, if any, available to others in the host country with the understanding that appropriate host country decisionmakers must be meaningful and essential participants in making such arrangements.¹⁴

The second point in the UNAIDS guidance document entitled *Ethical Considerations in HIV Preventive Vaccine Research* states,

Any HIV preventive vaccine demonstrated to be safe and effective, as well as other knowledge and benefits resulting from HIV vaccine research, should be made available as soon as possible to all participants in the trials in which it was tested, as well as to other populations at high risk of HIV infection. Plans should be developed at the initial stages of HIV vaccine development to ensure such availability.¹⁵

The guidance document's elaboration of this point states that "making a safe and effective vaccine reasonably available to the population where it was tested is a basic ethical requirement."¹⁵ Thus, the authors of the UNAIDS document make clear that they think reasonable availability is a fundamental ethical requirement beyond debate.

Similarly, the health law and bioethics group at Boston University has strongly advocated reasonable availability:

In order for research to be ethically conducted [in a developing country] it must offer the potential of actual benefit to

the inhabitants of that developing country. . . . [F]or underdeveloped communities to derive potential benefit from research, they must have access to the fruits of such research.¹⁶

And the Boston University bioethicists argue that without reasonable availability, the participants and community will be exploited:

Unless the interventions being tested will actually be made available to the impoverished populations that are being used as research subjects, developed countries are simply *exploiting* them in order to quickly use the knowledge gained from the clinical trials for the developed countries' own benefit [emphasis added].¹⁷

Although avoiding the phrase *reasonable availability*, even the 2000 revision of the Declaration of Helsinki seems to endorse something like the requirement in paragraph 19:

Medical research is only justified if there is a reasonable likelihood that the populations in which the research is carried out stand to benefit from the results of the research.¹⁸

Specification of the Reasonable Availability Requirement

Although widely supported, the reasonable availability requirement is vague. CIOMS acknowledges in its 2002 guidelines that “the issue of reasonable availability is complex and will need to be determined on a case-by-case basis” and then lists myriad “relevant considerations.”¹¹ Four main issues require specification: (1) the nature of the commitment; (2) who is responsible for fulfilling the requirement; (3) what constitutes making something reasonably available; and (4) who must have access (see Table 65.1). On each of these issues there has been a very wide range of answers. Thus, despite agreement on the very general reasonable availability requirement, there is substantial disagreement on how it should be specified and actually put into practice.¹⁹

First, how strong or explicit should the commitment to provide the drug or vaccine be at the initiation of the research trial? CIOMS seems to require an explicit, almost contract-like mechanism, agreed to before the trial. CIOMS’s guidelines state that this commitment should be “[a]greed to by all concerned parties before the research is begun” and that the “[s]ponsoring agency should agree in advance of the research.”¹¹ The 2000 revision of the Declaration of Helsinki endorses a much less explicit and stringent guarantee; it does not require availability to be ensured in advance.¹⁸ Conversely, NBAC goes further than CIOMS, not only requiring “agreements” but also requiring that mechanisms to ensure affordability and infrastructure to “support [the new intervention’s] proper distribution and use” are in place.¹⁴ Some commentators go further still, arguing that reasonable availability means more than “the mere assertion that the interventions will be feasible for use in the developing countries.” Rather, prior to beginning a study there needs to be “a real plan as to how the intervention will actually be delivered,” and this includes “identified funding” for upgrades to health-care infrastructure and roads if necessary.^{16,17}

Second, the original 1993 CIOMS requirement placed responsibility for ensuring reasonable availability on the sponsoring agency: “As a general rule, the sponsoring agency should ensure. . . .”¹⁰ The 2002 version expands this responsibility to include “the sponsor and investigator.”¹¹ NBAC suggests that the responsibility for the plan be on “researchers or sponsors,” although it is unclear who has responsibility for the actual provision.¹⁴ Conversely, the Declaration of Helsinki fails to specify who is responsible for guaranteeing reasonable availability.¹⁸ Importantly, the UNAIDS document suggests that the responsibility for fulfilling this requirement is broad-based, encompassing not just “health and research communities” but also “representatives from the executive branch, health ministry, local health authorities, and relevant scientific and ethical groups” in the host country.¹⁵ And still others seem to lay responsibility on “developed countries” without specifying any particular actors. Interestingly, although both CIOMS and NBAC suggest that host country decision makers be participants in negotiations about providing the

Table 65.1
Issues Involved in the Reasonable Availability Requirement

Source	How Strong and Explicit a Commitment?	Who Is Responsible?	When Is Access Reasonably Available?	Who Should Be Guaranteed Reasonable Availability?
CIOMS ¹¹	“Agree in advance of the research”	Sponsors and investigators	Unspecified	“Inhabitants of underdeveloped community in which the research was carried out” “Host community and country”
NBAC ¹⁴	“Negotiations and agreements” preceding the start of research, which include provisions for enhancing infrastructure	“Researchers or sponsors”	Unspecified	“Host country”
Helsinki ¹⁸	Does not require specific prior agreement	Unspecified	Unspecified	“Population in which the research is conducted”
Annas, Grodin, et al. ^{16,17}	Requires definitive commitments, including “funding identified”	Developed world	“Proper distribution and use”	“Host country”

interventions, almost none of the guidelines or commentators place *responsibility* for making drugs and other interventions available on the governments of developing countries.

Third, when is access reasonably available? Does going through the host country's regulatory process and licensing a new drug or technology qualify as making it reasonably available? Can the drug or intervention be priced at a market price, or does it have to be free to be reasonably available? What if it is provided at a subsidized price but is not free? If a new drug is provided at a subsidized price but many people still cannot afford it, is it reasonably available? None of the guidelines or commentators seems to accept licensing with the price set at a market rate as sufficient to satisfy "reasonable availability." However, neither do any of the guidelines or commentators specify how this issue should be resolved or offer a rationale for resolving it.

Fourth, to whom should the drug or other intervention be made reasonably available? The range of possibilities extends from the research participants, their local community, the region of the country from which they come, the entire country in which the research was conducted, the geographic region of the continent where the research was conducted, finally to every person who needs the intervention in the world. The choice obviously has substantial financial and logistical implications. Indeed, it may also influence the selection of research sites. If the sponsor or researchers have responsibility for providing the intervention to the host country, then there will be bias against conducting research projects in populous countries such as India or Indonesia, in favor of less populous countries such as The Gambia. CIOMS clearly suggests that the requirement extends beyond the research participants to the "host community or country."¹¹ But CIOMS does not specify what the parameters of the "host community" are, whether they are limited to villages, neighborhoods of cities, entire cities, or provinces. The Declaration of Helsinki also seems to suggest that the requirement extends beyond the research participants but uses the ambiguous phrase, the "population in which the research is carried out."¹⁸ NBAC seems to endorse the "host country."¹⁴ Annas and Grodin also contend that the entire "host country" must have the drug or intervention reasonably available.¹⁷ However, these guidelines and commentators do not offer a principled justification why they select the group they do.

Criticisms of the Reasonable Availability Requirement

Although ambiguity of the reasonable availability requirement is a problem, there have been other challenges. Nine distinct criticisms have been articulated challenging the very notion that reasonable availability is an ethical requirement for research in developing countries²⁰ (see Table 65.2).

First, and most important, critics argue that the reasonable availability requirement mistakes how to properly address exploitation.²⁰ Reasonable availability focuses on guaranteeing a *particular type* of benefit, but the fundamental requirement for addressing exploitation is to ensure a *fair level* of benefits, given the burdens and risks someone assumes as a research participant and the benefits others obtain.⁵ The key to exploitation is not *what* item people get, but *how much* they get.²¹ Another way to put this is that reasonable availability is like requiring that the baker gets access to bread rather than ensuring the baker is paid a fair amount of money.

Critics claim that CIOMS and others fail to understand the nature of exploitation and therefore miss the appropriate solution. Guaranteeing that a drug or other intervention is made available to the local community may correspond to the fair level of benefits sometimes, by chance, but at other times it may not correspond to the fair level of benefits.²⁰ For instance, for a very risky study, reasonable availability may not be fair because it is too little. Conversely, for a very safe trial, such as a vaccine trial, the reasonable availability requirement may necessitate providing too much benefit. A better approach is to calibrate the benefits to the burdens, rather than to guarantee a particular type of benefit.

Second, critics argue that the reasonable availability requirement seems to embody a very narrow notion of benefits. Everyone agrees that to avoid exploitation, participants and the community bearing the burden must receive a fair level of benefits.^{5,20,21} However, critics argue that the reasonable availability requirement seems to count only availability of the drug or intervention as a benefit. There are many benefits from the both the conduct and results of research beyond availability of the drug or other intervention: training of health-care personnel, construction of health-care facilities or other physical infrastructure, provision of health-care services beyond those required in the research study, and even declines in disease prevalence, such as drops in HIV, from educating the population about health care. These, too, must be considered in the evaluation of whether the research benefits the participants and larger community. Yet these are completely ignored by the reasonable availability requirement.^{20,21}

Third, the various conceptions of the reasonable availability requirement provide no justification for who should receive the benefits. The requirement is meant to minimize the chance of exploitation. Therefore, the requirement should be directed at those who are at risk of exploitation. This is not likely to be the entire host community and certainly should not include the whole country in which the research is being conducted.^{20,21} Critics argue that those who would require the entire country to receive reasonable availability to the drug in order to avoid exploitation, such as the Boston University group,^{16,17} have a mistaken notion of exploitation.

In the context of research, exploitation occurs when those who bear the risks and burdens of research are not provided sufficient benefits.^{5,20} Ethics requires ensuring that the research participants who clearly bear burdens receive benefits. The local community should benefit, to the extent it bears any burdens of the research. This suggests that the benefits should focus on the research participants and the host community to the degree that they bear risks and benefits. Because the entire country is unlikely to bear risks, it is not ethically entitled to benefits in order to avoid exploitation.

Fourth, the Nuffield Council on Bioethics argues that the reasonable availability requirement fails to acknowledge the actual process of translating research results into practice.²² Few drugs, vaccines, or other interventions are introduced into use based on the results of a single trial. As the Council notes,

A fundamental problem that must be acknowledged is that current guidance fails to reflect the reality that only rarely does a single research study lead to the discovery of a new intervention that can be introduced promptly into routine care. For example, before mefloquine was registered as an anti-malarial medicine, the [World Health Organization] WHO

Table 65.2
Nine Criticisms of Reasonable Availability

Criticism	Explanation
Mistaken conception of exploitation	Reasonable availability focuses on a type of benefit but exploitation focuses on a fair level of benefits. It is not what people get but how much they get.
Narrow conception of benefits	Reasonable availability counts only access to a drug, vaccine, or intervention as a benefit, and ignores other benefits, such as training, infrastructure, or health services.
Excessively wide group of beneficiaries	Reasonable availability requires access for host community or country. But addressing exploitation requires benefits only for those bearing risks or burdens of research, with no justification for conferring benefits on a whole country that does not bear a burden of research.
No single trial is definitive	Reasonable availability requires access to a drug, vaccine, or intervention after a single trial. But often it takes multiple confirmatory trials to prove the safety and effectiveness of an intervention.
Reasonable availability of knowledge undermines benefit	2002 CIOMS revision suggests obligation can be met by reasonable availability of “knowledge generated.” This dilutes importance of requirement.
Uncertainty of benefit	Reasonable availability requires benefit after successful testing. But in Phase III trials, equipoise holds that only half of new interventions are successful. Thus, new drug will be made available only in half of trials.
Misplaces responsibility for implementation	Reasonable availability places responsibility for providing drug onto sponsors and researchers who are not responsible for drug or vaccine regulatory approval and lack authority to provide development aid for provision of drugs or vaccines.
Unrealistic timeline for implementation	Reasonable availability requires rapid implementation. But even if not immediately implemented, some interventions can be implemented over time as prices fall and data on utility accumulates.
Providing one drug may be “golden handcuff”	Reasonable availability secures a particular drug, vaccine or other intervention. But if research proves another intervention is better, the community may be guaranteed the old drug not the newer, more effective one.

Special Programme for Research and Training in Tropical Diseases (TDR) conducted 18 studies on three continents.²²

Such a situation seems to be occurring regarding circumcision for prevention of HIV.²³ Despite one “successful” trial showing the efficacy of circumcision, many people are awaiting data from several confirmatory trials before evaluating whether this intervention should be recommended.²⁴ This is the natural process of evaluating health-care interventions. It means that it may be impossible from scientific and health policy standpoints to actually approve a medication after one or even a few “successful” trials. Data from other confirmatory trials might be necessary before an intervention can and should be made available.

Fifth, CIOMS changed the reasonable availability requirement in a way that undercut its impact. Between 1993 and 2002, CIOMS altered its requirement from reasonable availability of drugs and interventions to “ensuring that any intervention or product developed, *or knowledge generated*, will be made reasonably available for the benefit of the population or community [emphasis added]”^{10,11} Questions have been raised about whether adding this knowledge clause actually undermines the requirement.

Initially, the requirement seemed to be written with the idea that every research trial would result in a successful new drug or intervention that could then be distributed to the community. But it seemed to ignore or overlook early Phase I research that does not prove the effectiveness of a drug or other intervention but may only assess safety. In the 1993 requirement, CIOMS prohibited Phase I and II trials from being conducted in the developing countries to ensure that research did produce proven interventions that could be made reasonably available: “Phase I drug studies and Phase I and II vaccine studies should be conducted only in developed communities of the country of the sponsor.”¹⁰ How-

ever, this limitation was attacked by representatives of developing countries who objected to the restriction and demanded that Phase I and II studies be conducted in their countries. But Phase I and many Phase II research trials do not generate proven drugs or interventions that can be made reasonably available.

To address this problem, the 2002 CIOMS guideline included reasonable availability of the knowledge generated from the study.¹¹ Critics claim that CIOMS’s phrasing is problematic. It is not clear what making knowledge *reasonably available* means. Does this mean publishing it? Translating the data in the local language? More importantly, if interpreted as actually written, with the crucial word “or,”—that is, requiring that “any intervention or product developed, *or knowledge generated*, will be made reasonably available [emphasis added]”—then a sponsor could choose to provide *either* the product *or* the knowledge. Obviously providing the knowledge—the study data—is relatively easy and cheap and would obviate the need to provide the actual intervention. This phrasing seems to dilute the importance of the reasonable availability requirement.

Sixth, it has been argued that even in Phase III studies, the reasonable availability requirement provides an uncertain benefit to the community because it makes benefits dependent on whether the trial is a “successful testing” of a new product. If there is true clinical equipoise prior to the initiation of a Phase III trial conducted in a developing country, then the new intervention should be proven more effective in only about half of the trials.²⁵ Consequently, reliance on the reasonable availability requirement to provide benefits implies that the host community will receive sufficient benefits from only half or so of all Phase III studies. This is a very limited benefit.

Seventh, some critics argue that CIOMS is wrong in placing the responsibility for reasonable availability on researchers and

sponsors. They are researchers, not health policy makers or development funders. As the Nuffield Council argued,

[T]here is general agreement that researchers have some responsibilities regarding the provision of an effective intervention after a trial has ended, but disagreement about how far that responsibility extends. Certainly, the main function of the researchers is to undertake research. They cannot be expected to adopt a leading role in making effective interventions available.²²

Others have concurred, noting that it is often beyond the legal authority of researchers and some sponsors to guarantee reasonable availability. For instance, the National Institutes of Health (NIH) in the United States and the Medical Research Council (MRC) in Britain do not control drug approval processes in their own countries, much less in developing countries.²⁰ Further, the NIH and the MRC are legally limited to funding research and prohibited from funding development or health-care provision. Budgets for development and health-care services are usually in different government agencies, such as the U.S. Agency for International Development, and different departments, such as the Department of State, and are subject to different requirements than are medical research grants. Researchers and even sponsors usually have limited influence over the priorities of those agencies. The reasonable availability requirement, critics argue, is naïve and unrealistic about the actual workings of governments and foreign aid.

Eighth, critics have argued that the reasonable availability requirement implies too short a time horizon for implementation of interventions. The requirement fails to acknowledge that an intervention may be costly just after completion of the research, but that costs may drop—often substantially—over time, thereby expanding opportunities to implement the intervention and improve health. The Nuffield Council mentions the Hepatitis B vaccine and an integrated package of interventions to improve child mortality that had high initial costs.²² But over time the costs fell substantially, and host governments became more willing to allocate resources to the interventions. The Council warns that by implying that the intervention must be made available within a short time, the requirement might forestall its subsequent adoption:

[T]he costs of some interventions shown to be successful may not decline significantly until some time after the conclusion of the research. To describe all such research as therefore unethical may lead to the loss of [subsequent] opportunities to improve health care.²²

Finally, there is a worry that in the dynamic world of biomedical research, a pledge of reasonable availability of a single drug or intervention might become a “golden handcuff.”²⁰ Agreement to receive a specific drug, vaccine, or other intervention proven in the trial, rather than cash or some other transferable benefit, commits the population to using the specific intervention tested in the trial. But what happens if another drug, vaccine, or other intervention is proven more effective but in a different community? Pharmaceutical companies might be willing to provide their own drug directly, but would be unwilling to provide the product of a competitor. So the original community becomes tied to an outmoded intervention. This scenario is not so implausible. Such quick changes have occurred in the best drugs for prevention of maternal-fetal HIV transmission.

Some argue that an agreement guaranteeing reasonable availability could have an escape clause, requiring that if a more effective intervention is developed, the sponsor would provide money to the host community so that it could purchase the new, more effective intervention. It seems highly unlikely that any sponsor would consent to such an arrangement. Moreover, this response seems to recognize that the real benefit is not reasonable availability to the specific proven intervention but resources—the money—to purchase a set of benefits that the community deems valuable, which itself may evolve. Indeed, the idea that the community could have a clause requiring the sponsor to pay instead of making the drug, vaccine, or other intervention available undermines the ethical justification of the reasonable availability requirement itself. Once a specific proven drug is not deemed an indispensable benefit, the rationale for the reasonable availability requirement is negated.

Nuffield Council on Bioethics

One alternate account of providing benefits to host countries is that of the Nuffield Council. The Council does not endorse the reasonable availability requirement, but unfortunately has not offered an integrated alternative requirement. The Council seems to suggest that six actions are ethically necessary.²² First, participants in the trial should be monitored for possible long-term deleterious outcomes of the research beyond the completion of the trial. Second, members of both the control group and the intervention group should be provided “the intervention shown to be best (if they are still able to benefit from it) for an agreed period of time.” Third, the availability or unavailability of treatment beyond the end of the trial should be clearly explained to prospective participants during the consent process. Fourth, explorations should be made whether the treatment shown to be better can be introduced in a sustainable manner to the whole community or the country where the research was conducted. Fifth, the Nuffield Council endorses the NBAC’s recommendation that proposals submitted to institutional review boards (IRBs) or other research ethics committees (RECs) should include provisions for making new proven interventions available to some or all of the host country population, or should explain why the research should be done even if this is impossible.²² Finally, the Council requires that all research strengthen the capacity of developing countries to conduct health research: “Genuine partnerships should be promoted in order to strengthen expertise in research and institutional development and to maximize opportunities for the transfer of skills and knowledge.”²²

Fair Benefits Framework

Probably the most developed and detailed alternative to the reasonable availability requirement is the fair benefits framework.^{20,21} This view was elaborated by a widely representative group of researchers, IRB members, bioethicists, and others from the United States, Europe, and eight African countries at a conference in Malawi in 2001.

The fair benefits framework makes two fundamental assumptions. First, the key to avoiding exploitation is ensuring that the people who bear the risks and burdens of research receive fair benefits through the conduct and/or results of research. Second,

all types of benefits that might flow from research, not just access to a tested drug, must be considered in determining the fair benefits. The population at risk for exploitation is the relevant group to receive benefits; this includes the participants in the research study as well as any members of the community who might also bear burdens and risks for carrying out the research.

The fair benefits framework supplements the usual conditions for the ethical conduct of research. In this sense, it applies in addition to ensuring that the research has social value, that participants are selected fairly, that the research study has been subject to independent review by an IRB or REC, and that individual participants provide informed consent.^{6,7} Most importantly, the fair benefits framework is in addition to the risk-benefit evaluation of the particular study. The risk-benefit ratio of the study must be favorable; the benefits to individual prospective participants must outweigh the risks, or the net risks must be acceptably low.

To these widely accepted principles for evaluating the ethics of individual research studies, the fair benefits framework adds three additional principles for ensuring that study participants and others who bear burdens of the research get a fair share of the benefits of the research (see Table 65.3).

Principle 1: Fair Benefits. There should be a comprehensive delineation of tangible benefits to the research participants and the population from both the conduct and the results of research. These benefits can be of three types: (1) benefits to research participants during the research, (2) benefits to the population during the research, and (3) benefits to the participants and/or the population after completion of the research. It is not necessary to

provide each of these types of benefits. The ethical imperative is for a fair level of benefits. As the burdens on the participants and the community increase, so the benefits must increase. Similarly, as the benefits to the sponsors, researchers, and others outside the population increase, the benefits to the host population should also increase.

Principle 2: Collaborative Partnership. The population being asked to enroll determines whether a particular array of benefits is sufficient and fair. Just as there is no agreement on what constitutes a fair wage, there is no shared international standard of fairness in terms of benefits from a study; reasonable people disagree.²⁶ More importantly, only the host population can determine the value of the benefits for itself. Outsiders are likely to be poorly informed about the health, social, and economic context in which the research is being conducted, and they are unlikely to fully appreciate the importance of the proposed benefits to the population.

The population's choice to participate in the research must be free and uncoerced; refusing to participate in the research study must be a realistic option. Although there can be controversy about who speaks for the population being asked to enroll, this is a problem that is not unique to the fair benefits framework. Even—or especially—in democratic processes, unanimity of decisions cannot be the standard; disagreement is inherent in democracy. But how consensus is determined in the absence of an electoral process is a complex question in democratic theory beyond this framework to resolve.

Principle 3: Transparency. Because equity is determined by comparisons with similar interactions, fairness is relative. Therefore,

Table 65.3
Principles and Benchmarks of the Fair Benefits Framework

Principles	Benchmarks for Determining Whether the Principle Is Honored
Fair benefits	<ul style="list-style-type: none"> • Benefits to participants during the research <ol style="list-style-type: none"> 1. <i>Health improvement:</i> Health services that are essential to the conduct of the research that improve the health of the participants 2. <i>Ancillary health services:</i> Health services beyond those essential to the conduct of the research that are provided to the participants • Benefits to participants and population during the research <ol style="list-style-type: none"> 1. <i>Ancillary health services:</i> Health services provided to the population 2. <i>Public health measures:</i> Additional public health measures provided to the population 3. <i>Employment and economic activity:</i> The provision of jobs for the local population that stimulate local economic activity • Benefits to population after the research <ol style="list-style-type: none"> 1. <i>Availability of the intervention:</i> Provision of the intervention if it is proved safe and effective 2. <i>Capacity development:</i> Improvements in the health-care infrastructure, training of health-care and research personnel, and training of research personnel in research ethics 3. <i>Public health measures:</i> Additional public health measures provided to the population 4. <i>Long-term collaboration:</i> Development of additional research projects with the population 5. <i>Financial rewards:</i> Sharing of the financial rewards or intellectual property rights related to the intervention being evaluated
Collaborative partnership	<ul style="list-style-type: none"> • <i>Free, uncoerced decision making:</i> The population is capable of making a free and uncoerced decision; it can refuse participation in the research. • <i>Population support:</i> When it has understood the nature of the research trial, the risks and benefit to individual participants, and the benefits to the population, the population decides that it wants the research to proceed.
Transparency	<ul style="list-style-type: none"> • <i>Central repository of benefits agreements:</i> An independent body creates a publicly accessible repository of all formal and informal benefits agreements. • <i>Community consultation:</i> Forums with populations may be invited to participate in research, informing them about previous benefits agreements.

transparency—like the full information requirements for ideal market transactions—is necessary to allow comparisons with similar transactions. A population in a developing country is likely to be at a distinct disadvantage, relative to a sponsor from a developed country, in determining whether a proposed level of benefits is fair. To address these concerns, a publicly accessible repository of all benefits agreements should be established and operated by an independent body, such as the World Health Organization (WHO). Such a repository would permit independent assessments of the fairness of various benefits agreements by populations, researchers, governments, and others, such as nongovernmental organizations. Such a repository would facilitate the development of a *case law* set of standards of fairness that can evolve out of a number of agreements.

Along with the usual eight requirements for ethical research,^{6,7} the principles of the fair benefits framework ensure that (1) the population has been selected for a good scientific reason; (2) the research poses few net risks to the research participants; (3) there are sufficient benefits to the research participants and population; (4) the population is not coerced into participation; (5) the population freely decides whether to participate and whether the level of benefits is fair given the risks and burdens to the population of the research; and (6) there is an opportunity for comparative assessment of the fairness of the benefits agreements.

Criticism of Fair Benefits Framework

There has been limited criticism of the fair benefits framework, possibly because only a relatively short amount of time has elapsed since its delineation. Three main criticisms have been leveled.

First, the fair benefits framework accepts “the status quo in the host community as normative baseline for assessing research.”²⁷ This creates unequal bargaining, with the researchers from developed countries having more power to wait or go to alternative research venues. Thus researchers impose their agenda on developing countries. Second, using the status quo as the baseline means it is possible that “each party [can secure] a net benefit [and yet] the distribution of those benefits is hugely disproportionate.”²⁷ Finally, the fair benefits framework fails to delve into “root causes” of ill health but concentrates on the “symptomatic manifestations of deeper problems.” In this regard, it leads to a “piecemeal and ad hoc approach to the needs of those in the developing world.”²⁷ It focuses on health but does not explore other social structures that might improve health, such as the power distribution in a community, education of women, and so forth. Despite permitting benefits in many different sectors, from economic improvements to education, the fair benefits framework does not offer an integrated, unified approach to solving the problems of developing countries.

Importantly, these criticisms seem to apply not just to the fair benefits framework but also to the reasonable availability requirement. After all, the reasonable availability requirement accepts the status quo as the baseline for determining that availability to a new drug should be required. Moreover, its focus is decidedly piecemeal and partial. It considers benefits only in one sector—availability of drugs, vaccines, or other health-related interventions. By contrast, the fair benefits framework requires that in determining fair benefits, all sectors be assessed—ranging from economic conditions to education to public health measures.

The criticisms seem to miss the fact that the fairness of agreements is not determined just by bargaining. The purpose of the transparency principle is to provide an external check that independently assesses the fairness of agreements.

Human Development Approach

Yet another procedure for achieving fairness for research participants is known as the human development approach, proposed by Alex London.²⁷ It has only been outlined in the most general of ways. Importantly, it does not attempt to address just the problem of exploitation by researchers from developed countries conducting research in developing countries. Rather, it seeks to address global injustice. Further, the particular conception of justice involved is one that calls on people in developed countries—including researchers—to establish and foster “basic social structures that guarantee to community members [in developing countries] the fair value of their most basic human capacities.”²⁷

This is a very abstract claim. Its elucidation seems to imply two specific obligations. First, researchers must target “rudimentary health problems that can impede the ability of community members to function . . . [including] literacy and education . . . providing basic nutrition and rudimentary health care.”²⁷

Second, researchers must “expand the capacity of the basic social structures of that community to better serve the fundamental interests of that community’s members.” Furthermore, collaborative research initiatives “must directly and indirectly expand the capacity of the host community’s basic social structures either to meet the distinctive health priorities of that community’s members or to meet their basic health needs under distinctive social or environmental circumstances.”²⁷

It is a bit unclear what this means in a practical sense, but it does suggest that the emphasis must be on capacity development in the broadest sense. Indeed, the only specific suggestion to researchers from the human development approach is the following:

The imperative to try to make the results of successful research available within the host community increases in inverse proportion to the capacity of that community’s basic social structures to translate those results into sustainable benefits for community members. To the extent that the host community cannot translate the results into sustainable benefits for its population on its own, an imperative exists either to build partnerships with groups that would be willing to augment the community’s capacity to do so, or to *locate the research within a community with similar health priorities and a more appropriate health infrastructure*. Similarly, the imperative to provide an array of ancillary benefits to community members increases in inverse proportion to the community’s capacity to treat or ameliorate the ancillary health problems that researchers are likely to encounter [emphasis added].²⁷

Criticism of the Human Development Approach

The abstract nature and vagueness of the human development approach makes it difficult to be certain what it requires. But five preliminary criticisms seem plausible.

First, it mistakes the problem that ensuring benefits to host countries is meant to address. Most people accept that global injustice and exploitation are major ethical problems in the world. However, the purpose of specifying the extent of the obligation to provide benefits to developing countries that participate in biomedical research projects is to minimize the possibility of exploitation by developed country researchers and sponsors. Such benefits are not meant to address underlying background global injustice. The human development approach is thus speaking to a different issue from that being addressed by the reasonable availability requirement or fair benefits framework. There is a disconnect between the ethical challenges posed by conducting research trials in developing countries and the issues the human development approach takes itself to be addressing.

Second, the human development approach seems most relevant in helping to specify what research questions are being pursued in developing countries, rather than the benefits that flow from specific research protocols. That researchers should target “rudimentary health problems” that impede function seems to define the research agenda. It is not helpful in specifying what and how much benefits—in health, economic conditions, capacity development, and so forth—researchers or sponsors owe to the host community based on the specific projects to be initiated.

Third, depending on interpretation, the human development approach is too demanding, too undemanding, or too abstract and vague to be action-guiding. On one interpretation, the requirement to “expand the capacity of the host community community’s basic social structure to better serve the fundamental interests of that community’s members” is too expansive. This requirement seems to entail changing the entire fabric of a developing country’s society. Such an imperative is way beyond the legitimate requirements than can be asked of researchers or sponsors who are trying to conduct trials of prospective malaria or HIV vaccines. Conversely, if the requirement is simply to increase, by any amount, the capacity of a community’s health-care system, then this seems even more minimalist than the reasonable availability requirement or the fair benefits framework. Almost anything a developed country research team might do—train some local people to help with the project, build a clinic, provide economic stimulus—would count as expanding the capacity of the social structures. That such contradictory interpretations seem possible suggests that this requirement is too amorphous to specify for a researcher, or a sponsor, or an IRB what exactly must be done to fulfill the requirement.

Fourth, the *inverse proportion* standard seems unjustified. The human development approach seems to require researchers to provide ancillary benefits not based on what the researcher does, but based on the community’s preexisting needs. This raises many problems. Practically, this would create a huge disincentive to conduct research in very poor settings, because the obligations on researchers would be greater. Ethically, obligations typically depend on what one party owes, which is independent of the needs of the party to whom the obligation is owed. But under the human development approach, the extent of the obligation seems independent of the kind or magnitude of the researchers’ study. The same obligation seems to exist whether the researcher is conducting a small Phase I study or a massive Phase III vaccine trial. In addition, this approach seems to increase researchers’ obligations if others shirk their duty. If the obligations of researchers depend upon the extent of poverty or the inadequacy of community social

structures, the researchers’ obligations seem to depend upon whether others are fulfilling their duties.²⁸ A community could have terrible poverty or poor community social structure because its rulers are terribly corrupt. Why should a researcher’s obligations to provide benefits then increase? Obligations to help the poor of the world should not increase because their poverty is made worse by the shirking of obligations by others or by corruption or by problems of the community’s own making.²⁸

Finally, there is a deep contradiction in the human development approach’s recommendations. The only specific requirement from the human development approach seems to be that researchers ensure that the community where a trial is conducted can “translate those [research] results into sustainable benefits for community members.” This seems to mean that researchers must augment the community’s capacities to help its population. But if the community lacks the capacity to “translate those results,” then the researchers have no obligation with respect to it. According to the human development approach, the researchers should go somewhere else; they should conduct their research in a community “with similar health priorities [as the researcher] and a more appropriate health infrastructure.” This seems to suggest that researchers do not have obligations to help poorer communities but can pick and choose the community they conduct their research in. They can minimize their obligations by going to better off communities that already have the appropriate infrastructure. Thus, the specific guidance from the human development approach directly contradicts its ethical foundation, namely that “claims of justice cannot be limited to the boundaries of the contemporary nation-state” and that obligations go to enhancing the “most basic human capacities,” not just those of people in countries that have appropriate infrastructure. Indeed, the specific practical recommendation of the human development approach seems to mesh with one interpretation of the reasonable availability requirement, namely, that research is ethical only if there is already sufficient infrastructure to make the proven drug, vaccine, or other intervention available.

Conclusion

There is widespread agreement that to avoid exploitation, researchers must ensure that the participants and host community in which the research is conducted benefit from the research. The people and the host community could benefit from the conduct of the research and/or its results. Disagreement focuses on how they should benefit. Four different approaches have been offered. The reasonable availability requirement claims they must benefit by being given the drug or other intervention proven effective in the trial; that is the only ethically appropriate way for them to benefit. The Nuffield Council seems to think that providing the actual participants the intervention and providing capacity development to the larger community is sufficient. The fair benefits framework requires the participants and host community receive a fair level of benefits chosen from a collection of ten potential types of benefits. Finally, the human development approach requires enhancement of basic human capacities of host communities, with the level of enhancement determined by the level of deprivation of the community. Over time, the implications of these various approaches will be evaluated with appropriate refinements made.

The Standard of Care in Multinational Research

Introduction and History

Although the issue concerning *standard of care* has become prominent in the controversy concerning HIV/AIDS research in developing countries, it is not a new problem, nor is it a problem that only occurs in relation to multinational research.

Any biomedical research project in which the research protocol envisages that a group of, or all of, the research participants will receive a level of treatment that is less than the ordinary standard of care raises the issue of whether this is ethically justified. It is thus an issue that occurs in all randomized trials with a placebo group, if there is a known effective treatment.

The nature of the standard of care discussion has been influenced by the debate over the perinatal HIV transmission studies in the late 1990s and the historical development and the specific wording of the World Medical Association's (WMA's) Declaration of Helsinki¹ and the Guidelines of the Council of International Organizations of Medical Sciences (CIOMS)² (see Chapters 13 and 16). We will therefore initially present a short outline of the case that opened the standard of care debate and of the development of the regulatory instruments, in particular the Declaration of Helsinki. (Various national regulations also cover this issue, but we have decided not to include them in this analysis because of their great variability and limited relevance outside of their national context.)

In 1994, the AIDS Clinical Trial Group 076 study established that treating HIV-infected mothers with AZT during the last trimester of pregnancy, intravenously during delivery, and treating the newborn child for six weeks after birth dramatically reduced

perinatal HIV transmission, but at a cost of about US \$800 per pregnancy.³ This made the 076 regimen unaffordable in all of sub-Saharan Africa, in countries with the highest number of perinatal transmissions. The regimen was also logistically difficult to implement as part of routine prenatal care in other high prevalence countries. There was therefore an urgent need to develop affordable and feasible alternatives for these countries, and a number of trials with shorter versions of the regimen were initiated. All of these, except one trial in Thailand, used placebo in the control group. These studies led to a fierce debate about whether it is ever justified to use a lesser standard of care for the control group, in this case placebo, rather than the state of the art intervention, in this case the 076 regimen.

Although there was some criticism of the placebo studies in the literature from 1995,⁴ not much happened until the Public Citizen Health Research Group criticized the trials in a congressional hearing on bioethics in May of 1997.⁵ There were a number of news reports of these hearings, but they went largely unnoticed by the general media until Marcia Angell criticized the trials in a 1997 editorial in the *New England Journal of Medicine*.⁶ The editorial was accompanied by a Sounding Board article by Peter Lurie and Sidney Wolfe of the Public Citizen Health Research Group.⁷ They argued that the placebo-controlled trials were unethical because the control group was denied a proven beneficial treatment. According to section II.3 of the 1996 and then current version of the Declaration of Helsinki, all the participants "should be assured of the best proven diagnostic and therapeutic method."⁸ Lurie and Wolfe also claimed that a placebo trial might not require fewer subjects nor would it take longer to get the necessary results. They

rejected the argument that because the standard of care in developing countries was no treatment at all, research subjects in the placebo group would not be denied the treatment available *in that country*. They pointed out that the reason for this standard of care is economic, rather than medical. However, it would not be difficult for economic reasons to provide the participants in the study with AZT in the required amount: this would not add much to the cost of the study. Lurie and Wolfe recognized that it may not be justifiable to provide more expensive forms of care, such as treatment in coronary care units.

The respective directors of the U.S. National Institutes of Health (NIH) and the Centers for Disease Control and Prevention (CDC), Harold Varmus and David Satcher, defended the trials by arguing that placebo control was essential to the purpose of the trials:

The most compelling reason to use a placebo-controlled study is that it provides definite answers to questions about safety and value of an intervention in the setting in which the study is performed, and these answers are the point of research. . . . Comparing an intervention of unknown benefit—especially one that is affordable in a developing country—with the only intervention with a known benefit (the 076 regimen) may provide information that is not useful to patients. If the affordable intervention is less effective than the 076 regimen—not an unlikely outcome—this information will be of little use in a country where the more effective regimen is unavailable. Equally important, it will still be unclear whether the affordable intervention is better than nothing and worth the investment of scarce resources.⁹

The Declaration of Helsinki and the Standard of Care Debate

The Declaration of Helsinki was first promulgated by the WMA in 1964, but it was only with the 1975 revision, often referred to as Helsinki II, that it achieved the status of an internationally recognized basic document in research ethics. The 1964 version contained no paragraph relating directly to the standard of care, although one might interpret paragraph II.2 to contain the germ of a standard of care idea: “The doctor can combine clinical research with professional care, the objective being the acquisition of new medical knowledge, only to the extent that clinical research is justified by its therapeutic value for the patient.”¹⁰ In the 1975 revision, paragraph II.3 reads, “In any medical study, every patient—including those of a control group, if any—should be assured of the best proven diagnostic and therapeutic method.”¹¹ And this was amended in 1996 to read, “In any medical study, every patient—including those of a control group, if any—should be assured of the best proven diagnostic and therapeutic method. This does not exclude the use of inert placebo in studies in which no proven diagnostic or therapeutic method exists.”⁸

The final official steps in the development of the standard of care doctrine were in the last major revision of the Declaration, adopted by the WMA’s 52nd General Assembly in Edinburgh, Scotland, in October 2000, along with a Note of Clarification of paragraph 29 added by the WMA General Assembly in Washington, D.C., in 2002.¹ The work on this revision was started in 1997 when the American Medical Association proposed a signif-

icantly altered version of the Declaration of Helsinki. During the very long revision process that followed, the standard of care issue was one of the most discussed.¹² A proposed revision that was put forward in 1999, but rejected, contained this paragraph 18:

In any biomedical research protocol every patient-subject, including those of a control group, if any, should be assured that he or she will not be denied access to the best proven diagnostic, prophylactic or therapeutic methods *that would otherwise be available to him or her*. This principle does not exclude the use of placebo or no-treatment control groups if such are justified by a scientifically and ethically sound research protocol [emphasis added].¹³

This would have significantly weakened the standard of care rule.

In the text of this revision as finally approved, the term “best proven diagnostic and therapeutic method” from the 1975 revision was superseded by “best current prophylactic, diagnostic, and therapeutic methods.” This terminology may imply a slightly stricter standard, but the text (now paragraph 29 of the 2000 version) is otherwise very similar to the 1996 revision:

The benefits, risks, burdens and effectiveness of a new method should be tested against those of the best current prophylactic, diagnostic, and therapeutic methods. This does not exclude the use of placebo, or no treatment, in studies where no proven prophylactic, diagnostic or therapeutic method exists.¹

After the publication of the 2000 revision, this paragraph provoked substantial criticism and controversy. In 2002, the meeting of the WMA General Assembly in Washington, D.C., issued the Note of Clarification reaffirming the strict interpretation of paragraph 29:

The WMA hereby reaffirms its position that extreme care must be taken in making use of a placebo-controlled trial and that in general this methodology should only be used in the absence of existing proven therapy. However, a placebo-controlled trial may be ethically acceptable, even if proven therapy is available, under the following circumstances:

- Where for compelling and scientifically sound methodological reasons its use is necessary to determine the efficacy or safety of a prophylactic, diagnostic or therapeutic method; or
- Where a prophylactic, diagnostic or therapeutic method is being investigated for a minor condition and the patients who receive placebo will not be subject to any additional risk of serious or irreversible harm.

All other provisions of the Declaration of Helsinki must be adhered to, especially the need for appropriate ethical and scientific review.¹

The corresponding section in the CIOMS Guidelines reads:

Guideline 11: Choice of control in clinical trials

As a general rule, research subjects in the control group of a trial of a diagnostic, therapeutic, or preventive intervention should receive an established effective intervention. In some circumstances it may be ethically acceptable to use an alternative comparator, such as placebo or “no treatment.”

Placebo may be used:

- when there is no established effective intervention;
- when withholding an established effective intervention would expose subjects to, at most, temporary discomfort or delay in relief of symptoms;
- when use of an established effective intervention as comparator would not yield scientifically reliable results and use of placebo would not add any risk of serious or irreversible harm to the subjects.²

The use of “established effective intervention” makes the CIOMS Guidelines slightly less stringent than the Declaration of Helsinki, but not much. (The 1993 version of the CIOMS Guidelines had no specific guideline concerning this issue, but part of the commentary on Guideline 14 read, “If there is already an approved and accepted drug for the condition that a candidate drug is designed to treat, placebo for controls usually cannot be justified.”¹⁴) CIOMS added five pages of commentary to Guideline 11 showing an awareness of the complications involved in specifying exactly when the three exceptions in the guideline apply. The commentary touches on many of the issues discussed below, but wavers between an analysis on the level of research participants and an analysis on the level of states or societies.¹⁵

It has recently been argued by Reidar Lie and colleagues that the Declaration of Helsinki is in conflict with the international consensus on the standard of care issue, but this is disputed.¹⁶

Core Conception of “Standard of Care”

The core of the concept of “standard of care” is that there is, for each particular medical condition, a set of recognized treatments and care interventions that constitute the present “standard of care” for that condition. For different conditions this may range from no treatment at all, because there is no effective treatment or because no treatment is needed, to highly complex and expensive treatment regimens. The standard of care is the baseline against which other treatment regimens can be compared. Over time the standard of care for a given condition will often change as new research-based therapies supersede older and now obsolete treatments.

This core conception of standard of care is, however, not unproblematic on epistemological and normative grounds.^{17,18} There may be disagreement in the scientific community concerning which of two or more treatment modalities is the best (or most appropriate), and therefore there may be more than one particular treatment that has the status of the standard of care. This disagreement may occur within one country and one medical community, but it may also occur between countries.

There also may be disagreement concerning the criteria for identifying the standard of care. Is it (1) the best available treatment? (2) the most commonly used treatment? (3) the treatment that is promoted by the relevant authorities? (4) the treatment advocated by the common textbooks? (5) a treatment that is “good enough,” and so forth? For each of the options, there are further questions about the exact meaning of the criterion, for example, what do *best* and *available* mean in “best available treatment”?

The borders may be fuzzy and ill defined, and there may be large gray areas, but this does not preclude our distinguishing between clear cases. (The problem in identifying the “standard of care” is in many ways analogous to the problem in identifying

whether or not there has been negligence in malpractice suits.) In many instances we can identify whether a particular treatment falls within or outside the standard of care. If in a study of a new treatment for duodenal ulcer, a physician plans to give his or her control group placebo instead of proton pump inhibitors and antibiotics, the control group will be given something that is less than the current standard of care.

The ability to determine whether a particular proposed treatment falls below the standard of care critically depends on the identification of the relevant treatment universe. The standard of care for duodenal ulcer described above is valid in the United Kingdom or the United States, but it may not be valid in the rural areas of the most economically deprived countries in Africa.

One major determinant of the level of treatment offered as standard in a given health care system is the economic resources available to the health-care system. The standard of care issue is often most urgent in research being carried out in a health-care system with fewer resources than the health care system from which the researchers originate or in which the results are to be used. These resource differences can be very large, but it is important to note that disparities occur not only between countries but also within countries when there is tiered provision of health care.

To What Does Acceptance of the Standard of Care Commit Us?

The core ethical rationales for maintaining a standard of care restriction in the planning or assessment of research projects falls into three not mutually exclusive categories. The first possible rationale is the idea that people should be predictably (ex ante) worse off by participating in a biomedical research project than they would have been if they had not participated. The second is the idea that research participation should not cause predictable harm by deprivation of known effective treatment. The third is that it would be against the researchers’ professional obligations as medical doctors (or other health-care professionals) to treat any of their patients in a way that is not in the patients’ best interests.

Society permits people to participate in research that involves some level of risk, pain, and inconvenience for no therapeutic benefit. Consistency suggests society should allow similar negative effects caused by deviations from the standard of care. Therefore, the real standard of care issue is not whether any deviations from the standard of care can be justified, but whether and under what conditions *large* deviations from the standard of care can be justified.^{19–21}

An important question in this regard is: What is or is not in someone’s interests?^{19,22} What is or is not in a particular individual’s interests is an objective matter, despite the fact that the person’s subjective preferences codetermine these interests. Although the choice of the preferences is subjective, once they are chosen their fulfillment can be objectively assessed. Although research participants have a special role to play in determining this, we also know that human beings frequently act against their own interests. Indeed the idea of respect for persons, which underpins these guidelines, has two clear and sometimes incompatible elements, namely, concern for welfare and respect for autonomy. Because people often have self-harming preferences, well illustrated by smoking, drug abuse, overeating, or selfless altruism, they are sometimes bad judges of their own interests.

Individuals benefit from—or have a chance of living in—a society and, indeed, in a world in which medical research is carried out and that uses the benefits of past research. Medical research is of benefit both to patients and to research participants; it is in their interests to be in a society that pursues and actively accepts the benefits of research and in which research and its fruits are given a high priority. All individuals also benefit from the knowledge that research into diseases or conditions from which they do not currently suffer but to which they might succumb is ongoing. It enhances security and gives people hope for the future, for themselves and their descendants, and others for whom they care.

If this is correct, then each individual should have a strong general interest that there be research, and that there be well-founded research—not excluding but not exclusively on their condition or on conditions that are likely to affect them. All such research is also of clear benefit to everyone in the society. (This argument relies on the implicit premise that there is some realistic chance that some of the benefits of medical research have flowed or will flow to each person or persons that they care for.) A narrow interpretation of the requirement that research be of benefit to the subject of the research is therefore perverse.²³

The interest of the participant *cannot* be the only consideration, nor can it automatically take precedence over other interests of comparable moral significance. Claims that the patient's interest must always take precedence involve a straightforward mistake: Being or becoming a research participant is not the sort of act that could conceivably, in itself, augment either someone's moral claims or their rights. Any principle of equality would emphasize that *all* people are morally important and, with respect to one another, each has a claim to equal consideration. No one has a claim to overriding consideration. To say that the interests of the participant must take precedence over the interests of others must be understood either as a way of reasserting that a researcher's narrowly conceived professional interests must not have primacy over the human rights of research participants. It might emphasize some specific contractual duties. Or it might recognize that some, but importantly only some, research participants will attract merit by voluntarily shouldering significant burdens. However, as a general remark about the obligations of the research community, the health-care system, society, or indeed of world community, it is not sustainable.

Obligations of Researchers to Participants in Trials

What should be the obligations of researchers to their subjects? The strongest obligations to research participants are derived from a more general obligation to refrain from harming others. This is a specific instance of the obligation of nonmaleficence, which is the obverse of the obligation of beneficence.^{24,25} Such obligations are no more stringent to research participants than they are to anyone in similar need. That said, it will look like special pleading to reject the requirements of the Declaration of Helsinki.

Barry Bloom has produced a *reductio ad absurdum* of the standard of care we are discussing. He points out,

Few, if any, clinical trials in developing countries have evaluated whether simple, inexpensive interventions, such as aspirin and beta-blockers, will reduce mortality from heart

attacks and strokes, as they do in the industrialized world. . . . Were the standard of “best proven therapeutic method” to be literally invoked in such a trial, many study subjects suffering heart attacks would have to be provided with either angioplasty or coronary artery bypass surgery, which are hardly “reasonably available” in countries where per capita expenditures for health are \$10 per year or less.²⁶

Bloom is here using the wording of an earlier version of the Declaration of Helsinki, but the idea is for all practical purposes the same. Although Bloom's reminder is important, it cannot follow that because researchers cannot do everything that they are then permitted to do nothing. The question must be, what standard of care is appropriate given all the circumstances of the study, including all the costs involved? The impossibility of providing everything that might be interpreted as “best current prophylactic, diagnostic and therapeutic methods” does not lead to the conclusion that the only alternative is “local standards of care.” However, Bloom's *reductio* argument does at least show that the provisions of the Declaration of Helsinki cannot, as written, be universally applied.

Other things being equal, it is not justifiable to let people suffer when physician-researchers could protect them, nor is it normally ethical to leave people with poorer standards of care than could reasonably be provided for them.^{27,28} However, it is necessary to look more closely at the equality of other factors and at how to determine “what could reasonably be provided.”

The moral obligation that researchers try to ensure that others are not made unduly worse off applies to *all* others, not simply to the subjects of any trial. Therefore, when researchers are considering the others whom they must try not to make unduly worse off, they must also include those who may benefit from the results of the trial. Thus the argument that supports the best standard of care for those in the trial also supports the best standard of care for those who would benefit from the trial. No one would be made worse off by such a policy, and some will be made better off.

It merits insistence that leaving people no worse off than they would have been had no trial taken place is a minimum standard of care. The relevant question is not, will the participants be no worse off than they would have been? Rather it is, what obligations do researchers have toward people to protect them from avoidable harm?

What are the obligations of investigators to those who enter a drug or vaccine trial? The investigators' obligations are of course in part determined by what protections participants are judged to be entitled to. These obligations may also involve our conception of the professional obligations of medical practitioners or other investigators, which derive from their special role or responsibilities. More basically this question raises fundamental issues about the justifications for a particular research project and indeed the research enterprise more generally.

There is a difference between deciding what research is acceptable and should be done in the abstract—at the planning stage, when all people involved are unknown—and acting according to researchers' professional obligations when confronted with the individual research participant. It is generally assumed that health professionals in particular have specific and overriding obligations to those they deal with in their professional capacity. This is clearly a rule that works well in many situations. However,

it is not an absolute rule. There are many circumstances in which it is routinely broken—for instance, in balancing the home life of health professionals against their obligations to patients. Such balancing is also necessary in clinical research, as is the realization that the researcher is actually fulfilling two roles at the same time: in a health professional-patient relationship, and also in a researcher-voluntary research participant relationship.

When a person benefits from research but refuses to participate in it, that person clearly is acting unfairly. He or she is free-riding on the back of the contribution of others. When people volunteer to participate in research, they are doing what any reasonable, decent person should be willing to do if he or she wishes and expects to receive the benefits of research—at least when the risks and dangers to research participants are minimal or low. The level of protection required to render the risks of participation minimal is a question of fact, or at least of judgment, in each case.

Moreover, it is widely recognized that there is sometimes an obligation to make sacrifices for the community, or that sometimes the community is entitled to deny autonomy and even violate bodily integrity in the public interest. This obligation is recognized and accepted in a number of areas, including the following: control of dangerous drugs, control of road traffic, compulsory vaccination and screening tests, quarantine for communicable disease, compulsory military service, detention under mental health acts, and compulsory attendance for jury service at criminal trials.²⁹ Most of these involve some denial of autonomy and some imposition of public standards. However, these are clearly exceptional cases in which overriding moral considerations take precedence over individual autonomy.

If medical research is a public good shared by large numbers of people, then a number of conclusions may be said to follow:

- It should not simply be assumed that people would not wish to act in the public interest, at least when the costs and risks involved are minimal. In the absence of specific evidence to the contrary, if any assumptions are made, they should be that people are public-spirited and would wish to participate.
- It may be reasonable to presume that people would not consent to do things contrary to their own and to the public interest unless misinformed or coerced. The reverse is true when—as in vaccine trials—participation is in both personal and the public interest.
- If it is right to claim that there is a general obligation to act in the public interest, then there is less reason to challenge consent and little reason to regard participation as actually or potentially exploitative. We do not usually say, “Are you quite sure you want to?” when people fulfill their moral and civic obligations. We do not usually insist on informed consent in such cases. We are usually content that they merely consent or simply acquiesce.

Reexamining the Declaration of Helsinki's Requirements

The two requirements of the 2000 Declaration of Helsinki related to standard of care are “A.5: In medical research on human subjects, considerations related to the well-being of the human subject should take precedence over the interests of science and society” and “C.29: The benefits, risks, burdens and effectiveness of

a new method should be tested against those of the best current prophylactic, diagnostic, and therapeutic methods.”³¹ A narrow interpretation of the first requirement is unwarranted. In the case of research, a clear distinction cannot be sustained between the interests of the participants and the interests of other people who are equally entitled to concern, respect, and protection. The same arguments and the same ethical principles that require researchers to assure the best proven therapies to those *in* a study also require that those therapies be assured to *all who stand in need of them*.

What then would be a reasonable and ethical balance between these interests? Researchers must weigh carefully and compassionately what is reasonable to ask of potential participants in a trial for their free and unfettered consideration. However, provided potential research participants are given full information, and are free to participate or not as they choose, then the only remaining question is whether it is reasonable to permit people to choose to participate, given the risks and the sorts of gains and benefits that are likely. Is it reasonable to ask people to run whatever degree of risk is involved, to put up with the inconvenience and intrusion of the study in all the circumstances of the case? These circumstances will include both the benefits to them personally of participating in the study and the social value that will flow from the study to other persons, persons who are of course equally entitled to our concern, respect, and protection. Putting the question in this way makes it clear that the standards of care and levels of protection to be accorded to research participants who have full information must be, to a certain extent, study-relative.

The powerful moral reasons for conducting vaccine and drug trials are not drowned by the powerful reasons we have for protecting research participants. There is a balance to be struck here, but it is not a balance that must always and inevitably be loaded in favor of the protection of research participants. Research participants are entitled to the concern, respect, and protection of researchers, to be sure, but they are no more entitled to it than are the people who are threatened or are dying from HIV/AIDS or other major diseases.

It seems unethical to stand by and watch around 3 million people die each year of AIDS alone³⁰ and to avoid taking steps to prevent such loss—steps that will not put lives at risk and that are taken only with the fully informed consent of those who participate. Fully informed consent, although not foolproof, is the best guarantor of the interests of research participants. Residual dangers—for example, difficulties of constructing suitable consent protocols and supervising their administration in rural and isolated communities in populations that may have low levels of formal education—must be balanced against the dangers of not conducting the trial, which include the massive loss of life that diseases cause.

Researchers' Obligations of Beneficence and Justice

Nonmaleficence is not all of morality. We also have obligations of beneficence toward each other and obligations to act justly. We therefore have to consider the implications of the researcher's obligation of beneficence toward the potential and actual research participants. If the researcher is a health-care professional, his or her professional obligations may also come into play.

Many of the instances in which the standard of care issue becomes most acute involve resource-rich researchers and resource-poor participants. It is at least arguable that if persons deliberately place themselves in a situation in which they will be in contact with needy people, they also place themselves in a situation in which they will have to take their obligation of beneficence seriously. The standard argument that obligation of beneficence can and should not be discharged impartially—it is claimed to be impossible to benefit everyone—does not “protect” researchers who bring themselves in contact with a limited number of needy people whom they could benefit, if they chose to do so. The defense that “It is not my responsibility to help these people” is of questionable validity even when applied to the average citizen in a rich Western country.

The researchers could try to claim that their role as researchers limits their obligation of beneficence, but this is unconvincing. If a research participant collapses on the floor, there is clearly a duty to help him or her; and if the researcher discovers a serious but easily treatable condition unrelated to the research, there would be a moral duty to treat this condition, even if the participant could not pay.

However, this argument based on beneficence is quite general. It does not show that the researchers’ positive obligations should be discharged only within the research project, or only toward the research participants. Although we can therefore conclude that researchers cannot insulate themselves from obligations of beneficence, this has no direct bearing on the standard of care issue. The obligations can be discharged in many ways other than through changing the standard of care.

Effective Research Oversight

At this point it is important to enter a few caveats. First, not all research projects have a realistic chance of generating important new knowledge. Some ask uninteresting or trivial questions, and some are so badly designed that they cannot generate valid knowledge. The prospective research participant may not be in a position to discover this, and there is a need for prior research oversight to ensure that no one is asked to participate in research that is not likely to generate collective benefit.

Second, whereas it is true that we all have a personal interest in the progress of medical research—in order not to be a free rider, and to further my own interests and those of people I care about—it is not necessarily true that we all have the same kind of interest. In each specific research project, the benefits may simply be too remote from us. Therefore, the conclusion that a researcher has a right to ask for consent does not entail the further conclusion that any particular research participant has an obligation to give consent. For instance, the potential research participant may already have “done his bit for society” by contributing to other important social activities.

Third, a research oversight system for the real world has to take into account that researchers may have strong self-interested reasons for promoting certain research projects and that the rules that are formalized (for instance, concerning standard of care) have to strike the right balance between rigidity and flexibility. If the rules are too rigid, valuable research will be hindered; if they are too flexible, unscrupulous researchers will exploit them.

Is There a Larger Issue of Exploitation?

Until now, we have mainly focused on the question of whether research participants are exploited, but is there an issue of systemic exploitation? Two dimensions of this question need to be considered: (1) Are high-income countries exploiting low-income countries by performing research that follows the priorities or serves the interests of those societies or their people? (2) Is some of this research being conducted in a way that would not be allowed within the borders of the researchers’ own countries?

To take the first question first—whether low-income countries are exploited by research that does not serve their own interests—is not settled by that fact alone. As we have seen when considering the obligations of individual research participants, in societies there may be a duty on all of us to participate in research, primarily or even exclusively for the benefit of others. A claim of exploitation would have to rely on showing unfairness or some other asymmetrical wrongdoing in the overall “exchange” involved in the research.

The second question is more difficult. Here we can attempt only gestures toward a satisfactory answer. There are many reasons for which societies set limits for research that may be undertaken within their borders. And even if certain research is considered morally wrong in one country, it does not follow that it is unethical to carry out such research in other countries. It might, however, become wrongful if the other countries allow the research not because they have carefully considered the situation and decided to allow it, but instead because they are unable or unwilling to enforce suitable research ethics regulation.

A related issue is whether research sponsored by high-income countries and firms in those countries distorts the priorities of the health-care systems of low-income countries by focusing on “the wrong issues.” This is an important consideration, but it is not directly related to the standard of care. Research according to high-income priorities may respect standard of care restrictions, however specified, and research according to low-income priorities may breach them.

Study Design Implications

If we accepted the idea that true, uncoerced, informed consent is a sufficient condition for recruiting a person into a research project, the standard of care issue would disappear because it could be argued that the person in question had accepted a particular standard of care.

It is, however, the case that all national and international research ethics regulations of which we are aware conceptualize informed consent as a necessary but not sufficient condition. It is therefore necessary to include considerations of standard of care in the planning and design of biomedical research projects.

What are the implications of standard of care considerations for study design? The wording of the most important international documents is, unfortunately, ambiguous, and it is therefore not possible to derive precise design guidelines directly from these documents. Let us, nevertheless, analyze the relevant sections in the most recent Declaration of Helsinki and CIOMS Guidelines (the relevant sections have been reproduced above).

A few conclusions can be drawn with near certainty:

1. If an effective treatment for the condition in question is generally available in the locality in which the research takes place, this treatment or a treatment of similar effectiveness has to be offered to all research participants, if the condition in question is more than a minor.
2. In research taking place in a locality with a different local standard of care than the standard of care in the locality of the researcher or research sponsor, the use of the lower standard of care will require justification either in terms of the research question to be answered or because of strong methodological necessity.

Rather more tentatively, it can be suggested that negative deviations from the local standard of care may be easier to justify when the local standard of care is high. The Note of Clarification to paragraph 29 of the Declaration of Helsinki is centrally concerned with the need to allow placebo-controlled trials for regulatory or pharmaceutical industry-related purposes. Because the regulatory demands are primarily imposed by regulatory agencies in affluent countries, consistency would require them to allow this kind of relaxation of the standard of care in their own jurisdictions.¹⁵

Furthermore, the design question is complicated by the fact that the standard of care issue is often intertwined with other issues in the ethical evaluation of a research project. A larger deviation from the standard of care may be justifiable if the project is aimed at solving an important research question, or a deviation may be more problematic if consent procedures are questionable.

A New Principle of Research Ethics

It is always encouraging to be able to end on a positive note. We therefore propose the following addition to the Declaration of Helsinki:

Biomedical research involving human subjects cannot legitimately be neglected, and is therefore permissible, when the importance of the objective is great and the risks to and the possibility of exploitation of fully informed and consenting subjects is small.¹⁹

The recognition that the obligation to do justice applies not only to research subjects but also to those who will benefit from the research must constitute an advance in thinking about international standards of research ethics.

How would our conclusions apply to specific questions that often arise in the context of research? Let's see:

1. Does one have an obligation to provide the best current treatment to participants in a trial, when one could easily do so in the context of the trial and the results of the trial will benefit not the host country but the sponsoring country?

Here the answer is clear and simple. When the best current treatment could be offered easily in the context of the trial, obviously it should be offered, and the question of where eventual benefits will be felt is irrelevant.

2. Does one have an obligation to provide the best current treatment to participants in a trial when the best current

treatment is a life-saving intervention not available to the participants outside the research context, and when withholding that treatment is necessary for methodological reasons in order to identify improved interventions for patients in the host country?

To this, the answer is equally clear but more complicated. This question asks whether research participants may agree to enter a trial that can take place only if they are not given the best current treatment—a life-prolonging therapy not otherwise available to them, and one that would, if given, render the trial pointless. Here it seems to us that so long as the trial participants are clear and wish to go ahead on this basis, knowing that the benefits to themselves of entering the trial will be small but knowing also that they are helping in the development of a treatment that may help them or their compatriots later, they should be free to choose whether or not they wish to participate. Because by hypothesis they would not receive the life-prolonging therapy outside the context of the trial, and it could not be provided within that context because the trial could not then take place, they are not worse off than they would otherwise be, and they have a chance (albeit a small one) of being personally better off later, and a larger chance of contributing to the development of a therapy that will benefit others including those in their own country. Would our feelings about the ethics of their decision be altered if they knew that the primary beneficiaries would be foreigners rather than compatriots? We hope no one would be so mean-spirited as to think so.

Finally,

3. Are there limits to the obligation to run risks or forgo benefits for the sake of research, if the only beneficiaries are people in rich countries, and those who forgo the benefits are the poor?

The business about rich and poor countries can in a sense be seen as an irrelevance. It might, for instance, be only the poor in the rich countries that benefit. The fundamental question is more general: Can some people validly consent to enter trials from which they themselves will derive little or no benefit, primarily for the sake of others? Remember, the obligation we are talking of must be fully voluntary; there is no question of compulsion or coercion. In such a case, there seems no reason why people should not choose to benefit others even if those others are strangers, foreigners, or whatever. And the fact that the people who are most likely to benefit are strangers seems not to be made much worse by the fact that they are likely also to be foreigners.

Maybe what is hiding underneath the question above is not a question about the location of beneficiaries, but about regulatory hypocrisy. If a country will not allow a certain kind of research to take place within its jurisdiction because such research is seen to be morally problematic—for example, if it would not allow its own poor and untreated to participate in the research—but still wants to conduct the research elsewhere and reap its benefits, then the country is *prima facie* inconsistent and hypocritical. There is clearly a link between the wealth of a country and its ability to develop and enforce research ethics regulations, and if rich countries exploit weak regulatory systems in poor countries that may be a problem, but it is not primarily a problem about standard of care.

Responsiveness to Host Community Health Needs

There is near universal agreement within the scientific and ethics communities that a necessary condition for the moral permissibility of cross-national, collaborative research is that it be responsive to the health needs of the host community. It has proven difficult, however, to leverage or capitalize on this consensus in order to resolve lingering disputes about the ethics of international medical research. This is largely because different sides in these debates have sometimes provided different interpretations of what this requirement amounts to in actual practice.

The goal of the discussion that follows is to clarify the nature of this important moral requirement. The first section explains the requirement for responsiveness to host community health needs in the context of international medical research. The second section examines various formulations of this requirement as they are enunciated in some of the core consensus documents in research ethics. The third section then defends a particular interpretation of this requirement, and the final sections examine more liberal alternatives with the aim of highlighting points of agreement and assessing the significance of areas of disagreement.

Responding to the Developing World's Health Needs

The health inequalities that currently divide the developed from the developing world are not morally neutral. As the Ad Hoc Committee on Health Research Relating to Future Health Interventions of the World Health Organization (WHO) has noted, "The health of the world's peoples has improved more in the past four generations than in the whole of their history."¹ However, the size

and extent of these gains have differed radically between populations of economically developed countries and impoverished nations of the developing world. In 1990, for example, more than a third of the global disease burden could be attributed to a handful of conditions that are virtually unknown in affluent nations of the developed world. These conditions include communicable childhood diseases such as pneumonia, diarrheal diseases, malaria, and various vaccine-preventable infections, as well as malnutrition and high rates of maternal and infant mortality arising from poor reproductive health.¹ Not only are these conditions more likely to occur in circumstances of social and economic deprivation, they are also more difficult to treat under such circumstances; and the devastating toll that they take on the populations in which they are endemic only reinforces the very conditions of deprivation in which such health problems flourish. As a result, the staggering health problems that plague many communities of the developing world play a major role in perpetuating a cycle of impoverishment, premature mortality, and underdevelopment.

The distinctive health problems of the developing world are inextricably bound up with poverty and other forms of social and political deprivation. Recently, however, the attention of scientists, ethicists, and policy makers has focused on what is increasingly viewed as a form of deprivation that occurs in the context of medical research. What is sometimes called the *10/90 disequilibrium* or the *10/90 gap* refers to the statistic that roughly 90% of the global burden of premature mortality can be attributed to diseases that primarily affect populations of the developing world, but only 10% of the annual global research budget of \$50 billion to \$60 billion is targeted at those diseases. Instead, 90% of the money spent each year on medical research across the globe focuses on the

health needs of populations in the developed world, which account for only 10% of the global burden of premature mortality.¹⁻³ To some degree, therefore, wealthy populations of the developed world have been able to use the fruits of scientific inquiry to safeguard and to secure their health needs so effectively because their needs have been the direct focus of the overwhelming majority of scientific inquiry.

Recognizing the morally problematic nature of the 10/90 gap has generated support for increasing collaborative research activities in the developing world. At the same time, however, such support is tempered by the awareness that too often in the past, when communities in the developing world have participated in research activities, they have not benefited from the fruits of those efforts. Instead, these benefits have been enjoyed primarily by more affluent populations of the developed world.⁴ Such practices are now widely regarded as exploitative and, therefore, unethical. As a result, efforts to increase the involvement of the developing world in medical research have had to grapple with the difficult issue of how to achieve this goal while preventing the exploitation of those populations in the process.

One requirement that is intended to facilitate both of these goals is that cross-national collaborative research must be conducted in such a manner as to leave the host community better off than it was, or at least not worse off. This requirement supports another, namely, that international medical research must be responsive to the health needs and priorities of the host community. Together, these conditions constitute important moral constraints on permissible research, as well as substantive moral ideals toward which research should strive. Nevertheless, different interpretations of key concepts in these requirements have at times produced conflicting views about what these requirements amount to in actual practice.

Different Expressions of the Requirement

Perhaps the clearest statement of the requirement that collaborative international research be responsive to the health needs of the host community is presented by the Council for International Organizations of Medical Sciences (CIOMS), in collaboration with the WHO, in its International Ethical Guidelines for Biomedical Research Involving Human Subjects⁵ (see Chapter 16). Guideline 3 of the 2002 text governs “ethical review of externally sponsored research” and states in part, “The health authorities of the host country, as well as a national or local ethical review committee, should ensure that the proposed research is responsive to the health needs and priorities of the host country and meets the requisite ethical standards.” The phrase *health needs and priorities* introduces two key concepts and raises the question of their relationship. In order to understand what this guideline requires, it is necessary to clarify (a) what constitute the *health needs and priorities* of the host community and (b) what is required to show that a research initiative is sufficiently “responsive” to the host community’s health needs and priorities, so understood.

To begin with, *health needs* are concerns that are particularly important or urgent because of their close relationship to the ability of persons to be free from medical conditions that shorten their lives or prevent them from functioning in ways that are basic or fundamental to their pursuit of a reasonable life plan.⁶ In this respect, health needs stand in contrast to health-related wants or

desires, when these terms refer to things that may help to improve the functionality of persons but which lack this urgency.

Among the various health needs that exist within a community, some may be viewed as more urgent or important than others. For instance, prostate cancer and breast cancer may be health needs that are *represented* in a resource-poor community in the sense that a significant cohort of people may suffer from these conditions. Nevertheless, finding new means of treating these afflictions may not be a health priority of such a community if significantly larger numbers of people suffer and die much earlier in life from conditions such as malaria, tuberculosis, or HIV. When this is the case, the latter conditions might constitute health needs that are also health priorities of such communities. In other communities, however, finding new means of treating prostate or breast cancer may constitute important health priorities. Communities can differ, therefore, in their health priorities even when significant members of their populations have common health needs.

Every community is constrained to use its finite social, economic, and human resources to meet a wide range of basic needs of community members. As a result, communities may differ in their social priorities, giving greater or lesser priority to different needs, depending on their broader social circumstances. For example, fostering economic development through job growth may be a top priority in a community with high rates of unemployment and low per capita income levels. So might be expanding the country’s infrastructure or improving national security. Different communities may therefore view health-related issues, such as preventing the spread of HIV and providing a wide range of childhood vaccinations, as more or less of a priority than other social or economic concerns.

These rudimentary distinctions raise an important question about the requirement for responsiveness to host community health needs: Should the requirement be understood in a fairly restrictive way, according to which collaborative research initiatives should be required to focus on health needs that are also health priorities of the host community? Or should it be understood in a more liberal way, according to which it is sufficient for research to focus on a health need that is represented in the host community, even if it is not necessarily a health priority, so long as the research is adequately responsive to other priorities of the host community?

Perhaps the most natural reading of CIOMS Guideline 3 is that it requires research to be responsive to those health needs *that are also health priorities* of the host community. In this view, it is not sufficient to establish that the health need in question is merely represented in the host community. Rather, the health need in question must be sufficiently urgent or important that finding the means of addressing it represents a judicious use of the community’s scarce social resources.

On the other hand, a literal reading of Guideline 10 of the 2002 text appears to be consistent with the more liberal or permissive interpretation of this requirement. This guideline governs “research in populations and communities with limited resources,” and holds the following:

Before undertaking research in a population or community with limited resources, the sponsor and the investigator must make every effort to ensure that:

- the research is responsive to *the health needs and the priorities* of the population or community in which it is to be carried out [emphasis added]; and

- any intervention or product developed, or knowledge generated, will be made reasonably available for the benefit of that population or community.

Because “the health needs” of the host community do not necessarily fall under the scope of “the priorities” of that community in this statement, a literal reading of this guideline is consistent with the more liberal view.

To illustrate the importance of the difference between these two positions, consider the double-blind, randomized, placebo-controlled trial proposed in 2001 by the pharmaceutical company Discovery Laboratories. This trial would have compared the company’s new surfactant agent, Surfaxin, against a placebo in impoverished communities of Latin America. Surfactants are substances that are essential to the ability of the lungs to absorb oxygen, and roughly half a dozen surfactant agents are commonly used to save the lives of premature infants in countries of the developed world. In return for hosting this study, Discovery Labs offered to upgrade and modernize the intensive care units in which the study would take place, increasing the ability of host communities to provide neonatal care to premature infants. This study, however, provoked an outcry over its use of a placebo control, which critics charged violated the current standard of care for treating premature infants. But this study also raises a more profound question that must be addressed prior to concerns about standards of care. Namely, was this proposed project sufficiently responsive to the health needs of host community members?

The most natural reading of CIOMS Guideline 3 supports the verdict that this research was not morally permissible because it did not target a health need that was also a health priority of the host community. Several effective surfactant agents are already widely used in developed countries, but these agents are not available in the impoverished communities that would host this trial. Moreover, Surfaxin was not specifically designed for use in the developing world. It therefore did not have properties that would make it more likely to be deployed in the developing world or more likely to be effective in that context than existing surfactants.

According to the weaker requirement that is at least consistent with a literal reading of Guideline 10, however, this research could be seen as permissible. It targeted a health need that was represented in the host community, and supporters argued that it was responsive to other priorities of the host community—such as strengthening the health-care infrastructure, training and educating medical personnel, and perhaps also fostering economic activity that would result from hosting the research.

Each of these views represents a different way of trying to satisfy the requirement in CIOMS that “the research project should leave low-resource countries or communities better off than previously or, at least, no worse off.” In fact, the requirement for responsiveness to host community health needs can itself be viewed as emanating from the imperative in CIOMS that host countries should be left “at least, no worse off.” As a result, the core consensus documents in research ethics have been more concerned with the relationship between access to benefits and the *responsiveness* clause in this requirement than with clarifying the relationship between the health needs and the priorities of the host community.

Similar tensions exist within the responsiveness clause of this requirement, however. In the CIOMS guidelines, under the section, “General Ethical Principles,” for example, we are told that research in low-resource countries or communities, “should be

responsive to their health needs and priorities *in that* any product developed is made reasonably available to them, and as far as possible [should] leave the population in a better position to obtain effective health care and protect its own health [emphasis added]”. Here, responsiveness is equated with ensuring that the fruits of any successful research initiatives are made reasonably available in the host community. This statement also emphasizes the important role that medical research can play in helping communities safeguard their own health by discovering new diagnostic or therapeutic modalities. As I argue below, the requirement to ensure reasonable availability seems most appropriate when combined with the requirement that such research actually focus on health needs that are also health priorities of that community.

On the other hand, not all medical research is designed to vindicate a new diagnostic or treatment modality. Similarly, not all research that has this end succeeds in achieving its goal. However, research initiatives can be designed in such a way as to ensure that they provide host communities with indirect or ancillary benefits of various kinds.^{7,8,3} For instance, researchers can provide vaccinations or rudimentary medical care to community members. They can train and educate local medical personnel and thereby contribute to enriching local research capacity. In this regard, the commentary on Guideline 10 again appears to be consistent with a more liberal view. There we are told, “It is not sufficient simply to determine that a disease is prevalent in the population and that new or further research is needed: the ethical requirement of ‘responsiveness’ can be fulfilled only if successful interventions *or other kinds of health benefit* are made available to the population [emphasis added]”. Here it appears that the requirement of responsiveness can be met by providing other kinds of health benefits to the host community. As I argue below, this view seems most reasonable when conjoined to the somewhat weaker requirement that research need only focus on health needs that are represented in the host community as long as that enterprise is responsive to other priorities of that community. I will return to this point in the following section.

In some of the core consensus documents in research ethics the reasonable availability requirement eclipses entirely the debate over what is required in order to be adequately responsive to the health needs of the host population. The Declaration of Helsinki, for example, does not explicitly state that medical research must be responsive to the health needs of the host population (see Chapter 13). Paragraph 19, however, does state, “Medical research is only justified if there is a reasonable likelihood that the populations in which the research is carried out stand to benefit from the results of the research.”⁹ This paragraph, however, is often cited by commentators as an instance of the requirement that research be responsive to the health needs of the host community.^{4,10}

In its report, *Ethical and Policy Issues in International Research: Clinical Trials in Developing Countries*, the National Bioethics Advisory Commission (NBAC) affirmed that “Clinical trials conducted in developing countries should be limited to those studies that are responsive to the health needs of the community.”¹¹ The NBAC derives the requirement of responsiveness to host population health needs from the values of beneficence and justice. Following the Belmont Report¹² and the U.S. Department of Health and Human Services’ Common Rule, the NBAC holds that the requirement of beneficence is satisfied when the risks to research participants are reasonable in light of the prospect that the research initiative will generate either of two possible benefits: tangible

benefits to trial participants or increases in the “fund of human knowledge” (see Chapters 14 and 15). The NBAC then views the value of justice as requiring that “some of the benefits must accrue to the group from which the research participants are selected.”¹¹

According to the NBAC’s justification of the requirement for responsiveness to host community health needs, some members of the host community must benefit either from the increases in the fund of human knowledge generated by the research or from tangible benefits that come from research participation. Both interpretations of the responsiveness requirement outlined above, however, can be viewed as interpretations of the argument that the NBAC offers. Nevertheless, the NBAC finds that researchers and their sponsors have an obligation to take steps prior to initiating a research initiative to ensure that the fruits of any successful research will be made reasonably available to the host population. As I argue below, however, this requirement seems most reasonable when combined with an interpretation of responsiveness to host community health needs that requires research to focus on health priorities of the host community.

The Nuffield Council on Bioethics displays the clearest grasp of the existence of, and conflict between, the two views outlined above concerning the requirement for responsiveness to host community health needs. In paragraph 2.24 of its 2002 report, *The Ethics of Research Related to Healthcare in Developing Countries*, the Council notes that “in countries where nearly all research related to healthcare is externally funded, the priorities for research have been largely set by the external sponsors.”³ It also notes the existence of the 10/90 disequilibrium, or 10/90 gap, mentioned earlier. This leads the Nuffield Council to affirm, in paragraph 4.8, that there is a general moral duty to alleviate suffering; and this moral duty creates a more specific moral obligation to conduct research that deals with the health problems in developing countries. However, the Council stops short of requiring all externally funded research to target health needs that fall within the nationally defined health priorities of the host community. Its reason for this, articulated in paragraph 2.31, is that even research that does not target a local health priority can “offer considerable indirect benefits to host countries in the developing world because of the potential for strengthening the national capacity in research, in the form of improved infrastructure and training.” At paragraph 2.32, the Council therefore emphasizes that although it is important to encourage research that does advance local health priorities, this is not a necessary requirement because “all research contributes to the development of local skills and expertise in research, quite apart from the inherent value in diversity of research.”³

The Nuffield Council, therefore, explicitly recognizes the moral permissibility of externally sponsored, international research that does not focus on a health priority of the host community. Presumably, such research is morally permissible only to the extent that it targets a health need that is represented in the host community and conveys sufficient indirect benefit to the host community that it can be seen as advancing other priorities of that community, such as strengthening the local research capacity.

Focus on Health Needs That Are Health Priorities

The survey of core consensus documents presented in the previous section reveals two salient dimensions along which alternative

positions concerning the responsiveness to host community health needs requirement can be distinguished. For our present purposes, the most important distinction concerns whether international research initiatives are required to target health needs that are also health priorities of the host community or whether it is sufficient to target health needs that are simply represented in the host community, as long as the research is sufficiently responsive to other priorities of the host community. This distinction is represented by the rows in the matrix in Table 67.1. I have labeled the top row *Restrictive* and the bottom row *Permissive* to indicate that not only do views that fall into the lower row permit all research that would be permitted by views in the top row, they permit a wider range of research as well. Within each row, views may then be distinguished as more or less restrictive depending on whether they also endorse the reasonable availability requirement.

Because it is sometimes difficult to tell exactly which combinations of these views are being advocated in some consensus documents, it is worth briefly exploring the merits of these positions in their own right. The top row of the matrix in Table 67.1 represents a variety of views that have been defended by numerous commentators.^{13–17} Although these positions differ in significant ways, they share several basic tenets.

One shared tenet of views that occupy this row in the matrix is that an adequate understanding of a community’s health needs must consider the important connections that exist between the health status of people and the operation of a variety of basic social structures. One social structure that is particularly salient in this regard is a community’s local health-care system. As Jha and colleagues have emphasized, strengthening the *close-to-client* health system in developing countries would significantly increase the ability of local populations to access the effective medical interventions that already exist for some 90 percent of the avoidable mortality in low- and middle-income countries.¹⁸

The health status of individuals is also deeply affected by the way in which other basic social structures in their community allocate fundamental rights, such as who has access to literacy and education, including access to information about individual and public health; who has access to the means of productive employment; whose freedom of speech and association is protected; and whose sovereignty over their own person is respected. Whether or not the fundamental institutions of a community are directed at providing these social determinants of health can have a tremendous impact on the nature and extent of the health problems that members of that community face—as well as on the opportunities that are available to individuals to deal effectively

Table 67.1
Matrix of Models of Responsiveness to Health Needs

	<i>Reasonable Availability Is Required</i>	<i>Reasonable Availability Is Not Required</i>
Must target health needs that are also health priorities	Most restrictive	Less restrictive
May target health needs that are not health priorities	Less permissive	Most permissive

with those conditions that do arise. Communities that use their scarce social resources to invest in the basic capacities of community members have significantly greater success in staving off famine and epidemic disease. Those that do not direct community resources to these ends often create conditions in which starvation and disease flourish, sometimes on a massive scale.^{19,20}

At the same time, sickness and disease themselves threaten important interests of individuals and communities alike. On the one hand, they impede the ability of individuals to function on an equal standing with others by restricting the full range of social opportunities that are available to them and often shortening their lives. In turn, the inability of individuals to take effective advantage of the full range of the social and economic opportunities available to them can significantly impact the ability of communities to advance important social and political goals such as fostering education and economic growth.²¹

In light of these interrelationships, one of the views that occupies the top row of the matrix, the human development model, holds that various parties from developed countries, including government officials and the citizens they represent, have a duty to aid those in the developing world. It also holds that the duty to aid should be understood as a duty to assist those populations in developing and maintaining fair and equitable social structures that serve to safeguard and to advance the basic interests of community members.¹⁷ What is required in order to discharge this general duty will differ for various stakeholders depending on their ability to influence different aspects of the social structures in developing countries. For example, the citizens of developed countries have a duty to support efforts to make better use of existing knowledge, resources, and interventions that could make a significant impact on the lives of those in the developing world. However, this view recognizes that even when a greater share of existing resources are directed toward advancing this goal, scientific research still has an important role to play in this process.

When this general duty to aid is applied to researchers and to research sponsors, therefore, the human development model translates the duty into an obligation to ensure that scientific research is responsive to host community health needs in a particular way. The model assumes that research can function as a powerful engine for creating the understanding and the interventions that are necessary to bridge gaps between the basic interests of community members and the ability of that community's basic social structures to safeguard and advance those interests. In order to bridge such gaps, clinical research must focus on health problems of developing-world communities that cannot be met more effectively or efficiently through the application of existing resources. Such health needs may be novel in the sense that there are no known means of treating or ameliorating them, or they may be health needs that have to be met under novel circumstances. That is, effective interventions may exist, but it may not be possible to deploy them within the host community on a sustainable basis. As a result, inquiry may be necessary in order to ascertain how to best to meet those needs under conditions that are attainable and sustainable within the host community. By focusing on health needs that cannot be met more effectively or efficiently through the application of existing knowledge or resources, and by doing so in a way that seeks to bridge the gaps between important health needs of community members and the ability of basic social structures in that community to meet those needs, collaborative

research represents an important avenue through which the more general duty to aid may be discharged.

This view of the duty to aid, and the role of scientific research in advancing its goals, provides important guidance for selecting the criteria for determining which of a community's health needs should be given priority for research purposes. In particular, such criteria should be responsive to (a) the significance of the impact of a health need on the ability of individuals to access the full range of social opportunities that would otherwise be open to them, including their ability to cooperate in advancing important social goals, (b) the impact of these needs on equity and social justice in the host community, (c) the prevalence of these needs in the host population, and (d) whether they can be more effectively or efficiently met through the application of existing knowledge and resources. Some important steps have recently been taken in this regard by a variety of communities that have sought to define their national health priorities so that research can focus on what has been termed *essential national health research*, or ENHR.¹⁻³ ENHR refers to a strategy of systematic priority setting within which research questions can be identified and prioritized according to factors such as economic impact, cost effectiveness, effects on equity, social justice, and their contribution to strengthening research capacity in the host community.

Medical research that focuses on such health priorities has several important moral properties. Such research can make a strong *prima facie* claim to represent a just use of the host community's scarce social, economic, and human resources and to having significant social value because (a) these resources are being used to generate the knowledge, methods, and interventions necessary to expand the capacity of important social structures in the host community—such as the close-to-client health system—to address significant health needs of that community's members and (b) these needs could not be met more effectively or efficiently through the application of existing knowledge or resources.¹⁷ As a result, such criteria represent a valuable means of identifying research questions that are essentially directed at closing the so-called 10/90 gap.

Although these criteria provide general constraints on what can count as a health priority in the research context, the actual health priorities of a community must be identified through the collaborative efforts of a number of parties. It is essential, therefore, that the process of identifying these priorities be transparent and open to public scrutiny. Similarly, it is essential that this process involve the participation of community representatives from local as well as national levels, including representatives of relevant minority groups. In this way, research can be responsive to on-the-ground factors that influence the prevalence of the condition in question, as well as factors that influence the ability to effectively treat those who are afflicted with it. The goal of these requirements is to ensure accountability and legitimacy as well as scientific and social responsibility.

The importance of ensuring such a transparent and legitimate process of democratic consultation has recently been emphasized by what is known as the fair benefits approach to international research.^{7,8} This approach has also been a leading critical force in challenging the requirement of reasonable availability. Exploring the details of this approach and some of its possible variants will provide a clear context within which to evaluate positions that might fall into the cells in the Table 67.1 that are labeled "less restrictive," "less permissive," and "more permissive."

Less Restrictive Criteria for Permissible Research

The fair benefits approach has been critical of positions that require pretrial assurances of reasonable availability on the grounds that such requirements are overly restrictive and may actually work against the interests of developing world populations. This critical view of the reasonable availability requirement grows out of several concerns.

First, the fair benefits approach emphasizes that the reasonable availability requirement is relevant only to Phase III research. However, communities in the developing world might want to host Phase I or Phase II studies, or epidemiological studies, which are not designed to vindicate novel therapeutic or diagnostic modalities. Like the Nuffield Council, this approach also recognizes that there are numerous direct and indirect ways in which hosting a research initiative can benefit host communities. Such benefits might include the training of medical personnel, creating economic opportunities for employment, providing medical care, enhancing the local infrastructure, or enacting public health measures such as providing clean water. In fact, this approach holds that it might be possible for host communities to derive indirect benefits from hosting a research initiative that are more directly responsive to the larger priorities of that community than is the prospect of receiving access to the particular intervention being evaluated within that study. If this is the case, then requiring researchers and their sponsors to ensure reasonable availability puts an arbitrary roadblock in the way of research that might provide real benefits to developing world communities. It also paternalistically restricts the ability of host communities to bargain for the kind and amount of benefits that they desire most from a research initiative.

In its basic structure, therefore, the fair benefits approach represents an explicit defense of the more liberal version of the requirement for responsiveness to host community health needs identified in our survey of core consensus documents. Like those documents, this approach permits only medical research that is consistent with the values of beneficence and nonmaleficence. Research is permissible, therefore, only if there is a reasonable likelihood that it will leave the host community better off than it was, or at least not worse off. However, because the fair benefits approach views the reasonable availability requirement as overly restrictive, it adopts instead a mechanism of open deliberation and bargaining to achieve an exchange of benefits that is sufficient to leave the host community better off. Research initiatives must address “a health problem of the developing country population,” and they must ensure that host communities receive a fair share of the benefits that are generated from research participation. Of course, decisions about how much of which kinds of benefits make hosting research worthwhile depend crucially on the priorities of the host community. So such questions are left for members of the host community to decide. These decisions would be subject to public debate, and a record of previous agreements would be used as a benchmark for fairness. Using this deliberative process to identify which kinds of benefit constitute a “fair” share in light of the host community’s needs and priorities is meant to respect the autonomy of host community members and to ensure that the research has social value.

Because this approach requires that host community members receive a fair share of benefit from research that addresses “a health problem of the developing country population” without clarifying

whether the problem must be a health priority of the host community, several different versions of this position can be constructed. If “a health problem of the developing country population” is understood as referring to a health priority of the host community—which would place it in the top row of the matrix in Table 67.1—then it can provide a rationale for what I have labeled a “less restrictive” approach to international research. It is less restrictive in the following sense: In addition to permitting all of the research that is permitted by positions in the “more restrictive” cell, it also permits research that targets a health priority of the host community without requiring pretrial assurances that any fruits of that study—if there are any—will be made reasonably available to members of the host community. Such projects are morally permissible, however, only as long as they do provide members of the host community with a fair package of ancillary benefits.

This version of the fair benefits approach overlaps to a considerable degree with the human development approach. Both require research to focus on a health priority of the host community but this version of the fair benefits approach rightly emphasizes the importance of ensuring that the indirect benefits that can attend research participation are coordinated so as to be responsive to priorities of the host community. This is especially important in cases in which the research is not designed to vindicate a new diagnostic or therapeutic modality. After all, Phase III research must often build on prior epidemiological research and on Phase I and Phase II studies. When it is appropriate to carry out such studies in the developing world, the research should be justified according to the requirements of this version of the fair benefits approach. Here, too, the criteria outlined above for prioritizing a community’s health needs might also be used within the context of democratic consultation with host community members to determine which of the indirect benefits of research would best advance the community’s larger social priorities.

Tensions arise between this version of the fair benefits approach and other views that occupy the most restrictive cell in the matrix in the context of Phase III research. Proponents of the fair benefits approach worry that research sponsors and other funding agencies will be unwilling to commit themselves to funding interventions whose therapeutic or diagnostic properties have not been clearly established. They therefore worry that such reticence may hinder the conduct of valuable research.

In contrast, proponents of the reasonable availability requirement worry that without prior commitments, the knowledge that is gained from collaborative research will not have a material impact on the health needs of host community members. For instance, many commentators who were critical of the short-course AZT trials in the developing world were explicitly rejecting a view that would fall into the “less restrictive” area of the matrix in Table 67.1. In particular, they argued that it is not sufficient for research to target a health priority of the host community if members of that community never benefit from the application of the knowledge generated by such trials. After all, effective interventions exist for many of the most pressing health problems in the developing world, and many of these interventions were vindicated by research that was carried out in such populations. Nevertheless, many of these interventions have not made a significant impact on disease burdens in these communities because they are largely unavailable there. As a result, critics hold that the position labeled “less restrictive” does not go far enough toward advancing the health interests of developing world populations.⁴

To a large degree, such tensions reflect the difference between pragmatic and aspirational approaches to international research. The pragmatic approach gives priority to generating knowledge that can be used to advance the health needs of developing world populations, leaving the problem of how to make these advances materially available to be dealt with later. The more aspirational approach emphasizes that host community members will benefit from medical research only to the extent that the fruits of that enterprise are used to expand the capacity of local social structures to meet the needs of the community. From this standpoint, one component of the requirement for responsiveness to host community health needs includes having reasonable assurance that the research enterprise is part of a social division of labor in which the knowledge that it generates will actually be applied to advance the interests of host community members.

Careful consideration of the criteria for responsiveness that were articulated in the previous section can mitigate the tensions that exist between these views. In particular, within the human development model, a fundamental part of identifying research initiatives that are capable of closing gaps between the basic health needs of a community's members and the capacity of basic social structures in that community to meet those needs is identifying target interventions that can be effectively deployed under conditions that are attainable and sustainable in the host community.²² An important aspect of advance research planning, therefore, should be matching communities with research initiatives with the goal of ensuring that (a) the research target represents a health priority of the host community, (b) when research is designed to vindicate a therapeutic or diagnostic modality, there is a strong likelihood that any fruits of the research could be integrated into the basic social structures of the host community, and (c) the research initiative can provide an anchor for indirect benefits that are responsive to the broader priorities of the host community.

In all cases, research protocols should be accompanied by an assessment of the likelihood that the study intervention could be implemented in the host community, including an assessment of conditions that would need to be in place in order to increase this likelihood. Evaluations of whether pretrial assurance of reasonable availability is necessary should involve an explicit assessment of the likelihood that any knowledge generated could be used to expand the capacity of social structures in the host community to meet the basic health needs of community members—including an assessment of the extent to which the support of governmental, nongovernmental, or private entities is necessary to attain and sustain the conditions required for this goal.

Weakening the Criteria for Permissible Research

Significantly more liberal approaches to international research can be generated if the requirement in the fair benefits approach that research address “a health problem of the developing country population” is interpreted as permitting research that focuses on a health need that is merely *represented* in the host population. In such a view, as long as the ancillary or indirect benefits associated with the research are viewed as a fair return by members of the host community, then this position views positions that occupy the top row of the matrix as overly restrictive of important medical research and as paternalistically limiting the ability of developing world populations to advance their various interests and priorities.

Of the two cells in the permissive row, the less permissive view is conceptually unstable and perhaps incoherent. From the standpoint of the human development approach, it represents an inefficient way of advancing the fundamental interests of host community members, because it requires local governments and other funding agencies to spend scarce resources on interventions that do not necessarily address priority health problems of the host communities. From the standpoint of the “most permissive” view, the requirement of ensuring reasonable availability would only serve to prevent some research from taking place that would have otherwise offered benefits to host community members that they would have been willing to accept.

Although it seems clearly problematic in the abstract, this ad hoc approach is what appears to result from simply imposing the requirement of reasonable availability on all international research. As the Nuffield Council points out, most externally sponsored research in the developing world is driven by the priorities of the sponsoring entities. To the extent that the consensus documents canvassed earlier endorse the requirement of reasonable availability without clearly requiring research to focus on a health priority in the host community, these documents leave themselves open to withering criticisms from both more permissive and more restrictive perspectives.

The “most permissive” interpretation of the fair benefits approach is internally coherent and rationally compelling. It permits all the research that is permitted by views that occupy other cells in the matrix, while also permitting any research initiative that addresses a health need that is represented in the host community—so long as the host population receives what it views as a fair package of benefits in return. From this standpoint, hosting clinical research that generates significant indirect benefits for the host community, but which targets a disease problem that is not a priority in the host community might be seen as analogous to hosting a commercial plant that produces products that are enjoyed primarily by members of another community but which provides significant indirect benefits to the host community.

This view, however, raises a number of troubling concerns. To begin with, it is so liberal that it permits the continued use of developing world populations to answer questions that primarily address the health goals and priorities of the developed world. In this respect, it threatens to perpetuate or even to exacerbate the 10/90 gap. Second, the ancillary or indirect benefits that can be generated from research are unlikely to address root causes of disease in the developing world in a sustainable way. In particular, the disparities in bargaining power between research sponsors and host communities, combined with constant pressures to limit the costs associated with individual research projects, make it likely that there will remain a fairly low ceiling on the kind and extent of indirect benefits that host communities can access through the bargaining process.

Third, although it is true that medical research should be carried out so as to produce important indirect benefits, its most significant value lies in its ability to discover information necessary to improve the capacity of important social structures to minister to the health needs of community members. One of the critical reasons for the sharp gains in longevity and quality of life in the developed world over the past four generations has been the success of these nations in understanding health problems from a scientific standpoint and integrating that understanding not just into their respective health-care systems, but into the education

and lives of community members more generally.¹ In light of the profoundly urgent and pervasive health needs of the developing world, combined with the disparities in research representation represented by the 10/90 gap, strong reasons support changing funding priorities and creating incentives for governmental, non-governmental, and private entities to focus more directly on priority health problems of developing world populations.^{13–17} This process can be guided, at various stages, by understanding the requirement for responsiveness to host community health needs as holding that clinical research (a) must take health needs that constitute health priorities of the host community as the occasion for inquiry, and (b) must function as part of a social division of labor in which the fruits of such increased understanding have a high likelihood of being used to expand the capacity of that community's health-related social structures to meet the most pressing needs of community members.

Conclusion

When properly planned, scientific research can be a conduit for myriad direct and indirect benefits to host community members. The true social value of scientific research, however, emanates from its capacity to generate the knowledge, methods, and interventions necessary to enhance the ability of important social structures in the host community to address the most significant health needs of that community's members. Collaborative research initiatives should therefore be required to justify their responsiveness to host community health needs in these terms.

Acknowledgment

Conflict of Interest in Medical Research

Historical Developments

The topic of conflict of interest in medical research has become one of the standard issues in any textbook on research ethics and, particularly in the past decade, has also become a core component of the medical and bioethics literature. More than half of the articles on this subject published in the medical literature since 1966 were published since 1999. The significant increase in the number of such publications is undoubtedly related to the growing role of financial interests in the biomedical research enterprise. Particularly, since the 1980s, following the passage of the Bayh-Dole Act in the United States, which explicitly allowed the commercialization of federally funded research and promoted the patenting of biomedical inventions,¹ the pharmaceutical and biotechnology industries have taken on a more important role in biomedical research. Their influence has expanded through increased industry sponsorship of academic research and as a result of the growth in industry-organized research. The increase in the volume of conflict of interest commentaries, analyses, and policies is the most striking development, but there has also been noticeable shift in focus. Although the conflict of interest debate has historically focused on the conflicts faced by individual investigators, increasing attention is being paid to larger institutional and professional pressures that result from the commercialization of research and of academia. But the issue of conflict of interest is not new and is not exclusively associated with the context of commercialized research.

The Physician-Researcher and Conflict of Interest

Many of the historical examples of research controversies described earlier in this textbook can be seen as illustrations of a fundamental

tension that exists between researchers' commitment to scientific inquiry and their obligations, as health-care professionals, to promote the health and well-being of their patients. Significantly, most of the troublesome historical scandals took place in the context of governmentally sponsored research in which financial interests played little or no role. One only has to recall, for example, how researchers involved in the infamous Tuskegee syphilis study were so committed to gathering information on the physical progression of the disease in African American patients that they continued to observe the patients' decline until 1972, 29 years after effective medication for treating the condition became available^{2,3} (see Chapter 8). The physicians involved did not seem to appreciate how they were violating their primary obligation to their patients, an obligation imposed on them as members of the medical profession. Nor did they seem to recognize in the context of their study a moral duty to prevent harm. Their interest in research affected their professional judgment as clinicians and their commitment to their primary obligation to care for the sick.

Tuskegee and other research controversies illustrate well what conflict of interest is about. Few will suggest that the researchers involved in these studies consciously and purposely harmed their research subjects. Yet their clinical judgment and moral sensitivity were clouded by a blind focus on obtaining research results. In fact, in the context of conflict of interest, we often can see only in retrospect that people were likely blinded by a particular focus. We cannot enter the minds of people to determine their real motivation, but we deduce from what happened that their judgment was skewed by a focus on secondary interests.

The legacy of these historical controversies underlies the strong emphasis on the primary obligation to protect patients in

various guidelines and regulations dealing with conflicts of interest. They highlight, in a very blunt way, how devastating the consequences of an overzealous focus of medical researchers on obtaining research results can be.

The more subtle debate around the notion of clinical equipoise can also be seen as recognition of the crucial tension between the differing duties of researchers and clinicians (see Chapter 24). Indeed, the concept of clinical equipoise aims at sketching the conditions under which clinicians can ethically justify proposing participation in a clinical trial to their patient. The quandary that Charles Fried⁴ and later commentators such as Benjamin Freedman⁵ tried to solve is precisely the potential clash between the primary obligation of physicians to provide the best available individualized care and the primary obligation of researchers to conduct a medically important study—a study that involves research procedures that differ from individualized patient care. The limits placed on clinical research by clinical equipoise—for example, in its imposition of strict limits on placebo-controlled trials, or in its imposition of stopping rules—reflect an understanding that the obligations of clinicians can clash with the obligations of researchers; and that when this happens, there is a clear hierarchy between the interests of clinicians and the interests of researchers: the former trump the latter.

The U.S. National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, which was established in the wake of significant post-World War II research calamities, recognized in its 1978 report that researchers “are always in a position of potential conflict by virtue of their concern with the pursuit of knowledge as well as the welfare of the human subjects of their research.”⁶ This fundamental conflict of individual investigators is the primary reason why agencies such as the National Commission recommended an independent review of research protocols by research ethics committees (RECs) or institutional review boards (IRBs). (I will use the term REC, which is the term used in the Guidelines of the International Conference on Harmonization of Good Clinical Practice. The term IRB is confusing when used in the context of private review boards.)

Financial Conflicts of Interest

The recent literature on conflicts of interest focuses nevertheless very much on the impact of financial conflicts. There is a reason why it is appropriate to focus on financial conflicts of interest and to regulate these conflicts in more detail. Financial interests are objective, fungible, and quantifiable; they can easily be measured.⁷ Moreover, they can be dealt with more easily than many other types of influence that are inherent to any human endeavor. Evidence supports the claim that financial interests have an impact on the behavior of many physicians and researchers, as they do on many other people, and that such interests ought to be regulated more efficiently. Finally, the commercial boom in medical research also creates specific pressures that raise ethical and regulatory issues. Although IRB review of research protocols seemed in the 1970s an appropriate remedy for dealing with the fundamental conflict that exists in clinical research, it may no longer be sufficient to deal with different challenges to research raised in the modern research context.

The growing financial interests in drug development have led to a boom in the conduct of clinical trials.^{8,9} With more drugs in

the pipeline, and commercial pressure to get new medicines quickly onto the market, competition among pharmaceutical companies to find researchers and patients to participate in research has significantly increased over the past two decades. In 1998, 30,000 more physicians were involved in clinical trials in the United States than in 1988, an increase of 600%.¹⁰ Over the same period, there was a 60% increase in the number of community-based clinical trials.¹¹ Community-based physicians, most often remunerated through monetary incentives, are increasingly competing with researchers based in academic institutions for access to research participants.⁸ The conduct of clinical trials is shifting from the teaching hospitals of academic institutions to the offices of private physicians and contract research organizations.⁹ Whereas in 1994, 63% of clinical trials were taking place in academia, in 2004 that percentage had shrunk to 26%.¹²

As a result of the boom in research activities, more participants are also involved in medical research, increasing pressures on recruitment. There are no systematic national or international data on the total number of people who participate in research, but the available information suggests that that number is large. A 2005 investigative report published in *Bloomberg Markets* states that in the United States, industry annually spends \$14 billion to test experimental substances on humans and that “3.7 million people have been human guinea pigs,” but this report does not contain more details as to the period covered.¹³ In Canada, the Health Products and Food Branch reviewed more than 800 applications for clinical drug trials in 1998 and predicted an average 20% annual increase in clinical trials conducted in the country, which also suggests that the number of research subjects keeps climbing.¹⁴

Although there is no official information on how many people participate in clinical trials, the high number of drugs under development suggests that research participants are in high demand and that such research increasingly takes place in a highly competitive environment. In this environment, research participants have become a scarce and valuable commodity.¹⁵ One industry expert stated that recruitment of participants is the industry’s number one challenge in clinical research.¹⁶

Pressure to recruit participants exists not only because of the increase in the number of clinical trials being undertaken but also because of the competitive market environment, in which the speed of trials has significant financial implications. When an experimental drug or device has considerable medical and market potential, corporate sponsors of research and researchers themselves are under enormous pressure to ensure that the research is undertaken as efficiently and as quickly as possible. This explains why the use of financial recruitment incentives has become so important. Financial recruitment incentives are used both to stimulate patient recruitment among physicians and to entice patients or healthy research subjects to enroll in clinical trials.

At the same time, industry also is increasingly sponsoring academic research and creating closer ties to the academic research community. Corporate contributions to academic research are steadily increasing, particularly in many reputable institutions.¹⁷ Academic research institutions are increasingly part of the competitive research environment and are thus confronted with similar issues. The growing conflicts of interest in academia raise an additional concern—the potential disappearance of a truly independent and critical academic sector that could provide a counterbalance to commercially motivated research.¹⁸

Various Forms of Financial Conflicts of Interest

There are various ways in which researchers can have financial interests in research. Companies and contract research organizations often pay researchers incentives to recruit patients or to recruit them more quickly. Researchers may receive significant amounts of money in the context of research. As a result, some clinicians may be tempted to engage in clinical research because of the financial rewards offered. In the year 2000, the Office of Inspector General of the U.S. Department of Health and Human Services (DHHS) issued a report documenting various recruitment activities and confirming a growing interest in the lucrative aspects of conducting clinical trials. The report illustrates, for example, how a private family practice markets potential access to its patients for Phase I to Phase IV trials to sponsors of clinical trials.¹⁹

Financial conflicts can also be created by industry sponsorship of research projects and research centers. Institutional conflicts of interest created by large corporate donations can affect the attitude of individual researchers within the institution.²⁰ Research positions often depend on ongoing industry funding. In many academic institutions, clinical researchers have to find their own source of funding for at least part of their salaries. Industry funding is often easier to obtain than funding through granting agencies. Endowed chairs, even if they are established without any conditions attached, may create an expectation that the chair and/or junior faculty positions associated with the donation of the chair will be loyal to the donor.²¹

Researchers sometimes receive research-related rewards, for example in the form of expensive research equipment, books, or payment for participation at conferences. Some become members of speaker bureaus of pharmaceutical sponsors and receive payments for lecturing, or they are indirectly rewarded by receiving nominations to paid positions on corporate and expert advisory boards.

Financial interests also are increasingly created through the provision of investments and stock. Researchers may obtain stock or other direct financial interests in a company or in a product that is developed as a result of their research. For example, researchers and institutions involved in the Canadian Stem Cell Network can

receive stock in the company that has been set up to commercialize research conducted by members of the network. Researchers or their family members may also independently buy equity in the producers of pharmaceutical products that can be affected by their research.

The growing commercial interests in research are perhaps best demonstrated by an apparent increase in insider trading in the context of research. A recent study by Overgaard and colleagues seems to confirm earlier anecdotal reports that insider trading is indeed occurring in medical research.²² The study suggests that some people with inside knowledge about ongoing research projects are treating these projects as opportunities for financial gain. Interestingly, two recent publications raise the specter of insider trading by volunteer research participants, who may obtain valuable information about the likely success of a new compound because of their involvement in the research.²³

Concerns

Concerns about the impact of financial interests in research can be divided in two broad categories, and each of these categories can be associated with specific types of controversies. First, some controversies have highlighted how financial interests may affect the safety and well-being of human subjects by influencing the way researchers recruit subjects and how they treat subjects in the course of a clinical trial. Commercialization also may threaten the integrity of the research process, the production of data, and the publication and sharing of results. When commercial interests threaten to influence behavior in a way that affects the safety and well-being of human research subjects, the nature of the conflict is clear. It is a conflict between a secondary financial interest and the primary obligation of physician-researchers to protect the well-being of research subjects.

The impact of commercial interests on the integrity of research reveals a potential conflict between the primary duty of investigators to obtain scientifically valid results and the secondary interest of financial gain. This primary duty to conduct valid research is connected to the idea that there is, indeed, a higher calling to

Figure 68.1. Financial Conflict of Interest (Artist's Impression). Source: Andy Myer (artist) and Bruce Agnew. Reproduced with permission.

scientific inquiry than simply providing a set of positive results. Medical research aims at contributing to scientific progress and ultimately at promoting the health and well-being of patients and of the public at large. Even within an entirely commercial research setting, it is important to recognize that there is a public purpose to the research endeavor, that of providing a safe and effective product to the public; and a public interest in making sure that financial interests do not cloud the judgment of those who have a commercial interest in the outcome of the research. When research subjects are involved, the ethical obligation of respect for persons entails an obligation to conduct research that is valid and has value.²⁴ Antal E. Solyom invokes statements of the American Medical Association (AMA) about the important role of physicians to ameliorate suffering and promote well-being and argues that they imply that “clinical research is a *social good*.”²⁵

Financial Conflicts of Interest and the Well-Being and Safety of Research Subjects

Increased competition for access to research subjects has led to recruitment practices that can create significant conflicts of interests for researchers. Many more physicians outside academic research centers now participate in medical research—often not because of their interest in the study nor because of the intrinsic value of the study, but because of the financial rewards for recruiting patients and for participating in the research.

The fact that physicians are paid to provide service is hardly a new issue. Physicians in clinical practice are paid by patients, health insurers, or the public health-care system, generally on a fee-per-service basis. Although arguments have been made that this may create a conflict of interest, it is a fundamental aspect of clinical practice and not unique to the research setting, even if it does create problems of potential overuse. However, remuneration in the context of research takes forms different from remuneration in the clinical context. Some forms of remuneration resemble the fee-per-service model that physicians normally use in their clinical practice. Researchers are often paid the same amount as they would have earned for spending the same time with a patient or for performing the same clinical tasks, such as drawing blood, conducting specific diagnostic tests, or filling out forms. In those circumstances, the conflict of interest, although it clearly can create problems, is no different than those faced by clinicians who are paid for practicing medicine.²⁶ In fact, the AMA, in a general opinion on conflicts of interest, indicates that researchers’ remuneration by sponsors that is “commensurate with the efforts of the researcher on behalf of the company” is acceptable.²⁷ The Canadian Medical Association, in a policy on interactions with the pharmaceutical industry, states that physicians ought to accept remuneration for participation in research “only if such activity exceeds their normal practice patterns,” and it suggests that remuneration can replace lost income.²⁸

Despite the existence of these guidelines, more significant financial incentives are frequently offered to physicians in the context of clinical research. As the DHHS Office of Inspector General reported in 2000, research sponsors are increasingly encouraging health-care professionals to recruit subjects by offering recruitment incentives—often paying for the mere fact of referring a patient to a clinical trial, usually referred to as finder’s fees.¹⁸ Finder’s fees ranging between \$2,000 and \$5,000 per patient have

been reported in industry-sponsored research.²⁹ Other incentives include an extra payment for each 20 patients recruited; or, during the recruitment process, sponsors may offer bonuses when recruitment is not going fast enough, to induce competition among participating researchers. Payments may also be offered to reward researchers for managing to keep their patients enrolled in a clinical trial until the end of the trial. If part of a physician’s remuneration is dependent on keeping research subjects in a trial, decisions to remove participants who are not doing well from the study can be negatively affected.

Recruitment incentives may not always be clearly identifiable. They may sometimes be hidden in general payments to physician-researchers. For that reason, it may be difficult for IRBs to evaluate whether the money offered to researchers for participating in research is reasonable in relation to what they are expected to do. Access to the research project’s budget and a good understanding of its provisions are required to fully appreciate whether payments are of the nature of recruitment incentives, or constitute appropriate compensation.

When researchers have significant financial interests, there are concerns that their decisions may be influenced in a way that affects the safety and well-being of their research subjects, as well as the public at large. Delays in conducting the research can affect the profit margins of both the sponsor and the researchers, since they delay commercialization of the product. Researchers may perceive risks in the research to be less significant and may be inclined to move more quickly in trying a new compound on human subjects.

The 1999 Jesse Gelsinger case is often considered a paradigm case that highlights how significant financial interests of investigators and institutions in companies that are funding the research may be perceived as undermining the protection of the safety and well-being of human subjects in research^{30,31} (see Chapter 10). In that case, the lead investigator’s interests in the company involved were as high as \$13.5 million, an amount that he allegedly received for his 30 % share when the company was sold a couple of years after Gelsinger’s death.³¹ Various other investigators, institutional officials, and the University of Pennsylvania itself also had significant financial interests. A Food and Drug Administration (FDA) letter following Gelsinger’s death cited various problems with the gene transfer trial and violations of the FDA regulations.³² The FDA alleged that inclusion criteria were disrespected, that side effects had been underreported and that the regulatory authorities and the IRB had not been adequately informed of various important events and changes to the protocol. A picture emerges of investigators who may have been all too eager to push the trial along, notwithstanding indications of significant risks, and without appropriate consent.²⁹ Scientific zeal or the desire for public recognition and/or academic fame for curing a disease through gene therapy may have been a contributing factor.

In fact, there is no direct and unequivocal evidence in the Gelsinger case that investigators were driven by financial interests. We cannot enter the minds of those who have such interests and therefore cannot know for sure why researchers acted the way they did. In addition, researchers may often be unconsciously influenced by the lure of monetary benefits. It is therefore impossible to establish clear empirical evidence of a *causal* relation between financial interests and the behavior of researchers or the outcome of the study.

But the extent of the financial interests in the Gelsinger case and the nature of the misconduct together clearly created a per-

ception that the financial interests may have played a role. Not surprisingly, the death of Jesse Gelsinger fueled development of further conflict of interest policies by various regulatory agencies and professional organizations.³⁰ In 2000, for example, the American Society of Gene Therapy adopted a policy prohibiting researchers who are involved in obtaining informed consent, selecting participants, or clinical management of a trial from having any equity, stock options, or comparable financial arrangements with the trial sponsors.³³

Neither the lead investigator, James Wilson, nor any of the other investigators involved was ever formally convicted for the alleged fraud and other violations. In February 2005, the FDA announced that it had reached a civil settlement with the institutions involved and with Wilson. Under the agreement, the University of Pennsylvania and the Children's National Medical Center agreed to pay a total of over \$1 million. In addition, Wilson and two other investigators accepted restrictions on their research activities, including a five-year prohibition for Wilson to function as a sponsor of an FDA-regulated clinical trial.³⁴

Conflicts of Interest and Research Integrity

Threats to the validity of medical research are the second major concern associated with conflicts of interest. Since 2000, various agencies and official organizations, including the DHHS, the Association of American Medical Colleges (AAMC), and the Institute of Medicine (IOM) have explicitly cited the threat created by financial interests as a reason to consider major reforms into how research is organized and reviewed.^{30,35–37}

If the scientific validity of a study on which clinical practice will be based is flawed, consumers and patients can be harmed. In addition, public trust in medical research can be affected if it becomes apparent that conflicts of interest have undermined the reliability of data.

The integrity concerns can be divided into two broad categories. First, financial interests may have a subtle impact on the design of the study, the conduct of the study itself, and the interpretation of research data. Second, reports of various recent controversies reveal cases of outright manipulation and increasing control by industry over research questions and over dissemination of results through selective publication of data and ghostwriting. A detailed discussion of all of these aspects related to commercialized research exceeds the context of conflict of interest. Nonetheless, the nature of these controversies must be mentioned, to the extent that they show how some researchers have been influenced either because they have financial interests in the research or because commercial sponsors, by manipulating researchers' secondary interests, tempt them to act inappropriately.

There is a statistically significant association between source of funding for medical research and research outcome: Industry-funded studies are more likely to reach industry-friendly conclusions than studies that are not funded by industry (see Chapter 71). In addition, medical journals have a publication bias: Positive studies are more likely to be published than negative studies. This is not necessarily associated with financial conflicts of interest. Reports have shown an overall tendency of overrepresentation of positive studies in the medical literature. One recent study highlights the bias toward publication of positive results in clinical trials funded by the Canadian Institutes of Health Research.³⁸

Although this reflects a general problem associated with scientific publications, industry interests may add to the problem.

The studies on the relation between funding source and outcome raise at least a perception that financial interests can affect the conduct and interpretation of research. Other secondary interests beyond financial ones come into play, such as the interest academic researchers have in reporting to their academic superiors that they obtained significant research funding, and the interest in authoring publications. Indeed, researchers may be reluctant to protest against decisions of research sponsors not to publish studies, or to present only a selected set of research results, out of a concern to keep good relations with the sponsor for the purpose of future funding.²¹ They may also act on the basis of their own personal interest in obtaining easy publications and in enhancing their academic record.

The issue of authorship brings us to another phenomenon associated with the increased commercialization of medical research. Sponsors may hire medical service agencies to analyze and write up the final research results, and often offer the nearly finished manuscript as an easy publication to established academics in the field.⁹ The sponsor's motive is that academic authorship gives credibility to the research and helps to get the studies published in the most respected medical journals. Academic researchers may be happy that they can add a prestigious publication to their curriculum vitae. A 1998 article in the *Journal of the American Medical Association* reported that up to 11% of articles published in six leading academic journals used ghost authors.³⁹ A 2003 article in the *British Journal of Psychiatry* discusses in detail the publication strategy by a medical service agency, including the use of ghost authors, for the promotion of the drug sertraline.⁴⁰

Concerns about ghost writing and lack of access to the results of a study are at the core of another controversy surrounding selective serotonin reuptake inhibitors (SSRIs), which culminated in a lawsuit by New York State's attorney general against GlaxoSmithKline.^{41,42} The company was accused of "persistent and repeated fraud" related to its alleged encouragement to sales agents to misrepresent crucial safety and efficacy information in their dealings with physicians. The lawsuit charged that in 1990, a research unit of GlaxoSmithKline had conducted several studies focusing on the safety and efficacy of its blockbuster drug Paxil for the treatment of depression in children and adolescents. While the studies revealed an increased risk of suicidality, suicidal ideation, and agitation, and did not indicate significant efficacy, the company coordinated the publication of only a selection of positive results of one of the three studies in the *Journal of Child and Adolescent Psychiatry*.⁴³ Authors of the article included several prominent academic researchers. The lawsuit was settled out of court after the company agreed to pay a fine and publicize research results on a publicly accessible web site.

These controversies are connected to academia and involve academic researchers. Robert Steinbrook mentions that gag clauses remain common in clinical trial agreements signed by academic investigators.¹² Under such agreements, investigators cannot analyze the data without agreement from the sponsor and cannot publish any results without obtaining the consent of the sponsor. There is no uniformity in the approach taken by various U.S.-based academic centers with respect to contractual publication agreements.⁴⁴ Many academic institutions still allow provisions that give sponsors the right to interfere in one way or another in the publication of the research results, for example, by giving

them the right to draft the manuscript, control access to the data, or insert their own statistical analysis.

The phenomena of ghost authorship and publication restrictions have their place in a discussion of conflict of interest in medical research. The use of ghost authors is a clear violation of authorship guidelines of the International Committee of Medical Journal Editors⁴⁵ and of established research standards. When researchers submit themselves to publication restrictions they undermine their primary commitment to research integrity, which is among the core professional obligations of researchers. They make their primary obligation as researchers subordinate to the interests of the company that sponsors the research and to their secondary interest to add another publication to their CV.

Those who agree to become authors of a publication without any real involvement violate their primary obligation as researchers. Researchers who participate in the formulation of scientific arguments for publication normally require access to the full data and personal involvement in the analysis. If not, they can be considered to violate their primary obligation to have a full understanding of research results before participating in publication of the results. They also violate their primary obligation as researchers when they sign confidentiality agreements that put them in a position whereby they may not be allowed to publicize research results that were obtained in a trial.

Researchers fulfill other crucial functions in the research enterprise. Many are members of influential expert committees that provide advice to drug regulatory agencies or that develop clinical practice guidelines. They also often function as peer reviewers for scientific journals and write review articles describing the state of science in their area of specialization. Financial interests in companies whose profitability can be affected by their expert or review work may interfere with researchers' primary obligations in these positions. Many researchers realize this, although they may have a tendency to think that financial interests are more of a problem for other researchers than for themselves. A study on conflicts of interest among authors of clinical practice guidelines reveals that 89% of the authors of such guidelines had some form of financial relationship with companies whose interests might be affected by their recommendations.⁴⁶ When asked whether financial interests had affected the recommendations made in these guidelines, 19% of the respondents thought that financial interests had influenced their coauthors, but only 7% acknowledged that they themselves could be influenced.

One can argue also that researchers who participate in practices that undermine the integrity of medical research violate a primary commitment to society. Being able to conduct research, particularly when it involves human subjects, ought to be seen as a privilege that comes with societal obligations. Researchers have a professional commitment to conduct research with integrity and with a commitment to search for truth.

Historical Development of Remedies

Conflicts of interest can be dealt with through various means: disclosure, declaration to a hierarchical authority, regulatory review, increased monitoring, reorganization of the research setting, and outright prohibition. Disclosure is the most basic and historically most invoked mechanism to deal with conflicts of interest. The idea behind disclosure is that when people divulge the

interest they have, others can take this into consideration when judging the value of the research being conducted, the arguments put forth by researchers, or the potential impact that the interest may have on the researchers' actions.

Disclosure is used as a remedial tool at various levels. In clinical care, disclosure is seen as an important part of the fiduciary obligations of physicians. Trust is a crucial element of a fiduciary relationship, and those who are acting as fiduciaries must divulge any possible personal interest that could impact on their ability to act for the benefit of the other party.

In the context of research, there is disagreement as to whether researchers are in a fiduciary relationship with their research subjects. Support for a strict disclosure requirement based on the fiduciary relation between a physician-researcher and a patient can be found in the famous 1990 California Supreme Court case of *Moore v. Regents of the University of California*.⁴⁷ More recently, a U.S. district court in Florida found that a researcher who collected tissue samples to study Canavan disease did not have a fiduciary obligation toward donors and refused to recognize that researchers had an obligation to disclose their financial interests when collecting the samples; however, the court did leave open the possibility that research subjects could invoke unjust enrichment to challenge the financial gain made by researchers or sponsors based on the contribution of research subjects.⁴⁸

But even without a clear fiduciary relationship, it seems reasonable to argue that research subjects should be informed of any significant financial interests that researchers may have.¹⁰ The basis for this duty can be found in the ethical requirements of respect for persons, autonomy, and in beneficence.⁴⁹

Official reports and guidance documents do not always speak in one voice. The Council on Ethical and Judicial Affairs of the AMA emphasizes that any potential commercial applications of research involving human tissue must be disclosed to subjects and that human tissue should not be used for commercial purposes without the informed consent of the donor.⁵⁰ Conversely, recent conflict of interest guidance documents issued by the DHHS and by the AAMC do not endorse a strict disclosure obligation to participants. They give institutional authorities or IRBs and RECs leeway in determining when and to what extent financial interests ought to be disclosed.^{35,37} It is interesting to note that a 2004 study suggests that research subjects want to be informed of financial conflicts of interest.⁵¹

Disclosure is also a standard remedy to promote the integrity of the research process itself. Most established medical journals now require that authors of manuscripts submit a form in which they declare any potential conflicts of interest. The "uniform requirements" of the International Committee of Medical Journal Editors (ICMJE), an influential group consisting of the editors of the major medical journals, requires that authors disclose "all financial and personal relationships that might bias their work."⁴⁵ The Committee does not explicitly require that all conflicts also be printed, but it suggests that "[i]f doubt exists, it is best to err on the side of publication."⁴⁵ Although the most influential medical journals have taken the approach that conflicts of interest have to be explicitly declared in publications, many major science journals continue to hold that disclosure to readers is not necessary. A 2001 analysis of science and medical journals revealed that only about 13% of these journals had conflict of interest policies.⁵²

Several leading medical journals have followed a more stringent conflict of interest approach for review articles and editorials,

specifying that authors of such articles should have no financial ties to the producers of products or therapies that are discussed in the article, nor to their competitors. However, it tells us something about the commercialization of medical research that in 2002, the *New England Journal of Medicine* felt the need to soften its very strict “no-financial-interest” policy toward editorialists and review authors because the editors could no longer find sufficient authors without such interests, particularly in the context of clinical drug trials.⁵³ According to its new policy, only significant financial interests are prohibited, and less significant financial interests are evaluated on a case-by-case basis.

Disclosure is also the basis of other regulatory review mechanisms. As early as 1995, two U.S. agencies involved in medical research funding, the Public Health Service⁵⁴ and the National Science Foundation,⁵⁵ introduced regulations requiring disclosure of financial conflicts of interest in grant applications if researchers have an interest of more than \$10,000 or more than 5% ownership in a commercial entity.³⁰ In 1998, the FDA also adopted financial conflict of interest regulations that require disclosure of equity interests of more than \$50,000, and disclosure of payments to investigators unrelated to the costs of research if they amount to more than \$25,000.⁵⁶

Most academic institutions require researchers to disclose internally on an annual basis any external sources of income. While the purpose of these reporting obligations is often to verify whether employees are accepting external work that could interfere with their internal professional obligations, in the context of medical research they also aim at detecting conflicts of interest that could affect researchers’ ability to be independent in their research. Several institutions have set up specialized conflict of interest committees to scrutinize whether financial interests are of such nature that they may inappropriately impact research activities. In recent reports and guidance documents, the DHHS and the AAMC endorse the establishment of such specialized committees.^{35,37} In addition to emphasizing the need for IRBs or RECs to determine whether researchers with a conflict of interest should be allowed to conduct research involving human subjects, the AAMC recommends that conflict of interest committees collaborate with the IRBs or RECs and communicate information about any financial interests of researchers who submit protocols for review. The AAMC also recommends in both of its reports that conflicts of interest be subsequently disclosed by the IRB or REC to the research subjects.^{36,37}

It indeed seems important that IRBs or RECs are informed of financial interests that could inappropriately affect how researchers deal with research subjects, or how they conduct the research and analyze the results, so that research subjects can be informed of these interests. In institutions where no conflict of interest committees exist, IRBs or RECs should take the initiative to collect all relevant information about conflicts of interest. Many research ethics guidelines, such as the Canadian Tri-Council Policy Statement on Ethical Conduct for Research Involving Humans, explicitly mandate the REC to evaluate conflicts of interest.⁵⁷ Inasmuch as there is sufficient evidence to support the claim that financial interests often negatively affect research, it seems appropriate to treat them as a risk factor to be taken into consideration when evaluating a protocol. After the REC has weighed each conflict of interest and has determined that it does not disqualify the researchers from conducting the research, it is also appropriate that financial interests be divulged to research subjects.⁵⁸

Although RECs and institutional conflict of interest committees are playing an increasingly important role, there still is reason to be concerned about their ability to deal appropriately with conflicts of interest. First of all, RECs are already overburdened and understaffed. Second, in institutions without conflict of interest committees, RECs may not have members with the appropriate expertise to fully understand and appreciate the financial intricacies of research contracts and sponsorship agreements. Third, commentators have pointed out that RECs in academic centers are located within the institution in which research takes place and are staffed with people who often have close relationships with those submitting protocols for review.³⁰ REC members may have their own conflicts of interest, for example, when reviewing research projects submitted by their departmental superiors. In addition, their institution’s growing financial interest in research may contribute to potential institutional pressure on RECs.

As pointed out earlier, the majority of clinical trials are now undertaken outside of academic institutions. These clinical trials are reviewed by private RECs. Some of these private RECs are proprietary, in other words, set up by a company to review its own research, whereas the majority are separate, for-profit ventures, set up to review research protocols in exchange for payment of a review fee. These private commercial RECs face even more substantial conflicts of interest.⁵⁹ First, they are part of the commercialized clinical trials scene and owe their very existence to a lucrative research business. They are clearly more closely connected to industry interests than are academic RECs. REC members know that the context in which they operate is a for-profit one. Members of proprietary RECs are aware that their rejection of a protocol directly affects the profit margin of the company that determines their employment. A private REC’s decision to reject a protocol can have repercussions for future contracts because their revenue is based on clients’ willingness to use their services. Nothing in the regulatory structure in the United States or Canada prohibits clients from going to another private REC, even with the same protocol, although drug regulatory agencies now request that they be informed of any REC review and rejection by other RECs.

Notwithstanding the fundamental conflict of interest faced by for-profit RECs, particularly in a system that does not prohibit forum shopping, drug regulatory agencies rely very much on private RECs for the review of clinical trials. Some of them have become key players in the industry. According to a *Bloomberg Markets* report, the most successful U.S. private IRB, Western IRB, reviews more than half of the new drug submissions to the FDA.¹³ In light of IRBs’ significant public role, the lack of tight regulation is surprising and seems inappropriate.

New Developments: Toward More Stringent and Structural Conflict of Interest Policies

More stringent as well as more structural approaches to remedying conflicts of interest have gained much support in the last decade. A common thread in many of these recommendations is a move away from reliance on case-by-case measures that focus on the integrity of individual researchers and toward more regulatory and structural interventions. This seems directly related to the realization that individual investigators’ conflicts of interest have increased, and that growing commercial pressures on the research

sector as a whole need to be addressed. It no longer seems reasonable to argue that conflict of interest issues can be sufficiently addressed by focusing on individual researchers in isolation and by relying on mere disclosure procedures. Various controversies in the context of drug development have highlighted the growing power of the industry to influence the conduct and outcome of research and to control the flow of information resulting from clinical research. Legislative initiatives such as the Bayh-Dole Act, as well as funding initiatives encouraging commercialization of academic research, have made it harder for individual academic researchers to avoid conflict of interest situations.⁶⁰ Remedies that focus on individual behavior do not address the underlying causes of the demise of scientific integrity and the commercial pressure on researchers and institutions.²⁰

Since 2000, the need to deal with conflicts of interest more widely has been recognized explicitly by various organizations and committees. The National Bioethics Advisory Commission emphasized in its 2001 report, *Ethical and Policy Issues in Research Involving Human Participants*, that institutions ought to develop appropriate policies on financial conflicts of interests and that reliance on IRB review is insufficient.⁶¹ The IOM in 2003 produced similar recommendations about the need for a systematic and specialized review of both individual and institutional conflicts of interest. Interestingly, the IOM report also specifically recommended that institutions develop policies to assess the conflicts of interest of IRB members.³⁰ The AAMC issued a report on individual conflicts of interest in 2001, followed the next year by a report on institutional conflicts of interest. In 2003, the DHHS launched a consultation process to develop new guidelines on financial relationships in research,⁶² which resulted in a 2004 Guidance Document for IRBs, investigators, and institutions.³⁵ The Guidance Document emphasizes, as does the 2002 AAMC report, that financial conflicts of interest can create institutional pressures that have to be addressed at an institutional level.

Both the AAMC report and the DDHS Guidance Document suggest that individual or institutional financial interests in research may sometimes be so significant that the research should not take place in that institution. They further point out that institutional responsibilities for research activities should be separated from the management of the financial interests of the institution. The AAMC also clearly relinquishes disclosure as the primary mechanism to deal with conflicts of interest. The Association introduces a stringent—albeit rebuttable—presumption in the context of individual conflicts of interest that those with a financial interest in research should not participate in that research, unless the REC determines that there are special reasons why the researcher should be allowed to be involved.³⁶ Special reasons would include the special expertise of the researcher or specific institutional technology or knowledge that is not readily available elsewhere. Other recommended options include the establishment of special monitoring programs for both the informed consent procedures and for the conduct of research itself.

Other prominent organizations also are exploring ways to strengthen conflict of interest policies. After media reports revealed that several influential researchers at the U.S. National Institutes of Health (NIH) had significant financial interests in companies that could benefit from research undertaken by the NIH, and that systematic exceptions had been permitted to the existing conflict of interest rules,^{63,64} NIH Director Elias Zerhouni proposed stringent conflict of interest regulations in February

2005, which would have significantly restricted outside activities of NIH officials with “entities substantially affected by NIH programs, policies, or operations.”⁶⁵ Under the proposed regulations, NIH researchers and their immediate family members were, for example, not allowed to have any financial interests in companies whose activities could benefit from their NIH-related activities. The proposed regulations were the subject of intense debate and were criticized, particularly from within the organization, as being too stringent.⁶⁶ New standards were subsequently published in August 2005 to accommodate the expressed concerns.⁶⁷ The new standards permit certain outside activities that seemed to be prohibited under the initial proposal, such as class lectures, serving on data and safety monitoring boards, and participating in grant and peer review committees. The new standards also limit the restriction on holding financial interests in substantially affected organizations to senior NIH employees and their immediate families and allow these people to have investments in such companies that do not exceed \$15,000.

Professional organizations, academia, journal editors, and health policy analysts have argued strongly for other, more systemic measures to combat some of the phenomena discussed earlier. Many of their recommendations in that context do not directly target individual conflicts of interest but rather aim to alter underlying structures and conditions under which researchers may be enticed by financial rewards or hindered by financial interests of sponsors.

Journal editors, for example, have taken several steps in an attempt to restore the credibility of scientific publications. In the past decade, most journals have introduced more detailed authorship forms, in which they explicitly ask authors to confirm that, in line with the criteria introduced by the by the ICMJE, they (1) have made substantial contributions to the conception and design, or acquisition of data, or analysis and interpretation of data, (2) have drafted the article or revised it critically for important intellectual content, and (3) have approved the final version.⁴⁵ Although this measure relies very much on the honesty of the submitting authors, it constitutes a confirmation of the importance of access to data and of genuine authorship. It forces researchers to take personal responsibility for their actions. Journals are also considering strengthening the requirements of disclosing conflicts of interest. One journal announced in 2005, for example, that authors who do not disclose conflicts of interest when submitting an article will be banned from submitting other articles in the future.

In addition to taking measures to disclose some authors' financial interests and promote genuine authorship, the ICMJE has recently endorsed a new policy requiring registration of clinical trials before the start of the trial, as a precondition for the subsequent publication of trial results in their journals.^{45,68} The idea behind this requirement is that when trials are registered, it becomes harder to hide results that do not provide interesting or positive results for sponsors. The registration of clinical trials promotes openness and makes it more likely that results will be scrutinized and challenged. Transparency of the research process promotes accountability and can also put pressure on researchers to be more critical when being invited to join a research project that is coordinated or even controlled by sponsors. In addition, it may give academic authors who have participated in commercially funded research a stronger argument when they insist that the results of the study should be published.

Even before the ICMJE introduced this system as a precondition for submission, registration of clinical trials had been promoted in the United States, for example through the NIH's establishment in 2000 of a clinical trials databank: ClinicalTrials.gov.⁶⁹ In 2002, the FDA issued a guidance document imposing an obligation for all clinical trials involving serious and life-threatening diseases to be registered with this databank. This requirement notwithstanding, a recent study indicated that of 127 cancer protocols sponsored by industry that met the inclusion criteria, only 47% were in fact submitted to ClinicalTrials.gov for registration.^{70,71}

Public registration of clinical trials has been recommended by various other organizations and groups. In 2005, a group of 9 research organizations and 131 international researchers signed the Ottawa Statement, which called for the introduction of a stringent, mandatory, and universal registration requirement for clinical research.^{72,73}

This idea of setting up a worldwide mandatory registration system for clinical trials has been formally endorsed by the World Health Organization (WHO), following recommendations made by the International Clinical Trials Registry Platform (ICTRP), a WHO working group that consulted extensively with various stakeholders.⁷⁴ Although the research community and industry⁷⁵ agreed on the importance of introducing some form of registration, there had been significant disagreement about how much detail should be provided in this public registry and about the timing of the release of specific information about the trials, such as scientific title, primary and secondary outcomes, and sample size.⁷⁶ The ICTRP concluded that detailed registration is essential and provided an extensive list of required registration entries. Registration of clinical trials is clearly seen as a first step. A new working group is now evaluating the need to develop a registry of research results.⁷⁷

Other commentators have called for more drastic measures to curb the potential negative impact of industry's control over medical research. Marcia Angell and Sheldon Krimsky both argue in recent books that it is crucial to separate those conducting medical research and those who have a financial interest in the outcome of the research.^{17,78} They both recommend that a new drug testing agency be established that would control the development and conduct of clinical trials. The agency would determine, in dialogue with the company that submits a request, the appropriate design of a clinical trial aimed at testing efficacy and safety of a new compound. An independent accredited drug testing center would then conduct the trial and analyze the results. Although Angell and Krimsky do not elaborate on this further, it is appropriate to think about how academic research units could be involved in such a newly designed clinical trials process coordinated through a government drug testing agency. Instead of negotiating directly with industry, and thereby facilitating the use of financial incentives that can create significant conflicts of interest, academic researchers would be involved in clinical trials through an intermediate governmental structure. Various conflict of interest issues discussed above, for example those related to the use of recruitment incentives and to the phenomenon of ghost authorship, would be more tightly controlled and could likely be avoided.

Wayne A. Ray and C. Michael Stein have come up with a more detailed proposal for regulatory reform of the drug regulatory system that addresses several of the problems discussed earlier.⁷⁹ They recommend the establishment of three new independent

centers: a center for new drug approval, a center for postmarketing studies, and a center for drug information. The center for new drug approval would be more independent from industry funding and would be better informed of all ongoing clinical trials. The center for postmarketing studies would fund independent studies to evaluate the long-term efficacy and safety of drugs that are introduced on the market. The center for drug information would more tightly control how research results and data are presented to the public.

Conclusion

The establishment of one or more new independent clinical trials agencies is among the most drastic measures that have been proposed to curb the impact of conflicts of interest. The proposal fits within an overall trend over the past two decades toward a more systemic approach to conflicts of interest. A new clinical trials agency would obviously not solve all of medicine's conflict of interest woes. Indeed, conflicts of interest can also exist when researchers work for government agencies. In addition, clinician-researchers have to reconcile inherent conflicting interests within clinical research. And even if an independent agency is established, industry interests in other areas of medical research will likely remain. Increased vigilance, informed by continuing empirical evaluation of the potential impact of structural relations between sponsors and medical researchers, is crucial in the context of the growing commercialization of medical research. Promotion of integrity through educational initiatives, disclosure of conflicts of interest, changes to academic evaluation criteria, and administrative review of conflicts of interest within various institutional settings remain valuable tools to improve research integrity. But the proposal for a more fundamental separation between those who conduct research and those who have an interest in its outcome reflects an understanding that the growing commercial interest in research cannot be addressed by reliance on traditional disclosure policies, review by research ethics boards, or the very divergent reporting obligations organized within academic institutions. More structural changes are needed to restore the public trust in medical research. Better regulatory control over conflicts of interest would constitute recognition of the fact that medical research is a vital activity of crucial public importance and that protecting the integrity of medical research is crucial to protect trust in medicine itself.

The Concept of Conflicts of Interest

As the practice of medicine and the conduct of biomedical research have become increasingly commercialized, the risk that financial or other similar interests could improperly influence the conduct of physicians, researchers, and other professionals has correspondingly risen.¹ This risk is at the root of the problem of conflict of interest that now confronts all professionals who seek to pursue the venerable goals of their profession while responding to the new and appealing demands of the marketplace. Prominent among the professionals who must deal with these potential conflicts are clinical researchers. Especially since passage of the Bayh-Dole Act in 1980, industry has become increasingly involved in clinical research. Commercial considerations are playing a greater role in decisions about research, even in academic and other not-for-profit institutions. In response to this growing influence of commercial interests, there has been a corresponding increase in the number and scope of regulations designed to control conflicts between these interests and the core goals of research. Despite the greater attention that conflicts of interest are now receiving, uncertainty persists about what constitutes a conflict of interest, why such conflicts should be regulated, and what standards should guide their regulation.

Brief History

In the 1970s the ability to use recombinant technologies to splice DNA and create microorganisms that produced proteins spawned the biotechnology industry. Although this development did not create the problem of conflicts of interest in biomedical research, it dramatically changed its emphasis and scope.² New biotechnology

companies, such as Genentech and Biogen, were founded by academics to commercialize their scientific innovations. The new enterprises created more intimate links between industry and academia than had existed before. At the same time, traditional pharmaceutical companies began investing in biomedical research centers, donating large sums to academic institutions in exchange for the right to turn the discoveries into profitable applications. In 1974, Harvard Medical School signed a \$23 million, 12-year agreement with Monsanto, which supported laboratory research into antiangiogenesis factors.³ Monsanto received the rights to an exclusive worldwide license for all inventions created as part of the research it supported. Soon thereafter Harvard signed an agreement with DuPont for \$5 million to support a new genetics department at the medical school. In 1980, Hoechst AG donated tens of millions of dollars over 10 years to fund a Department of Molecular Genetics at the Massachusetts General Hospital in exchange for receiving exclusive licenses for all commercially exploitable discoveries.⁴

The Bayh-Dole Act in 1980 significantly accelerated the trend toward closer links between industry and academia. The Act permitted universities and other research institutions to hold and license patents on discoveries funded with federal grants. The law stimulated large and steady increases in industry-academic collaborations. The number of patents granted to universities increased. The sources of funding for biomedical research shifted. Although earlier more than half came from the federal government, now nearly 60% comes from private industry⁵ (see Figure 69.1).

There were early attempts to control the conflicts of interest to which these collaborations gave rise. After the creation of biotechnology companies closely linked with university research

laboratories in the early 1980s, California required professors in its state colleges and universities to disclose any financial interests they had in such companies.

A major scandal at the Harvard-affiliated Massachusetts Eye and Ear Infirmary (MEEI) in 1988 gave greater prominence to the problem and stimulated further reform. An ophthalmology fellow there, Scheffer C.G. Tseng, developed a vitamin A-based ointment for dry eye syndrome, a painful condition in which the eye cannot maintain a tear film.^{6,7} After preliminary positive findings, Tseng sold the rights for the treatment to Spectra Pharmaceutical Services for \$310,000. At the time Tseng also owned 530,000 shares in the company, which, as an article in *Nature* noted, “hoped to market the very same vitamin A-enriched jelly that Tseng was smearing onto the eyeballs of his patients.”⁷ One senior physician at the MEEI who was Tseng’s adviser also owned shares in Spectra and had contributed to early research on the treatment.

In a clinical trial of Tseng’s treatment, the protocol was changed numerous times in ways that seemed to be dictated more by commercial than by scientific interests. For instance, the protocol had originally called for 50 patients, but 250 patients ended up being treated. After Spectra received orphan-drug status for the vitamin A treatment, it sold stock to the public, and Tseng sold some shares at a substantial profit. However, the research was beginning to show that the jelly was no more effective than a placebo. Because of concerns about the changes in protocol and conflict of interest, the study was stopped and subjected to external investigation by Harvard and MEEI. Although the investigation found that no scientific misconduct had occurred and no patients had been harmed, the possibility of more serious abuse in the future had become clear. Harvard Medical School appointed a committee

to examine the risks and to propose new conflict of interest rules.^{8,9}

In the mid-1980s, the leading general medical journals began requiring authors to disclose financial conflicts of interest. In 1984, the *New England Journal of Medicine* started to include notes indicating funding sources for the studies it published, as well as “direct business associations by a corporation that has financial interest in the work being reported.”^{10,11} The *Journal* asked authors to voluntarily submit a statement of financial interests to the editors, who would then determine whether to include the information along with the article. In 1985, *JAMA* adopted a similar policy, which was recently revised.¹² In 1988, the International Committee of Medical Journal Editors adopted a policy that requested that authors voluntarily disclose financial interests related to the article.¹³

Beginning in the mid-1990s, concerns about financial conflicts of interest among academic researchers led to the creation of new rules and the strengthening of existing rules in the biomedical research community. Some professional societies began requiring their own officers and authors who submitted abstracts to their annual meetings or articles to their journals to disclose any conflicts of interest.

Another impetus to the regulation of conflicts in clinical research came from publicity following the death of Jesse Gelsinger in September 1999 (see Chapter 10). The 18-year-old Gelsinger had taken part in an experimental gene transfer study at the University of Pennsylvania. Shortly after one of the treatments, he died. His death—the first reported death ever directly attributable to a gene transfer experiment—triggered an avalanche of revelations. There were questions about the quality of informed consent at the university. There were charges that the university had failed

to promptly report both animal data showing toxicities and toxic side effects with previous patients that could have suspended, if not closed, the study.

In response to a query from the National Institutes of Health (NIH), gene transfer researchers all over the country revealed more than 650 dangerous adverse reactions they had also previously kept secret, including several deaths. In addition to these problems, the case highlighted the dangers of conflicts of interest. James M. Wilson, one of the lead investigators, had founded Genovo, Inc., a biotechnology company focused on gene transfer technologies. He and his family held 30 percent of the company's stock while Genovo supported his gene transfer research with millions of dollars a year. The university itself held 3.2 percent of the company's stock. Although the causal relationship between Wilson's and the university's financial interests and the research violations that ultimately lead to Gelsinger's death is controversial, this case prompted calls for stricter conflict of interest rules not only at the university but at other research institutions.

Soon thereafter, in a decision closely watched in medical schools throughout the country, the Harvard Medical School faculty rejected a proposal, which had been supported by some of its own prominent faculty and researchers in other schools, that would have liberalized its conflict of interest policies.¹⁴ In October 2002, after two years of study, the Association of American Medical Colleges issued a comprehensive analysis of conflict of interest and proposed recommendations for stricter rules.¹⁵ Other professional societies also further strengthened their conflict of interest rules.¹⁶

But by 2004, some observers began to worry that pressure for stronger conflict of interest rules had led to overreactions in some institutions.¹⁷ They feared that charges of conflict of interest were being made irresponsibly, and that rules were being expanded indiscriminately. Press and congressional revelations about relationships between NIH researchers and biomedical companies led the new NIH director to propose new and tougher rules.¹⁸ But many scientists both within and outside of the NIH criticized these rules as overbroad and draconian.¹⁹ They cited the proposed rule that prohibited secretaries and food handlers from holding stock worth more than \$15,000 as an inappropriate expansion of the idea of conflict of interest, and argued that these extreme measures would discredit the legitimate applications of the idea. They also criticized charges of conflict of interest for researchers who provided investment advice as mistaken.²⁰ As a consequence of these criticisms, the regulations were modified in 2005.²¹

Fundamental Elements

A conflict of interest is a set of circumstances or conditions in which professional judgment of a primary interest, such as the integrity and quality of research, tends to be unduly influenced by a secondary interest, such as personal financial gain.^{22,23} Three elements of this definition require further explanation: the two kinds of interest and the nature of the conflict.

The Primary Interest

All professionals have a primary interest, which creates obligations defined by the goals of their profession. For teachers, it is to educate their students; for judges, it is to render justice; for physicians, it is to promote the health of their individual patients. The

primary interest of biomedical researchers is to conduct and disseminate research that generates knowledge that can—directly or through additional research—lead to understanding of biological systems and improvements in human health.

Exactly identifying the primary interest may sometimes be controversial, but there is usually agreement that, whatever it is, it should have decisive weight in the professional decisions an individual or institution makes. An individual researcher should be primarily interested in the integrity of the research, not income or reputation, and not even the welfare of potential patients who may be affected by the research. A medical or research institution should be primarily interested in maintaining the quality of the research, not in maximizing its endowment or burnishing its reputation.

The Secondary Interest

Beyond their primary interest in the integrity of research, researchers have secondary interests, which are both professional and personal. The other professional interests include receiving recognition for their scientific contributions, obtaining grant support, mentoring research fellows, and doing their part as citizens of their research institutions.²⁴ In addition to their role as biomedical researchers, they may have other professional responsibilities as clinical physicians, department chairs, interviewers for medical school or residency admissions, and leaders of professional societies. Like other professionals, researchers also have personal responsibilities in such roles as parents, family breadwinners, community leaders, and political activists. From the perspective of the professional role as a researcher, all of these activities create secondary interests. None is usually illegitimate in itself, and some are even a necessary and desirable part of the professional practice of researchers. After all, research requires financial support, and profitable research can save lives. The secondary interests are objectionable only under circumstances in which they tend to have greater weight than the primary interest.

Conflict of interest rules typically focus on financial gain, not because it is more potent or corrupting than the other interests but because it is relatively more objective, fungible, and quantifiable.²² Money can be measured, and it can be traded for other goods. In addition, monetary conflicts may be easier for people to understand and thus are more likely to undermine public trust in the research enterprise.²⁵ Furthermore, there is usually little controversy over whether financial interests should be secondary, and thus should not influence the integrity of a professional's judgment, whereas some other interests, such as professional reputation, might be regarded as a competing primary interest. It is therefore a mistake to object to the regulation of financial conflicts by pointing to the many other kinds of potential conflicts. Because it is not feasible to regulate most of these other interests, it is all the more important to control financial conflicts.

Financial interests come in many different forms. Financial interests that benefit the researchers personally include stock holdings and options, consulting fees, honoraria for speaking, payments for serving as an expert witness, and licensing fees if distributed to the individual researcher. The financial interests of the researcher's spouse and dependent children must also be considered. The financial rewards of a spouse who might consult for a drug company could influence the researcher's judgment.

The most common and difficult interests to regulate are not directly personal in these ways. Direct financial support for a research protocol or program and in-kind gifts, such as specialized reagents or equipment, may be useful or even necessary for the research, but if they come from sources with a strong interest in the outcome of the research, they may still be suspect. If such support constitutes only a fraction of the total funding for a research project or program, it is less problematic.

The Conflict

It is important to understand that a conflict of interest refers to a *tendency*, not an occurrence. Experience, common sense, and some psychology research data demonstrate that in certain circumstances some individuals and institutions may let secondary interests have excessive weight in their professional decisions and thereby distort their professional judgment. Rules that control this tendency, even if the threat is actualized in relatively few cases, are intended to protect against this risk. Therefore, a conflict exists whether or not a particular individual or institution is actually unduly influenced by the secondary interest. It exists if the individual or institution is making decisions under circumstances that, based on past experience, tend to lead to distortions in judgment. When a researcher owns substantial shares of stock in the company that is the sole funder of the research on a new drug, there is reason to believe that the conclusions are more likely to favor the drug, or more likely to remain unpublished. Preventing dissemination of research results can be an even more dangerous form of distortion than publication of false results, which can potentially be checked by peer review.

When there is no chance that individuals can affect a primary interest—that is, when they do not have decision-making authority regarding a primary interest—then they cannot have a conflict of interest. For example, in biomedical research, if staff members do not have authority or power to determine how a study will be designed, conducted, interpreted, or disseminated, then they do not have a conflict of interest with respect to that study.

In determining whether a conflict exists, why not consider particular decisions or cases instead of general tendencies or circumstances? First, it is usually impracticable to conduct the kind of investigation that would be necessary to determine what actually motivates professional decisions in individual cases. Second, it would often be impossible to do so. Usually there are multiple considerations that could affect judgment. For researchers, relevant considerations that influence their judgment often include the absolute and relative importance of a scientific question compared with competing projects, the speed with which the research can be accomplished, the availability and commitment of potential collaborators, and the cost of the research in terms of time and money. It is often difficult if not impossible for the decision makers themselves to determine how much various considerations affected their judgment.

Third and most importantly, citizens who are affected by the research and others to whom the researchers are ultimately accountable are often not in a position to assess the motives of researchers in individual cases. It is neither possible nor desirable that the process of research should be regularly open to the kind of invasive investigation that would be necessary to determine individual motives. We therefore need general rules to govern con-

licts, even if they are overly broad and prohibit some conduct that, if it could be fully investigated, would be perfectly legitimate.

These considerations also show that the common distinctions between *potential* or *perceived* conflicts and *actual* conflicts of interest are not helpful. All conflicts of interest are potential because they refer to tendencies. And all conflicts involve perceptions or appearances because they are specified from the perspective of people who do not have sufficient information to assess the actual motivations of a decision maker and the effects of these motives on his or her judgment.

Contrasting an actual conflict with a perceived conflict leads to two opposite but equally unhelpful conclusions. First, it encourages the mistaken idea that, though perhaps one should try to avoid even the appearance of a conflict, the appearance is not as bad as the actual conflict; it is, after all, a “mere” appearance. This neglects the fact that the prohibited conflict is in fact already an appearance, a perception in the sense described above, and therefore cannot be a lesser offense simply because it is an appearance. The effect of insisting on the distinction is to undermine the basic rationale for prohibiting any conflict of interest; it makes a conflict seem not so serious unless we can point to evidence that a person was actually motivated to favor secondary over primary interests. When a researcher’s judgment is *actually* distorted by acceptance of a gift or the prospect of royalties, the violation is no longer simply a conflict of interest but rather is the victory of the wrong interest. It becomes another, different kind of offense, one that may involve negligence, abuse of power, or even dishonesty and bribery.

The second unhelpful conclusion goes in the opposite direction. It encourages overly broad and excessively subjective rules, which can be used to raise questions about conduct or agreements that are perfectly proper. With a loose notion of perception or appearance, circumstances that cause anyone to be suspicious—even uninformed citizens or muckraking reporters—come to count as conflicts of interest. It is therefore important to limit conflicts to circumstances specified by rules grounded in past experience and interpreted by reasonable persons on the basis of relevant and publicly available facts. Those facts include such considerations as whether the person with the alleged conflict has decision-making authority, and the extent to which the secondary interest is related to the primary interest.²⁶

Finally, conflicts should not be taken to include all the conflicting interests that researchers may confront in practice. There is a tendency to treat conflicts of interest as just another kind of choice between competing values, such as the familiar dilemmas that arise from the use of patients in research. However, in these clinical trial dilemmas, both of the conflicting interests (for example, the safety of the subjects and the integrity of the research) might be considered primary. Both have a presumptive claim to priority, and the problem is to decide which to choose. Accordingly, these are often called conflicts of commitments as distinct from conflicts of interest. In conflict of interest cases, one or both of the primary interests are assumed to have priority, and the problem is to ensure that the secondary interest—such as financial return—does not dominate. This asymmetry between the interests is a distinctive characteristic of conflict of interest problems.

Paradigmatic Examples

The classic case of a conflict of interest involves a researcher who owns stock in or consults for a pharmaceutical company, and who

also serves as the principal investigator in a clinical trial evaluating whether a drug manufactured by that company is safe and effective. In such a case, the researcher's primary interest should be in designing a rigorous and valid trial, conducting the trial responsibly, collecting data thoroughly and accurately, interpreting the data objectively, and disseminating the data widely. The researcher's financial interest might distort judgments at any one or all of these stages of the process. The researcher might design a trial comparing the pharmaceutical company's drug to a competitor's drug used at a less than effective dose or designate an outcome measure that is of marginal clinical relevance; the researcher might overlook relevant outcomes or stop data collection prematurely; the researcher might overinterpret the results; and, if the study's findings are adverse, the researcher might not publish them or, if they are favorable to the company's drug, might publish them multiple times in different formats.

The case becomes somewhat more complex if the researcher does not hold stock in the company whose drug is being evaluated in the trial, but holds stock in or consults for a pharmaceutical company that produces a rival drug. Even if the trial is not a direct comparison with this competitor's drug, the researcher may still have a conflict of interest because he or she has a financial interest in having the research trial fail.

Similarly, members of institutional review boards (IRBs) or research ethics committees (RECs) can have financial conflicts of interest if they hold stock in, consult for, or receive honoraria to speak for a pharmaceutical or device manufacturer, and the IRB or REC reviews a protocol that is evaluating a drug or device made by the manufacturer. In this case, the member's primary obligation is to rigorously evaluate the ethics of the research protocol. The member's personal financial interest in the company could lead to overestimating the social value of the research, inadequately assessing the scientific validity of the design, or underestimating the risks while overstating the benefits of the research.

Conversely, individuals may have financial interests, such as owning stock in a pharmaceutical company or receiving honoraria for speaking engagements, that do not constitute conflicts of interest. If a principal investigator who conducts clinical research on vaccines owns stock in a pharmaceutical company that manufactures no vaccines and conducts no research on vaccines, there is no conflict of interest. Without a financial interest related to vaccines, the researcher's judgment regarding the design, conduct, interpretation, and dissemination of clinical trials of vaccines cannot be distorted by any interest arising from owning the stock. The value of the pharmaceutical company's stock will not be affected by the results of the vaccine research.

Similarly, a researcher conducting a clinical trial on a drug may, without creating a conflict of interest, accept an honorarium from potential investors who wish to learn about the trial.²⁷ Because the honorarium is not contingent on the choice of a particular trial design or result, it is unlikely to influence judgments regarding the conduct, interpretation, or dissemination of the results. There are serious ethical and legal concerns when clinical researchers offer paid advice to investors.²⁸ However, these involve the risks of insider trading, breaches of confidentiality, and the exploitation of special medical knowledge for the exclusive benefit of people who are willing or able to pay. These risks are distinct from those produced by conflict of interest, though they may be equally or more harmful.

Accepting honoraria from investors should be distinguished from cases in which the researcher is paid to speak about the trial by the pharmaceutical company whose drug is being evaluated. This is obviously improper if data are presented in a biased way. But it is a conflict of interest even if the data are presented objectively, because of the circumstances.

People involved in a research trial may have financial interests that do not constitute conflicts of interest. For instance, the secretary for the principal investigator might hold stock in the pharmaceutical company whose drug is being studied by the investigator. This does not constitute a conflict of interest because the secretary has no decision-making authority over the design, conduct, interpretation, or dissemination of the research related to the drug. The secretary cannot decide what outcomes to assess, whether the results indicate the drug is clinically beneficial, or whether and where to publish a paper about the trial results. A harder case is the research fellow who has no authority but might have some power to affect the results by changing how the data are collected or analyzed.

Conflicts of interest arise not only for individual researchers but also for research institutions, including universities and affiliated hospitals. These institutions have primary responsibilities for overseeing the research conducted by their faculty. Research institutions might license patents, collect milestone and royalty payments, hold stock or options in pharmaceutical, biotechnology, device, or other biomedical companies, and might receive donations or other payments from companies whose products are the subject of research at the institution. Such financial interests could induce university officials to be less aggressive in monitoring the research conducted at their institutions.

A former university president, Derek Bok, has observed, "Universities do not come to the task [of controlling conflict of interest in research] with entirely clean hands, for they, too, may have financial interests that could conceivably bias the results."²⁹ He noted that the principal purpose of the consortia that some universities, such as Columbia and Duke, have formed to bid for contracts from pharmaceutical firms to test new drugs is not to support cutting-edge research, but rather to earn money. Schools that benefit from these consortia have a large stake in preserving the relationships with the companies whose products they test. "To that extent, they have an incentive to avoid results that will disappoint their corporate sponsors."²⁹ That they put their financial gains to other good uses does not eliminate the conflict. It may make the conflict more insidious. Furthermore, such financial interests may affect IRB or REC review, making these panels reluctant to judge industry-sponsored studies as lacking in value or having biased designs.

Purposes of Safeguards

A common criticism of conflict of interest rules is that they unfairly punish ethical researchers for the misdeeds of the few unethical ones. Rules regulating conflicts in research are a "serious insult to the integrity of scientists" who have any financial connection with industry, a prominent critic writes.³⁰ "To ascribe a conflict of interest automatically in such situations amounts to an assumption that the sponsor's interests have influenced the investigator . . . and that the research findings are different from what they would

otherwise have been.”³⁰ Criticisms of this kind reflect a widely held view of conflict of interest rules, but the view derives from a mistaken understanding of the purposes of the rules.

The first purpose of the rules is to maintain the integrity of professional judgment. The rules seek to minimize the influence of secondary interests, such as personal financial gain, that are irrelevant to the merits of decisions about the conduct of research. The rules do not assume that any researcher will necessarily let financial gain influence his or her judgment. They assume only that there is uncertainty about motives—that it is often difficult if not impossible to know with the required degree of confidence what has influenced decisions. Given the general difficulty of discovering the real motives on which people in complex situations act, it is safer to decide in advance to remove, as far as possible, factors that could distract anyone from concentrating on the primary goals of research.

Judging the results of decisions is not an adequate substitute for guarding against improper motives, as some commentators seem to assume. Peer review admittedly offers some protection against mistaken or fraudulent results presented for publication. But the integrity of a particular piece of published research is not the only concern. The possibility that the results of a particular research project might turn out differently because it is funded by an interested party is only one danger against which conflict of interest rules are directed. The decision not to disseminate negative results is usually not reviewed by anyone other than the researcher and the sponsor. More generally, we should also be concerned about influences on the direction of the research and the choice of topics—for example, the tendency of industry-sponsored researchers at academic institutions to put more emphasis on commercially useful research than on basic research.³¹

The second purpose of conflict of interest rules depends even less on the assumption that a researcher will produce biased results because of a conflict of interest. That purpose is to maintain confidence in professional judgment. Here the point is to minimize conditions that would cause reasonable persons to suspect that professional judgment has been improperly influenced, whether or not it has. Maintaining confidence in professional judgment is partly a matter of prudence. To the extent that the public and public officials distrust the profession, they are likely to demand greater external regulation of research, and are likely to supply fewer resources for its support. Because of these possible effects, the purpose is also distinctly ethical. Since the actions of individual researchers can affect public confidence in the whole profession, individuals have an obligation to other people—specifically, a duty to make sure that their own conduct does not impair their colleagues’ capacity to conduct research.³²

The purposes of conflict of interest rules should not be diluted by stretching the rules beyond their appropriate limits. They are not intended to capture the whole range of improper conduct in which researchers may engage. The rules do not seek to prevent other kinds of unethical conduct, such as fraud or deception, or unprofessional conduct, such as incompetence or negligence.

Standards

Standards for assessing conflicts of interest identify factors that make conflicts of interest more or less severe. The severity of a

conflict depends on (1) the *likelihood* that professional judgment in the relevant circumstances will tend to be unduly influenced by a secondary interest, and (2) the *seriousness* of the harm or wrong that is likely to result from such influence (see Table 69.1).

In assessing the likelihood, we may reasonably assume that within a certain range, the greater the value of the secondary interest—the larger the financial gain—the more likely its influence on researchers’ judgments. Below a certain value, the gain is likely to have no effect on judgments. This is why, for example, *de minimis* standards are appropriate for gifts. The value should also generally be measured relative to typical income for the relevant class of researchers, and relative to the scale of the research project. For instance, \$10,000 in value is likely to have more effect on a research fellow with a lower income than on a senior principal investigator with a substantially larger income.

The scope of the conflict refers to the duration and depth of the relationship of the researcher and the commercial entity. Longer and closer associations increase the scope. A continuing relationship as a member of the board or chief scientific officer of a company, for example, creates a more serious problem than the acceptance of a one-time grant or gift. Consulting agreements that extend for years or honoraria that cover years of speaking are more problematic than one-time arrangements. Likewise, serving on a company’s scientific advisory board, which intimately ties the researcher to the fate of the company, is more likely to affect the researcher’s judgment than occasionally speaking for the company.

The extent of discretion—how much latitude a researcher enjoys in the exercise of professional judgment—partly determines the likelihood that a financial interest will influence the research. The more closely the research methods follow conventional practice, the less room there is for judgment, and hence for improper influence. Similarly, the less independent authority the professional has in a particular case, the less latitude there is for improper influence. A conflict involving a lab technician, for example, is generally less severe than one involving a principal investigator. A researcher also may enjoy less independent authority if he or she is part of a large team overseeing a research trial and is subject to oversight by a data safety and monitoring board (DSMB), rather than being responsible only for external auditing of the data collection. In assessing the extent of the researcher’s discretion, however, it is important to consider the independence of other members of the executive committee, DSMB, and other oversight bodies. If some of the other individuals also have relevant financial interests, then independence of judgment might well be compromised.

In assessing the seriousness of a conflict, we should consider first the value of the primary interest: the integrity of research. The potential effects of a conflict include not only the possibility of direct harm to the research project, but also the indirect harm that results from a loss of confidence in the judgment of the individual researcher and the integrity of future research.

The greater the scope of consequences, the more serious is the conflict. Beyond its impact on the research of a particular individual, a conflict may have effects on the research of colleagues. Questions such as these should be considered: Will the fact that this drug company is sponsoring this research project tend to undermine confidence in the results of the work of other researchers in the institution? Will it undermine their ability to raise funds from other sources? Claims of academic freedom should not be allowed to obscure the fact that the actions of any

Table 69.1
Likelihood and Seriousness in Evaluating Conflicts of Interest

Standard	Considerations	Examples
Likelihood	Value of the secondary interest	<ul style="list-style-type: none"> • The size of the investment relative to the overall income of a researcher or an institution • The structure of the incentives • The importance to the research
	Scope of conflict	<ul style="list-style-type: none"> • Is the arrangement a one-time interaction or a continuing relationship? A single payment for research support is not as risky as an ongoing investment in the company.
	Extent of discretion	<ul style="list-style-type: none"> • How much room there is for influence of secondary factors? The greater the number and importance of researchers' judgments the higher the likelihood of conflict.
Seriousness	Value of the primary interest	<ul style="list-style-type: none"> • The more central the research, the more risk if there is a conflict. • To what degree does a conflict affect the trust in other researchers?
	Scope of consequences	<ul style="list-style-type: none"> • What types of harms might result for research participants, the integrity of the study, or approval of a product? • What are the effects on the profession as a whole, or on research funding in general? • Will an institution's arrangements encourage others to do the same and further erode professional standards?
	Extent of accountability	<ul style="list-style-type: none"> • Are the potentially harmful outcomes discoverable by others and reversible? • Is there review by independent researchers or an outside body?

particular researcher may substantially affect the independence or freedom of colleagues.

Institutional Safeguards

Disclosure

The most common safeguard against conflicts of interest is disclosure. Disclosure operates by giving people who may be affected by the results of the research, or who may otherwise need to assess the risks of distorted judgment, the information they need to make a decision about the integrity of the research. By knowing about the financial interest, the readers of an article or the reviewers of a research protocol can make their own decisions about the likelihood and seriousness of a distorted judgment in the conduct of the research.

The disclosure may be made to any of a variety of groups: (1) conflict of interest committees established by institutions to oversee faculty conflicts, (2) IRBs reviewing particular research protocols, (3) journal editors, (4) readers of research abstracts and journal articles and audience members at oral presentations, and (5) participants in research trials. There is wide agreement about the appropriateness of disclosure to groups 1 through 4. But even

here, there is reason to question whether the disclosures that are typically given to these groups are as accurate and complete as they should be. Some researchers evidently do not even understand the requirements for disclosure imposed by journals or even their own institutions.³³ Some institutions have established training programs to try to remedy this problem. Some journals no longer simply ask researchers whether they have conflicts of interest but prompt them to specify their financial interests in detail.

What should be disclosed? The *de minimis* level of financial interest, below which there is no need for disclosure, varies considerably. Many organizations and research institutions have adopted the levels advocated by the Association of American Medical Colleges suggesting that below \$10,000 in value, disclosure is not required.¹⁵ The U.S. Food and Drug Administration (FDA) has an even higher *de minimis* threshold for clinical researchers. Conversely, other organizations, such as the American Society of Clinical Oncology (ASCO), argue there should be no *de minimis* threshold. ASCO maintains that all financial interests, no matter their current value, should be disclosed to journal editors, readers of the society's journal and abstract book, and audience members at its meetings.¹⁶

As for research participants, the fifth group listed above, the requirements of disclosure are more controversial. Many people believe that research participants are entitled to information about

the researcher's conflicts because they are bearing the risks of the interventions. To withhold the information is at best to treat them paternalistically and at worst to exploit them without their consent. Others argue that disclosure serves more to protect the researcher from criticism than the research participants from risks. It is merely a way of evading responsibility—shifting the burden of making the decision to the participants, who are usually not well-placed to assess the significance of any conflicts. Unlike fellow physicians and researchers reading a journal article, most participants do not have sufficient background to make independent evaluation of the disclosure. If the participants must for medical reasons participate in the research study—or if it is strongly in their interest, given their disease and other options—then the information about financial interests is not especially helpful. The disclosure may increase the anxiety of these participants and decrease the trust of the public in the research enterprise.

There are other problems with disclosure. It leaves the financial interest intact, giving the impression that the researchers are ethically approved and do not have to be further concerned about their entanglements with industry. Importantly, if disclosure to research participants is not standard, then other methods of protecting against conflict of interest become even more necessary. More generally, when disclosure only reveals a problem, without providing any guidance or means for resolving it, we should seek other ways—either as a substitute or a supplement—to deal with the conflict of interest.

In the case of institutional conflicts of interest, it is difficult to see how disclosure alone could be an effective remedy. Individual researchers are typically expected to disclose their conflicts to the institution itself through its conflict of interest or ethics committee or IRB. To whom should the institution disclose? An external body could be authorized to oversee the actions of the institution regarding any research in which it has a financial interest. But whether such a body can be truly independent and effective is questionable if, as is usually the case, the institution creates and sustains the body. Nevertheless, if the conflict of interest cannot be eliminated, and the institution's expertise is essential for the research, then the establishment of such an external body may be the best remedy, provided its members are substantially independent.

Management

A second safeguard would create procedures for managing the conflict of interest. Potential mechanisms include assigning a colleague without a conflict to obtain the informed consent from research participants, establishing an independent external audit of the data, and instituting a separate DSMB to evaluate the study's data. Why try to manage rather than prohibit conflicts? Management techniques are necessary when other safeguards, such as divestiture or blind trusts, are unavailable. Such techniques might also be preferable when the participation of the conflicted researcher is necessary for the project. For example, the inventor of a new technology, who holds a patent on it and has founded or served as a scientific adviser to a company that licensed it, may have irreplaceable skills needed in the early phase of the clinical research. Management rather than prohibition might also be appropriate when the research involves a rare disease, and the particular researcher may be in a unique position to conduct the actual research because of expertise, access to appropriate patients, or a specialized referral network.

Prohibition

Finally, prohibition may be necessary to guard against some types of conflicts. In all the types of prohibition, a researcher with a financial interest related to the research is either prevented from engaging in the research itself or required to forgo all financial gains related to the research. Prohibition must usually operate in conjunction with disclosure. We do not know what to prohibit until the financial interests are revealed at least to an ethics committee, IRB, or some other authority in a position to issue the prohibition. Unlike either disclosure or management, prohibition ensures that a financial interest cannot create a conflict of interest.

Prohibition has been used in major clinical trials. An instructive example is the post-CABG (post-coronary artery bypass graft surgery) clinical trial, a multicenter randomized, double-blind study to determine whether lowering cholesterol and antithrombotic treatments lowers the subsequent development of blockage of the venous grafts to heart arteries. The investigators and members of their immediate families in this study were not permitted to

buy, sell, or hold stock or stock options in any of the companies providing or distributing medication under study for the following periods: from the time the recruitment of patients for the trial begins until funding for the study in the investigator's unit ends and the results are made public; or from the time the recruitment of patients for the trial begins until the investigator's active and personal involvement in the study or the involvement of the institution conducting the study (or both) ends.³⁴

Further, the investigators were prohibited from serving as paid consultants to the companies during the same period.

The rules also applied to "all key investigators, not just the principal investigator."³⁴ They provided that "people who provide primarily technical support or who are purely advisory—with no direct access to the trial participants or data—[are] not be subject to these policies unless they are in a position to influence the study's results or have privileged information on the outcome."³⁴ Thus the policy applied to physicians who merely enrolled patients but did not influence the design, interpretation, or dissemination of the study findings.

Other organizations that have prohibited researchers from having financial interests in their research have drawn the circle to whom the prohibitions apply more narrowly. For instance, ASCO's rules prohibit principal investigators from having any personal financial interest, such as consulting fees or honoraria or equity, in the research in which they are participating.

According to this policy, physicians who merely enroll patients in a study are not prohibited from having financial interests in the study because they do not control the design, overall conduct, interpretation, or dissemination of the research.

Conclusion

The problem of conflict of interest in clinical research has become more challenging as the conduct of the research has become more dependent on commercial support and the products of research have become more profitable for commercial enterprise. The need

for a better understanding of the nature of conflicts of interest and a clearer formulation of rules to govern those conflicts are therefore even more necessary than in the past. A firmly grounded policy for regulating conflicts can support greater confidence in the profession of research and the results it produces. It can enable researchers and research institutions better to pursue their main mission. It can help them to concentrate more resolutely on their primary interest in conducting research that respects the highest standards of scientific integrity as they produce knowledge for the benefit of society.

Empirical Data on Conflicts of Interest

The clinical research landscape changed dramatically during the final two decades of the twentieth century. Unprecedented investment in both basic and clinical research led to a six-fold increase in biomedical research expenditures. In 2001, industry funded 60% of biomedical research expenditures, compared to 32% in 1980, with industry providing a majority of funding by the mid-1990s^{1,2} (see Figure 70.1). This shift in funding sources was fueled in large part by the passage of the Bayh-Dole Act in 1980.³ The act encouraged universities and medical schools to commercialize research conducted with government funds by providing them the exclusive patent rights.³ The potential revenues from these arrangements, combined with decreasing clinical revenues, resulted in a substantive growth partnership between academic medical centers and industry.⁴

However, the evolution in the scope and nature of clinical research has not been without controversy.^{4,5} Recent media attention has increased public awareness about conflicts of interest in research.^{6,7} Initial events involved individual researchers reporting difficulties with disseminating the results of their industry-sponsored research.^{8,9} The deaths of several participants in research led by investigators with apparent financial conflicts of interest also raised media attention.^{7,10,11} More recently, widely used drugs such as cerivastatin and rofecoxib were removed from the market because of safety concerns amid worries about whether clinical trial data were suppressed by industry sponsors.^{12–16} Public trust in research has therefore waned, as prospective trial participants and clinicians have become concerned about the financial conflicts of interest inherent in industry-sponsored research.^{17,18}

Industry sponsorship has been an engine of innovation; however, it has also been associated with both real and perceived ethical lapses in the conduct of research. In this chapter, we describe financial conflicts of interest (COIs), provide data demonstrating how financial COIs can promote bias, and present details about approaches for managing COIs.

Types and Prevalence of Conflicts of Interest

Three types of financial conflicts of interest can affect clinical research: project-specific, researcher-specific, and institutional.

Project-Specific Conflicts

Project-specific COIs refer to industry funding that supports the design and conduct of an individual study. The majority of clinical research conducted in the United States now involves this type of conflict, because industry sponsorship of clinical research is more than double government spending. In 2002, companies that were members of the Pharmaceutical Research and Manufacturers of America (PhRMA), the industry's trade association, spent \$18 billion on Phase I, II, and III clinical trials, whereas the National Institutes of Health (NIH) spent only \$8 billion (see Figure 70.1).^{19,20}

The prevalence of project-specific financial conflicts also becomes apparent in reviews of published manuscripts. Recent analyses of disclosed conflicts of interest in randomized controlled trials published in leading medical journals found that approximately

Figure 70.1. National Biomedical Research Expenditures

two-thirds of Phase III trials were sponsored either completely or partially by industry.^{21–23}

Researcher-Specific Conflicts

In addition to industry support of a specific study, investigators may have personal interests in either the study sponsor or the agent being investigated. The data show that these relationships are relatively common; it is estimated that one-third of investigators at academic institutions have some type of personal financial relationship with industry sponsors^{24–27} (see Table 70.1). Krinsky et al. cross-referenced a database of 789 published manuscripts with authors' affiliations and patent applications and found that 34% of manuscripts had at least one author with a financial interest.²⁶ Among authors of randomized controlled trials published in high-impact general medical journals, the most common types of financial disclosures appear to be employment (30%), consultancies and honoraria (22%), and grants (18%).²⁸ Less common types of financial ties include serving on an educational or speaker's bureau (7%) and serving on an advisory board. Notably, the financial ties that receive the most attention, namely royalties from patents (1% of conflicts) and stock ownership (7%), are actually among the least common types of ties.

Institutional Conflicts

Institutional conflicts of interest arise when institutions or institutional decision makers have financial interests that might influence or appear to influence the conduct or oversight of research involving human subjects.^{29,30} The institution as a corporation may have financial interests in the form of royalty or equity interests in companies that sponsor research or whose value could be affected by ongoing research in institutional departments. Institutional decision makers, such as trustees or board members, senior officers of the institution, or members of institutional bodies responsible for research oversight—that is, institutional review boards (IRBs) or conflict of interest committees—may also have a variety of research-related financial interests, including consulting fees, speaking honoraria, corporate board membership, or equity holdings. A 2005 survey of 893 IRB members at academic insti-

tutions found that 36% reported having at least one industry relation in the past year.

The prevalence of institutional conflicts of interest has not been assessed in a systematic manner.^{25,31} Only one study investigated the prevalence of equity ownership among both non-medical and medical academic institutions. The Association of University Technology Managers found in 2003 that 61% of U.S. member institutions reported forming at least one start-up company, receiving equity in 67% of start-up companies formed.³² The prevalence of other types of institutional financial interests or personal financial ties held by institutional decision makers has not been examined.

Conflicts of Interest and Their Influence on Research

Concern about conflicts of interest in research is centered mostly (though not exclusively) on worries that such financial ties might compromise or have a negative influence on research and the way it is conducted. In this section, we will present data about the effect of financial interests on various parts of the research process: (1) research topic choice, (2) study design, (3) study conduct, (4) data interpretation, (5) data reporting and dissemination, (6) study outcome, and (7) research participant safety (see Table 70.2).

Research Topic Choice

Even before a research study is designed or conducted, critics warn that researchers could already be influenced by financial ties.^{27,33,34} One study found that researchers with commercial support were significantly more likely than those without such support to report taking for-profit considerations into account when choosing a research topic (35% vs. 14%, $p < 0.001$), reporting that their choice of topic was affected “somewhat or greatly by the likelihood that the results would have a commercial application.”²⁷ Another study, which surveyed investigators conducting research studies on antianginal therapies, found that although most researchers conducted their clinical trials because of interest in the topic, 45% of the researchers reported that they

Table 70.1
Prevalence of Conflicts of Interest

<i>Study</i>	<i>Study Sample</i>	<i>Financial Interaction</i>	<i>Results</i>
University Scientists			
Blumenthal (1996), ²⁷ Campbell (1998) ¹³⁵	Faculty members in the life sciences at the 50 U.S. universities receiving the most funding from the NIH	Industry sponsorship of research	28% of faculty received industry research funds. 43% of faculty received research-related gifts (equipment, biomaterials, discretionary funds).
Boyd (2000) ⁷⁶	Positive disclosure forms submitted from 1980 to 1999 by faculty at the University of California, San Francisco	Consultantship, gifts, personal funds, equity interest	7.6% of faculty investigators reported financial ties with sponsors, including speaking fees (34%), consulting (33%), advisory board positions (32%), or equity (14%).
Published Manuscripts			
Krimsky (1998) ²⁴	Published manuscripts	Technology transfer, new venture formation	34% of articles had at least one author with a personal financial interest in the results.
Gross (2003) ²⁸	Published randomized controlled trials	Study funding source	37% of RCTs published in leading medical journals were industry-sponsored.
Buchkowsky (2004) ¹⁵⁰	Published clinical trials	Study funding source, author affiliation with study sponsor	Among 100 trials published in 1997–2000: 62% had sole or partial industry funding, and 66% of industry-sponsored studies had at least one author with industry affiliation.
Perlis (2005) ¹⁵¹	Published clinical trials (psychiatry)	Study funding source, author conflicts	60% of 397 studies published in leading psychiatric journals in 2001–2003 received industry funding. 47% included at least one author with a financial conflict.
Ridker (2006) ¹⁵²	Published superiority trials in cardiovascular medicine	Study funding source	66% of 303 studies that were published in leading medical journals in 2000–2005 and disclosed funding source were sponsored by industry.
Institutions			
Stevens (2004) ³²	Members of the Association of University Technology Managers	Technology transfer, new venture formation	61% of institutions had formed at least one start-up company. 67% of institutions had received equity in start-up companies formed. 94% (30 of 32) of responding U.S. hospitals had formed start-up companies.
Other			
Ashar (2004) ¹³⁶	Practicing internists	Involvement in industry-sponsored trials	22% of surveyed internists in Maryland reported that they engage in industry-sponsored clinical trials.
Choudhry (2002) ¹³⁷	Professional society guideline authorship committee members		87% of guideline authors had industry relations. 58% reported industry research support. 38% served as consultants/employees.
Campbell (2006) ¹⁵³	Institutional Review Board (IRB) members at academic institutions	Financial relation with industry in the prior year	22.6% received research funding from industry. 14.5% served as a paid industry consultant. 36.2% reported ANY financial relation.

Table 70.2
The Effects of Financial Conflicts of Interest on Research

Research Process	References	Issues
Choice of topic	Massie (1984) ³³ Blumenthal (1986), ³⁴ Blumenthal (1996) ¹⁴⁰	Almost half of researchers report that they would not have conducted their clinical trials without industry funding. Researchers with commercial support are more likely to report taking for-profit considerations into account when choosing a research topic.
Study design	Anderson (1991), ⁴² Cho (1996), ⁴³ Djulbegovic (2000), ⁴⁴ Kjaergard (1999), ⁴⁵ Liebeskind (1999) ⁴⁶ Clifford (2002), ³⁶ Davidson (1986), ³⁷ Djulbegovic (1999), ³⁸ Jadad (1996), ³⁹ Neumann (2000), ⁴¹ Knox (2000) ¹⁴² Bero (1992), ⁴⁷ Rochon (1994) ⁴⁸	Industry-sponsored research is of higher quality compared to nonindustry sponsored research. Industry-sponsored research is equivalent in methodologic quality to nonindustry sponsored research. RCTs published in industry-sponsored supplements were generally of lower quality than those published in the parent journals.
Study conduct	CONVINCE trial (2003) ¹³⁸ Apotex's deferiprone trial (1996) ⁸	Case examples of trials that were stopped early for "commercial reasons."
Data interpretation	Stelfox (1998) ¹⁴³ Barnes (1998) ⁵²	Researchers are more likely to recommend the use of a drug if they have financial ties to industry. Researchers are less likely to talk about the negative effects of smoking if they have an affiliation with tobacco companies.
Data reporting and dissemination	Melander (2003), ⁵⁷ Whittington (2004) ⁶² CLASS (2000), ⁶¹ Friedberg (1999) ¹⁴⁴ Chan (2004) ⁷⁰ Rochon (1994) ¹⁴⁶ Olivieri-Apotex case (1998/99) ⁸ Dong-Boots case (1997) ^{9,66} Spitzer-GSK case (2004) ⁶⁷ Bayer case (1999) ¹⁶ ICMJE (2004) ⁶⁸ Blumenthal (1997) ¹⁴⁷	Industry favorable results are more likely to be published than results not favorable to industry. An example of biased reporting: the CLASS study published results of only 6 months of a yearlong study in which clinical implications of the results were different. Biased reporting is not associated with industry funding. Biased reporting is associated with industry funding. Cases of industry withholding data. Publication bias at peer-reviewed journals can select against publication of negative clinical trial results. Researcher publication delay associated with industry relationships and engagement in commercial activity.
Study outcome	Various ^{25,37,43,44,48,52,53,55,76,77,81,143,144,148,149}	Industry-funded clinical research leads to pro-industry results more frequently than nonindustry funded research.
Participant safety	Jesse Gelsinger case at University of Pennsylvania ^{10,11} Fred Hutchinson Cancer Research Center bone marrow transplant protocol ⁷	Case of research participant being enrolled in a study in which researchers had significant financial interests. Participant was not eligible and researchers had not notified the FDA of severe side effects experienced by prior subjects or four animals that had died after undergoing similar treatment. Researchers with significant financial interests enrolled participants in a study in which 80/82 participants died of various causes while participating in the study. No evidence implicating COI in patient safety.

would not have conducted their trials had they not had funding from the pharmaceutical industry.³³ Results such as these indicate that industry relationships may influence researchers in their choice of research topic.²⁷ However, little else is known about the influence that financial considerations or commercial viability have on researchers' choices of research topic, and there are many motives and factors that make this determination.

Study Design

To measure the methodological rigor of published trials, researchers utilize quality assessment grading systems that have evolved over nearly 45 years.³⁵ These comprise selected methodologic criteria addressing key components of quality, such as randomization, blinding, and predetermination of sample size.

Several studies demonstrate that industry-sponsored research appears to be of similar methodologic quality to nonindustry-sponsored research. Using various quality assessment tools, 11 studies have reported that industry-sponsored research is either of equivalent^{36–41} or better^{42–46} methodologic quality than nonindustry-sponsored studies. However, two studies found that randomized clinical trials (RCTs) published in industry-sponsored supplements were generally of lower quality compared with RCTs published in parent journals.^{47,48}

Although methodologic grading is an important component of quality assessment, it falls short of determining a study's overall quality.³⁵ Evaluation of study design (that is, the relevance of the question asked or the use of appropriate control therapies) is absent from these grading systems and may contribute to bias in important but subtle ways.

Several studies have investigated the relation between sponsorship and the choice of comparison agents. Two studies found that industry-sponsored studies were significantly more likely to use inactive controls (i.e., placebo or no-therapy controls) than were nonindustry-sponsored studies.^{44,45} Another study found that industry-sponsored RCTs of oral fluconazole for systemic fungal infections tended to use poorly absorbed oral drugs as comparison agents, thus favoring the success of fluconazole.⁴⁹ Finally, two reviews of clinical trials suggested that the dose of the industry-associated drug tended to be higher than that of the comparison agent in industry-sponsored studies.⁵⁰

Data Analysis and Interpretation

Once data from clinical trials have been collected, researchers must interpret and synthesize the data. There has been some concern that researchers' conflicts of interest could bias this process within individual studies, as well as when authors collect and summarize the body of evidence in a given field. The VIGOR study of the anti-inflammatory pain medication rofecoxib (Vioxx) raised such concerns; critics have suggested that the cardiovascular risks associated with Vioxx were obscured. The analysis of cardiovascular events reportedly employed a different termination date than was used for the cardiovascular outcome, effectively removing three myocardial infarctions from the Vioxx group. Further, trial data suggesting that Vioxx was associated with important adverse events such as arterial thrombosis were not included in the study manuscript.

One study demonstrated that authors' financial ties could be associated with their interpretation of a body of evidence surrounding a specific clinical question. Stelfox et al. reviewed all studies published in 1995 and 1996 on the debated topic of the safety of calcium channel blockers to treat hypertension and ischemic heart disease and classified conclusions as supportive, neutral, or critical.⁵¹ They found that 96% of the supportive authors had financial relationships with manufacturers of calcium-channel antagonists, as compared with 60% of the neutral authors and 37% of the critical authors ($p < 0.001$). Perhaps even more surprising, this trend held true for those researchers who had a financial interest in any manufacturer. When the results were stratified by type of financial tie, the same trend was observed for researchers receiving honoraria, support for educational programs, and research funding, but did not hold true for those researchers who served as consultants or were employed by manufacturers.⁵¹

Another area of research where apparent bias in data synthesis can be observed is in articles discussing the health effects related to tobacco. In one study of 106 review articles on the health effects of passive smoking, 37% of the reviews concluded that passive smoking is not harmful to health. The authors found that 94% of reviews conducted by tobaccoindustry-affiliated authors reported that passive smoking was not harmful, while only 18% of reviews conducted by non-affiliated authors reached that conclusion.⁵² After controlling for article quality, the only factor that predicted a review's conclusion was whether or not the author had received funding from or participated in activities sponsored by a tobacco company (odds ratio, 88.4; 95% CI, 16.4–476.5; $p < 0.001$). Examples such as these caution that one should be concerned not only about the financial ties of researchers involved in the trials themselves, but also about the financial interests of authors who synthesize or integrate existing data to make clinically relevant recommendations.

Data Reporting and Dissemination

It has been suggested that conflicts of interest could also bias the manner in which the data are presented and reported.^{52–57} Clinical research that produces results favorable to the drug or device being studied is more likely to be published than clinical research that produces results that are not favorable.^{57,58} As a result, the published body of evidence available to clinicians, or to authors of clinical guidelines, would favor the industry's therapeutic agent. This problem can be further exacerbated by duplicate publications of studies demonstrating favorable outcome.⁵⁹ Conversely, adverse events associated with the experimental agent may be minimized or underreported.^{60,61}

There are several recent examples of this bias, most notably in the use of selective serotonin reuptake inhibitors (SSRIs) to treat depression in children. One study conducted an analysis of 42 placebo-controlled trials of SSRI drugs submitted to Swedish drug regulators.⁵⁷ Of the 21 studies in which the experimental drug was found to be more effective than placebo, the results of 19 (90.5%) were published, whereas of the 21 studies in which the experimental drug was not more effective than placebo, only 6 (28.6%) were published. Furthermore, the data from three of the studies with industry-favorable results were published multiple times, resulting in duplicate publications; none of the studies with nonindustry-favorable results gave rise to duplicate publication.

In a second example, researchers from the United Kingdom conducted a meta-analysis of data from randomized trials that evaluated five different SSRIs against placebo.⁶² The authors reviewed articles that were either published in peer-reviewed journals or unpublished and reviewed by the U.K. Committee on the Safety of Medicines. When published data alone were considered, it appeared that there was a positive risk-benefit ratio for all five of the drugs studied. However, when unpublished data were also considered, the data indicated that the risks outweighed the benefits for four out of the five drugs studied. This discrepancy raises concern, because the results of studies such as these are likely to affect the prescribing habits of doctors.⁶³

However, it is unknown what caused the failure to publish results. This publication bias could be due to (1) industry withholding trial data, (2) the bias against publishing negative studies at peer-reviewed journals, or (3) researchers delaying or withhold-

ing data, whether because of a lack of interest in publishing negative results or due to the influence of industry ties.^{8,9,37,58,63–65}

Industry Data Withholding

There have been several high-profile attempts by industry to prevent publication of negative data.^{8,9} One such case involved Betty Dong, a researcher at the University of California at San Francisco (UCSF) who was conducting a study sponsored by Boots Pharmaceuticals to compare Boots' brand name version of levothyroxine with three competing products.⁹ Dong found that the four preparations were bioequivalent; Boots blocked publication of her results, claiming that the study was flawed. A UCSF independent investigation found that the study had been conducted according to rigorous scientific and ethical standards. When Dong submitted her results for publication in 1994, Boots forced her to withdraw the study, citing a confidentiality clause in her contract. Under pressure from the Food and Drug Administration (FDA), the results were finally published in 1997.⁶⁶

In another example, a study that surveyed leading life science companies, 56% of company representatives reported that the research conducted in universities is "often or sometimes kept confidential beyond the time required to file a patent."²⁷

In 2004, New York Attorney General Eliot Spitzer sued GlaxoSmithKline (GSK), charging that the company violated New York State law by withholding negative data about one of its drugs, Paxil, used to treat depression in children.⁶⁷ Spitzer charged that GSK had conducted at least five studies on the use of Paxil in treating depression in children, yet the results of only one of those studies were published. In the studies that were not published, the results failed to demonstrate efficacy of the drug and, further, demonstrated a possible increased risk of suicidal intention. Spitzer's complaint cited a 1998 internal GSK memo, which states that the company must "manage the dissemination of these data in order to minimi[z]e any potential negative commercial impact."⁶⁷ The lawsuit was settled when GSK agreed to establish a public database including summaries of all GSK-sponsored studies involving a GSK drug.

Journal Publication Bias

In a recent statement, the International Committee of Medical Journal Editors (ICMJE) acknowledged that medical journal bias is a problem.⁶⁸ "Unfortunately, selective reporting of trials does occur, and it distorts the body of evidence available for clinical decision making," the ICMJE said.⁶⁸ It noted that at least some selection bias occurs because journal editors are "generally more enthusiastic" about publishing trials with positive results and "typically are less excited" about publishing those with negative results.⁶⁸

Researcher Publication Delay or Data Withholding

Publication of results—including positive results—can be delayed by other factors as well. One study that surveyed over 2,000 life sciences faculty members found that one-fifth of respondents had delayed publication for more than six months during the past three years to allow for patent application/negotiation, to resolve intellectual property rights disputes, to protect their scientific lead over competitors, or to slow the distribution of undesired results.⁶⁴

Delays in publication were associated with participation in a research relationship with industry (OR 1.34; 1.07–1.59) and engagement in commercial activities (OR 3.15; 2.88–3.41).⁶⁴ Results such as these suggest that financial relationships could lead to researchers delaying the dissemination of their research results. It must be noted that these data were collected from life science researchers and not researchers conducting clinical research.

There have, however, been examples of this reporting bias seen in the dissemination of clinical research data. One example of this is seen in the published article in *JAMA* of the Celecoxib Long-term Arthritis Safety Study (CLASS). In the published trial, which compared the use of celecoxib with traditional nonsteroidal antiinflammatory drugs (NSAIDs) in the treatment of osteoarthritis and rheumatoid arthritis, the investigators concluded that celecoxib "was associated with a lower incidence of symptomatic ulcers and ulcer combinations combined" than traditional NSAIDs.⁶⁹

However, this conclusion was reached from an analysis that took into account only the first 6 months of data from a study that was designed for a 12-month endpoint. The complete 12-month study data—which were not published but were available to the FDA—showed no proven safety advantage for celecoxib over NSAIDs in reducing ulcer complications, a direct contradiction of the published 6-month results.^{14,15} The editors of *JAMA* were not told of the complete study data at the time the article was published.^{12,13} In addition, an author of an accompanying favorable editorial published with the CLASS study had not been provided with the full 12-month study data either. "I am furious. . . . I wrote the editorial. I looked like a fool. But . . . all I had available to me was the [6-month] data presented in the article," the author, M. Michael Wolfe, was quoted as saying in the *Washington Post*.¹²

Data regarding the association between differential reporting and industry sponsorship, however, show a mixed picture. In one cohort study including 99 clinical trials (half of which were industry-funded), Chan et al. looked for unreported and incompletely reported trial outcomes in these trials, comparing published trial results with study protocols and protocol amendments.⁷⁰ Although both unreporting and incomplete reporting of efficacy outcomes (71% and 92% prevalence, respectively) and harm/safety outcomes (60% and 81% prevalence, respectively) were found, there was no significant statistical association between this reporting differential and the presence of industry funding. Many studies suggest that occurrences of differential reporting are probably due to selective reporting of trial data, often due to outcomes not being statistically significant.^{65,71–75}

However, other studies and case examples have found that industry sponsorship was associated with reduced reporting of unfavorable results.^{12–15,56} One study, which reviewed original research articles on cost or cost-effectiveness analyses of six oncology drugs, found that studies sponsored by the investigational drugs' manufacturers were less likely than nonprofit-sponsored studies to report qualitative conclusions that were unfavorable to the drug being studied (5% vs. 38%, $p = .04$), whereas overstatements of quantitative results were not significantly different (30% vs. 13%, $p = .26$).

Regardless of why, it is apparent that differential reporting and dissemination *does* occur, and this phenomenon could explain—at least in part—the preponderance of pro-industry results among published industry-sponsored studies.^{53,55}

Study Outcome

Data suggest that industry-funded clinical research leads to pro-industry results more frequently than does nonindustry-funded research.^{25,37,43,44,51–53,55,56,76–81} This could be a result of several factors that have already been raised: problems related to data dissemination, study designs that favor pro-industry results, issues related to study conduct, or biased reporting of trial results.

To attempt to quantify the impact of financial conflicts of interests on biomedical research, a meta-analysis of eight articles, which together evaluated 1,140 original studies, assessed the relation between industry sponsorship and outcome in original research. Aggregating the results of these articles showed a statistically significant association between industry sponsorship and pro-industry conclusions, in that the odds of a positive study outcome were about 3.6 times higher for industry-sponsored than for nonindustry-sponsored studies (OR 3.60; 95% confidence interval, 2.63–4.91).²⁵ Subsequent analyses have demonstrated consistent findings among different samples of trials and after adjusting for study quality and sample size.^{23,77}

However, studies such as these do not necessarily demonstrate biased or compromised studies; these data could be explained by an industry “pipeline” issue. That is, industry is likely to commit resources only to clinical research that is likely to yield positive results.^{25,37,79} In addition, industry could preferentially support trial designs that favor positive results.⁴⁴

Participant Safety

Although safety is probably the most important aspect of research, there are no data about whether financial interests compromise the safety and well-being of trial participants. This gap is mostly a result of the lack of data on the overall safety of clinical research in general. However, there have been multiple cases in which critics charge that conflicts of interest threatened the safety of research participants.

One such example is the Jesse Gelsinger case. Gelsinger, an 18-year-old research participant, died in a gene transfer study at the University of Pennsylvania in 1999. After Gelsinger’s death, the FDA concluded that he had been placed on the protocol and given an infusion of genetic material despite the fact that his liver was not functioning at the minimum level required by study criteria. Additionally, the researchers had not notified the FDA of severe side effects experienced by prior subjects, nor of four monkeys that had died after undergoing similar treatment, information that the FDA claimed would have resulted in halting the study. The researchers conducting the study had significant financial ties to the company sponsoring the study. After investigations by the FDA and an outside panel appointed by the University of Pennsylvania, three of the researchers were sanctioned and two institutions were fined^{10,11} (see Chapter 10).

In a second case, 83 out of 85 research subjects who were enrolled in a 12-year bone marrow transplant protocol at Fred Hutchinson Cancer Research Center in Seattle died of various causes while participating in the study; an independent investigation found that researchers and the institution had almost \$300 million worth of holdings in a company sponsoring part of the study.^{7,82} Although this information provoked a lawsuit charging

that conflicts of interest compromised participant safety, one must be careful not to draw unsubstantiated conclusions. The individuals enrolled in this study had terminal cancers and the study was conducted over 12 years, thus it is difficult to use survival as a meaningful outcome for this type of study. In fact, the researchers were cleared of conflict of interest allegations in the lawsuit that was brought against them by some participants’ families.^{83,84} Thus although there have been cases in which the safety of clinical research appears to have been compromised, it is difficult to draw any concrete conclusions about whether these errors were caused by the influence of financial ties on researcher judgment, especially due to the lack of data about the safety of clinical research in general.

Protections Against Conflict of Interest

Having examined the influences that financial conflicts of interest can have on research, it is necessary to understand what sort of protections are in place. There are three main types of protection: disclosure, management, and prohibitions.

Disclosure

Disclosure of researchers’ financial ties to industry is the most widely used protection. Researchers are required to disclose their financial ties to a variety of audiences, including COI and other institutional committees, journal publications, and research participants. The rationale for disclosure as a mechanism for mitigating the potential adverse effects of conflicts of interest is that end-users of the scientific data should be informed about the nature and scope of the conflicts involved with a particular study and its investigators, so that they can weigh this information when they assess the validity of the research.

Disclosure in Journals

With the rise of controversy over conflicts of interest in research, medical journals have increasingly adopted disclosure policies.^{24,85} In the 1980s, some journals began implementing voluntary conflict of interest disclosure policies that encouraged researchers to disclose financial relationships and research funding; but studies published in the mid-1990s found that only about one in four journals had adopted such policies.^{24,86} Although ICMJE guidelines state that the source of study support and the role of industry sponsors must be disclosed by authors, a 2003 study of 268 articles found that adherence to these guidelines was variable; overall, 89% of articles disclosed the source of study support but only 8% of industry-sponsored studies disclosed the role of the study sponsor.²⁸

One study published in 1995 found that 26% of editors who participated in a survey required authors to disclose funding sources,⁸⁷ and another study found that as of 1997, only 15.8% of 1,396 scientific and biomedical journals had an explicit conflict of interest policy in place.⁸⁶

Disclosure to Research Participants

The idea of requiring disclosure of individual and institutional COIs to research participants has attracted increasing attention.^{88–90} Some bioethicists and researchers assert that such disclosures

would help participants make informed decisions when considering participation in a research study and would maintain public trust and transparency in the research enterprise.^{88,89,91–93} In addition, disclosure of conflicts to participants could potentially limit the extent to which researchers and institutions engage in financial relationships with industry.⁸⁹

The 2000 revision of the Declaration of Helsinki mandates that “in any research on human beings, each potential subject must be adequately informed of . . . the sources of funding, any possible conflicts of interest, [and the] institutional affiliations of the researcher.”⁹⁴ Other groups, including the American Medical Association, have also recommended disclosure to research participants.^{95–98}

Although disclosure of COIs to participants may have a face validity, the strategy has been criticized as well. Some critics have expressed concern that participants may not be in the best position to interpret the disclosed information or recognize their options (other than not participating in the research study).^{88,89,92} Others have suggested that disclosure to participants places responsibility on them, rather than on researchers and institutions, thereby putting the onus on the least powerful group.^{89,99} Furthermore, one author has asserted that disclosure of relatively inconsequential conflicts of interest may disrupt the relationship between the physician and the patient (or the researcher and the participant).⁸⁹ However, a 2005 survey of 253 cancer trial participants found that over 90% expressed little or no worry about financial ties that researchers might have with pharmaceutical companies.¹⁵⁴ Additionally, the majority of respondents indicated that they would still have enrolled in the trial even if their researcher owned stock (76%) or could potentially receive royalty payments (70%).

Management

COI management strategies can be conceived of as a continuum that encompasses all strategies for reducing the impact of COI beyond disclosure and short of outright prohibition. Management of COIs can be conceptualized as an attempt to ensure the safety and autonomy of potential participants, the objectivity of science, and the transparency of the entire scientific process. There are several distinct approaches to management, including clinical trial registration, data safety and monitoring boards, independent consent monitors, and mechanisms to ensure investigator independence.

Clinical Trial Registration

There have been recent calls to implement a clinical trials registry in response to concerns about selective reporting of clinical trials. One approach to ensure access to trial data has involved reframing the concept of nondisclosure from a scientific and ethical issue into a legal one: A case filed by then New York State Attorney General Elliot Spitzer charged GlaxoSmithKline (GSK) with fraud for not disclosing all clinical trial results concerning the safety of depression medications in children. As part of the subsequent settlement, GSK developed a publicly accessible clinical trials registry containing the results of all GSK-sponsored studies.^{67,100} Fewer than three years later, the newly available GSK clinical trial registry was used as a key data source in a high-profile meta-analysis questioning the safety of the diabetes medication rosiglitazone. The validity of this analysis was questioned, in part

because it was based on the only type of data available to the authors—pooled data, rather than patient-level data that would allow for more robust statistical analysis. Large clinical trials are still underway, and the final word on rosiglitazone’s safety is still to be determined. Yet this incident reinforces both the potential advantages of transparency—allowing independent assessment of drug safety—and the disadvantages of only partial transparency. The lack of access to primary data led to decreased methodologic rigor.

The ICMJE confronted this issue in 2004, stating that “honest reporting begins with revealing the existence of all clinical studies, even those that reflect unfavorably on a research sponsor’s product.”⁶⁸ As such, ICMJE members agreed to adopt a clinical trials registration policy, requiring investigators to register their trials in a free public registry as a condition for consideration for publication. All clinical trials, defined by the ICMJE as “any research project that prospectively assigns human subjects to intervention or comparison groups to study the cause-and-effect relationship between a medical intervention and a health outcome,” must be registered as or before participants are enrolled; this definition explicitly excludes Phase I trials that assess toxicity and pharmacokinetics.⁶⁸ The registry must include—at a minimum—the 20 criteria specified by the World Health Organization.⁶⁸ Notably, the ICMJE clinical trial registry does not require that results be included in the registry.

Institutional Conflict of Interest Policies

An important difference exists between oversight of investigator and oversight of institutional conflicts of interest. In the former case, an institutional committee oversees investigators, whereas in the latter case the institution is overseeing itself.³⁰ The execution of such self-regulation and oversight is challenging. Although several models have been proposed for both internal and external oversight of institutional conflicts of interest, little is known about which methods are used in practice.^{2,30,101–103}

Regulatory agencies and professional societies have issued guidance documents on the management of institutional conflicts of interest.^{96,104–107} Suggested strategies focus largely on ensuring a “firewall” between institutional officials who oversee research efforts and those responsible for technology transfer and investment decisions. Additionally, institutional decision makers who hold personal financial interests in matters that come under their oversight are expected to recuse themselves or divest their holdings. IRB members, who are charged by the university with overseeing research, are specifically required by DHHS (45 CFR 46.107(e))¹⁰⁸ and FDA (21 CFR 56.107(e))¹⁰⁹ regulations to recuse themselves from participating in any deliberations concerning protocols in which they have conflicting interests. However, adherence to these policies was called into question by a recent national survey of IRB members. Of the IRB members who reported having financial conflicts pertaining to a protocol that had come before their IRB, about one third indicated that they rarely or never disclosed the relationship to an IRB official.

Authorship and Accountability Requirements

In response to concerns about the integrity of publications resulting from industry-sponsored clinical research, the ICMJE in 2001 established criteria for authorship and accountability in publications reporting on clinical trials.¹¹⁰ These standards require authors to reveal the sponsor’s role in the study, and some

journals have implemented a requirement for the responsible author to sign a statement stating that “he or she accepts full responsibility for the conduct of the trial, had access to the data, and controlled the decision to publish.”¹¹⁰ To ensure investigator independence, ICMJE standards also state that articles in which the sponsor had sole control over the trial data or decision to publish trial results will not be published.

Some journals have implemented more stringent requirements in order to ensure independence in data interpretation. In 2005, *JAMA* issued a new conflict of interest policy requiring industry-sponsored studies to give the raw study data to an independent statistician for a second, independent statistical analysis in order to be considered for publication.⁶³ This statistician must be given the raw study data, “along with the study protocol and the pre-specified plan for data analysis” and must “verify the appropriateness of the analytic plan and conduct an independent analysis of the raw data.”⁶³ *JAMA*’s policy also requires industry-sponsored studies to have at least one investigator with full access to study data who is not employed by any commercial funding source.⁶³

Prohibition

Finally, the strictest protection for conflicts of interest is prohibition. Prohibitions can be against types of conflicts of interest (e.g., industry consultation is not allowed), or amounts of financial interests (e.g., cannot have financial ties that total over \$10,000 per year), or can require researcher divestiture to be a part of a study or removal of a researcher from a study. For example, the NIH has implemented new policies regarding the conflicts of interest of its employees. As a result of allegations that NIH researchers allowed consulting fees to influence research decisions involving the companies’ products, the Department of Health and Human Services and the Office of Government Ethics issued new conflict of interest regulations. The new policy, which stands in contrast to past policies in which ties with industry were widely accepted, includes prohibition of employment, consulting, and speaking for a *substantially affected organization* (SAO)—although exceptions can be allowed—as well as prohibitions against senior employees and their dependents owning more than \$15,000 worth of stock in an SAO.^{111,112}

Challenges to Implementing Effective Safeguards

Implementing policies that are effective in regulating conflicts of interest is a challenging process for both government and private institutions. The challenges include promoting consistency of conflict of interest policies and maintaining awareness and adherence to these policies.

First, although disclosure is considered the most widely used protection, there are no consistent standards for disclosure, and thus requirements vary widely between institutions and journals and often lack specificity.^{25,87,125–128} One study, conducted in 2001 by the U.S. General Accounting Office (now the Government Accountability Office, GAO), examined the disclosure policies of five major research institutions and found that their rules regarding disclosure and prohibitions of financial interests differed considerably.¹²⁹ The study found that the five universities had different threshold amounts for disclosure, different disclosure

timelines, and different processes for managing disclosed conflicts of interest. Another study that examined the 100 institutions receiving the most NIH funding in 1998 found that 55% of policies required all faculty members to disclose, whereas 45% required only the principal investigator or those conducting the research to disclose.¹²⁸ This study also found that only 19% of the policies specified limits on the extent of researchers’ financial ties and only 12% specified limits on the acceptable amount of delay in publication of research results.¹²⁸ The authors of this study caution that variability in conflict of interest policies could cause “unnecessary confusion among industrial partners or competition among universities for corporate sponsorship” and could ultimately weaken public confidence in university research.¹²⁸

Second, even if institutions do have conflict of interest policies, researchers are not necessarily aware of or well informed about these policies.^{128,130} For example, a survey of UCSF and Stanford researchers found that 58% were not able to accurately describe the conflict of interest policy at their institution.¹³⁰ Also, even if conflict of interest information is disclosed, the disclosed information may not necessarily be well recorded or readily available to those who need it, such as IRBs. Problems such as these indicate that research institutions need not only to implement coherent conflict of interest policies, but also to educate faculty members in order to make these policies useful.

Furthermore, data suggest that even if conflict of interest policies are in place, adherence to these policies may be deficient. One study examined adherence to the ICMJE’s 1997 uniform requirements for manuscripts submitted to biomedical journals.^{28,131} Only 69% of articles reporting on an industry-sponsored trial disclosed the nature of the relationship between the authors and the study sponsor, and only 8% reported the role of the study sponsor in the methods section.²⁸ Furthermore, only 89% of studies disclosed the source of study support as required by the uniform requirements.

Even with heightened awareness of the need for disclosure, authors may still fail to disclose to the extent required by journals. When several authors failed to disclose to *JAMA* in 2006 any potential conflicts of interest (beyond conflicts related to the study under review), the journal published letters of apology from the authors to readers and wrote an editorial response to emphasize the seriousness of this omission.^{23,132}

Finally, variations in the contractual provisions within clinical trial agreements may allow industry sponsors to exert influence over industry-funded research despite the best intentioned conflict of interest policies. Clinical trial agreements are one of the legal tools by which relationships between institutions and industry are regulated. However, clinical trial agreements infrequently delineate protective provisions, such as requirements that results be published, and frequently allow for restrictive provisions, such as prohibitions against allowing researchers to share information with third parties after trial completion.^{133,134} Given the heterogeneity in clinical trial agreements among academic medical centers, there is also concern that companies could “shop for” the most permissive settings in which to sponsor research.¹³⁴

Conclusion

With the increased involvement of the pharmaceutical industry in the clinical research enterprise, financial conflicts of interest in

clinical research have presented a fundamental challenge to ensuring objectivity and independence in research conduct. Financial conflicts of interest appear to be common, whether in the form of industry sponsorship of clinical research studies or through personal financial ties between researchers and pharmaceutical companies.

It is important to note that conflict of interest is not synonymous with bias. The vast majority of researchers and institutions carry on credible and ethical research regardless of whether a conflict of interest is present. However, data strongly suggest that financial conflicts can threaten the integrity of the research process through several mechanisms, such as influencing the choice of research topic, selection of control agents, research conduct, and outcome, as well as the interpretation, reporting, and dissemination of clinical research data.

In order to protect against the negative consequences of any conflicts of interest, there are three main types of protections in place: disclosure, management, and prohibitions. Recently, medical journals have been at the forefront of instituting disclosure and management policies, requiring the creation and use of publicly accessible clinical trial databases, and ensuring objectivity by the use of independent statisticians to review industry-sponsored trial data. In addition, the federal government and many professional organizations have imposed stricter regulations on the involvement and financial ties that researchers, such as those at the National Institutes of Health, can have with industry organizations.

There still remain several barriers to ensuring the independence and objectivity of clinical researchers in the face of conflicts of interest. Nationally, conflict of interest policies vary widely, and data regarding the awareness of and adherence to such policies remain less than ideal. Furthermore, contracts between clinical researchers and industry sponsors are presenting even greater challenges.

In order to avoid biased judgment of researchers and institutional decision makers, conflict of interest policies need to be augmented and made more uniform, and institutions must make sure that safeguards for preventing the negative influences of conflicts of interest are in place. The involvement of industry in the clinical research enterprise is important, but precautions must be taken to ensure that clinical research continues to be conducted in an objective and ethical manner.

Industrialization of Academic Science and Threats to Scientific Integrity

Historical Perspective

Relationships between academia and industry have existed since the early 1900s, when more than half of all trustees of U.S. universities were from the industrial sector.¹ However, academic-industry relationships (AIRs) and commercialization began in earnest when chemical and pharmaceutical companies began to undertake research and sought university help in solving scientific problems. Commercialization of research got another boost as universities established independent organizations to commercialize the results of faculty research. The earliest of these was the Research Corporation, which was formed in 1912 to manage pollution technology developed at the University of California.¹ A similar technology transfer organization was created in 1925 when the University of Wisconsin formed the Wisconsin Alumni Research Foundation (WARF) to commercialize a patent on the technology for irradiating dairy products to instill vitamin D in them—a process that virtually eliminated rickets as a childhood disease.² The purpose of organizations like WARF and the Research Corporation was to keep commercial activities “at arm’s length” out of fear that they would compromise the integrity of the academic research enterprise. Despite the fact that these firms conferred great benefit on the public, their creation met with considerable angst within the halls of the academy.

In the late 1970s and 1980s, events in the fields of science, law, and public policy converged to fuel an upsurge in the commercialization of academic research in the life sciences.³ This revolution began in the then nascent field of biotechnology and resulted from the 30-year investment by the federal government in science following the Second World War. Perhaps the most im-

portant scientific breakthrough was the discovery and subsequent commercialization of recombinant DNA technologies by Stanley Cohen and Herbert Boyer in the early 1970s, along with parallel breakthroughs in monoclonal antibody technologies, fermentation technologies, genetic sequencing, and genetic synthesis.⁴ These discoveries emerging from the field of biology would soon overtake the field of chemistry as the source of new drugs—a concept that pharmaceutical companies clearly recognized and that motivated them to establish relationships with academic based researchers and organizations to take advantage of the biological revolution occurring in academia.

The biotechnology revolution occurred alongside a series of public policy developments that facilitated AIRs. As a result of economic concerns driven by rising oil prices and stagnant corporate productivity, elected officials began to explore policy changes that would stimulate the U.S. economy. Policy makers saw academia as a rich, untapped source of new technologies that could jump start the sagging corporate sector and ultimately the economy as a whole. One problem identified by officials was the lack of motivation on the part of academic scientists and their institutions to aggressively exploit the commercial potential of their research—much of which was funded by the federal government through the National Institutes of Health (NIH), the National Science Foundation (NSF), and the Department of Defense. A watershed event in this regard was the 1980 passage of the Bayh-Dole Act, which allowed universities and individual researchers to claim ownership of the intellectual property resulting from federally funded research, which then could be licensed to companies.⁵ In essence, Bayh-Dole stoked the fires of academic commercialization by creating a new and potentially large

stream of revenues flowing to academia from the commercial sector.

A third development, this time in patent law, added additional fuel to the fires of academic commercialization. As a result of the U.S. Supreme Court's 1980 ruling in the *Diamond v. Chakrabarty* case, it became possible to patent new life forms resulting from biological manipulation.⁶ Many of the most promising technologies for drug development were emerging from the creation of novel cells and the substances these cells produced, but companies needed a way to protect the commercial value of these discoveries. The *Chakrabarty* decision provided such protection and ultimately reassured universities and industry that commercial ventures based on biotechnology could be economically viable.

As a result of these tri-part changes in science, policy, and law, a number of large, high-profile relationships between academic institutions and industry developed. One of the highest profile relationships was a 1980 agreement between the Massachusetts General Hospital (MGH) and a German chemical and drug company, Hoechst AG. Hoechst funded not only research at the MGH, but also the creation of a new Department of Molecular Genetics and the construction of a research building.⁷ Other relationships were established between Harvard Medical School and the DuPont Co, Washington University at St. Louis and Monsanto, Yale University and Bristol Meyers, and the University of California at Berkeley and Novartis, among others. At the same time, new start-up companies founded by university faculty and located proximal to major universities emerged in Massachusetts and California, including Amgen, Novartis, Genentech, and Chiron. Overall, from 1980 to 1990 it was estimated that university faculty participated in the founding of 500 life science companies in the United States.⁷ Further, in 2001 the journal *Nature* reported that one-third of all the biotechnology companies in the world had been founded by faculty members at the University of California.⁸

The 1980s and 1990s witnessed a virtual gold rush of activity among academics, universities, and industry via the patent system, a surge dominated by the life sciences (see Figure 71.1). In the 1970s, patent awards to academic institutions were in the range of 250 to 350 per year. In 1980, awards totaled 390, whereas in 2000, they reached 3,087, a nearly eight-fold increase in just 20

years.⁹ Almost one-half of those patents were in the life sciences, up from 15% in 1980.

Over the decade of the 1990s, university technology transfer activities increased at a tremendous rate. For example, the number of professional staff devoted to university research commercialization activities increased more than three-fold from approximately 438 full-time employees to more than 1,300 full-time employees.⁹

At the turn of the 21st century, the commercial activities of academic faculty and institutions again gained national prominence. Numerous studies detailing the nature, extent, and consequences of academic-industry relationships,¹¹⁻¹⁴ including case studies of alleged conflicts of interest in clinical research,¹ drew critical press attention.

At the urging of the newly created Office for Human Research Protections and the Secretary of Health and Human Services, the federal government aggressively promoted the need for government to assist universities in the identification and management of relationships with industry through a draft interim guidance.¹⁵ The goal of the guidance was to help university administrators with academic-industry relationships without imposing any specific prohibitions. Organizations representing medical schools and universities pressed the federal government to hold off making the guidance final, asking for an opportunity to create their own task forces to make recommendations.

Core Conception

AIRs are defined as arrangements in which academic scientists carry out research or provide intellectual property in return for financial compensation in the form of cash, equities, and other considerations. Table 71.1 provides a conceptualization of the various types of AIRs.

Ethical Issues

The academic life science research enterprise in the United States rests on at least four, and perhaps more, fundamental assumptions

Figure 71.1. Trends in University Patents (1979–2001).¹⁰ (Data from U.S. Patent and Trademark Office.)

Table 71.1
Conceptualization of AIRs

<i>Type of Relationship</i>	<i>Definition</i>	<i>Comments</i>
Research	Industry support of a scientist's university-based research, usually in the form of a grant or a contract. ¹²	Institutions benefit financially because research grants support salaries and facilities that otherwise would have to be supported by the institution, fund raising, or other grants.
Consulting	Provision of advice, service, or information by an academic faculty member to commercial organizations. ¹⁶	Individual scientists can retain funds from these activities over and above their institutional salaries. Institutions can benefit financially in cases in which faculty could use these funds to support professional activities that otherwise would be charged to the institution.
Licensing	Granting industry the rights to commercialize university-owned technologies.	These relationships are often negotiated and managed by an office of technology transfer located within the universities, medical schools, and independent hospitals, and research facilities. ¹⁷ In most universities, faculty share some of the financial benefits of licensing relationships with their institutions.
Equity	Participation by academic scientists in the founding and/or ownership of new companies commercializing university-based research, especially in biotechnology.	Often new companies, which are cash-poor, provide equity or options to purchase equity as compensation for relationships such as the consulting and licensing relationships described above. ¹⁸ This equity may be held by individual scientists as well as academic institutions.
Training	Companies provide support for graduate students or postdoctoral fellows, or contract with academic institutions to provide various educational experiences (such as seminars or fellowships) to industrial employees. ¹¹	Institutions benefit because these relationships defray the costs of graduate training. For example, in 2005 the Massachusetts General Hospital accepted \$6.5 million from industry to dramatically expand its graduate medical education programs including live lectures in 24 cities, teleconferences, and webcasts. ¹⁹
Gifts	The transfer of scientific or nonscientific resources, independent of an institutionally negotiated research grant or contract, between industry and academic scientists. ²⁰	Examples of gifts include equipment, biomaterials, discretionary funding, support for travel to professional meetings, and entertainment-related items such as tickets to sporting events, cultural events and dinners.

regarding what is considered to be appropriate and/or inappropriate conduct in science. The first assumption is based on the ideal of truth in the pursuit, generation, transmission, and application of knowledge.²¹ That is, science should above all be completely free from any form of dishonesty, bias, or distortion. Many worry that relationships between academics and industry could motivate scientists to report findings that are not true, ignore other results, or mislead people while giving talks at professional meetings.

A second fundamental assumption is that scientific information, data, and materials should be shared in the scientific community. Robert Merton, a leading sociologist of science, described this assumption as "communism" in which the results of science are owned by the community and the individual scientist's rights are limited to the honor and fame that may come from a discovery.²² Open sharing of scientific results is believed to contribute to the most efficient advance of science by preventing scientists from wasting effort and other scarce resources in repeating past work, and by enabling them to build on colleagues' success. Sharing also creates a sense of shared purpose among scientists. However, although developments in public policy, law, and science have brought about increased relationships with industry, these changes may also have increased the amount of secrecy in science primarily associated with protecting intellectual property rights through the patent system.

The third fundamental assumption is related to the safety of those who serve as research participants. Investigators are required to ensure that the risks to participants in human research are minimized. Many fear that relationships with industry may

encourage investigators to inappropriately enroll patients in trials, which might increase the chances that research participants suffer negative health outcomes, despite the fact that there are no data beyond anecdote and speculation to support this concern.²³

The fourth assumption is self-regulation. The primary responsibility to ensure that members of the scientific community honor the assumptions of the ethical contract described above rests with the scientific community itself and the organizations that comprise it: universities, professional associations, and nonprofit institutes.^{24,25} Of course, numerous governmental encouragements and restrictions have been enacted to supplement the scientific community's own efforts—such as institutional review boards and NIH conflict of interest rules. But the scientific community assumes and jealously protects an inherent professional right and responsibility to regulate itself. The assumption of self-regulation related to relationships with industry is reflected in a complex web of university- and hospital-based institutional reporting systems, conflict of interest committees, and other mechanisms in the scientific infrastructure that are designed to disclose and manage relationships with industry. This self-regulation is designed to ensure that universities have the flexibility to adapt to their unique situations related to relationships between industry and their faculty.

Empirical Data

The most recent nationally representative data regarding the prevalence and magnitude of AIRs in the life sciences stem from

surveys of industry representatives and life science faculty conducted in the mid-1990s.^{11,12} In 1994, senior level executives at life science companies in the United States were surveyed. Based on industry reports, it was estimated that 88% of companies employed academic faculty members as consultants. A survey of basic scientists at the 50 most research-intensive U.S. universities found that 60% of respondents had consulted in the three preceding years (35.2% with a privately held company and 24.5% for a public company).¹¹

More than half of surveyed companies supported university-based research either through research grants or contracts. Among faculty members, 28% of respondents reported receiving research support for their university-based research from industrial sources. The prevalence of support was greater for researchers in clinical departments (36%) than for those in nonclinical departments (21%). Characteristics of industry funding in the life sciences suggested that grants tended, on average, to be small in size and short in duration. Industry respondents indicated that 71% of company-supported projects in 1994–1995 were funded at less than \$100,000 a year. Only 6% of responding firms provided annual funding of \$500,000 or more. For 84% of the firms that had relationships with academia, the typical relationship lasted two years or less.¹¹ Industrial support also constituted a relatively small proportion of the total research funding to universities in the mid-1990s, about 12% of the total.

Another commonly reported form of industrial support of academic scientists is through research gifts.²⁰ Among life science faculty in the 50 most research-intensive universities, almost half (43%) received research gifts, independent of a grant or a contract from industry, in the three years preceding the study. The most widely reported gifts received from industry were biomaterials (24%), discretionary funds (15%), research equipment (11%), trips to professional meetings (11%), and support for students (9%). Of those receiving a gift, 66% reported the gifts were important to their research.

There are limited national data on the frequency of equity or licensing relationships among faculty. In 1992 Krinsky and colleagues found that as many as 34% of lead authors of articles published in 14 major biological and medical journals had a financial interest in a company with activities related to their published research. Krinsky also found that 15% of lead authors from Massachusetts institutions had personal financial interests in a company supporting their research.²⁶ A study of disclosures at a single research institution, the University of California at San Francisco, found that 7.6% of clinical principal investigators had some form of personal financial ties to industry.¹⁴ A third of these reported temporary speaking engagements for companies, a third involved the investigator holding a paid position on a scientific advisory board or board of directors, and 14% related to the ownership of equity in a firm.¹⁴

Relationships Between AIRs and Bias of Reporting

In recent years, a significant body of research and commentary has suggested that relationships between academic scientists and industry have an impact on the content of scientific reports emerging from industry-supported research.^{8,25,27–29} The most comprehensive study to date is an analysis of 23 studies of the impact of academic-industry relationships on the outcomes of

science that was published in 2003. This analysis found “a statistically significant relationship between industry sponsorship and pro-industry conclusions.”³⁰ In other words, industry-funded studies are significantly more likely to yield results that favor industrial sponsors than would be expected by chance alone. Examples of scientific areas in which industry-funded studies reached pro-industry conclusions included randomized clinical trials in multiple myeloma, economic analyses of oncology drugs, studies of nicotine and cognitive performance, nonsteroidal anti-inflammatory drugs, and calcium channel blockers.

That is not to say that all industry-funded studies are intentionally biased. It may be that industry selectively funds research that is most likely to yield favorable conclusions, or that industry-funded studies address different questions than nonindustry-funded studies. Others have suggested that there are a number of reasons why some pharmaceutical funded studies are more likely to yield pro-industry results. These reasons include the following:

1. Selecting a comparison drug that is known to be inferior to the sponsor's drug
2. Selecting an inappropriate dose of the comparison drug
3. Using multiple endpoints for the study and selecting the endpoint that presents the sponsor's drug in the best light for publication
4. Doing multicenter trials and selecting results for publication from centers that are most favorable
5. Selectively presenting results from subgroup analyses³¹

At the time of this writing, no study had been published exploring researchers' beliefs and experiences regarding these phenomena.

Relationships Between AIRs and Data Withholding/Secrecy

A significant body of empirical evidence dating from the mid-1990s demonstrates that relationships with industry are associated with secrecy in science. A 1996 survey of life science faculty in the 50 most research-intensive U.S. institutions found that 14.5% of those with funding from industry reported engaging in trade secrecy compared with 4.7% of those without funding from industry.¹² In addition, a 2002 study found that those with research funding from industry were significantly more likely to delay publication of their research results by more than six months to allow for the commercialization of their research.³²

Relationships Between AIRs and Protection of Human Research Participants

There are no systematic data regarding the impact of AIRs on the protection of human research participants. However, industry relationships have been associated with concerns about the treatment of human research participants. Perhaps the best known case involved the death of a 19-year-old, Jesse Gelsinger, in a gene transfer study at the University of Pennsylvania in 1999¹ (see Chapter 10). A subsequent investigation of the case found that James Wilson, one of the principal investigators and the director of the University's Institute for Human Gene Therapy, which conducted the study, held patents on various aspects of the study's procedures. In addition, Wilson and the University of Pennsylvania held stock in a company that stood to benefit if the study

was successful. Despite Gelsinger's death, the company was eventually sold, and Wilson's and the University of Pennsylvania's equity stakes were valued at \$13.5 and \$1.4 million, respectively.¹

Concern has also arisen about IRB members' relationships with industry. Because IRBs are charged to protect human subjects in clinical research studies, the behavior of its members is crucial to the safety of research at their institution. A recent survey of faculty members serving on IRBs found that consulting relationships with industry are common, with about half (47%) of all faculty IRB members having served as a consultant to industry in the previous three years.³³ It is possible that relationships with companies could impact members' IRB-related activities and attitudes, and such ties clearly raise issues related to conflicts of interest.

Concern regarding conflicts of interest and IRBs erupted in 1999 at Duke University when at least 2,000 studies involving human research participants were suspended after the federal government determined that Duke did not adequately protect patients involved in such studies.³⁴ Among the 20 deficiencies cited by the Office for Protection from Research Risks—predecessor of the Office for Human Research Protections—was the suggestion that conflicts of interest on the part of senior-level administrators at Duke had compromised the ability of Duke's IRBs to make independent and unbiased decisions regarding research protocols. Although this is far from conclusive, the inspector general of the Department of Health and Human Services concluded, "There has been no progress in insulating IRBs from conflicts that can compromise their mission in protecting human subjects."³⁵

University Disclosure and Management

For the most part, the primary responsibility for the disclosure and management of relationships with industry has been vested in the university and faculty, as a form of professional self-regulation. Because there is wide variation in universities in terms of their size, research intensity, history, culture, and ownership status (public/private), it is not surprising that there is wide variation in university policies and procedures related to the reporting, oversight, and management of relationships with industry. A content analysis of the conflict of interest policies at the 100 universities that received the most funding from the NIH in 1998 found that disclosure policies varied widely across institutions. For example, 55% of the policies required disclosures from all faculty members, whereas 45% required only faculty who were principal investigators to disclose. Also, less than 20% of institutional policies specified limits on faculty financial relationships with industry, and 12% provided specific limits on the amount of time publication may be delayed.¹³ However, the fact that universities have policies and practices about the disclosure and management of relationships does not mean these policies are enforced or that they are effective in preventing misconduct. For example, a survey of the conflict of interest policies at U.S. institutions receiving more than \$5 million in funding from the NIH or the NSF found that the management of conflicts and penalties for nondisclosure were almost universally discretionary.³⁶

Policy Implications

The data presented above have numerous policy implications for academia and industry. First, policy attention is needed to address

inconsistencies in the disclosure of industry relationships. Full disclosure constitutes a minimally acceptable response to the demonstrated risks posed by industry relationships. As a result, a minimum set of uniform disclosure policies and practices related to industry relationships should be adopted by all universities, associated teaching hospitals, and academic clinical facilities. These policies and procedures should be developed by an independent organization with significant input from the academic community, such as the National Academy of Sciences.

Currently, there is wide variation regarding which individuals are required to disclose their relationships with industry. Because evidence clearly indicates that AIRs exist related to the education, research, and patient care missions of universities, it is necessary that all individuals holding faculty appointments and all academic administrators at the level of department chair and above (even if they do not hold faculty appointments) should disclose their own and their immediate family members' relationships with industry on an annual basis.

However, reliance on disclosure alone in addressing the risks associated with AIRs is inadequate for a number of reasons.^{29,37} First, although disclosure is intended to bolster public confidence in the integrity of the research enterprise, it may have the opposite effect of raising widespread concern and promoting calls for reform. Second, disclosure is perceived as accusatory and carries negative connotations—particularly in academic settings that tend to have more participatory governance structures. Third, in many cases, individuals and institutions to which disclosures are made may not have the skills or authority to use the information to manage conflicts of interest. Further, universities have no mechanism to verify the accuracy of faculty disclosures and thus could easily be deceived by inaccurate or incomplete disclosures. According to one commentator, "The net effect of all of these reservations is that open disclosure is of extremely limited value."²⁹ Disclosure may be necessary; universities and government cannot manage relationships they don't know about. But it is not sufficient.

Beyond disclosure, it is essential to maintain the autonomy of individual institutions regarding the review and management of relationships with industry once they are disclosed along important dimensions such as research intensity, public/private status, and institutional size. For example, we believe it should be left to the institution to decide which relationships are acceptable and which are not, which relationships require additional monitoring by the institution and which do not, and the form such monitoring or oversight should take (such as oversight by a single individual or a committee). Although the federal government may be able to provide guidance on such issues, we believe it is imprudent at this time to vest the absolute authority regarding these issues in any single institution or organization. Additional recommendations regarding the management of relationships with industry can be found in our published work and will not be repeated here.³⁸

Implications for Study Design

In designing studies funded or influenced by industry, scientists should keep the risks associated with these relationships in mind. Regarding the risk of industry bias, studies should be designed and executed to test hypotheses that are carefully selected to avoid favoring one outcome or another. The responsibility for ensuring

the integrity of the scientific enterprise rests solely with the investigative team and is embodied in the choice of appropriate study endpoints, comparison drugs, dosing levels, data analyses, and reporting procedures.

Regarding secrecy, academic researchers should not accept any contractual provisions or make any noncontractual agreements that delay publication of results beyond the time needed to file a patent application. Nor should they accept contract provisions that prohibit the sharing of information, data, and materials with other scientists who wish to replicate published work. Further, all publications describing the results of scientific experiments should include sufficient detail about the way an experiment was done to allow for replication of the published research.

Regarding the protection of human research participants, IRBs or other similar institutional bodies or groups can assist in protecting human participants related to the risks of relationships with industry discussed above. In all proposals sent to the IRB, scientists should disclose whether they or one of their family members have any relationship with the study sponsor(s). When relationships exist, the complete details of the relationships should be fully disclosed to the IRB. Once the study is in progress, scientists should notify the IRB if a relationship changes or if a new industry relationship is formed that is related to the study.

Unresolved Issues and Data Requirements

Numerous aspects of academic-industry relationships could benefit from the collection of additional empirical data. There are no current, comprehensive, publicly available data on faculty members' or government scientists' relationships with industry or commercial activities. At the institutional level, there are no comprehensive data on the nature, extent, and consequences of universities,' medical schools,' and hospitals' relationships with industry and commercial activities. Even when data on commercialization and industry relationships are collected by individual institutions, the data rarely delve deeply into details of the relationships and are rarely shared with individuals outside of the institution, especially private institutions.

In addition to a much more extensive data collection effort, we believe it is necessary that the debate about AIRs and commercialization be balanced and fair. Though we have focused in this chapter on the problems associated with AIRs, we acknowledge that these relationships also have benefits that are important to preserve and promote.³⁸ For example, relationships with industry provide scientists with resources to conduct research, write papers, attend conferences, support students, and develop new products and services that likely would not be supported from nonindustrial sources. There can be little doubt that these activities result in scientific advance and innovation in health care. The critical challenge is to find a way to manage the risks of AIRs while preserving their many benefits.

Fraud, Fabrication, and Falsification

Honesty is one of the core values of science, but for many years there have been concerns about dishonesty and deception in research. In 1830, the mathematician and inventor Charles Babbage (1791–1871) wrote about unethical practices that he had observed in British science. He discussed examples of hoaxing, forging, trimming, and cooking data. Hoaxing and forging occur when one makes up data; trimming occurs when one clips off pieces of data that do not agree with one's hypothesis; and cooking occurs when one manipulates data in order to make them appear to be more accurate than they really are.¹ In 1847, the American Medical Association (AMA) was formed to promote professionalism in medical practice and research. In 1849, the AMA formed a board to analyze quack remedies and debunk fraudulent claims made by snake oil salesmen.²

Dishonest practices in research have been described as “fraud” or “research misconduct.” There are two different senses of fraud: the ordinary meaning of the word and a precise, legal meaning. Fraud, in the ordinary sense of the word, connotes dishonesty, deception, trickery, forgery, and related concepts. The *American Heritage Dictionary* defines fraud as “[a] deception deliberately practiced in order to secure unfair or unlawful gain.”³ Although data alteration would seem to fit this definition, the ordinary meaning of the word *fraud* lacks the precision that is needed for a clear discussion of data alteration in science. Dishonest activities in science may involve complex manipulations of data that can be difficult to distinguish from honest activities.

The legal meaning of fraud also does not adequately describe some of the dishonesty that one finds in science. *Black's Law Dictionary* defines fraud as “a knowing or reckless misrepresent-

ation of a material fact that induces a person to act to his or her detriment.”⁴ A researcher who misrepresents the truth or conceals a material fact in an official communication with the U.S. government, such as a grant application or progress report to a granting agency, could face legal liability for fraud under contract law, tort law, or the False Claims Act (FCA). If the government wins an FCA lawsuit, the defendant must repay the money he has fraudulently obtained and pay treble damages. Under the *qui tam* provisions of the FCA, individuals may bring lawsuits on behalf of the government and win up to 30% of the award if the lawsuit is successful. A half dozen misconduct cases have resulted in lawsuits against research institutions under the FCA.⁵

Although this legal definition of fraud is useful in understanding dishonest activities in science that are also illegal, it is not very helpful in understanding data fabrication or falsification. First, many actions that do not fit the legal definition of fraud would still be considered highly unethical in research. For example, fabrication or falsification of an immaterial (or irrelevant) fact in a scientific paper would be considered misconduct in science, even though it would not fit the legal definition of fraud. Second, some actions that fit the legal definition of fraud might not be considered to be research misconduct. For example, a person who makes a reckless misrepresentation that induces others to act their detriment would commit fraud, but this action might be considered an honest error in science. Misconduct involves intentional deception.⁶ Errors, even reckless ones, are unintentional. An error in research may constitute negligence—even gross negligence—but not misconduct.

To avoid confusions that may occur by using the term fraud to describe dishonest actions in science, this chapter will focus on research misconduct instead of research fraud.

What Is Research Misconduct?

Since the 1980s, different governments and funding agencies have used different definitions of research misconduct. The U.S. government used several different definitions of research misconduct during that time.⁷ After several years of debate, in 2000 the White House Office of Science and Technology Policy (OSTP) developed a federal definition of misconduct that has been adopted by all federal agencies that support intramural or extramural research, including the National Institutes of Health (NIH) and National Science Foundation (NSF). The policy was implemented in 2005. According to the OSTP definition,

[r]esearch misconduct is defined as fabrication, falsification, or plagiarism in proposing, performing, or reviewing research, or in reporting research results. Fabrication is making up data or results and recording or reporting them. Falsification is manipulating research materials, equipment, or processes, or changing or omitting data or results such that the research is not accurately represented in the research record. . . . Plagiarism is the appropriation of another person's ideas, processes, results, or words without giving appropriate credit. Research misconduct does not include honest error or differences of opinion.⁸

There are several important points to consider about this definition. The definition limits research misconduct to three types of misdeeds: fabrication, falsification, and plagiarism—known unofficially by the acronym FFP. Other definitions of misconduct, such as those used by other governments or some earlier federal definitions, are broader than the categories of fabrication, falsification, and plagiarism. In 1989, the Public Health Service (PHS), which oversees the NIH, used a definition of research misconduct that included FFP as well as “other practices that seriously deviate from those that are accepted in the scientific community.”⁹ The Wellcome Trust, the largest biomedical research charity in the United Kingdom, has developed a definition of misconduct that is broader than the OSTP definition. Under the Wellcome Trust definition, misconduct includes “deliberate, dangerous, or negligent deviations from accepted practices in carrying out research” and “failure to follow established protocols if this failure results in unreasonable risk or harm to humans, other invertebrates, or the environment.”¹⁰ The OSTP chose a narrower definition of misconduct for several reasons: (1) Most researchers regard fabrication, falsification, and plagiarism as serious offenses because they all involve dishonesty in science; (2) it is more difficult to define and adjudicate ethical problems, such as “serious deviations from accepted practices in carrying out research”; and (3) research institutions complained that a broader definition was unnecessary and unmanageable.⁷ Most research institutions have policies and procedures that address other types of unethical or illegal conduct not covered by the OSTP definition, such as harassment, violations of human or animal research regulations, theft, mismanagement of funds, and so forth (see Tables 72.1 and 72.2).

It is important to note that the OSTP definition of misconduct encompasses many research activities beyond publication, such as

Table 72.1
Definition of Research Misconduct

-
- *Research misconduct*: Fabrication, falsification, or plagiarism in research. Honest errors and disagreements are not research misconduct.
 - *Fabrication*: Making up data or results and recording or reporting the fabricated material.
 - *Falsification*: Manipulating research materials, equipment, or processes, or changing or omitting data or results such that the research is not accurately represented in the research record.
 - *Plagiarism*: The appropriation of another person's ideas, processes, results, or words without giving appropriate credit.
-

proposing, performing, or reviewing research. For example, misconduct includes fabrication or falsification of data on an application for a federal grant; it also includes plagiarism of ideas from a grant application.

Honest errors or differences of opinion are not classified as misconduct. This limitation is important, because error and disagreement are common in scientific research. Indeed, one might argue that scientific progress cannot occur without them.⁶

Conflicts of interest also are not classified as misconduct. Although conflicts of interest can undermine the integrity and trustworthiness of research, they are not ethically or legally equivalent to fabrication, falsification, or plagiarism. Scientists with a conflict of interest can still conduct good research, provided that they do not allow their financial or personal interests to bias their scientific judgment. Moreover, conflict of interest is covered by other federal rules aimed at eliminating or managing conflicts (see Chapters 68–71).

Even though the definition of research misconduct is fairly straightforward, it may be difficult to apply in some borderline cases involving manipulation of data or images. Most researchers exclude erroneous or anomalous data points, such as statistical outliers, from their analysis of the data. Indeed, it is seldom the case that researchers report the results of every single experiment related to a particular project. However, although some trimming and editing of data is common in scientific research, deceptive trimming—especially trimming that affects the overall results of research—can be considered falsification of data.⁶ Problems can also arise in the manipulation of digital images of biological structures, which play an important role in many different fields including cytology, genetics, genomics, pathology, anatomy, and virology. Researchers can use software such as Photoshop to cut, paste, amplify, reverse, soften, blur, brighten, or darken various features of digital images. Some alteration of digital images is acceptable in research, provided that it is used to help the audience better understand data and it is not used to mislead. But image manipulation that affects the interpretation of data may constitute data fabrication or falsification.¹¹

The OSTP definition of misconduct now applies to all biomedical research funded by the U.S. government. Research institutions that receive federal contracts or grants are responsible for the initial investigation and adjudication of allegations of scientific misconduct. Most research institutions have developed their own policies that define research misconduct and procedures for investigating and adjudicating misconduct allegations. These procedures should conform to requirements recommended by the OSTP, such as fairness, confidentiality, protection of whistle blowers, and due process. Before institutions conduct formal

Table 72.2
Research Misconduct and Serious Deviations From Accepted Research Practices

	<i>Unethical</i>	<i>Illegal*</i>
Research Misconduct		
Fabrication (making up data)	Yes	Yes
Falsification (changing data)	Yes	Yes
Plagiarism	Yes	Yes
Serious Deviations From Accepted Research Practices		
Inadequate record keeping	Yes	No
Refusing reasonable requests to share data, materials, or methods	Maybe**	Maybe**
Gross negligence in research	Yes	No
Destruction or theft of property	Yes	Yes
Using statistical techniques to misrepresent data	Yes	No
Interfering with a misconduct inquiry or investigation	Yes	Yes
Making a false accusation of misconduct	Yes	No
Exploitation or poor supervision of students or subordinates	Yes	No
Undeserved or inappropriate authorship	Yes	No
Duplicate publication	Maybe**	No
Breaching confidentiality in peer review	Yes	No
Violations of laboratory safety rules	Maybe**	Yes
Violations of rules for the protection of human subjects	Maybe**	Yes
Violations of rules for research on laboratory animals	Maybe**	Maybe**
Failure to disclose conflicts of interest	Maybe**	Maybe**
Misuse of funds	Yes	Yes
Financial fraud	Yes	Yes
Sexual or other harassment	Yes	Yes

* *Illegal* means “violation of United States government statutes or regulations.”

** *Maybe* means “depends on the situation/circumstances.”

investigations into misconduct allegations, they conduct inquiries to determine whether the allegations are frivolous or lack merit. Institutional sanctions for misconduct range from censure, reduction in privileges or salary, to loss of employment. Institutions are also responsible for reporting misconduct investigations and findings to sponsoring agencies, which have the option of conducting their own investigations and implementing their own sanctions. Federal sanctions for research misconduct range from supervision in the future use of federal funds in research to debarment from eligibility to receive federal funds for research. From 1994 to 2003, the PHS took 133 administrative actions against researchers who were found to have committed misconduct.¹²

Notable Cases of Misconduct or Alleged Misconduct in Biomedical Research

Throughout history, biomedical researchers have had a reputation for honesty and integrity. However, there are some notable episodes in which even the most prominent researchers have committed, or appeared to have committed, data falsification or fabrication, plagiarism, and other misdeeds (see Table 72.3). The

founder of the modern theory of heredity, Austrian monk and botanist Gregor Mendel (1822–1884), has been accused of research misconduct. In 1936, statistician R. Fisher published a paper analyzing the data that Mendel reported in his paper on the genetics of plant hybrids. Fisher found that the data Mendel reported agreed more closely with his hypotheses than would be expected if the data had been generated from natural experiments, which would have some random fluctuations. Fisher concluded that “the data of most, if not all, of the experiments have been falsified so as to agree closely with Mendel’s expectations.”¹³ According to some estimates, Mendel’s data were so close to the values predicted by his hypotheses that the odds were 33,000 to 1 against his actually having obtained the data from his observations.¹⁴

Even though the evidence appears to support the view that Mendel was either exceedingly lucky or falsified some of his data to conform to his expectations, this conclusion is not consistent with his character. Mendel was a very careful scientist with a reputation for thoroughness and integrity.¹⁴ His scientific peers did not recognize his work, but he was convinced of its importance. One would not expect someone like him to alter data to fit his theories. However, in his will, Mendel made the unusual request that his laboratory notebooks be destroyed after his death. One could speculate that he made the request in order to secure

Table 72.3
Well-Known Cases of Alleged Misconduct in Biomedical Research

Case, Date(s)	Issues	Outcome
Gregor Mendel, 1865	Data falsification	No resolution
Piltown Man, 1908–1953	Fabrication	Fabrication found
Cyril Burt, 1970s	Fabrication, falsification, plagiarism	No resolution
William Summerlin, 1973	Fabrication	Admission of guilt

his reputation after death, but the scientific community will probably never know for certain why he made this request or whether he falsified data.¹³

One of the most infamous episodes of data fabrication in the history of biology occurred in the beginning of the 20th century. After Charles Darwin (1809–1882) published his *On the Origin of Species* in 1859, scientists who accepted his theory of natural selection were interested in finding evidence in the fossil record linking humans and apes. In 1908, an amateur geologist and a prominent British paleontologist claimed to have found the skull of a “missing link” between man and apes in a gravel bed at Piltown, England. For many years, researchers accepted the skull as authentic, because it was consistent with their anthropological and archeological theories. By the 1930s, doubts about the authenticity of the skull began to arise when it was found to be inconsistent with other hominid fossils. In 1953, physical and chemical tests proved that the skull was a fake: the upper part of the skull was a fossil that had been artificially aged to appear older than it was, and the lower jaw was not even a fossil.¹⁵

In the 1970s, the famous psychologist Cyril Burt (1883–1971) was accused of fabricating and falsifying data in his studies of identical twins, fabricating data on declining levels of intelligence in the United Kingdom, falsely claiming relationships with collaborators, and falsely claiming to be the originator of factor analysis in psychology.¹⁵ Burt, who held the chair of psychology at University College London for 20 years and was the official psychologist of the London City Council, argued that intelligence was strongly genetically determined. Burt’s defenders claimed that he did not falsify or fabricate data, and that the problems with his data were due poor record keeping or errors. Because these allegations were made after he was dead, only Burt’s defenders responded to these charges.

Another famous fabrication incident took place in 1974 at the prestigious Sloan-Kettering Institute in New York. In 1973, William Summerlin joined Robert Goode’s transplantation immunology laboratory at Sloan-Kettering. Summerlin, who was a well-known immunologist, had been studying organ transplantation. Summerlin believed that organ rejection could be prevented by culturing organs in a tissue culture for days or weeks before

transplantation. Other scientists were having difficulty replicating Summerlin’s work. To prove his hypothesis, Summerlin conducted some experiments that he claimed involved the transplantation of tissue between genetically unrelated strains of mice. In the experiments, Summerlin cultured and then “transplanted” patches of skin from black-haired mice onto white-haired mice. He hoped to prove that his hypothesis was correct by showing that the white-haired mice would not reject the patch of skin with black hair.

A laboratory assistant who was in charge of taking care of the mice noticed that alcohol could wash away the black color on the white mice. The assistant reported this finding to Goode, who suspended Summerlin from his work so that a committee could investigate the incident. Summerlin soon confessed to using a black felt tip pen to produce patches of black hair on the white mice. The committee examined Summerlin’s other experiments and determined that Summerlin and several collaborators had fabricated data relating to the “transplantation” of corneas in rabbits. The committee also found that Summerlin was probably suffering from an emotional illness. The committee recommended that Summerlin be granted a medical leave of absence, correct the irregularities in his work, and publish retractions. Summerlin claimed that he fabricated data because he was under a great deal of personal and professional stress. The scandal ruined the career of Goode, who was one of the top immunologists in the country at the time.¹⁶

In 1981, John Darsee, a highly productive postdoctoral fellow at Harvard Medical School, was accused of fabricating and falsifying data in a dozen papers and abstracts. Darsee’s supervisor was cardiologist Eugene Braunwald, who was chair of medicine at Brigham and Women’s Hospital and Harvard Medical School. A committee investigating the incident found that Darsee committed misconduct in five of the papers that he published with faculty at Harvard, including Braunwald, and eight papers that he published with faculty at Emory Medical School, where he was a doctoral student. The committee also found that Darsee had fabricated data in two undergraduate papers that he published while at Notre Dame. Although the committee did not find that the coauthors had committed misconduct, it raised serious questions about their responsibilities as coauthors, because many of the fabrications in

Darsee's published papers would be obvious to an expert in his field upon a careful reading of those papers. Eventually, 17 papers and 53 abstracts coauthored by Darsee were retracted. Even though this episode ended Darsee's career as a biomedical scientist, he went on to pursue a career in clinical medicine.¹⁷

Infamous cases of plagiarism also occurred in the 1980s. In one case, E.A.K. Alsabati, a Jordanian biologist, republished in his own name articles by others that had previously appeared in obscure, small-circulation journals. In some cases, he simply retyped the articles and submitted them for publication. Although Alsabati never admitted any wrongdoing, several scientific journals, including *Nature* and the *British Medical Journal*, published excerpts from the original articles right next to Alsabati's articles.¹⁵

In 1983, two science journalists, William Broad and Nicholas Wade, published *Betrayers of Truth: Fraud and Deceit in the Halls of Science*.¹⁸ The book raised the public's and media's awareness of unethical conduct in science. Broad and Wade also accused Isaac Newton, Robert Millikan, and Gregor Mendel of manipulating data to produce sought-after results.

The Baltimore Affair

From 1986 to 1996, a scandal took place that had a major impact on science policy in the United States. The scandal, which became known as the Baltimore affair, centered on a paper published in the journal *Cell* in 1986. The paper had six coauthors, including the Nobel laureate David Baltimore.¹⁹ The paper reported that inserting a single antibody gene from another strain of mice can induce a mouse's own antibodies to change their molecular structure, suggesting a new mechanism of immunity. The experiments, which were funded by the NIH, were conducted at the Whitehead Institute, a research center associated with the Massachusetts Institute of Technology (MIT) and Tufts University. Margot O'Toole, who was a postdoctoral fellow working under the supervision of Assistant Professor Thereza Imanishi-Kari, one of the paper's authors, became suspicious when she found 17 pages from Imanishi-Kari's lab notebooks that she believed contradicted the results reported in the paper. After failing in her attempt to reproduce these results, O'Toole informed review boards at Tufts and MIT about her suspicions of possible fabrication or falsification.²⁰

Internal investigations by committees at Tufts and MIT found some errors in the research but no evidence of misconduct. The NIH's Office of Scientific Integrity (OSI) reviewed these findings and launched its own investigation. In April 1988, Representative John Dingell (D-Mich.), chairman of the House Commerce Committee's Oversight and Investigations Subcommittee, held several hearings on fraud in science, including the Baltimore case. The Secret Service assisted in the investigation by seizing and analyzing Imanishi-Kari's notebooks. Baltimore testified before the House subcommittee and defended the research. He described the investigations conducted by the NIH and Congress as a "witch hunt."²⁰

The scandal continued to generate headlines during the early 1990s. Baltimore resigned from his position as president of Rockefeller University in 1992 due to his involvement in the scandal. In 1994, the Office of Research Integrity (ORI), formerly the OSI, concluded that Imanishi-Kari had fabricated and falsified data. Tufts asked Imanishi-Kari to take a leave of absence after the

ORI issued its findings. However, an appeals panel at the Department of Health and Human Services (DHHS) exonerated Imanishi-Kari in 1996. The panel concluded that the evidence against her was unreliable or uncorroborated. To this day, Imanishi-Kari maintains her innocence in the affair. She admits to poor record keeping but she denies that she ever falsified or fabricated data. Most researchers with knowledge of the case believe that Imanishi-Kari was not guilty of fabrication or falsification and that Baltimore was unfairly tainted by the scandal that now bears his name. Many researchers were also concerned that some members of Congress may have used the case for political gain.²⁰

In the 1980s and 1990s there were several other high-profile misconduct scandals in the biomedical sciences. The House subcommittee that reviewed the Baltimore case also impugned Stephen Breuning, a psychologist who had been accused of misconduct in 1983, on charges of falsifying reports to the National Institute of Mental Health (NIMH). In 1987, the NIMH found that Breuning reported nonexistent patients, fabricated data, and falsified data on grant applications. In 1988, Breuning was convicted of criminal fraud and sentenced 60 days of imprisonment and five years' probation. He also had to pay \$11,352 in restitution to the University of Pittsburgh.⁶

In 1993, the ORI concluded that Roger Poisson, a Canadian surgeon conducting research as part of the National Surgical Adjuvant Breast and Bowel Project (NSABP), had falsified data on 117 patients from 1977 to 1990. In one instance, Poisson falsified an informed consent document. Poisson admitted that he subscribed to a loose interpretation of the NSABP's inclusion and exclusion criteria for the study and said that he tried to admit as many patients as possible to the study so that they would have a chance of qualifying for advanced treatment methods.²¹ The House subcommittee also held hearings on the case and learned that Bernard Fisher, chairman of the NSABP and a University of Pittsburgh cancer researcher, who discovered the misconduct, had published several papers containing the falsified data.²² The ORI ordered Fisher to reanalyze the data. The results of the reanalysis showed that the falsified data had no effect on the research results. The reanalysis, which was published in the *New England Journal of Medicine*, showed that lumpectomies are effective at treating breast cancer tumors less than 4 cm in diameter.²³ Fisher claimed that he was forced to resign his position at the University of Pittsburgh to appease Congress and the National Cancer Institute, which sponsored the NSABP. Even though the ORI found that Fisher did not commit misconduct, he sued the government for damaging his reputation. The NIH had labeled 93 of Fisher's papers with the warning "scientific misconduct—data to be reanalyzed" on its computerized databases.²¹

In 1996, a reviewer for the journal *Oncogene* challenged a paper submitted by a graduate student working in the lab of Francis Collins, the director of the National Human Genome Research Institute and head of the Human Genome Project. The reviewer questioned the data in the paper and accused the student of misconduct. Collins examined the student's research records and determined that the student had committed misconduct. The student confessed, and Collins retracted five papers the student had published with coauthors and wrote a letter to more than 100 scientists advising them of problems with the papers. Although Collins handled this episode well, he was concerned

that neither he nor his senior scientists had detected problems with these papers before they were submitted for publication. He described the entire ordeal as the most devastating experience of his life.¹⁷

Two Stunning Cases in 2005

One of the most expensive cases of research misconduct occurred in 2005, when Eric Poehlman, a well-known expert on menopause, aging, and metabolism, admitted to falsifying data on 15 federal grant applications and 17 publications. The NIH and the Department of Agriculture had awarded Poehlman \$2.9 million worth of grants based on falsified data. Poehlman, who had held an academic appointment at the University of Vermont College of Medicine, was barred for life from receiving any federal research funding and retracted 10 papers. Poehlman also agreed to pay the federal government \$180,000 to settle a civil lawsuit; he could have received a \$250,000 fine and up to five years' imprisonment. Poehlman's scam began to unravel in 2000, when research assistant Walter DeNino discovered inconsistencies in a longitudinal study of aging. According to DeNino, Poehlman switched some data points to make it appear that some of his subjects were becoming sicker over time. DeNino filed a complaint against Poehlman, and an investigative committee at the University of Vermont found that Poehlman had falsified data in several papers. In one of those papers, a highly cited study on menopause published in the *Annals of Internal Medicine* in 1995, most of the experimental subjects did not exist. In 2001, before the investigation ended, Poehlman left the University of Vermont and took a position at the University of Montreal. He left the University of Montreal in January 2005.²⁴

Another high-profile case occurred in 2005, when South Korean scientist Woo Suk Hwang admitted to fabricating data used to support a groundbreaking article published in *Science* in February 2005, which purported to demonstrate the derivation of 11 embryonic stem cell lines using nuclear transfer techniques (i.e., therapeutic cloning). A panel at Seoul National University, where Hwang conducted the research, found that none of the DNA in the 11 cell lines reported in the article matched the DNA in the cell lines of the human subjects used in the experiment. The panel also determined that Hwang faked data in a paper he published in 2004 on therapeutic cloning, and that coauthorship on the 2005 paper had been awarded for merely procuring eggs. The panel did not challenge Hwang's claim to have produced the world's first cloned dog, Snuppy.²⁵ Hwang, who had become a national hero, resigned from his position and faced up to 10 years in prison if convicted of fraud. In another ethical twist, the world also learned that two of the egg donors for the 2005 article, junior researchers working in Hwang's laboratory, may have been coerced.²⁵ Had Hwang's work been valid, it would have indicated that one of the main goals of stem cell research, therapeutic cloning, is achievable. Researchers have sought to develop therapeutic cloning because the stem cells produced by this process would be genetically identical to those of the patient, because they contain the patient's own DNA. Organs and other tissue grown from these stem cells would be less likely to be rejected by the patient's immune system than tissue produced by other techniques. The South Korean scandal dealt a severe blow to embryonic stem cell research, and gave ammunition to critics of therapeutic cloning.²⁶

Regulatory Responses to Research Misconduct

The misconduct scandals in federally funded biomedical research in the 1980s had a major impact on U.S. government policies. In 1989, the PHS formed two agencies, OSI and the Office of Scientific Integrity Review (OSIR), to review misconduct allegations against PHS-funded researchers and provide information and support for research institutions. In 1992, the PHS replaced these two agencies with the ORI, which is located with the DHHS. The ORI oversees all research integrity activities for the PHS, which oversees NIH research. The ORI investigates allegations of research misconduct and sponsors educational and research activities;²⁷ it has sponsored conferences on research integrity and has funded grants to conduct research on research integrity. Other federal agencies have their own structures for dealing with research ethics issues. For example, the National Science Foundation's (NSF's) Office of Inspector General (OIG) oversees research integrity activities for that agency. The Food and Drug Administration's (FDA) Office of Regulatory Affairs deals with research integrity problems related to privately funded research submitted to the FDA. The ORI has the authority to investigate allegations involving FDA research if the research is partly supported by the PHS.²⁸

In 1989, the NIH began requiring institutions that receive training grants to meet training requirements for education in responsible conduct of research (RCR) for graduate students funded by NIH grants. Universities have taken a variety of approaches to fulfilling this NIH requirement, ranging from formal courses in RCR, to RCR seminars or workshops, to RCR training incorporated into existing courses in research methods. In 2000, the NIH began requiring its intramural researchers to receive education in RCR. The NIH now requires intramural researchers to take an online, introductory course in RCR as well as to receive annual updates. In the fall of 2000, the ORI mandated that all personnel receiving PHS grants also receive instruction in nine core topics in RCR, which included data management, authorship and publication, peer review, mentoring, collaboration, research misconduct, conflict of interest, research animals, and research with humans. When the George W. Bush administration came to power in 2001, the PHS suspended the mandate on the grounds that the ORI had not followed proper procedures for issuing formal administrative rules. As of 2007, the policy was in limbo.⁶

The National Academy of Sciences (NAS) has issued two major reports related to research ethics. The first report, published in 1992, examined misconduct in science.²⁹ It developed a definition of scientific misconduct, attempted to estimate the incidence of misconduct, and examined some of the causes of misconduct. The second report, published in 2002, focused on promoting integrity in scientific research. The report stressed the importance of education in research ethics, mentoring and leadership, and institutional self-assessment.³⁰ In 1989, the NAS also published *On Being a Scientist*, a useful handbook on research ethics. The handbook, which was revised in 1995, is available on the web.³¹

Empirical Data on Research Misconduct

Estimates of the incidence of misconduct in research vary greatly.³² In one of the most reliable surveys, 6%–9% of students

and faculty reported direct knowledge of fabrication, falsification, or plagiarism.³³ However, estimates based on 200 confirmed misconduct cases reported to ORI over a 20-year period yield a rate of one misconduct episode per 100,000 researchers per year.³² One of the difficulties with estimates based on this sort of analysis is that misconduct is probably underreported. The ORI is interested in gathering more evidence about the incidence of misconduct and has sponsored research to try to address this issue.

Even if one supposes that the misconduct rate is quite low, this does not mean that misconduct is not a serious problem for researchers. Fabrication, falsification, plagiarism, and other highly unethical research activities can negatively affect the integrity and reliability of the published research record, destroy cooperation and trust among researchers, and undermine public support for science. Additionally, fabrication or falsification in clinical research can cause harm to human research participants or the public health.²¹ For example, if clinical researchers falsify data concerning adverse events in human studies, then agencies that oversee research, such as the FDA and institutional review boards, may lack the information they need to protect other research subjects from harm. If clinical researchers fabricate or falsify data pertaining to the safety of a new drug, and the FDA approves the drug on the basis of erroneous data, then the drug could severely harm or kill people. However, it is worth noting that most of the well-known cases of misconduct in biomedicine have involved basic research, not clinical research. In the NASBP case, Poisson's misconduct did not have an impact on the overall results of clinical recommendations.

Since the 1980s, there have been two prevailing explanations for research misconduct.⁶ Some scientists and researchers claim that misconduct is committed by individuals who are morally corrupt, mentally unstable, or under great financial or emotional pressure. If they are right, misconduct is a rare event that results from a few bad apples. However, most organizations and scholars who have studied that problem argue that misconduct is due to the institutional, social, and economic factors in the research environment, such as financial and proprietary interests in research, problems with the supervision of subordinates, the mentoring relationship, tenure and promotion policies, the pressure to publish, careerism, the need to recruit patients for clinical trials, and publication practices. Although money does not automatically corrupt researchers, there is a growing concern about the influence of financial interests in science.³⁴ One commentator has described conflicts of interests as risk factors for misconduct.³⁵ It is worth noting, however, that most of the well-known misconduct cases have occurred in publicly funded research instead of privately funded research, which would suggest that factors other than money, such as ambition or arrogance, play a greater role in causing misconduct. However, the fact that most of the well-known cases of misconduct have occurred in government-funded research does not prove that private research is more ethical than public research. One very simple explanation for the fact that the private sector has fewer misconduct cases is that we generally know more about publicly funded research than we know about privately funded research. In public research, government agencies publish their findings of misconduct. In private research, misconduct can occur beneath the cloak of trade secrecy. Obviously, these issues merit further study.

Conclusion: Education and Oversight

A commitment to honesty lies at heart of the research enterprise. Honesty plays an important role in every step in the process of research, from designing the experiment, to recording data, to analyzing and interpreting data. Although honesty seems like a fairly straightforward issue in scientific research, this is far from the case. Scientists often must make complex judgments and decisions concerning the conduct of research that have an important effect on the objectivity, reliability, and integrity of their data and results. To promote honesty in science and prevent research misconduct, researchers and institutions should take the following steps:

- Senior researchers (or mentors) should help junior researchers (or students) learn how to strive for honesty and integrity in science. They should teach junior researchers how to design experiments, collect and record data, and analyze and interpret data. They should teach their students about the importance of honesty in all aspects of scientific communication, including not only research but also grant writing, peer review, publication, and expert testimony. This education can take place in research methods courses, research ethics courses, or during informal discussions in a laboratory or office.
- In addition to educating junior researchers, senior researchers should properly supervise junior researchers. They should establish protocols and standard operating procedures to provide guidance for junior researchers. They should also communicate directly with junior researchers on a regular basis about their research obligations and responsibilities.
- Universities and research organizations should support efforts to educate junior researchers about the ethical conduct of research. They should provide money and staff for courses, workshops, seminars, lectures, or other activities designed to enhance the research ethics curriculum.
- Universities and research organizations should also develop policies and procedures related to honesty in science, which should address research misconduct, fabrication, falsification, plagiarism, supervision of subordinates, and data management.
- Universities and research organizations should establish clear and fair procedures for investigating and adjudicating allegations of misconduct, including protection for whistle blowers, protection of the rights of the accused, and confidentiality.

The Obligation to Publish and Disseminate Results

For better or for worse, publication is the medium by which the scholar's work is distributed and judged. Thus much of a scholar's reputation depends upon what, where, and how much he or she publishes, and on how that work is received publicly by others.¹

—Donald Kennedy

The Ethical Basis for Scientific Publication

The job of a scientist was summarized by Benjamin Franklin (1706–1790) as “[t]o study, to finish, to publish.” Michael Faraday later wrote much the same thing.² Both recognized that scientific work cannot exist until it is published. Only then can fellow scientists have the full details in order to judge the worth of the science and attempt replication or refutation. To quote the National Academy of Sciences' report *Responsible Science*, “Science is a cumulative activity in which each scientist builds on the work of others. Publication of results is an integral and essential component of research because it enables others to gain access to each scientist's contribution.”³ Research institutions that receive public money, including almost all major universities, receive public esteem, support, and tax advantages because it is generally acknowledged that they exist for the public good. If research is locked up within the institutions, the health of the public cannot be served. It is for this reason that university regulations include the unfettered right to publish.⁴ It is for this reason that clinical scientists, whether they work in academe or in commercial

organizations, have the obligation to publish. To be a researcher implies being an author, and to be an author implies publication, and so dissemination.

The individual who agrees to participate in research as a subject in a clinical trial takes on the hardships and risks for the benefit of mankind, and the pact between participant and researcher implies that the results will be broadly known. Few would undertake this altruistic task if they thought that their results would remain hidden or be held as trade secrets. Clinical scientists, therefore, have a particular obligation to publish, governed by the Declaration of Helsinki (see Chapter 13). Article 11 states, “Medical research involving human subjects must conform to generally accepted scientific principles, be based on a thorough knowledge of the scientific literature, other relevant sources of information, and on adequate laboratory and, where appropriate, animal experimentation.”⁵ If results are not published, the scientific literature will be deficient, and it will be impossible to meet the standard of Article 19: “Medical research is only justified if there is a reasonable likelihood that the populations in which the research is carried out stand to benefit from the results of the research.” Finally, Article 27 states in part, “Both authors and publishers have ethical obligations. In publication of the results of research, the investigators are obliged to preserve the accuracy of the results. Negative as well as positive results should be published or otherwise publicly available. . . . Reports of experimentation not in accordance with the principles laid down in this Declaration should not be accepted for publication.”⁵

What Constitutes Work Deserving of Publication?

Investigators alone have to judge when a piece of their study is mature enough for publication. In the field of clinical trials, they must guard against premature publication of reports that can directly affect the treatment of patients. Though there are no rigid rules, the aim of publication must be to convey the most useful information in the most efficient form, and each publication should be a substantive contribution. Investigators lose the respect of their colleagues if they are perceived as merely advancing their own self-interest by slicing their work into numerous fragments ("salami publication" of "least publishable units") to maximize the number of their publications.⁶⁻⁸ This tactic greatly decreases the value of the combined publications to the reader, who must search multiple sources, each inevitably containing much repetitious material. A similar inappropriate practice, called the "meat extender" tactic, is to keep publishing the same study with the addition of small amounts of data in each article.⁹ Each paper should contain sufficient information for the reader to assess its validity and replicate the results.

What Constitutes Publication and Dissemination?

Publication of a clinical study is the action of making it publicly known. Strictly speaking, this would include sticking a manuscript on a bulletin board; but because that would so limit the spread of the information compared with printing it in a journal, publication is not considered to have occurred unless the information has also been disseminated ("spread abroad, diffused") to more than a few colleagues or, say, outside a sponsoring company. Roughly half of conference abstracts result in later published articles. Lectures, conference abstracts and posters are all forms of dissemination. By and large, journals approve of such presentations as working papers, even if they are in print before conferences, and do not disqualify the later, fully refined manuscripts on the basis of duplication. Until the last decade, publication and dissemination have almost invariably denoted appearance in print. The majority of journals now appear in both print and electronic versions, whereas some are entirely electronic. The general standards for publication and dissemination in either medium are the same.

Additional Databases or Trial Banks

Print journals are expensive to produce and wasteful of natural resources, so they usually have strict limits on the space available for articles. This forces the authors to select what data to present, and these data must be sufficient to buttress all the authors' conclusions. There may be large amounts of background information that readers might request, and which the editors assume as a condition of acceptance that the authors will provide. Electronic publication expands the ability of the authors and the journals to provide databanks of information, for example *trial banks* of data on clinical trials they publish. Such systems are still being developed and assessed.

Redundant (Duplicate) Publication and Prior Publication

Medical journals strongly discourage duplicate submission to different journals for publication lest two journals "unknowingly and unnecessarily undertake the work of peer review and editing of the same manuscript, and publish (the) same article," both claiming the right to publish and to own the copyright.⁸ The guidelines of the International Committee of Medical Journal Editors (ICMJE) define *redundant* or *duplicate* publication as "publication of a paper that overlaps substantially with one already published in print or electronic media." The guidelines go on to state, "The bases of this position are international copyright laws, ethical conduct, and cost-effective use of resources. Duplicate publication of original research is particularly problematic, since it can result in inadvertent double counting or inappropriate weighting of the results of a single study, which distorts the available evidence."⁸

If repetition of previously published data is necessary, as von Elm et al. write, "authors must acknowledge the main article overtly by using a cross-reference."¹⁰ Moreover, these authors caution, "Covert duplicate publication has been widely disapproved. This practice is wasteful of the time and resources of editors, peer reviewers, and readers, and it is misleading because undue weight is given to observations that are being reported repeatedly. When duplicates are inadvertently included in a systematic review, the conclusion of that systematic review may change."^{10,11} Finally, covert duplicate publication is dishonest and undermines the integrity of science.^{10,12,13}

Journal editors frequently have to make judgments about the extent of overlap between two or more of the authors' manuscripts or their published work. Prior publication may be judged to have occurred if substantially the same article has appeared in conference proceedings that were circulated, on paper or electronically, to more than a very few people, and authors are advised to check the policies of the journal to which they propose to submit their work. Editors are helped when prospective authors enclose copies of related, possibly overlapping manuscripts either to be submitted elsewhere or in press. Because the discovery of deception results in publication of a notice, or even a retraction, there are reasons beyond correct scientific behavior for authors to be open about parallel manuscripts. The standards for acceptable secondary publication are listed by the ICMJE.⁸

The Author's Obligation to the Reader: To Maintain Trust

As readers, we must be skeptical, but we must start with the assumption that, though the authors might be mistaken, their report is a fair representation of what they observed. We are forced to accord them trust because we cannot be in their institutions, checking their work. This implies that, as Lederberg has said, "Above all, the act of publication is an inscription under oath, a testimony."¹⁴ Authors make an unseen pact with their readers which require authors to be accountable. Authors have the duty to respond openly and promptly when questions are raised that challenge their findings. This may, for example, involve the provision of unpublished data, whether or not this is required as a condition of their funding.³ Without this acceptance of accountability,

authorship is meaningless, and the trust that binds authors and readers is broken. It is for this reason that the idea of anonymous science, popular 300 years ago, was abandoned: Trust could not be expected or granted. Authorship may bring credit; it invariably carries responsibility. This, rather than glory or priority, is what gives authorship both meaning and importance.

The Social Role of Authorship

Published articles are not merely the means whereby new work is communicated between scientists. They also serve a crucial social role in establishing priority, reputation, and standing. Publications are necessary for the correct attribution of credit for scientific discovery, and they constitute the coins by which academics proceed along the toll road of promotion.¹⁵ The number and worth of publications, and the prestige of the journals in which they have appeared, may constitute the most important factors in assessments for academic tenure and promotion.

History and Definition of Authorship

The present discussion is limited to modern clinical research. The standards for authorship in, for example, particle physics, in which scores or hundreds of coauthors are common, or for philosophy, in which the single-authored paper still persists, may differ markedly from those governing authorship of clinical studies and trials. The standards for other professions may vary even more widely. For example, in the legal profession, an opinion written by law clerks, when published, carries the name of the judge alone,¹⁶ movie screen writers operate under still another system.¹⁷

The term *author* derives, like the word *augment*, from the Indo-European base *aug-* (to multiply) and the Latin *augere* (to increase, to originate or grow). The word has been used in England since the 14th century as denoting “[o]ne who sets forth written statements; the composer or writer of a treatise or book.”¹⁸ As Vickers points out, “The author emerged as a professional writer in the sixth century B.C., and many of the attributes we associate with authorship—a sense of individual identity, in style, attitude, literary structure; a hatred of plagiarism; a respected role in society—were already found in abundance in Greco-Roman antiquity.”¹⁹ In literature, we may argue whether there was a real person called Homer, or whether his works were the product of an oral tradition carried on by many tellers of tales. Or we can dispute whether John Fletcher wrote more than half of the *Henry VIII* that we usually attribute to Shakespeare.¹⁹ But it is our expectation that in fiction, now as in the past, there is usually only one author. That author is expected to take responsibility if, for example, plagiarism or libel are alleged.

Scientific Authorship

Terms change. As science grew and branched into a separate series of disciplines, it was proposed in the 1830s at the British Association for the Advancement of Science, whose members seemed uncomfortable being called *savants* or *philosophes*, that those who practiced science, by analogy with artists, be called *scientists*.¹⁸ The

members adopted the word at the suggestion of their cofounder, William Whewell, who in 1833 had invented the word at the request of the poet Coleridge.²⁰ In the century or so that it took for this word to take hold, it continued to be assumed that investigator-scientists, when they wrote up their observations, were to be called *authors*, so no new term evolved simultaneously. The concept of an author developed when cooperative work was rare and the author of a scientific article, like that of a novel, was almost invariably one person. In science, it was not until around 1955 that the average number of authors per scientific article rose above two, and this has occurred in numerous clinical disciplines.^{21–24}

Since then, the total number of scientists has multiplied, as has their total number of publications²⁵ and the number of authors per publication.²⁶ The cause was the increasing need for specialists to invite scientists in other disciplines to collaborate with them. As the proportion of one- and two-author publications fell, the proportion with three, four, or more authors rose.²¹ One scientist, Yury Struchkov, published one article every 3.9 days for 10 years, whereas 20 researchers worldwide published at least once every 11.3 days throughout the decade of the 1980s.²⁷ More than half of these researchers were biomedical investigators who ran medium-to-large laboratories.²⁷ Over the last half of the 20th century, the average number of authors per published article has grown exponentially.^{26,28}

One factor remained constant, however: It was usually impossible to link the job title of the coauthor to the job he or she had actually done in the research. Team research, introduced to manage the increasing complexity of research, had brought with it problems in assigning both credit and responsibility. A notable example of team research is the clinical trial, and the number of clinical trial reports with more than 100 authors began to climb, also exponentially, after 1990.²⁹

The Obligations of Coauthors to Each Other

When they submit manuscripts, scientific authors have obligations to their patients, institutions, journals, and readers. Some of these are symbolized in the forms and checklists that journals require them to sign. But coauthors are also accountable to each other. The severe consequences on the lives and careers of the innocent coauthors of a fraudulent researcher serve as reminders that each individual on the byline has to take responsibility for something more than his or her own narrow contribution, and that each has the duty to help assure the integrity of the whole article. Each author must be willing to support the general conclusions of a study, and assist in answering questions after publication⁷ (see Boxes 73.1–73.3).

Why Is Credit for Authorship So Key?

At the deepest level, the author wants to be heard and acknowledged. “Most books are not valuable ‘properties’; they’re voices, laying perpetual claim to their authors’ existence,” wrote the poet Thomas Mallon, whose book *Stolen Words* tells the story of how a serial plagiarist robbed him of his work and took over his life.³⁰ This has been so from the earliest times, and there are many accounts of the anger authors have expressed when their work was

plagiarized.¹⁹ In science, there are other factors that make authorship credit so coveted. A place on the byline is properly earned by the contribution of the author to the research, and the community, broadly speaking, recognizes that. Indeed, given the fact that publications are the product of working researchers, the place publications have in our system of rewards, and the ease with which an investigator's publications may be counted, it is no surprise to find how strenuously scientists fight for that place.

Authorship Disputes

It is because credit for authorship has taken on such an important social and professional role that scientists view authorship with so much anxiety and passion, and it is for these reasons that disputes about authorship are so frequent, so wasteful of time, and so badly resolved. Though scientists as diverse as Newton and Freud have expressed concerns about correct attribution of credit, their issues were largely with researchers who were not their collaborators. But an inevitable consequence of increasing the number of coauthors is that it becomes harder to form the one-to-one relationships necessary to secure trust among the authors,³¹ and it should be no surprise that disputes between authors are increasing exponentially.³² Vagueness as to roles and responsibilities among coauthors has resulted in a failure to examine and disclose uncollegial or even fraudulent behavior. Though scores of articles have been written on the problem and many solutions advanced, such disputes still arise frequently and until recently, we were little further in achieving consensus on how to resolve them. Indeed, at present the Department of Health and Human Services' Office of Research Integrity does not even consider authorship disputes, leaving these cases for their institutions to tackle.³³

The Two-Sided Coin of Authorship

The coin of academic advancement is authorship.¹⁵ That coin has two sides, credit and accountability. When there is one author, there is rarely any problem with assigning responsibility. But the expansion in numbers of authors per paper to an average of about six has led to a tendency to dilute responsibility while seeming not to diminish credit. To medical editors, one of the consequences of coauthorship seems to be the excessive credit that may be assumed by each of the coauthors. Whether that is true or not, responsibility certainly becomes diluted, and a consequence of coauthorship seems to be that the greater the number of coauthors, the less responsibility any will take for the whole. The result is that coauthors of fraudulent scientists have insistently denied knowing anything about the fabrications or, indeed, almost anything about the offending papers.^{34–38} When questions have arisen about the integrity of published papers, too often the wretched editor has been told in effect that the paper was an orphan. Yet if coauthors cannot assure quality and detect problems, the reader is entitled to ask, Who can?³⁴

Misuse of the Current System of Credit

From the mid-1970s on, coincident with the growth of multiple authorship, there has been a steady accumulation of problems due

to practices destructive of the trust between authors and their readers. Coauthors showed themselves unwilling or unable to assure themselves of the integrity of their colleagues' work. In several cases, prominent journals published entirely fabricated data concerning imaginary series of patients, yet the coauthors had never bothered to satisfy themselves as to the existence of patients or data.^{15,34,36,38–40} Other authors have failed to disclose highly relevant data bearing directly on the efficacy and harms of drugs.^{41–46} In several instances, the sponsors of studies that produced unfavorable results have taken the data, analyzed them in misleading ways, and published the slanted analyses in order to preempt the investigators.^{4,47,48} In order to increase apparent support for new therapies, the same results in the same trials have been reported numerous times in different journals under different authors' names.^{13,49}

Two widespread and pernicious practices further distance those who reap the credit from appearing on the byline from accountability for their articles: in the first case by having spurious authors on the byline, and in the second by omitting those who wrote the article from the byline. The first is *honorary* or *guest* authorship, usually bestowed on senior colleagues who did nothing to justify authorship, in order to gratify them and to lend the articles an aura of authority.^{15,50} There have been numerous instances in which the coauthors of fabricating authors have had to suffer public humiliation, so being invited in as a guest author has its dangers.^{34,36–38, 51} The second unethical practice is *ghost* authorship.^{52,53} Hiding the names and affiliations of the real authors is a deception practiced on the reader, often in order to achieve greater sales. Whole companies make their living by ghostwriting articles,⁵⁴ and in the case of research reviews, in which bias in selection is easily introduced, the academics who are paid to have their names as the sole authors may have been asked to give only the most cursory glance at the contents.⁵⁵ Their willing participation in such a practice is unethical.

Disagreement About Who Is Responsible for the Content of an Article

Cases of gross scientific misconduct have revealed disagreement in the scientific community about who is responsible for each part of an article when there are several authors, each brought in because they have different areas of expertise. It is fairly simple when, as has happened, the authors turn out to have been so ignorant of their own publication that they did not have the expertise to realize their published figure was factitious.⁵⁶ However, three prominent cases have caused controversy. In the first (Box 73.1), when a researcher at the University of California, San Diego (UCSD) was found to have fabricated and falsified research, his university conducted a close examination of all his 137 publications and declared 60 of them to be fraudulent or questionable. The university found many of the coauthors guilty of a culpable degree of carelessness, while recognizing that it might be unfair to hold all coauthors responsible for all parts of an article.³⁶

In the second (Box 73.2), a National Institutes of Health (NIH) inquiry found two researchers at Stanford University guilty of scientific misconduct in relation to several multiauthored articles.^{39,40} Stanford held that all the coauthors shared responsibility for the whole of each of their articles, whereas the NIH panel decided that this was too high a standard and "not feasible in

Box 73.1
The Slutsky Case

Robert Slutsky, a cardiologist at the University of California, San Diego (UCSD), resigned in 1985 when a member of a promotion committee noticed apparent duplications of results in 2 of his published articles.^{36,102} Slutsky's lawyer asked that 15 of his articles, published in 8 journals, be retracted. However, over 7 years Slutsky had published 137 articles (one every 13 working days), which left a cloud over a large amount of published work. UCSD took this extremely seriously. Over a year, 10 faculty members investigated Slutsky's 137 articles, and finally declared that 77 were valid, 48 "questionable," and 12 "fraudulent." In November 1987, the UCSD committee investigating the affair published its full results in the *New England Journal of Medicine*.³⁶

The investigating committee also examined the role of the coauthors. The members asked, "In multi-authored papers, can one expect, for example, the statistician to know personally how the data were collected?" The committee concluded,

An unrealistic standard cannot be applied in judging the culpability of coauthors. But the standards should be higher than that of many of Slutsky's coauthors . . . many have been careless about verifying the accuracy of publications that carry their names. We believe this to be a culpable degree of carelessness. Acceptance of gift authorship (in which no scientific contribution was made) is also a culpable act of deliberate misrepresentation.

Unhappily, this remarkably determined effort to hold coauthors responsible and to clean up the literature is not the norm.

contemporary multidisciplinary research."³⁹ Correspondence in *Science* revealed the depth of disagreement after another case of misconduct, ranging from the view that all authors must share credit and blame equally, to the counter view that such a requirement would raise the risks of collaboration to suicidal levels and was unrealistic.⁵⁷⁻⁶³

More recently, in the Schön case (Box 73.3), in which nearly two dozen articles had to be retracted, a committee of inquiry created by Schön's employer found his collaborators guiltless and unaccountable, despite the fact that they had received widespread public acclaim at the time the work had been published.^{37,64}

The lesson taught by numerous cases of fraudulent, frivolous, confused, and deceptive authorship is that authors have often concentrated solely on the credit that accrues to them, and that action must be taken by researchers, institutions, and journals to make accountability an equally essential component of authorship.

Initiatives to Promote Good Publishing Practices

The answer to the frivolous way in which some scientists have regarded their trusted position as authors is to link credit closely to accountability. Perhaps sensing the need for accountability as coauthors have increasingly crowded onto bylines over the years, authors have assumed that they were conveying information about who was responsible for the article by the way collaborators' names were ordered on the byline. Scientists have been dogmatic in giving their views about what each position in the sequence of authors

Box 73.2
The Stanford Case

In 1987, Philip Berger, director of the Stanford University Mental Health Clinical Research Center, resigned after an audit of research funds turned up problems with the research itself.¹⁰³ The university investigative panel found that in studies of neurotransmitters, cerebrospinal fluid from senile patients had been included among the "normal" controls; that 10 published articles contained analyses based on these controls; and that in 3, exclusion of these control values invalidated the conclusions of the articles.¹⁰³ At Stanford's request, all the authors wrote letters of correction or retraction to the journals. The university report held all the coauthors to be responsible, though the university provost, noting that at that time there were no generally accepted standards for the amount of responsibility to be borne by each co-investigator, asked the university faculty to formulate such guidelines.¹⁰³

The National Institute of Mental Health (NIMH), which had been prodding Stanford into a deeper investigation, decided to review the case and held its own inquiry.³⁹ NIMH's report was issued in June 1989—before the creation of the NIH Office of Scientific Integrity and, later, the Public Health Service Office of Research Integrity, to oversee such investigations.

The NIMH report concluded that the members of its panel "did not believe that all the coauthors share responsibility for a paper. However, the panel believed that the responsibility is necessarily and properly focused on each coauthor's area of expertise." The panel concluded that "the burden of responsibility lies with the senior clinical coauthors Drs. Berger and Stahl." The report further noted,

The panel believed it was doubtful that inspections by the coauthors would have revealed the errors in the data base. To have identified these errors, the coauthors would have had to be made aware of the circumstances of recruitment for all the normal control subjects and would have had to have access to each patient's medical records. The panel believed that this detailed and in-depth level of knowledge by all collaborators is not feasible in contemporary multidisciplinary research.³⁹

Unlike Stanford, the NIMH panel vindicated all but the two senior authors.¹⁰⁴

should mean to the reader—but these views are inconsistent. They range from the contention that the first author is always the junior fellow, the last the most senior individual, and the second the senior statistician or the physician who entered most patients, to the view that all positions are equal and names should be arranged alphabetically—a practice that some journals adopted until they found themselves avoided by authors late in the alphabet.⁶⁵⁻⁶⁷ Surveys, however, have shown that although everyone is sure what the order means, everyone else, even in the same subspecialty, has a different reading.⁶⁸ The information, then, is broadcast in an idiosyncratic code, and the reader is never allowed into the secret, which is why Davies et al. found great variability in ways of assessing authorship, say, for promotion.⁶⁹ Davis and Gregeman proposed that allocation of credit could be indicated by assigning each author a numerical fraction corresponding to the work done.⁷⁰ The names were to be ordered according to this fraction. Perhaps because this seriously meant article was written in a humorous way, no one took them up on the idea.

Box 73.3 The Schön Case

Jan Hendrik Schön, a highly productive solid-state physicist working at Bell Laboratories, published over 90 articles in four years, most listing him as first author. In 2001, he published 1 paper every 8 days, most of them describing important advances in a number of fields. His sensational results attracted close scrutiny, and when several researchers noted republication and manipulation of his figures, an inquiry was held in 2002.¹⁰⁵ A panel of independent experts assembled by Bell Laboratories examined allegations concerning 25 separate articles in which Schön had had a total of 20 coauthors.^{37,105} The panel noted that “if valid, the work he and his coauthors report would represent a remarkable number of major breakthroughs in condensed-matter and solid-state physics.”

The investigating panel (the Beasley Committee) found Schön guilty of scientific misconduct and he was fired by Bell Laboratories. At the same time, the panel members noted that “all device fabrication, physical measurement, and data processing . . . were carried out (with minor exceptions) by Hendrik Schön alone, with no participation by any coauthor or other colleague. None of the most significant physical results was witnessed by any coauthor or other colleague.”³⁷ Finding “no evidence that the laboratory practices of any coauthor of Hendrik Schön . . . are outside the accepted practices of their fields,” the committee “completely cleared” the coauthors of scientific misconduct. However, it devoted a section of its report to the coauthors’ professional responsibility. “By virtue of their coauthorship,” it noted, “they implicitly endorse the validity of the work.”³⁷

“The Committee found this to be an extremely difficult issue, which the scientific community has not considered carefully,” the report said. “Therefore, no clear, widely accepted standards of behavior exist.” Central to collaborative research, the committee said, lay

the question of professional responsibility [that] involves the balance between the trust necessary in any collaborative research and the responsibility all researchers bear for the veracity of results with which they are associated. The Committee does not endorse the view that each coauthor is responsible for the entirety of a collaborative endeavor: the relative responsibility of researchers with very different expertise, seniority and levels of participation must be considered.

The Committee concluded that the coauthors had “in the main, met their responsibilities.”

Following the report, the American Physical Society revised its ethical guidelines. No longer were all coauthors to be held to a standard of equal responsibility. The new guidelines stated that all authors shared some degree of responsibility for the whole, but only some have responsibility for the entire paper.¹⁰⁶ In a correspondence following the Schön decision, I pointed out that to find all the coauthors guiltless of misconduct and of failure to meet their professional responsibilities effectively meant that they can have contributed nothing that merited authorship to the research.⁶⁴

The International Committee of Medical Journal Editors Statements

Over the years, the International Committee of Medical Journal Editors (a.k.a., the Vancouver Group) has developed the following criteria:

Authorship credit should be based on (1) substantial contributions to conception and design, or acquisition of data, or

analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

- Acquisition of funding, collection of data, or general supervision of the research group, alone, does not justify authorship.
- All persons designated as authors should qualify for authorship, and all those who qualify should be listed.
- Each author should have participated sufficiently in the work to take public responsibility for appropriate portions of the content.⁸

These criteria have been widely adopted in biomedicine. In addition, journals have become much more helpful in publishing their criteria and what they expected of authors. Unfortunately, abuses continue, and several studies have shown widespread ignorance of these criteria by authors, or when they did know, extensive flouting of the rules.^{71,72}

Efforts to Limit the Number of Authors

Arguing that in any group, only a few can truly carry out all the functions that would qualify them as authors,²⁸ editors have tried to limit the number on the byline. These efforts have been doomed partly because they were arbitrary, partly because there are good scientific reasons for groups to form for a common purpose, and partly because the editors kept having to make exceptions to their own rules. The ICJME decreed initially that no more than three authors should be listed, but increased this to six in 1994. Molecular biologists have persuaded the National Library of Medicine to list 25, and we can expect these numbers to increase.

The Concept of Contributorship

Things began to change with the realization that abuses of authorship were at the root of many of the problems medical editors encountered, and the editors held a conference on authorship in Nottingham, England, in 1996. A proposal by myself and my colleagues was debated and largely approved, and was published the next year.⁴⁰ The essence of the proposal was as follows: Instead of concentrating on credit, everyone should focus on strengthening the trust necessary for the author-reader relationship. Authors (who should satisfy the ICMJE criteria) should, before sending in their manuscripts to journals, decide who had contributed what—the job each researcher had actually done, rather than the official position each occupied. They should then list the contributions of each author, in rough order of perceived importance of contribution, and editors should publish this information for the readers. Each part of the work would be attributed to one or more of the author/contributors on the byline. Further, one or more of the authors would take formal responsibility for the integrity of the whole, acting as *guarantor*. If questions later arose, it would be easy to tell who was responsible for answering them.

It was noted at the time that the system was descriptively precise, and, being transparent, in the best traditions of science. It is fair, and discourages ghost and guest authorship. It might even

discourage fraud by making lying harder.⁷³ It also removed a curious anomaly. The custom had long been that those who contributed least, namely those acknowledged for their help, had their contributions specified for the reader, whereas the contributions of the individuals on the byline remained vague. The new system would still acknowledge individuals, but now authors would also reveal their contributions. An important benefit might prove to be to improve the system of academic promotions and appointments, because panels would be able to rely on the explicit statements of candidates at the time the articles were published, instead of their later recollections. The original proposal suggested that for scientific articles, the term *author* be dropped completely in favor of *contributor*, in order to make the point. This proved too radical for the community to swallow.

The system was adopted rapidly by a number of journals, led by *The Lancet*⁷⁴ and *BMJ* (formerly the *British Medical Journal*). It was shown to be simple to manage and to take up little page space.⁷⁵ It was subsequently debated at three retreats held by the Council of Science Editors, and endorsed by them and by the World Association of Medical Editors. In 2003, the two largest general scientific journals, *Nature* and *Science*, adopted the policy,⁷⁶ as did the NIH.⁷⁷ The ICMJE statement now reads, "Some journals now request and publish information about the contributions of each person named as having participated in a submitted study, at least for original research. Editors are strongly encouraged to develop and implement a contributorship policy, as well as a policy on identifying who is responsible for the integrity of the work as a whole."⁸

As the statement rightly points out, "While contributorship and guarantorship policies obviously remove much of the ambiguity surrounding contributions, it [sic] leaves unresolved the question of the quantity and quality of contribution that qualify for authorship."⁸ This is why the ICMJE criteria for authorship remain important.

As more journals adopt the system of disclosing contributions, as transparency and clarity are achieved, and as attention is focused on guaranteeing the integrity of the whole, the controversies over who is responsible for what part of the research when allegations of misconduct arise following publication should die down.

Naturally, it has taken a long time for this innovation to diffuse to the thousands of biomedical journals. However, now that the disclosure of contributions of authors has become the standard, it is interesting to note that in 1941, the inventors of penicillin fully disclosed their individual contributions to this seminal study in a footnote to their article in *The Lancet*.⁷⁸

The Problem of Large Trials

Large, multicenter trials have been the first to face up to the issue of indicating which of the investigators did what. A good example is given by the report of the fourth ISIS trial, published in 1995. This listed 2,000 "members," conveniently divided into committees for writing, data monitoring, and so on, and with a detailed description of the tasks of the unit overseeing the research.⁷⁹ However, the 1993 Ig Nobel prize was accepted by the *New England Journal of Medicine* on behalf of the 972 GUSTO investigators listed as coauthors for one article, at two words per author.^{80,81} Clearly, not everyone satisfied the conditions necessary

to claim authorship. Some editors tried to decree limits, and clinical researchers naturally objected, arguing that if we are not to penalize those who take the trouble to conduct large, multicenter trials, while rewarding those who publish small, uncontrolled trials, such editorial limits on the number of authors were self-defeating.^{15,82} It is becoming accepted that the core group who design and direct the study, analyze the data, and write the article should be named on the byline as authors, writing for the others who are bundled together in the study's name thus: "for the XYZ Investigators." Their names are then listed fully in the acknowledgments. Once again, it is important that all those who appear as named authors on the byline satisfy the ICMJE criteria and have their individual contributions listed for the reader. For a fuller treatment of the problems of indexing and citation when there is group authorship, and for discussion of the issue of authorship for research groups, see Flanagan et al., 2002.^{83,84}

The ICMJE recommendations for authorship of trials are as follows:

When a large, multi-center group has conducted the work, the group should identify the individuals who accept direct responsibility for the manuscript. These individuals should fully meet the criteria for authorship defined above and editors will ask these individuals to complete journal-specific author and conflict of interest disclosure forms. When submitting a group author manuscript, the corresponding author should clearly indicate the preferred citation and should clearly identify all individual authors as well as the group name. Journals will generally list other members of the group in the acknowledgments. The National Library of Medicine indexes the group name and the names of individuals the group has identified as being directly responsible for the manuscript.⁸

Investigation and Retraction

The obligations of the authors require that some of them take part in audit of their trials, to ensure the integrity of the data. The obligations authors undertake also require prompt investigation of allegations of fraudulent behavior. If a retraction is advised after a finding by a properly constituted investigative panel, it is the duty of all the coauthors to correct the literature with a retraction linked prominently to the original article.⁸ There are excellent models provided for this by Weiss and his colleagues of the Cancer and Leukemia Group B⁸⁵ and by Hoeksema et al.⁸⁶ Such an audit system uncovered the fabrications of the South African researcher Werner Bezwoda,⁸⁷ and, in contrast to cases in which retraction has failed to occur,³⁶ has helped patients and their physicians.

Ethical Requirements of Authors and Journals Introduced by Commercial Sponsorship

Article 27 of the Declaration of Helsinki states in part, "Negative as well as positive results should be published or otherwise publicly available. Sources of funding, institutional affiliations and any possible conflicts of interest should be declared in the publication."⁸ In the area of clinical trials, the obligation to publish, clearly laid out in the Declaration of Helsinki, may be at odds with the wishes of the commercial entities that have sponsored a study.

The sponsors may insist that they own the data, and may want to exercise full control over the clinical researchers, suppress unfavorable results, and proceed legally against researchers who try to publish.^{4,47,48,88,89}

There are several ways in which a literature biased in favor of commercial products may occur. Prudent investment of resources will limit manufacturers to sponsor trials of products for which they have strong prior evidence that the result will be favorable for their product, and, for regulatory approval, sponsors will demand rigorous conduct of the trials. There is some evidence that sponsors will try to influence the analysis and reporting of those trials they allow to be published. For example, both the VIGOR and CLASS COX-2 inhibitor studies were incompletely reported, with the effect that in the former report, a toxic effect was concealed, and in the latter, the fact there was no advantage to the new drug was concealed.⁹⁰ Failure to report outcomes, and so bias trial reports, is common, and particularly in the reporting of harms, is associated with commercial funding.^{91,92} There is overwhelming evidence that sponsors will try to control dissemination of results.

Clinical researchers, particularly when they work in universities, in which publication is not merely a privilege and a right but also a duty, face severe conflicts unless their contract with a sponsor ensures them an unfettered right to publish, full access to all the data, and control over the analyses. Because of recent scandals, there is a strong movement, based on scientific, ethical, and legal principles, to forbid restrictive contracts and allow full dissemination of trial results. For example, on December 10, 2004, the Association of American Medical Colleges issued a statement "strongly supporting the elimination of restrictive confidentiality clauses in clinical trial contracts between pharmaceutical companies and academic or physician researchers."⁹³

So many episodes of deceptive behavior have occurred associated with the widespread takeover of clinical trials by industry, and the resulting secrecy and bias, that editors and reviewers no longer instinctively trust the authors to present a faithful account of the work.^{49,94-97} The reputation of a journal, which is what attracts authors, is inevitably bound up with that of the authors and their articles. Medical editors are naturally solicitous of their journals' reputations, not least because circulation and income depend on those reputations. To this concern is added the wider consideration that it is the editor's duty to publish information valuable for the public's health, and there are numerous studies to show that financial ties bias reporting in ways that act to the detriment of optimal patient care.

As a direct consequence of very many scandals associated with commercial and financial influences on the behavior of researchers, and the extensive and well-documented bias in reporting,⁹⁹ journal editors have, over the past 25 years, introduced a wide range of assurances to be sought from authors to try to bolster the editors' faith in the integrity of the work. As a result, to fulfill the ethical and practical requirements of authorship in most large medical journals, authors must expect to attest to the editor, and disclose to the reader, several sorts of information. These will vary between journals, and potential authors should always check with the specific journal's instructions for authors.

In general, authors must disclose their affiliations and the names, research institutions, and sites of all members of the research group. They must provide information, to be published, on all possible relevant financial ties, and their funding and support. They must provide a statement about the role of the sponsor,

particularly an assurance that they, the authors, had complete freedom to publish and had control over, and access to, all the data. If there is any doubt about this and about their freedom to analyze the data (for example, if the statistical analysis was done by someone paid by the sponsors), the journal may demand independent statistical analysis and review of all the data as a condition of acceptance. Readers seeking an example of this should look at the disclosures in a report of a trial by Gallant et al., in which the contributions of the authors are also disclosed.⁹⁸

Events in 2004 and 2005 associated with trials of COX-2 inhibitors and selective serotonin reuptake inhibitors have underscored the crucial clinical importance of publication of all trials and, equally essential, the registration of trials at inception.^{83,94} This is an ethical duty that falls on the authors, and the editors of journals are now insisting that they will not publish trials unless the authors provide evidence that their trials have been registered, preferably at inception, with a large, easily accessible register.^{94,99} The ICMJE published a statement on this in September 2004.⁸

Finally, in order to help to ensure the ethical conduct of research, each publication should note that the trial was approved by an institutional review board or other ethical committee and that informed consent was obtained from all participants. These items are often left out, especially when the article is a secondary publication from a trial whose main results have already been published.¹⁰⁰

Policy Implications and Unresolved Ethical Issues and Requirements

The massive publicity during 2004 following the revelations of unpublished trials on antidepressants in children and COX-2 inhibitors in adults threw a spotlight on serious ethical deficiencies in the conduct of corporate sponsors of trials, who have dragged their feet for years on the issue of trial registration and publication. It also reflected badly on the many clinical researchers whom the manufacturers sponsored, and who had written the reports (or acquiesced in their suppression), many of whom had multiple financial ties.^{46,94} The behavior of both groups was unethical, and the community of clinical researchers should note that this failure of investigators and their sponsors to take the responsibilities of authorship seriously was directly contrary to the words and intent of the Declaration of Helsinki. It took a lawsuit to move industry to reluctant acquiescence.¹⁰¹ The subject also was being considered in the U.S. Congress, but the issue would go away if authors behaved ethically. In the meantime, it is urgent that researchers be reminded of the ethical responsibilities that author/investigators take on when they conduct and report trials.
