Acknowledgments

A book such as this is a truly collaborative effort, and we have incurred many debts along the way for which we owe thanks. We must first thank those who contributed chapters to our volume. Without their time and effort, this volume would not exist. The contribution of a chapter to an edited volume is often a thankless task, and it is one that does not receive the recognition we believe it deserves. So we here signal our indebtedness to our contributors and give our heartfelt thanks. We hope that the volume is sufficiently well received and widely read such that our contributing authors receive the recognition for their hard work that they deserve.

At the National Institutes of Health, we have many to thank. We are delighted to thank our behind the scenes editor, Bruce Agnew. Bruce read every chapter with his very keen editorial eyes, and offered editorial and substantive suggestions on each chapter. This was an enormous undertaking, and Bruce did it with his characteristic good humor and aplomb. The volume is much better because of his input. Near the end of the process, Rose Murray and Becky Chen stepped in and helped us track down art work and permissions. This, too, was a large undertaking, and Rose and Becky were instrumental in helping us wrap things up. Justine Seidenfeld helped us put together material for one chapter, and we thank her for that. Finally, we gratefully acknowledge the

financial assistance provided by the Department of Bioethics, The Clinical Center, National Institutes of Health.

We received a great deal of help from archivists, librarians, and staff at a number of institutions who found material for us and provided us with high-resolution images to include in this volume. To those who helped us at the following institutions, we give our thanks: Bentley Historical Library, University of Michigan, Ann Arbor, Mich.; Chemical Engineering, New York, N.Y.; March of Dimes, White Plains, N.Y.; American Philosophical Society Library, Philadelphia, Penn.; Medical Arts and Photography Branch, National Institutes of Health, Bethesda, Md.; Rutgers University Libraries, Special Collections and University Archives, New Brunswick, N.J.; Indiana University Libraries, Bloomington, Ind.; Frederick L. Ehrman Medical Library Archives, New York University School of Medicine, New York, N.Y.; Royal College of Physicians, Heritage Collections, London, England; United States Holocaust Memorial Museum, Washington, D.C.; and the University of Virginia Library, Special Collections, and Historical Collections, Charlottesville, Va.

Last but not least, we thank our editor at Oxford University Press, Peter Ohlin, for very helpful advice and guidance from day one, as well as tremendous patience.

Introduction 3

I A Selected History of Research With Humans

- 1 Walter Reed and the Yellow Fever Experiments 9
Susan E. Lederer
- 2 The Nazi Medical Experiments 18
Paul J. Weindling
- 3 The Imperial Japanese Experiments in China 31
Takashi Tsuchiya
- 4 The Randomized Controlled Trial of Streptomycin 46
Alan Yoshioka
- 5 The Salk Polio Vaccine Field Trial of 1954 61
Marcia L. Meldrum
- 6 The Jewish Chronic Disease Hospital Case 73
John D. Arras
- 7 The Hepatitis Experiments at the Willowbrook State School 80
Walter M. Robinson and Brandon T. Unruh
- 8 The Tuskegee Syphilis Experiment 86
James H. Jones

- 9 HIV Research 97
John Y. Killen Jr.
- 10 The Gelsinger Case 110
Robert Steinbrook

II Codes, Declarations, and Other Ethical Guidance for Research With Humans

- 11 An Ethical Framework for Biomedical Research 123
Ezekiel J. Emanuel, David Wendler, and Christine Grady
- 12 The Nuremberg Code 136
George J. Annas and Michael A. Grodin
- 13 The Declaration of Helsinki 141
Richard E. Ashcroft
- 14 The Belmont Report 149
Tom L. Beauchamp
- 15 Regulations for the Protection of Humans in Research in the United States: The Common Rule 156
Joan P. Porter and Greg Koski
- 16 International Ethical Guidance From the Council for International Organizations of Medical Sciences 168
Juhana E. Idänpään-Heikkilä and Sev S. Fluss
- 17 The Council of Europe 174
Pēteris Zilgalvis
- 18 The European Community Directives on Data Protection and Clinical Trials 180
Deryck Beyleveld and Sebastian Sethe
- 19 National Bioethics Commissions and Research Ethics 187
Eric M. Meslin and Summer Johnson

III Context, Purpose, and Value of Clinical Research

- 20 Exploitation in Clinical Research 201
Alan Wertheimer
- 21 The Nature, Scope, and Justification of Clinical Research: What Is Research? Who Is a Subject? 211
Robert J. Levine
- 22 Four Paradigms of Clinical Research and Research Oversight 222
Ezekiel J. Emanuel and Christine Grady
- 23 The Role of Patient Advocates and Public Representatives in Research 231
Rebecca Dresser

IV Scientific Design

- 24 Equipoise and Randomization 245
Steven Joffe and Robert D. Truog
- 25 The Ethics of Placebo-Controlled Trials 261
Franklin G. Miller

- 26 Challenge Experiments 273
Franklin G. Miller and Donald L. Rosenstein
- 27 Emergency Research 280
Jason H. T. Karlawish
- 28 Research With Biological Samples 290
David Wendler
- 29 Genetic Diagnostic, Pedigree, and Screening Research 298
Eric T. Juengst and Aaron Goldenberg
- 30 Deception in Clinical Research 315
David Wendler and Franklin G. Miller
- 31 Epidemiology: Observational Studies on Human Populations 325
Douglas L. Weed and Robert E. McKeown
- 32 Behavioral and Social Science Research 336
Felice J. Levine and Paula R. Skedsvold
- 33 Phase I Oncology Research 356
Manish Agrawal and Ezekiel J. Emanuel
- 34 Surgical Innovation and Research 367
Grant R. Gillett

V Participant Selection

Section A. Fair Participant Selection

- 35 What Is Fair Participant Selection? 377
Leslie A. Meltzer and James F. Childress
- 36 Incentives for Research Participants 386
Neal Dickert and Christine Grady
- 37 Recruiting Research Participants 397
Franklin G. Miller

Section B. Special Populations

- 38 Research Involving Women 407
Christine Grady and Colleen Denny
- 39 Research With Ethnic and Minority Populations 423
Bernard Lo and Nesrin Garan
- 40 Research Involving Economically Disadvantaged Participants 431
Carol Levine
- 41 Research Involving Those at Risk for Impaired Decision-Making Capacity 437
Donald L. Rosenstein and Franklin G. Miller
- 42 Research With Children 446
Alan R. Fleischman and Lauren K. Collogan
- 43 Research With Captive Populations: Prisoners, Students, and Soldiers 461
Valerie H. Bonham and Jonathan D. Moreno
- 44 Research With Identifiable and Targeted Communities 475
Morris W. Foster and Richard R. Sharp

- 45 Research With Healthy Volunteers 481
Albert R. Jonsen and Franklin G. Miller
- 46 Research With Fetuses, Embryos, and Stem Cells 488
Ronald M. Green

VI Risk-Benefit Assessments

- 47 Risk-Benefit Analysis and the Net Risks Test 503
David Wendler and Franklin G. Miller
- 48 Assessing and Comparing Potential Benefits and Risks of Harm 514
Nancy M. P. King and Larry R. Churchill
- 49 Risk-Benefit Assessment in Pediatric Research 527
Sumeeta Varma and David Wendler

VII Independent Review and Oversight

- 50 The Origins and Policies That Govern Institutional Review Boards 541
Charles R. McCarthy
- 51 Models of Institutional Review Board Function 552
Angela J. Bowen
- 52 Evaluating the Effectiveness of Institutional Review Boards 560
Marjorie A. Speers
- 53 Data and Safety Monitoring Boards 569
Lawrence M. Friedman and Eleanor B. Schron
- 54 The Food and Drug Administration and Drug Development: Historic, Scientific, and Ethical Considerations 577
Robert Temple and Sara F. Goldkind

VIII Informed Consent

- 55 A History of Informed Consent in Clinical Research 591
Erika Blacksher and Jonathan D. Moreno
- 56 Philosophical Justifications of Informed Consent in Research 606
Dan W. Brock
- 57 Legal and Regulatory Standards of Informed Consent in Research 613
Alexander M. Capron
- 58 The Therapeutic Misconception 633
Paul S. Appelbaum and Charles W. Lidz
- 59 Empirical Issues in Informed Consent for Research 645
James H. Flory, David Wendler, and Ezekiel J. Emanuel
- 60 The Assent Requirement in Pediatric Research 661
David Wendler

IX Respect for Human Research Participants

- 61 Confidentiality 673
James G. Hodge Jr. and Lawrence O. Gostin

- 62 Liability and Compensation for Injury of Research Subjects 682
Wendy K. Mariner
- 63 The Obligation to Ensure Access to Beneficial Treatments for Research Participants
at the Conclusion of Clinical Trials 697
James V. Lavery

X Multinational Research

- 64 Appropriate Ethical Standards 711
Ruth Macklin
- 65 Benefits to Host Countries 719
Ezekiel J. Emanuel
- 66 The Standard of Care in Multinational Research 729
Søren Holm and John Harris
- 67 Responsiveness to Host Community Health Needs 737
Alex John London

XI Clinical Investigator Behavior

- 68 Conflict of Interest in Medical Research: Historical Developments 747
Trudo Lemmens
- 69 The Concept of Conflicts of Interest 758
Ezekiel J. Emanuel and Dennis F. Thompson
- 70 Empirical Data on Conflicts of Interest 767
Lindsay A. Hampson, Justin E. Bekelman, and Cary P. Gross
- 71 Industrialization of Academic Science and Threats to Scientific Integrity 780
Eric G. Campbell and David Blumenthal
- 72 Fraud, Fabrication, and Falsification 787
David B. Resnik
- 73 The Obligation to Publish and Disseminate Results 795
Drummond Rennie

Credits and Permissions 805

Index 809

The Oxford Textbook of
Clinical Research Ethics

This page intentionally left blank

Ezekiel J. Emanuel Robert A. Crouch Christine Grady
Reidar K. Lie Franklin G. Miller David Wendler

Introduction

The last decade has witnessed tremendous controversy surrounding the ethics of clinical research. There have been disagreements over the use of placebos in developing countries when there are effective but costly therapies available in more developed countries; there has been uncertainty over researchers' obligations to participants once trials are complete; there have been disagreements over research with children and mentally incapacitated patients; and there is widespread condemnation of academic researchers' financial conflicts of interest. The deaths of Jesse Gelsinger and Ellen Roche while both were enrolled in clinical research, and the suspension of clinical research at Duke, Johns Hopkins, and other major research institutions has created concern over the safety of clinical research. Suppression of data on adverse drug events by pharmaceutical corporations has created concern over the integrity of both researchers and the research enterprise. Probably nothing signifies this controversy and its public nature better than the April 22, 2002, issue of *Time* magazine, whose cover depicted a human being in a hospital gown inside a cage, under a caption that read, "How Medical Testing Has Turned Millions of Us into . . . Human Guinea Pigs."¹

Of course, this is not the first era of controversy surrounding clinical research. At least three periods of sustained controversy have occurred before this latest decade. In the late 19th century, there was an important controversy surrounding the search for the cause and a cure of yellow fever. As Susan Lederer describes in Chapter 1, Guiseppe Sanarelli was an Italian researcher working in South America. Working with the legacy of Koch and Pasteur's isolation of microorganisms as causes of disease, he declared that he had isolated the bacillus that caused yellow fever, and was able to induce yellow fever in five people by infecting them with the

agent. (Leave aside that yellow fever is caused not by a bacillus but by a virus.) His work was categorically condemned by many researchers, most importantly by William Osler, at the time the world's most prominent and famed physician and chairman of medicine at Johns Hopkins Medical School and soon to be Regius Professor of Medicine at Oxford. At a professional meeting in 1898, Osler declared, "To deliberately inject a poison of known high degree of virulency into a human being, unless you obtain that man's sanction, is not ridiculous, it is criminal."²

After the yellow fever controversy there was the entire episode of Nazi medicine and medical research. As delineated by Paul Weindling in Chapter 2, this period entailed a myriad of the most gruesome and horrific experiments, from placing people in freezing water until they died to subjecting them to very low atmospheric pressures until they exploded, from injecting them with typhoid to Mengele's twin experiments. Part of the horror was how many German researchers were able to use their research samples and data after the war to continue as respected researchers.

Then beginning in the early 1960s, there was a series of research scandals in the United States that culminated in the revelations about the Tuskegee Syphilis Study. This period began in July 1963 with the Brooklyn Jewish Chronic Disease Hospital case, which is described by John Arras in Chapter 6. Prominent cancer researchers "injected live cancer cells into 22 chronically ill and debilitated patients" without informing them that cancer cells were being used. Patients were unaware that this was not a therapeutic intervention to treat their condition, but was rather an experiment to gain scientific knowledge. Furthermore, the patients were not asked for their consent to the study.

Then in 1966, Henry K. Beecher, a prominent anesthesiologist at the Massachusetts General Hospital and professor at Harvard Medical School, published a paper in the *New England Journal of Medicine* entitled “Ethics and Clinical Research.”³ In it, he delineated 22 cases that he claimed were extracted from an original list of 50 cases. He noted that these cases came “from leading medical school, university hospitals, private hospitals, governmental military departments (the Army, the Navy, and the Air Force), governmental institutes (the NIH), Veterans Administration hospitals, and industry.” Beecher wrote that these cases represented “troubling practices” in which many of the patients never had the risk satisfactorily explained to them, and further hundreds did not know that they were the subjects of an experiment although they suffered grave consequences as a direct result.

It should be noted that Beecher may not have been careful in all of the 22 cases he criticized. As Walter Robinson and Brandon Unruh note in Chapter 7, although Beecher strongly condemned the Willowbrook hepatitis studies—which left an enduring taint upon its principal investigator, Dr. Saul Krugman—this research seems to have fulfilled ethical requirements and, upon closer examination, to have been conducted in an ethical manner.

As bad as some of Beecher’s cases were, worse was revealed in 1972 when the Tuskegee Syphilis Study was disclosed to the public. As described by James Jones in Chapter 8, this study has a great many troubling and unethical aspects. Not only was the scientific justification of the study questionable when it was initiated in the 1930s, the actual trial entailed multiple layers of deception, and trial personnel actively prevented the participants from getting medication—penicillin—to which they were entitled. In the 1960s, a social worker working for the U.S. Public Health Service in San Francisco, Peter Buxton, learned about Tuskegee from coworkers and launched a one man crusade to stop it. As Jones notes, this prompted an internal ethical evaluation of the study, which ultimately sanctioned continuing the study. Only when subjected to public scrutiny through an Associated Press story in 1972 did the trial get halted by the Secretary of the Department of Health Education and Welfare.

Of course, these are not the only scandals or controversies involving clinical research. There were less well known but nonetheless strong condemnations of the appalling research experiments committed by the Japanese military in World War II, well described by Takashi Tsuchiya in Chapter 3. In the 1980s, as John Killen notes in Chapter 9, debate surrounded trials of drugs for HIV/AIDS and whether the research subject protections were excessively paternalistic. Importantly, a big change occurred in this era when research participants were major participants in the debates and, in a surprise to many, challenged the oversight of clinical research as excessively protectionist and paternalistic.

In one sense, such scandals and debates have been quite beneficial. These controversies have forced the reexamination of fundamental issues long deemed settled and produced much of the ethical guidance for clinical research. As Carol Levine has observed, our approach to the ethics of clinical research was “born in scandal and reared in protectionism.”⁴ Although this may overstate the case a bit, it is certainly true that the condemnation of Sanarelli’s claims led Walter Reed to carefully reflect on his yellow fever studies and to delineate five key safeguards: (1) auto-experimentation, with the researchers serving as participants (including the fact that one, Jesse Lazear died as a result); (2) use only of adult participants; (3) signed, written contracts with research

participants; (4) financial payment to the participants; and (5) declaration in the papers that each participant gave his consent, forerunner to the current practice of indicating in published papers that the research was conducted in accord with ethical guidelines. The judicial decision in the post war trial of the Nazi doctors, *United States v. Karl Brandt et al.*, articulated the Nuremberg Code.⁵

In the wake of the Jewish Chronic Disease Hospital case and other scandals, the U.S. Public Health Service required independent review of research studies to assess the risk-benefit ratio and the adequacy of measures to obtain informed consent. The Tuskegee scandal prompted the creation of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research by the U.S. Congress. In April 1979, this Commission issued its Belmont Report, which articulated respect for persons, beneficence, and justice as the “broader ethical principles [to] provide a basis on which specific rules may be formulated, criticized, and interpreted.”⁶ The Commission also induced the Department of Health, Education and Welfare to adopt regulations requiring that institutional review boards review all research protocols before they were begun and other safeguards. Similarly, worries about HIV studies in developing countries led to the International Ethical Guidelines for Biomedical Research Involving Human Subjects promulgated by the Council for International Organizations of Medical Sciences (CIOMS).⁷

Although forcing needed change, these controversies have also stymied clinical research. They have made well-intentioned researchers uncertain of how they can act ethically and how to design an ethical clinical research trial. For instance, ongoing disagreement about the ethics of using placebo controls in developing countries that cannot afford expensive medications or interventions may have inhibited the initiations of studies in developing countries; disagreement about researchers’ obligations to health needs of participants that are unrelated to the purposes of research has prevented studies from occurring; different views on what benefits must be provided at the conclusion of trials have generated charges of exploitation; and controversy about the ethics of paying research participants has led many to condemn studies because they are “coercive.”

One problem with these controversies is that although bio-ethicists, research ethics boards, regulatory agencies, international organizations, and others debate what is the ethical thing to do, research must proceed and researchers must make decisions in planning and conducting research studies. This creates challenges for researchers and induces worries that even actions chosen conscientiously and with good intentions may be charged with being unethical. This may cast a chill on research.

Another problem is that the disputes have generated huge amounts of literature—commentaries, conceptual analyses of issues, and empirical research studies. The growth of the literature is not a problem per se. Indeed, good analyses can lead to wider and deeper understanding of many issues. But poor analyses can inappropriately condemn actions and studies as “exploitative,” “coercive,” or “unjust,” thereby inhibiting perfectly ethical research. In addition, a vast literature may make it hard for experts in research ethics, let alone clinical researchers, to be able to know what is the current status of an issue, such as payment to research participants, use of stored biological samples, improving informed consent, or enrollment of people who are mentally incompetent, or what constitutes minimal risk. Although there have been

comprehensive review articles on a few relevant topics, there has not been a comprehensive and systematic synthesis and critical analysis of the research ethics literature in all areas. The need for comprehensive reviews is especially critical when it comes to synthesizing empirical studies. Such reviews require collecting large numbers of studies, synthesizing data based on different methodologies, and critically comparing results. The reviews that do exist have generated results that have challenged common assumptions and surprised many people, including experts in the field. For instance, the common assumption that using videos or interactive computer programs will enhance understanding during the informed consent process has been challenged by a comprehensive review. Similarly, the contention that the quality of informed consent is worse in developing countries compared to developed countries was not substantiated when all available studies were analyzed.

A third problem relates to the available ethical guidance. Many codes or declarations were responses to scandals. Walter Reed's five principles were a response to Sanarelli's ethical violations; the Nuremberg Code was a response to the Nazi war crimes; the Belmont Report was a response to Tuskegee Syphilis Study; the ethical guidelines of the Advisory Committee on Human Radiation Experiments was a response to the radiation experiments in the United States; and the latest revision of the Declaration of Helsinki⁸ was a response to the controversy surrounding placebo-controlled trials in developing countries. A major problem with such response to scandals is that these guidelines, codes, and declarations focus on the specific issue or issues raised by the scandal and use the scandal as the litmus test for their recommendations. There has been little effort to reflect on a more general ethical framework to guide research ethics, free of the emotional outrage based on the latest egregious violations when, as Bishop Butler put it, "we sit down in a cool hour."

One consequence is that there are contradictions among these various "authoritative" guidelines. For instance, the Nuremberg Code does not permit research with people who cannot consent—children and mentally incapacitated individuals—whereas other guidelines permit such research under certain circumstances; the Declaration of Helsinki seems to prohibit placebo controls whenever there is a proven treatment, whereas most other guidance, including that from CIOMS, the Nuffield Council,⁹ and the National Bioethics Advisory Commission,¹⁰ permits such trials under certain circumstances; and CIOMS requires reasonable availability of a drug in a country if it has been proven effective in that country, but this is not required by other guidance including the Declaration of Helsinki and the Nuffield Council.

Further, many of the reviews of ethical issues in clinical research that do exist focus on research work from one country and tend not to be representative of international perspectives. This lacuna prevents comparisons of laws and regulations as well as accepted norms of practice across countries. This has inhibited the identification of areas of agreement and disagreement, and led to claims that upon closer examination seem untenable.

In large measure, this textbook is an effort to remedy these and related lapses. One of its primary aims is to create a comprehensive and systematic synthesis of all the literature relevant to the ethics of clinical research, broadly construed. The textbook addresses all the topics of the ethics of clinical research and attempts to consider all the material written on each topic. It is comprehensive in covering the history of the triumphs of clinical

research as well as the scandals—and the formal guidance and scholarship that arose in the wake of these scandals. It analyzes such topics as the various perspectives of different groups of research participants, the assessment of risks and benefits, the operation of institutional review boards, informed consent, and what we know about conflicts of interest. We have tried to define the domain of the ethics of clinical research broadly, encompassing everything that might be relevant to the ethical consideration of a clinical research protocol, from regulations to the social context of research, from fraud and conflict of interest to confidentiality.

The survey is comprehensive in another way: It synthesizes both conceptual work, on issues such as payment to research participants or the involvement of women and children in research, and empirical studies on such topics as informed consent and financial conflicts of interest.

The survey is comprehensive in yet a third way: It focuses not just on the United States but on ethical debates, guidelines, regulations, studies from all over the world. Largely because so much clinical research has been funded by and conducted in the United States, much of the early development of research ethics occurred in the United States. However, with the ongoing and ever accelerating expansion of biomedical research in other countries—that is, with the globalization of research—there will be scandals, guidelines, regulations, and empirical studies from both developed and developing countries outside the United States. Doubtless this will affect research ethics. Although those in the United States often focus on individual rights, autonomy and informed consent, a shift to a global perspective may lead research ethics in new directions, perhaps with a greater emphasis on the impact of research on the wider community. In any case, to reflect and anticipate this globalization, we have tried to include authors from as many countries as possible.

The organization of the textbook is also meant to be instructive. Too often ethical considerations of controversial research trials are chaotic and haphazard, jumping from discussions of informed consent to considerations of risks and potential benefits to posttrial availability of interventions to use of stored tissue samples, and so on. This textbook aims to provide a systematic structure: Parts III through IX follow the logical sequence of development of clinical research protocols, and therefore of the ethical issues that have to be considered along the way. Research begins with defining the questions to be addressed, by what methodologies and in what relevant populations; only toward the end of preparing a research project are the issues of informed consent relevant. The organization and structure of the sections mirror this sequence to provide guidance through the research development process. Our intention is to have the formal structure of the book reemphasize how ethical issues can be addressed in a systematic manner, rather than in a disorganized manner. Hopefully, such an organized manner of analysis will contribute to improving the ethical evaluation of research protocols.

To achieve the goals of the textbook—comprehensiveness, systematic analysis, and wide ranging and international perspectives—we invited the world's leading authorities to contribute chapters. These individuals speak with tremendous knowledge and practical experience. We also sought to identify individuals from many different countries to ensure diverse perspectives and experiences. We believe the collection of over 85 authors from a variety of countries constitutes the very best scholarship on research ethics available.

Furthermore, we asked them to provide comprehensive summaries of their topics. After presenting the diverse perspectives fairly, we expected the authors to inject their own assessments. Why? Because this gives authors an opportunity to provide educated assessments of potential future developments of the ethical issues they have examined. We believe that this combination of comprehensive summaries and editorial perspectives of the author provides the best balance for interesting, informative, and vibrant chapters.

Our aim was to provide a book useful in training researchers and others. Over the last decade, there has been substantial emphasis on capacity development related to research in developing countries. Some of this attention has also focused on improving skills in the ethical review of research. Simultaneously, it has been observed that researchers and members of research review committees in developed countries have lacked training and knowledge in the ethical conduct of clinical research. Consequently, there has been recognition of the needs and efforts in both developed and developing countries to provide training in research ethics. Unfortunately, useful educational materials are lacking. This textbook is part of our efforts to address this deficiency. We hope teachers and students of research ethics will find it useful.

We are acutely aware that at best this textbook provides substantive guidance. This is necessary but not sufficient for ethical clinical research. In 1931, Germany enacted what many believe to be the first systematic, national research ethics guidelines. While these guidelines were in place, the Nazi violations were occurring. Guidelines are not self-enforcing. Researchers, research ethics committees, regulators, and others must enforce the rules. However, enforcers need to know what to enforce. A textbook such as this is absolutely necessary. Before we can enforce, we need to elucidate and specify what needs enforcement. We therefore hope that this is a book that researchers, members of ethics review committees, bioethicists, students, patient advocates, regulators, and others can consult to obtain clear guidance regarding the issues they confront. We hope it becomes a reliable and valued reference work.

In preparing any book, editorial decisions must be made that themselves will be controversial. How broadly or narrowly to define the textbook's subject? What specific topics to include or exclude? How much space to allocate to each topic? Which of several authorities in a particular area should be invited to author a chapter? The editors have wrestled with each of these issues and many others. There is no escaping contentious decisions that will annoy and even offend people. We accept full responsibility for these

choices, with the knowledge that this is a work of contemporary reflection and scholarship, not the final account of research ethics. As research proceeds and additional challenges arise, further constructive analyses and refinements will be necessary. This is for future editions.

A Selected History of Research With Humans

This page intentionally left blank

Walter Reed and the Yellow Fever Experiments

On October 27, 1900, the front page of the *New York Times* brandished the headline “Mosquito Carries Yellow Fever Germ.” The special report described how the investigations conducted by U.S. Army surgeon Walter Reed and his colleagues—Aristides Agramonte, James Carroll, and Jesse Lazear—established that the *Aedes* mosquito served as the “intermediate host” for the so-called parasite of yellow fever.¹ Through a series of elegant and painstaking experiments, the members of the Yellow Fever Commission demonstrated that yellow fever was not transmitted via bodily contact or through infected clothing. Because there was no animal model for yellow fever, these experiments necessarily involved human beings. Two members of the Yellow Fever Commission—Lazear and Carroll—participated in early trials with “loaded” mosquitoes. Later, the members of the Commission secured human subjects, both American soldiers stationed in Havana and recently arrived Spanish immigrants, who agreed to be exposed to infected mosquitoes and to the bed linens and clothing taken from patients dead from yellow fever. Fortunately, after investigator Jesse Lazear succumbed to yellow fever in 1900, no other individuals died as a result of their participation in the yellow fever experiments.²

Yellow fever was a major threat to American lives and American commerce in the early 20th century. The successful demonstration of how this often deadly disease was transmitted inspired confidence that the disease could be effectively controlled. United States physicians hailed Walter Reed and his colleagues as scientific heroes and martyrs (both Lazear who died in 1900 from yellow fever and Reed who died following an appendectomy in 1902) for the yellow fever work, which was also taken as a sign of

America’s growing presence in the world of medical science. With the memory of yellow fever fresh in their minds, Americans initially celebrated Reed as the one “who gave to Man control of that dreadful scourge—yellow fever,” as Harvard University president Charles Eliot put it in 1902 when he conferred an honorary degree upon Reed.³

As the threat of yellow fever receded, however, the work of the Yellow Fever Commission came to symbolize the willingness of medical researchers to risk their own lives in search of medical knowledge. Reed’s willingness to risk life and limb in the name of science—both his own life and those of others—was celebrated, in spite of the fact that he had not actually participated in the yellow fever studies. But Reed was more than a risk-taker; his use of a written contract signed by the experimenter and the research subject offered an example of humane experimentation that in the 1970s could be marshaled to counteract “sweeping moral agitation by earnest and sometimes sentimental and unwise persons” who claimed that all research on human subjects was wrong.⁴ This contract, provided in both English and Spanish for the Spanish immigrants who agreed to participate in the studies, outlined the risks of participation in the yellow fever study and the benefits, including medical care and a sum of American gold (\$100 for their participation, \$200 if they contracted yellow fever). Now touted as “a milestone in the evolution of ethics in medical research” for its introduction of “informed consent,” Reed’s contract represented a distinct departure from research practices in the early 20th century.⁵ But then, as now, social and political factors influenced the meaning of consent and its place in research ethics.

The Problem of Yellow Fever

It would not be exaggeration to describe yellow fever as the scourge of the American South. The disease exerted an effect disproportionate to its relative mortality rate, because even when it failed to kill the patient, it left evidence of its ravages. Signs of classic yellow fever included chills, high fever, muscle aches, liver failure, and jaundice (producing yellow skin). Many patients experienced hemorrhaging from the nose, gums, and stomach, producing what was known as “the black vomit.” (In Spanish, the name for the disease was *vomito negro*.) Estimates about mortality from the disease ranged from 10% to 60%.⁶ An outbreak of yellow fever led people to abandon their neighborhoods by any means available. The consequences for commerce were often as deadly as the disease; those too poor to flee the city were reduced to begging for food and going without sustenance. In 1898, when the United States declared war against Spain following the sinking of the battleship *Maine*, U.S. officials realized the threat that yellow fever posed to American troops. Their fears were well grounded; although some 400 American soldiers lost their lives in what Secretary of State John Hay memorably dubbed “a splendid little war,” more than 2,000 American men fell victim to yellow fever. In the face of the disorder and death caused by yellow fever, it is easy to see why the demonstration of its mode of transmission would be considered front-page news in 1900.

The signs and symptoms of yellow fever were well known, but the cause of the disease remained obscure. With the advent of a new paradigm of disease causation, the germ theory, in the late 19th century, physicians and researchers successfully documented the causes of many diseases, including leprosy (1873), anthrax (1876), and tuberculosis (1882). In 1897, the Italian bacteriologist Giuseppe Sanarelli, working in Montevideo, Uruguay, announced that he had discovered the bacillus that caused yellow fever in the blood of patients with yellow fever. Conforming to Koch's postulates, the conventions identified by German researcher Robert Koch to establish the etiology of disease, Sanarelli claimed to have cultured *Bacillus icteroides* (a bacterium in the hog cholera group) and to have injected it into five patients at a Montevideo hospital, producing the signs of what he described as “classic yellow fever.” Three of his patients reportedly died from the disease. Efforts to replicate Sanarelli's findings failed. Although investigators working with yellow fever epidemics in New Orleans, Havana, Brazil, and Mexico sought to locate the bacillus both in living patients with yellow fever and in yellow fever cadavers, the evidence for Sanarelli's bacillus remained conflicting and unsatisfactory.⁷

Army Surgeon General George M. Sternberg was one of Sanarelli's harshest critics. When he secured from the Secretary of War the appointment of a Board of Medical Officers to investigate yellow fever, Sternberg instructed the officers to evaluate the Italian researcher's report and to explore the possibility of an “intermediate host” in the transmission of the disease. The possibility that the mosquito served as the intermediate host for yellow fever had first been raised in 1881 by Carlos Finlay, a Cuban physician. Finlay not only identified the correct mosquito (*Culex*, now known as *Aedes aegypti*) as the vector, but he provided Reed and his colleagues samples with which to start their own mosquito colony. Finlay championed the mosquito theory but he offered little persuasive evidence that this was the only way that the disease could be transmitted. With the successful dem-

onstration in 1898–1899 by Italian researchers Giovanni Grassi and Amico Bignami and English medical officer Richard Ross that anopheline mosquitoes transmitted malaria, the mosquito hypothesis for yellow fever gained currency. It remained for the members of the Yellow Fever Commission to establish that the *Aedes* mosquito transmitted yellow fever, and that the disease did not spread through clothing, linens, and body fluids of infected individuals.⁸

The Design and Conduct of the Experiments

To establish the etiology of the disease, the members of the Yellow Fever Commission evaluated Sanarelli's claims for *Bacillus icteroides*. Autopsies on 11 patients dead from yellow fever failed to produce evidence of the bacillus in cultures of blood, liver, spleen, kidney, bile, and small intestine. Using one's own body or that of a colleague was a longstanding convention for many physicians. In August 1900, two of the Commission researchers, Jesse Lazear and James Carroll, undertook experiments on themselves. Lazear, for example, placed an infected mosquito on Carroll's arm to observe the effects. Although unpersuaded at this time of the mosquito's role, Carroll became a supporter when he developed a severe attack of yellow fever following the bite, and came close to death. In September 1900, in circumstances that remain unclear, Jesse Lazear similarly developed yellow fever. Whether the result of a deliberate infection or an accidental inoculation, Lazear died from the disease on September 25, 1900, the first official “martyr” of the Yellow Fever Commission.

Reed and his colleagues were persuaded about the mosquito's role in the transmission of yellow fever, but they also wanted evidence to convince those who resisted the idea. Reed approached Cuba's governor general for permission to solicit approval from the Spanish consul for a plan to recruit recently arrived Spaniards for volunteers in these studies. General Leonard Wood, also a physician, not only endorsed Reed's plan but provided an additional sum of \$10,000 to support the research. To demonstrate that the mosquito was solely responsible for transmission of the disease, Reed and his colleagues sought evidence that other traditional routes of infection failed to cause yellow fever. One commonly held theory was that fomites (inanimate objects such as infected bed linen, clothing, and blankets) transmitted yellow fever. To establish that fomites did not play this role in the disease, Reed ordered the construction at Camp Lazear of two frame buildings with wire screen windows and doors to ensure that mosquitoes could not enter (see Figure 1.1). In one experiment, three nonimmune Americans (an assistant surgeon and two privates) entered the infected room where they unpacked boxes filled with sheets, pillow cases, and blankets “purposely soiled with a liberal quantity of black vomit, urine, and fecal matter.” Using the soiled linens and wearing the fouled garments of yellow fever patients, the Americans remained in the contaminated room for 20 days and emerged free from yellow fever. In another fomite study, James Hildebrand, a member of the Alabama Infantry and Hospital Corps, spent 20 days sleeping on a towel soaked in the blood of a patient who had died from yellow fever. A series of experiments in the fomite house established that the disease did not spread in this manner.

Reed, Agramonte, and Carroll wanted to demonstrate that yellow fever was a blood-borne disease, either by “loaded mos-

quitoes" (mosquitoes that fed on patients with active yellow fever) or through experimental injections of blood from patients with active yellow fever. When these "loaded mosquitoes" fed on volunteers who had never had yellow fever, the volunteers developed the disease. Warren Jernegan, for example, an American member of the Hospital Corps, followed his stint in the fomite house by volunteering to be bitten by loaded mosquitoes. He did not develop yellow fever until he subsequently received a subcutaneous injection of blood in January 1901 from a patient with an experimental case of yellow fever. He recovered from the severe case of the disease that the injection caused. In January 1901, when the volunteer who was scheduled to receive an experimental injection refused to participate, Walter Reed apparently volunteered to receive the injection, but Carroll vehemently objected (the disease was regarded as more dangerous to men over 40 such as Reed). Instead, a young American hospital corpsman, John Andrus, volunteered for the injection, received the subcutaneous injection, and developed a severe case of yellow fever, from which he made a slow recovery. A second American volunteer, a civilian related to the wife of an American officer stationed in Cuba, also received two injections of filtered blood from patients with active yellow fever. He developed yellow fever from the second injection, and also recovered. A third American volunteer, Albert Covington, developed a very severe case of yellow fever when he received an injection of the filtered blood serum from an experimental case of yellow fever.⁹

In addition to the 18 Americans (2 civilians, 15 enlisted men, and 1 officer) who participated as research subjects in the yellow fever studies, some 15 Spanish immigrants similarly underwent infection with "loaded" mosquitoes or received subcutaneous injections of the blood taken from yellow fever patients. At least 6 Spanish men developed yellow fever when they were bitten by infected mosquitoes, and one man, Manuel Gutierrez Moran, developed the disease when he received an injection of blood from a yellow fever patient. At least 6 other Spanish immigrants received bites or injections but did not develop the disease. All survived their bouts with experimental infections.

By September 1900, the work of the Reed Commission proved conclusively that the *Aedes* mosquito was the vector of yellow fever, and that there was an interval of about 12 days between the time that the mosquito took an infectious blood meal and the time it could convey the infection to another human being. In early 1901, the Commission established that the disease could be produced experimentally by the subcutaneous injection of blood taken from the general circulation of a yellow fever patient during the first and second days of his illness.

The establishment of the mosquito's role in the transmission of yellow fever offered a solution to the problem of the disease, namely eradicating the mosquito and the insect's breeding spaces. In December 1900, the Army began an extensive cleanup of the city of Havana, using fumigation (with sulfur, formaldehyde, and insect powder). By the second half of 1901, Havana health authorities reported no cases of the disease for the first time in the memory of many of the citizens. Using similar methods of fumigation, drainage of low lying areas, and larvicides, William Gorgas led the campaign to rid the Panama Canal Zone, Panama City, and Colon of yellow fever. Perhaps not surprisingly, the measures taken against the *Aedes* mosquito greatly reduced the incidence of malaria, caused by a different mosquito species, in the region.

Contract and Consent

One unusual feature of the yellow fever experiments was the introduction of a written document that outlined the risks involved in the efforts to transmit yellow fever and the reality that there was no effective treatment for the disease. Available in both English and Spanish, the document described how the “contracting party” consented to experiments authorized by the U.S. secretary of war to determine the mode of transmission of yellow fever and acknowledged the risks:

The undersigned understands perfectly well that in case of the development of yellow fever in him, that he endangers his life to a certain extent[;] but it being entirely impossible for him to avoid the infection during his stay in this island, he prefers to take the chance of contracting it intentionally in the belief that he will receive from the said Commission the greatest care and the most skillful medical service.⁴

Perhaps equally important to the Spanish immigrants (who were desirable subjects, presumed to be nonimmune because of their recent arrival in Cuba) was the paragraph that promised \$100 in American gold for two months as an experimental subject, with the further promise of an additional \$100 in gold if the subject developed yellow fever. The document explicitly acknowledged the potential for death by explaining that the additional \$100 would go to a family member in the event of a subject’s death.

Reed’s use of a written contract between investigator and research subject was not the first effort by an American physician to identify explicitly the responsibility for participation in research. In 1822, William Beaumont, a U.S. Army physician serving in a remote Michigan outpost, received an urgent request to treat a French Canadian voyageur shot at close range in the abdomen. A musket ball had splintered Alexis St. Martin’s rib, and a portion of his lung, “as large as a turkey egg,” protruded from the wound. Although Beaumont tried unsuccessfully to close the wound, he soon became convinced that this “accidental orifice” could provide unparalleled information about human digestion. Between 1822 and 1832, Beaumont subjected St. Martin to an extended series of observations and experiments. St. Martin often balked at the doctor’s efforts to obtain samples of his stomach fluid, record temperatures of his internal organs, and suspend various foodstuffs into the opening to observe digestion. To ensure St. Martin’s compliance, Beaumont engaged attorney Jonathan D. Woodward to draw up a contract that specified St. Martin’s duties and his compensation. Adapting the standard legal language for the binding of an indentured servant, Woodward noted that the French Canadian would:

Submit to, assist and promote by all means in his power, such Physiological and Medical experiments as the said William shall direct or cause to be made on or the stomach of him, the said Alexis, either through or by the means of, the aperture or opening thereto in the side of him, the said Alexis, or otherwise, and will obey, suffer, and comply with all reasonable and proper orders or experiments of the said William, in relation thereto, and in relation to the exhibiting and showing his said Stomach, and the powers and properties thereof, and of the appurtenances and powers, properties, situation and state of its contents.¹⁰

In exchange for St. Martin’s willingness to undergo observations and to be exhibited for the purpose of science, the third paragraph

of the contract stipulated that he would receive \$150 for one year’s service, \$40 at the start and the remainder at the end of the year. (In 2005 terms, \$150 was worth approximately \$2,600.) In addition to this cash payment, Beaumont agreed to provide food, lodging, and clothing. Woodward witnessed the contract; he also signed St. Martin’s name on his behalf. Although St. Martin could not write his name, he appended his own mark next to the signature.

This contract has been described as the “first documented instance in the United States where concern for patient welfare was demonstrated, and acknowledgement of human experimentation obtained, via formal written informed consent.”¹¹ Such a characterization, however, is misleading. This was an employment contract drawn up by the employer rather than a written informed consent document. It does not illustrate concern for patient welfare so much as the researcher’s concern about obtaining the subject’s compliance with the investigations. Nowhere, for example, does the document acknowledge the physical distress or discomfort that accompanied the experiments; there was no discussion of potential and or permanent risk, and there was no provision for withdrawing from the agreement. When St. Martin died in 1880, the Canadian physician William Osler sought to preserve the celebrated stomach for the U.S. Army Medical Museum. Members of St. Martin’s family did not welcome this news; to prevent postmortem removal of the organ, his family kept his body in their home longer than usual despite the hot weather to promote the decomposition and render the body less attractive to physicians. To thwart theft of his remains, the family asked that his grave be dug eight feet below the surface “to prevent any attempt at a resurrection.”¹⁰

Unlike the contract between Beaumont and St. Martin, the Reed contracts can be understood as early examples of “informed consent.” Reed and his colleagues took pains to ensure that volunteers understood the risks associated with their participation in the experiments. The historical record suggests that Reed’s volunteers were able to withdraw from the experiment when they considered the risk of injury or death too great.

Exactly why Reed instituted the practice of contracts is a matter of speculation. Certainly Reed and his superior, Army Surgeon General Sternberg, were aware of the criticism that Sanarelli had received for the experiments in which he infected immigrants, without their consent, with *Bacillus icteroides*, wrongly thought by Sanarelli to be the cause of yellow fever. Sternberg, for example, was present at the 1898 meeting of the Association of American Physicians wherein University of Michigan physician Victor Vaughan dismissed Sanarelli’s experiments as “simply ridiculous.” The revered Canadian physician William Osler, the medical educator who introduced bedside teaching for medical students at Johns Hopkins Hospital and the same physician who had attempted to procure St. Martin’s viscera, blasted Sanarelli for his experiments. “To deliberately inject a poison of known high degree of virulency into a human being, unless you obtain that man’s sanction, is not ridiculous,” Osler insisted, “it is criminal.”¹² In the 1898 edition of his enormously popular textbook, *The Principles and Practice of Medicine*, Osler took the extraordinary step of censuring the Italian bacteriologist and the “unjustifiable experiments” on yellow fever. In harsh language, Osler demanded that Sanarelli’s research receive “the unqualified condemnation of the [medical] profession.” Osler offered a similar condemnation of such conduct when he testified on the subject of

medical research before the Committee on the District of Columbia of the U.S. Senate in 1900.²

Sensitive to the criticism surrounding Sanarelli's exploitation of hospital patients, Sternberg took pains to distinguish the Army Commission's investigations from those conducted by the Italian bacteriologist. In 1901, in a popular article on the mosquito and yellow fever, Sternberg emphasized that nonimmune Spanish immigrants and the American soldiers and civilians who participated in the Reed experiments participated with full knowledge of the risks. "The non-immune individuals experimented upon were all fully informed as to the nature of the experiment and its probable results and all gave their full consent." In addition to being fully informed, Sternberg explained that those who became ill received "the best possible care," and moreover left the experiment with the salutary advantage of being "immune" to the disease which had caused "the death of thousands and tens of thousands of Spanish soldiers and immigrants who have come to Cuba under the orders of their Government or to seek their fortunes."¹³

Sternberg communicated his concern for the human subjects directly to Aristides Agramonte, the Cuban-born physician who served with Reed, Lazear, and Carroll on the Yellow Fever Commission. In May 1900, Sternberg wrote Agramonte about the possibility of resolving whether yellow fever could be transmitted by injecting a healthy man with blood from a yellow fever patient, and emphasized the need to obtain permission: "If you have the opportunity to repeat the experiments and settle this important matter in a definite way," Sternberg noted, "you will bear in mind the fact that they should not be made upon any individual without his full knowledge and consent."² Although Agramonte believed that he never received sufficient credit for his role in the yellow fever studies, he similarly emphasized that the volunteers were fully informed about the nature of their participation. Unlike other commentators, Agramonte insisted that newly arrived Spanish men were necessary as subjects, because the American volunteers preferred the fomite tests rather than the bites of infected mosquitoes. As the only Spanish speaker, Agramonte was charged with identifying newly arrived Spaniards and questioning them about their previous exposure to yellow fever. Because the Army had promised the Spanish consul to use only men over the Spanish age of consent (25 years), Agramonte verified the men's ages and also tried to ensure that the men had no wives or children dependent upon them. "When the selection was finally made, the matter of the experiment was put to them," Agramonte explained:

Naturally they all felt more or less that they were running the risk of getting yellow fever when they came to Cuba and so were not at all averse to allow themselves to be bitten by mosquitoes; they were paid one hundred dollars for this, and another equal sum if, as a result of the biting experiment they developed yellow fever. Needless to say, no reference was made to any possible funeral expenses. A written consent was obtained from each one, so that our moral responsibility was to a certain extent lessened. Of course, only the healthiest specimens were experimented upon.¹⁴

As Agramonte's explanation makes clear, there was concern about the well-being of the men, as well as recognition that death might result. Although the investigators made no mention of funeral expenses, insisting that the subjects have no dependents may have communicated the threat (together with the information that in

case of death from yellow fever, a family member would receive the additional \$100).

Sternberg, Reed, Agramonte, and Carroll were also aware that using Spanish immigrants was potentially explosive. At the Pan-American Medical Congress held in Havana in 1901, a Cuban physician criticized the use of the men in dangerous experiments. This criticism echoed the stories in the Havana press, which in November 1900 had denounced the American doctors for injecting poison into unsuspecting immigrants and called on the Spanish consul to investigate these "horrible charges." As a preemptive measure, Reed, Carroll, and Agramonte called on the Spanish official, showed him the signed contracts with the men, and as Agramonte later recalled, the official "being an intelligent man himself" instructed the investigators "to go ahead and not bother about any howl the papers might make."¹⁴

Reed and his colleagues adopted written contracts with their research subjects for many reasons. The written permission statements, as Agramonte noted, served to lessen the moral responsibility for putting lives at risk, but the risks remained real. Although none of the volunteers died as a result of their participation, the shadow of death had been cast by Lazear's untimely end. In the yellow fever research in Havana that followed the Reed Commission, several volunteers, including a young American nurse, Clara Maas, died from yellow fever.

The Legacy of Walter Reed

Walter Reed died in 1902 from complications following an appendectomy. His death, at the height of his fame, produced an outpouring of remembrances and an also immediate apotheosis into the pantheon of American medical heroes. Reed's death represented a great loss to national medical aspirations, not least because he seemed America's most plausible candidate for a biomedical hero of the stature of European researchers Joseph Lister, Robert Koch, or Louis Pasteur. Moreover, his death meant that American medicine lost its most likely contender for the newly established Nobel Prizes, which then as now were awarded only to the living.

That Reed succumbed to surgical complications rather than yellow fever hardly slowed his commemorators, who quickly glossed over the distinction between medical heroism and martyrdom. Although Lazear lost his life to yellow fever, Reed perished because his prodigious labors in Havana had sapped his energy: "No one will ever know how much of physical expenditure the investigations upon yellow fever cost Dr. Reed," noted one physician, who observed, "There is good reason to believe that Dr. Reed's health was severely shaken by the anxious experiences of this period, and he did not regain his former vigor up to the time of the illness which carried him off."¹⁵

Despite his untimely end, and perhaps sensitive to the potentially problematic features of experimenting on local individuals, some American physicians adopted the Yellow Fever Commission's use of written contracts with their research subjects. Assigned to the Philippine Bureau of Science in Manila, American physicians Ernest Walker and Andrew Sellards in 1912 obtained written permission from the inmates of Bilibid Prison for their studies of amoebic dysentery. Before feeding the prisoners gelatin capsules containing the pathogens of dysentery, the doctors explained the experiment using the prisoners' "native dialect,"

Figure 1.2. Walter Reed, standing in white uniform with colleagues, as Jesse Lazear inoculates James Carroll with an infected mosquito. Source: Dean Cornwell (1892–1960), *Conquerors of Yellow Fever*, 1939. Reproduced with permission of Wyeth.

advised the prisoners of the possibility that they would contract dysentery, and informed them that neither “financial inducement” nor “immunity to prison discipline or commutation of sentence” was available. The prisoners gave written permission for their participation.²

Sellards continued this practice when he returned to the United States. Stationed at the Base Hospital at Camp Meade, Md., in 1918, Sellards pursued investigations into the transmission of measles. The officers and men who volunteered for the study signed a written statement: “I hereby volunteer as a subject for inoculation with measles in order to promote the work undertaken in the United States Army for securing a protective inoc-

ulation against this disease.” The volunteers, who received “no reward” for their participation, were informed that the Surgeon General expressed his appreciation for their “patriotism and devotion to duty.”¹⁶

Investigators used written contracts with research subjects sporadically in the decades between 1920 and 1970. In most cases, these did not represent efforts at informing subjects; rather they served as “releases” or “waivers of responsibility” intended to indemnify the researcher and the institution in case of a bad outcome. In many cases, investigators were more likely to obtain written permission from prison inmates than any other group, a testament to the legal nature of the transaction.

Medical researchers found martyrs like Lazear and near-martyrs like Reed particularly valuable both in their ongoing bid for public esteem and as a tool in battling those who protested animal experimentation. In 1923, when the American Association for Medical Progress was established, the group quickly adopted the cause of volunteers in medical research as a means to undermine antivivisectionist attacks on medical investigators. As one 1927 pamphlet published by the association—titled *How Yellow Fever Was Conquered*—put it, “If the bodies of men like these are not too sacred to dedicate to such work as they performed, is it too much to ask that the bodies of a few rats or rabbits or guinea pigs shall be dedicated to work of equal importance?”¹⁷ The cultural power of medical martyrdom was underscored in 1928 by the yellow fever deaths of three researchers on a Rockefeller mission in West Africa—Hideyo Noguchi, William Young, and Adrian Stokes. The *New York Times*, which reported Noguchi’s death on its front page, branded the loss “a sacrifice of medical science in defense of humanity against the great tropic scourge” and eulogized Noguchi as a “martyr of science.”¹⁸ Such events reinforced the collective martyrology attached to yellow fever, and with it, the cult of Reed as emblematic of the self-sacrificing scientist.

In the 1950s the formation of the Walter Reed Society demonstrated the Army surgeon’s continuing usefulness to the biomedical research community. In 1951, the National Society for Medical Research, an advocacy group established to defend animal experimentation, sponsored the formation of the Reed Society, an “honorary” association composed of men and women who had served medical science as volunteer experimental subjects. Applicants were asked to submit a statement from the investigator who had experimented on them, and (as the printed application form instructed) to describe “in simple, non-technical language the nature of your research and/or experience which qualified you for membership in the Walter Reed Society. Be as colorful, dramatic and specific as possible.” By 1953, the Society reported 103 members.^{19,20} The Society did not survive the 1960s, when the use of research subjects—mentally retarded children, elderly patients, and others—became the subject of controversy and debate among the research community and the wider public.

That leaders of the National Society for Medical Research selected Reed as their patron illustrated the durable and supple appeal of Reed the investigator. Reed’s legacy was significant, in the words of the Society charter, because “he risked his life in a series of brilliant experiments leading to the conquest of yellow fever.” In the wake of questions about research ethics prompted by both the Nuremberg Doctors Trial and concerns about American research, Reed’s behavior as a researcher became an important symbol for medical investigators. In the literature of the Walter Reed Society and in popular magazines like the *Saturday Evening Post*, Reed became not just a successful researcher, but a self-sacrificing researcher. Major Reed, explained one author in the *Post*, “first dramatized the use of human guinea pigs during the historic yellow fever experiments.”²¹ These experiments, like those honored by the Reed Society, involved heroic self-experimentation, not the exploitation of involuntary or unsuspecting subjects.

It was Reed’s decision to risk life that also attracted admirers. Amid the heightened urgencies of the Cold War, Reed’s dedication to finding the solution to the problem of yellow fever could be invoked by military leaders intent on preparing America for the atomic age. In discussions over the feasibility of developing a

nuclear-powered airplane, Brigadier General James Cooney, representing the Atomic Energy Commission’s Division of Military Applications, deployed Reed in an effort to support the deliberate exposure of military personnel to whole-body radiation to determine its effects on humans. In a transcript about the debate on the need for military-purpose human experimentation, declassified for the Advisory Committee on Human Radiation Experiments in 1995, Cooney stated, “Personally I see no difference in subjecting men to this [whole-body radiation] than I do to any other type of experimentation that has ever been carried on. Walter Reed killed some people. It was certainly the end result that was very wonderful.”²² Cooney argued for the need to recruit “volunteers both officer and enlisted” to undergo exposure to up to 150 rads whole-body radiation to resolve the question and prevent “thousands of deaths” as the result of not knowing the effects of this radiation.²³

Reed’s risk taking also resonated with one of the key figures in the reformulation of research ethics in the 1960s and 1970s, Henry K. Beecher. The Harvard professor of anesthesiology not only conducted human experiments on opiates and analgesics, but also called attention to lapses of professional judgment and morality in mainstream American clinical research in a now famous 1966 article in the *New England Journal of Medicine*.²⁴ In his 1970 volume *Research and the Individual*, Beecher acknowledged that most patients were unwilling to risk their lives for the sake of science; but there were exceptions, those “rare individuals who perhaps seek martyrdom or devoted investigators such as Walter Reed and his colleagues, whose lonely exploit is still celebrated 70 years or more after the event.” When he discussed the regulations that governed the use of volunteers in military experimentation, Beecher noted the irony that the yellow fever experiments would not have been possible at the time he was writing. According to the Special Regulations of the Army adopted in January 1949, “unduly” hazardous or unnecessary experimentation would not be tolerated. Under these rules, Beecher observed, “Walter Reed’s triumph would not now be possible!”²⁵ Perhaps unaware of Reed’s written contracts with his research subjects, Beecher did not mention their use in the yellow fever research.

In the 1970s, internist William B. Bean, a prominent medical editor and an experienced clinical investigator (and self-experimenter), was perhaps the first to identify the written contract Reed used with the yellow fever participants. Although he had published earlier articles about Reed and the Yellow Fever Commission in 1952 and 1974, he had made no mention of the written document.^{26,27} He first did so when he delivered the Fielding H. Garrison Lecture in 1976 at the American Association for the History of Medicine on Walter Reed and human experimentation, reminding his listeners that concern for individual rights, even amid the groundswell of public concern over unethical human experiments, could be taken too far. Four years after the revelation of the Tuskegee Syphilis Study and two years after the passage of the National Research Act (which required, among other things, the written consent of the research subject), Bean invoked Reed as an exemplar of the relationship of the physician-investigator to the subject and patient. “In our concern for the rights of the individual we must not forget that society has rights too,” Bean argued. “Anyone living in society has a debt to it. Experimental biological science is necessary to advance curative medicine and public health. Exclusive focus on individual and

HUMAN VOLUNTEERS IN MEDICAL RESEARCH

personal rights may accelerate the decline of society down the path of its own self-destruction.”⁴ Bean described Reed’s contract as a “sacred scientific document” which gave “substance and symbol of a written agreement to informed consent.”⁴

Today most Americans associate Walter Reed with the hospital that bears his name, the Walter Reed Army Medical Center in Washington, D.C. Within the medical research community, perhaps, some trace of Reed’s exploits linger. In 1997, for example, as he called on physicians to volunteer as subjects in a HIV vaccine trial, Charles F. Farthing, a member of the International Association of Physicians in AIDS Care, reminded his fellows: “It is time to follow in the tradition of Louis Pasteur, Walter Reed, and hundreds of other colleagues who made the commitment to be the first human subjects in critical clinical trials.”²⁸

This speaker was doubtless unaware that not only had Reed not participated in clinical trials, but that Pasteur, according to the historian Gerald Geison, had misled his contemporaries about the evidence for his rabies vaccine when he first tested it on a young boy.²⁹

Reed’s legacy is a complex one, compounded of self-experimentation, heroism and martyrdom, and genuine concern for the men who risked their lives in the yellow fever experiments. The written documents he used to ensure that subjects recognized the risk of their participation illustrate that many American physicians have grappled with the moral and political issues raised by using human beings in research. These issues will no doubt remain with us, so long as human beings are essential to the process.

The Nazi Medical Experiments

Hitler's racial state and racial war provided German doctors and their associates with the opportunity to inflict unparalleled medical atrocities. These involved not only research but also using medical knowledge and resources for a race-based program of public health and genocide. The Nazi government imposed no mandatory professional standards on the conduct of experiments—although Germany had earlier adopted such standards—and no international humanitarian or medical agency intervened to protect the victims. German physicians experimented to advance medical and racial science, and to contribute to the German war effort. They exploited bodies, used body parts and internal organs for research, and drained the blood of Jews and Slavs for use as a cell culture medium and to support transfusion. The exploitation of human beings for medical research occurred within the broader context of how the Nazis harvested hair, gold fillings, and any other usable body parts from victims of the Holocaust.

Physicians and medical and biological researchers took a central role in the implementation of the Holocaust and exploited imprisonment, ghettoization, and killings as opportunities for research. They defined the characteristics of Jews, Gypsies, and Slavs as pathological. They demanded that mental and physical disabilities be eradicated from the German/Aryan/Nordic race by compulsory sterilization, euthanasia, and segregation of racial “undesirables.” Doctors and medical ancillaries identified and registered racial “inferiors” in surveys, collecting data on pathological physical and mental traits.

Adjudicating an individual's racial ancestry or deciding on a diagnosis could be a matter of life and death. The killing proce-

dures included poison gas; initially, carbon monoxide was used—first for euthanasia and then in the extermination camps of Belzec, Sobibor, and Treblinka. A modified form of the pesticide Zyklon B was used at Auschwitz.¹ Other methods of killing were by phenol injection and calculated use of starvation. Physicians offered medical support for the mass killing by undertaking selections for the gas chambers and by killing the weak and disabled in the interest of Germany's racial “health.”

Research abuses were integral to the Nazi genocide. Doctors were interested in “racial pathology,” attempting to prove that Jews responded differently to infections. Because laboratory animals were in increasingly short supply during the war, physician/researchers experimented on racial “inferiors,” especially children. In the event, most of the research was found to be scientifically worthless, poorly planned, and often replicating results that had already been established through clinical observation. However, the high status of German medical research meant that U.S. and British researchers expected to find some of the data useful after the war. During that time, researchers screened German research work on aviation physiology and the nerve gas sarin. The scientific value of the German research has been debated since 1945. Some scientists have maintained that the German results were in some cases scientifically valid, but others condemned wholesale such research, calling for destruction of the records.^{2–8} The experiments and associated medical war crimes violated the physician's ethic of care to the sick and suffering. Belatedly, the Nuremberg Code with its requirement of “voluntary consent” was promulgated by the presiding judge at the close of the Nuremberg Medical Trial in August 1947^{9,10} (see Chapter 12).

German Medical Science Before the Nazis

Changing standards of medical ethics and research practices early in the 20th century paved the way for the Nazi medical atrocities. An upswing of experimental medicine and the penetration of racial ideas into biology were predisposing factors.

German medical education had long been science-oriented. A research-based thesis was required for an M.D., and university teaching required an extended Habilitation thesis. Since the era of discoveries by the bacteriologist Robert Koch from the mid-1870s to the 1890s, many German medical researchers had followed an informal ethical code of performing either self-experiments or experiments on their own children before experimenting on others. However, other physicians experimented in orphanages and prisons, and the bodies of executed criminals were routinely delivered to anatomical institutes.¹¹ Eugenics and the spread of hereditary medicine gave rise to the idea that the physician should act in the interests of the national community and race, rather than maintaining an inviolable bond of care for the individual patient.

In the years before the Nazi takeover, experimental medicine did raise some public and governmental concern. The case of the hepatologist Hans Eppinger provides a representative example. Eppinger, an innovative experimental researcher and clinician in Germany and then Austria, performed invasive research without consent on patients in public wards in Vienna in the 1930s. When his practices became known, public and political concern increased over “human guinea pigs” in hospitals.^{9,12–14}

In 1930, in response to the accidental use of a contaminated batch of BCG vaccine (bacille Calmette-Guérin vaccine, used

against tuberculosis) at Lübeck, public protests against therapeutic failures and unethical experiments resulted in the formulating of guidelines on human experiments. The Reich Circular on Human Experimentation of February 28, 1931, laid down some key requirements; at the time, these regulations were the most advanced in the world in safeguarding the patient and research subject. They included the following provisions:

5. Innovative therapy may be carried out only after the subject or his legal representative has unambiguously consented to the procedure in the light of relevant information provided in advance. . . .
6. The question of whether to use innovative therapy must be examined with particular care where the subject is a child or a person under 18 years of age. . . .
12. c. [E]xperimentation involving children or young persons under 18 years of age shall be prohibited if it in any ways endangers the child or young person.

There is no evidence that clinical researchers followed these guidelines, particularly after the Nazis came to power in 1933.^{15–17}

Nazism and the Second World War removed civil rights and humane ethics, opening the floodgates to successive waves of unscrupulous experimentation and research abuses. Nazi values stressed the priorities of the nation and race. The sick individual was seen as a burden on the fit, a category defined in physical and racial terms. The state had coercive powers not only to detain and segregate the sick but also to intervene in the body.

After the Nazis achieved power, medical research received increased resources as part of racial health and welfare policies.

Figure 2.2. Nazi Freezing Experiment at Dachau, September, 1942. SS Sturmbannführer Dr. Sigmund Rascher (right) and Dr. Ernst Holzloehner (left) observe a Dachau prisoner who has been immersed in a tank of ice water in an attempt to simulate the reactions of the extreme hypothermia suffered by pilots downed over frigid seas. Researchers constantly lobbied for experimental resources and opportunities. This suggests that the experiments and other medical abuses of the Nazi era were not perpetrated just by a small group of unscientific racial fanatics, who were unrepresentative of the German medical profession, but rather that the atrocities reflected attitudes that were broadly shared in the German medical profession.

Nazification of Medical Values

To understand how researchers viewed their experimental subjects as having lives of lesser value, we have to take account of the Nazi restructuring of medicine and public health on a racialized basis. After the Nazi takeover in 1933, Jewish doctors were purged from universities, hospitals, and public health appointments. They endured harassment and violence from their medical colleagues and students. The Nuremberg laws for racial segregation of 1935 imposed penalties on “Aryan” physicians with a non-Aryan spouse. Despite these restrictions, Jewish doctors retained their right to claim reimbursement of fees from sickness insurance funds. Finally, however, in 1938 Jewish doctors were delicensed: A Jewish physician lost the title of *Arzt* (physician) and was referred to as *Krankenbehandler* (treator of the sick).¹⁸ The Nazi state centralized public health services to implement racial policies, and medical associations (the *Ärztekammer*) were placed under the

Nazi Physicians League. The longstanding German eugenics and racial hygiene movement was Nazified. Roman Catholic, Jewish, and socialist eugenicists were purged from eugenic associations and institutes for hereditary research.¹⁹ “Aryan” physicians obtained the academic posts and contracts of dismissed Jewish and dissident colleagues.^{18,20–23}

Research in many branches of medicine intensified in the mid-1930s. Simultaneously, municipal and state health offices were combined; this facilitated compulsory sterilization and the registration of disabilities and malformations, and became a preliminary step toward euthanasia. In addition, many physicians forged alliances with the Nazi system of power, seeing an opportunity to formulate and implement social legislation. In 1930, the human geneticist Fritz Lenz saw the Nazi Party as offering the best hope for a eugenically planned society. The psychiatric geneticist Ernst Rüdin took a leading role in drawing up the sterilization law enacted in July 1933 and implemented from January 1934. Fritz von Wettstein and Hans Nachtsheim, both geneticists at the Kaiser Wilhelm Society (*Gesellschaft*)—later the Max Planck Society—backed the implementation of the sterilization law. Sterilization proved a powerful force in accelerating the shift to a unified state and municipal public health system. It targeted a range of clinical conditions, notably schizophrenia, muscular dystrophy, Huntington’s chorea, epilepsy, severe mental defect, and chronic alcoholism. Sexual and mental abnormalities attracted special interest in psychiatric genetics. Otmar von Verschuer led the way

in twin studies, using the Frankfurt public health clinic as a base from 1935–42. An estimated 340,000 persons were forcibly sterilized in Germany and in German-annexed Austria between 1933 and 1945.

At the opening of the Nuremberg Medical Trial, Telford Taylor gave a political explanation to the research atrocities: “In the tyranny that was Nazi Germany, no one could give such a consent to the medical agents of the State; everyone lived in fear and acted under duress.”²⁴ The years 1933 to 1939 saw medical researchers stigmatizing ethnic groups and people with disabilities as social burdens of low-grade intelligence. The textbook on human heredity by the botanist Erwin Baur, the anthropologist Eugen Fischer, and human geneticist Lenz endorsed such views.^{25,26} Although the sterilization law did not specify race itself as meriting sterilization, ethnic minorities were vulnerable to being sterilized. We see this with the evaluation and sterilization of the children of black French troops and Germans, who were derogatively referred to as “*Rheinlandbastarde*” (“Rhineland bastards”). A total of 385 mixed-race children were forcibly sterilized in 1937 after extensive evaluations from a psychological, anthropological, and genetic point of view. They would have been between ages 13 and 16.²⁷

In June 1936, a Central Office to “Combat the Gypsy Nuisance” opened in Munich. This office became the headquarters of a national data bank on so-called “Gypsies,” and atrocities against German and other European Roma (“Gypsies”) continued into the war years. Robert Ritter, a medical anthropologist at the Reich Health Office, concluded that 90% of the “Gypsies” native to Germany were “of mixed blood.” He described them as “the products of matings with the German criminal asocial sub-proletariat” and as “primitive” people “incapable of real social adaptation.” Ritter’s views shaped the research by Eva Justin on the “primitive nature” of 148 Roma children raised apart from their families. Justin analyzed the children’s psychology at the St. Josefspflege Roman Catholic children’s home. At the conclusion of her study, the children were deported to Auschwitz, where all but a few were killed. In 1943, Justin was awarded a doctorate for her life history research on these “racially alien” children.^{28,29} Overall, the Germans murdered an estimated 25,000 German and Austrian Sinti and Roma, as well as 90,000 Roma from lands under Nazi occupation. Physicians exploited the mistreatment and murder for research in the “Gypsy Camp” at Auschwitz and at Dachau, where the painful seawater drinking experiments, conducted in 1944, left the Roma victims utterly exhausted.

After Germany annexed Austria in March 1938, a group of energetic medical researchers at the Vienna medical school—notably, Eppinger, the anatomist Eduard Pernkopf, and the psychiatrist Maximilian de Crinis—utilized the opportunity for clinical and racial research on vulnerable groups like the disabled, the racially persecuted, and those with inherited metabolic and physical anomalies. From September 25 to 30, 1939, anthropologists in Vienna took plaster face masks and anthropological measurements of 440 “stateless” Jewish men held in the Praterstadion, the sports stadium. Most were then sent to the concentration camp of Buchenwald and did not survive. This is an early example of coercive research, on terrorized victims in a life-threatening situation, ending in the deaths of many. In June 1941 Austrian anthropologists went to Amsterdam to conduct research on Dutch Sephardic Jews as part of “the comprehensive racial plans.” British officers refused to comply with plans for photographing British, Australian, and Maori prisoners of war.^{30,31}

Table 2.1**Major Events in the Nazification of German Medical Research**

Date	Event
1905	Germany’s Racial Hygiene Society is founded.
Oct. 1, 1927	Kaiser Wilhelm Institute for Anthropology, Human Heredity and Eugenics is created.
Feb. 28, 1931	Reich Guidelines on Human Experimentation are issued.
Jan. 31, 1933	Hitler comes to power.
July 1933	Sterilization Law is enacted. Eventually, an estimated 340,000 people are compulsorily sterilized in Germany and Austria.
1937	Mixed-race children in the Rhineland are sterilized.
Sept. 1939	Jews held prisoner in the Vienna Sports Stadium are subjected to anthropological research.
Sept. 1939	Euthanasia programs begin, targeting “worthless lives.” Eventually, an estimated 256,000 people are killed.
Feb. 1942	Sigmund Rascher begins lethal aviation medicine experiments at Dachau to test survival and determine the point of death in high altitude and severe cold conditions.
Aug. 1942	Women prisoners at Ravensbrück are deliberately injured for experiments on wound infection.
Mar. 1943	Ravensbrück prisoners protest and manage to sneak information on human experimentation out to the Polish underground.
April 1943	Josef Mengele assigned to Auschwitz as a “Camp Doctor.”
April 1944	Roma (“Gypsy”) prisoners are subjected to seawater drinking experiments at Dachau.
Nov. 1945	John Thompson identifies “medical war crimes.”
July 31– Aug. 1, 1946	International Scientific Commission on War Crimes, and Guidelines on Human Experimentation proposed at Pasteur Institute.
Dec. 1946	Nuremberg Medical Trial begins; 23 Nazi physicians or administrators are accused of war crimes and crimes against humanity.
Aug. 16, 1947	Panel of judges at Nuremberg Medical Trial convicts 16 defendants and pronounces the Nuremberg Code of medical research ethics.

Another early example of coercive experiments were those conducted by Georg Schaltenbrand, a former Rockefeller Foundation fellow, in the neurological clinic at Würzburg. He performed painful lumbar punctures, extracting spinal fluid for research on multiple sclerosis, which he believed was infectious. The victims were German, and at least one was a Nazi Party member. The research was carried out without consent and left victims in pain.^{32–34}

German research atrocities included the use of body parts for histological and neurophysiological research. In some cases, research was carried out on living persons who were then killed to obtain their organs to see if there was a defect in the brain accounting for abnormal behavior or psychosis, or to assess the effects of infection on internal organs. This was known as hereditary pathology, or *Erbpathologie*.

The war at first disrupted clinical research. Because of the call of research personnel for military service, 1940 marked a low

point in the numbers of coercive human experiments. But in 1938, the SS had established a Hygiene Institute in Berlin, supported by SS chief Heinrich Himmler, which was transferred to the Waffen-SS (Armed SS) in the war when it sponsored war-related human experiments. Prime target groups were Soviet and Polish prisoners. Hermann Göring took over as president of the Reich Research Council in July 1942 to remedy the fragmentation of German research and to energize it by setting strategic targets. The SS physicist Rudolf Mentzel aligned research with wartime needs as president of the reorganized *Deutsche Forschungsgemeinschaft* (DFG, or German National Research Council). His deputy, the publisher and SS administrator Wolfram Sievers, was later convicted at the Nuremberg Medical Trial and hanged (see Table 2.2 later in this chapter).

Later phases of the war saw an upsurge of atrocities for scientific research. Often we know about the experiment, but not about the victims. The anatomist August Hirt murdered 86 victims for the collection of Jewish skeletons at the Reich University of Strassburg. The victims were selected in Auschwitz and sent across Germany to Alsace to be killed in the gas chambers of Natzweiler-Struthof.³⁵

Euthanasia

A medical lobby around Hitler began pressing for the euthanasia of mentally and physically disabled adults and children in 1935, but the practice was not imposed until Hitler issued a secret decree in 1939. By the end of the war, however, Nazi euthanasia programs had killed an estimated 256,000 people.³⁶

Of course, “euthanasia” was a euphemism. The killings did not correspond to conventional notions of “releasing” an individual who so wishes from the pain and suffering of a terminal and incurable illness. Rather, the Nazi euthanasia programs targeted “worthless lives” (*lebensunwertes Leben*)—“undesirables” such as the infirm, non-Aryans, or adolescents who challenged authority. Hitler saw the sick as an economic burden on the healthy, and he wished to rid the German race of the “polluting” effects of the “undesirables.” The practice of institutionalized medical murder also allowed deliberate killing to obtain body parts for scientific research and a range of other abusive research practices. Some physician/researchers killed patients to order so that autopsies could be performed.

Standard accounts of Nazi “euthanasia” have claimed that euthanasia arose when a father petitioned the Führer that his malformed child should be killed.^{37,38} This account was derived from the exculpatory testimony of Karl Brandt at the Nuremberg Medical Trial. In an important contribution, Benzenhöfer has shown that such an infant indeed existed; but the dates of the child’s birth and death mean that any petition to Hitler occurred only after the decision to unleash euthanasia had been reached.^{39,40} Brandt, Hitler’s escort surgeon, was one of the medical advisers who convinced the Führer of the need for killing of so-called “incurables.” Brandt was convicted at Nuremberg of war crimes and crimes against humanity, and was hanged.

Four distinct euthanasia programs were carried out. The first—code-named “T4” after the street address of the central office, Tiergarten Strasse 4—supposedly provided a panel of legal adjudicators to decide individual cases. But instead of a legal procedure of notification and appeal, a doctor at the T4 office made decisions on the basis of cursory scrutiny of clinical records. According to

Nazi records, 70,263 persons were killed in this operation. In its second phase—after a widely publicized sermon attacking the program by the Bishop of Münster, Count Clemens von Galen, in 1941—clinicians ran the killing programs on a decentralized basis, deciding themselves who was to die.

A separate program targeted disabled children: The killings occurred in special pediatric units by means of long-term starvation or lethal medication. Between 1939 and 1945, an estimated 5,000 children were “euthanized.” One rationale for this program was the pretense that somehow the killing of severely disabled children could be condoned as in accord with parental wishes and historical precedent. In fact, psychiatrists exercised pressure on parents unwilling to give their children up. Often false promises of therapy were made to overcome parental resistance.

Children were killed in designated clinical wards called *Kinderfachabteilungen* (“special care units for children”). Thirty-eight of these killing wards are known, but the *Kinderfachabteilungen* are far from fully researched. In annexed Czechoslovakia the *Reichsausschuss Kinderverfahrung* (the “Reich Committee for Child Behavior”) in Dobruška, near Pilsen, worked in conjunction with T4 and had a hand in the removal of children from the site of the erased village of Lidice. A fourth euthanasia program was carried out in concentration camps: More than 20,000 people were selected from the concentration camps for killing at the euthanasia centers, established in 1939–40 in psychiatric hospitals. By one estimate, there were 216,000 German and Austrian victims of euthanasia. In addition, an estimated 20,000 Polish and 20,000 Soviet victims were killed. A reasonable estimate is a total of 256,000 euthanasia victims.³⁶

Euthanasia often was linked to medical research, although there is no comprehensive analysis of such killings. Julius Hallervorden of the Kaiser Wilhelm Institute (KWI) for Brain Research, a component of the Kaiser Wilhelm Society, obtained brain specimens from patients whose clinical records were “of interest.” Jürgen Peiffer—a German neuropathologist who discovered that he had unwittingly used the brains of 19 euthanasia victims for publications in 1959 and 1963, and who afterward devoted much effort to documenting the criminal practices and legacy of his specialty—has established that 707 brains stored at Hallervorden’s Department of Neuropathology came from euthanasia victims.⁴¹

Similarly, at the Children’s Ward in Wiesengrund in Berlin, the pathologist Ostertag examined 106 brains from killed children. He studied small children with such conditions as microcephaly, had them filmed, and then had them killed. Peiffer observes that brains were delivered to researchers as a result of personal networks rather than any centralized distribution.

Directors of *Kinderfachabteilungen* were invited as guest researchers by the KWI for Brain Research between 1939 and 1942. Researchers at the prestigious Kaiser Wilhelm Society, especially researchers at the KWIs for Psychiatry, Brain Research, Anthropology, and Biochemistry, were involved in human experiments and research on body parts of killed persons.

From August 1943 to 1945, intensive research took place on “mentally defective” children at Heidelberg. A professor of psychiatry, Carl Schneider, was not only an adjudicator for euthanasia but also saw the program as an opportunity for histopathological research. He wanted to determine the difference between inherited and acquired mental deficiency. In one experiment, 52 children were examined, each for six weeks in the clinic. They were subjected to many forms of physical force and terror as part of psy-

chological and psychiatric tests, including a painful X-ray of the brain ventricle. In addition, they were held under cold and warm water to test their reactions. Schneider hoped to correlate the results with anatomical lesions. In the event, 21 of the children were killed deliberately to compare the diagnosis made when they were alive with the postmortem pathological evidence.⁴²

Many other children's bodies were also used for research. At the Vienna clinic *Am Spiegelgrund*, where about 800 children were killed, researcher Heinrich Gross examined 417 children's brains.⁴³ The clinical investigations of the children were often painful. In 1942–43 Elmar Türk carried out tuberculosis immunization experiments at the Vienna General Hospital Children's Clinic and *Am Spiegelgrund* involving the infection, killing, and dissection of the children.²³

SS Medical Research

Heinrich Himmler, who was commander of the SS and chief of the German police, was ambitious for the SS to control German medicine, transforming universities and medical faculties into centers of racial ideology and practice. In the early 1930s, the geneticist Fritz Lenz evaluated SS officers' racial fitness. The next step was for groups of SS medical officers to take courses of 19 months duration at the KWI for Anthropology in 1934 and 1936. Some undertook various tasks in the SS Race and Settlement Office, which formulated racial policy in the occupied East. The Waffen-SS established medical services that became the Hygiene Institute of the Waffen-SS under the bacteriologist Joachim Mrugowsky, whose holistic approach to infectious disease was critical of genetic determinism. (Mrugowsky also was convicted at Nuremberg and hanged.) In 1936, the SS took control of the German Red Cross through Reichsarzt-SS Ernst Robert Grawitz. Within the SS, medical researchers competed, all seeking to go further than their rivals in their research practices.

The human experiments have often been seen as solely conducted by SS doctors on Himmler's orders. However, other agencies collaborated with the SS. For example, the Luftwaffe (German Air Force) provided pressure chambers and support personnel for Sigmund Rascher's lethal pressure and cold experiments in March–April 1942 at Dachau. Rascher, a Luftwaffe officer, conducted murderous experiments on at least 200 Soviet prisoners and Catholic priests to establish the point of death from cold and low pressure. The research was calculated to be lethal. The experiments came under the control of the Luftwaffe, whereas Rascher's link to the SS was informal. Certainly, Rascher kept Himmler informed about the progress of the experiments.

The SS *Ahnenerbe* (Ancestral Heritage) research organization came under Sievers. Its medical research activities owed much to the initiative of August Hirt, professor of anatomy at Strassburg, who joined the *Ahnenerbe* and the Waffen-SS in April 1942 (he had joined the SS in 1933). The SS anthropologists Bruno Beger and Fleischhacker assisted Hirt in developing an anatomical museum. The *Ahnenerbe* Institute for Military Research supported experiments in Dachau and the concentration camp of Natzweiler in Alsace, where experiments on mustard gas were undertaken. The *Ahnenerbe* authorized Hirt and his assistant to select 29 women and 57 men for transfer from Auschwitz in August 1943 for the human skeleton collection at Strassburg. The *Ahnenerbe* also supported vaccine experiments.

Some professors who held SS rank, such as Karl Gebhardt, developed medical research facilities. Gebhardt established a research facility at the orthopedic clinic of Hohenlychen. (He also was Himmler's personal physician; later, he was convicted at the Nuremberg Medical Trial and hanged.) Importantly, although the SS exerted influence on the medical faculties of Berlin, Munich, Jena, and Marburg, and over the "Reich Universities" of Posen and Strassburg, it did not have unlimited power over academic researchers. There was constant friction in these universities, so that SS influence remained precarious. Rascher could not obtain a Habilitation thesis for experiments on a new type of blood stypic because of opposition within these faculties, indicating academic exclusiveness and a sense that ethical standards had been violated.

However, the concentration camps were under SS control, and scientists came to Himmler and the SS with requests to conduct research on concentration camp prisoners. Erwin Dingschuler at Buchenwald, in conjunction with pharmaceutical companies, sought support in the upper echelons of the SS for research on typhus vaccine—circumventing his superior, Mrugowsky, who suggested that experiments be conducted on naturally occurring cases of infection, rather than on cohorts of deliberately infected prisoners. The bacteriologist Gerhard Rose also took this view, and criticized Ding at a military medical conference. Yet later on, both Mrugowsky and Rose were involved in lethal experiments and were convicted at Nuremberg. Mrugowsky was sentenced to death and was hanged; Rose was sentenced to life imprisonment, but the sentence was reduced and he was released in 1955.

Other researchers opportunistically approached the SS for research support and facilities. Gynecologist Carl Clauberg, a Nazi Party member although not an SS officer, conducted cruel and painful experiments on women prisoners at Auschwitz, using various forms of injections to induce sterility. Others, notably the SS doctor Horst Schumann, experimented extensively with X-ray sterilization. The experiments at the concentration camps of Auschwitz, Buchenwald, Dachau, Sachsenhausen, Neuengamme, and Natzweiler-Struthof demonstrate the strong support from the SS and Himmler personally.

Geneticist Hans Nachtsheim (never a member of the Nazi Party), of the KWI for Anthropology, collaborated with SS medical research at the sanatorium of Hohenlychen. Here, the pathologist Hans Klein, an associate of Nachtsheim, dissected glands extracted from 20 children selected by Josef Mengele at Auschwitz. The children were transported to Neuengamme, where they were injected with tuberculosis bacilli and later killed.^{33,44–47} Nachtsheim took the view that it was ethically permissible to experiment on persons who were going in any case to be killed.

Yet the SS was not alone in sponsoring such abusive research, and the researchers were not all SS members. Kurt Blome—who disguised intended chemical warfare experiments as "cancer research"—had refused to join the SS, although he was a Nazi, remaining loyal to the SA storm troopers. The malariologist Claus Schilling, who experimented at Dachau from 1942 to 1945, infecting over a thousand victims to test vaccines, was neither an SS officer nor even a Nazi party member. Moreover, not all the experimenters were German. Danish SS doctor Vaernet experimented on homosexuals at Buchenwald, and other researchers were ethnic Germans from the East, such as Fritz Klein from Romania. Overall, we find a great range of types of experiments, perpetrators, and victims.

Many research atrocities were concealed for decades and are only now coming to light. Not long after the war, it became fashionable to presume that only SS-sponsored research was abusive. Ignoring links to non-Nazi researchers reinforced the view that the experiments were carried out by a small number of unscientific fanatics. The West German Medical Chambers made such a claim in a statement in 1949 to the World Medical Association.^{48,49} This underestimate has remained until recently the orthodoxy.

Abusive Civilian Research

We are now returning to the view that many German researchers were involved in unethical experiments that were carried out in all sorts of locations. The atrocities were not limited just to human experiments but included a broad range of abuses conducted in support of research, such as killing to obtain body parts, rounding up people in racial groups for human behavior studies before sending them to be killed, tests of X-ray sterilization, and scientifically motivated clinical atrocities like the forcible draining of blood. We therefore find that rather than just a thousand deaths,⁵⁰ the Nuremberg Medical Trial focused on “atrocities committed in the name of medical science.” Telford Taylor charged that “[t]he victims of these crimes are numbered in the hundreds of thousands.”²⁴ Taylor included both living and dead victims, and all research-related atrocities. His estimate was realistic if the estimated 256,000 euthanasia victims and 340,000 sterilization victims are included, as medical research provided the scientific basis for these programs. Beyond this, racial anthropology took a major role in legitimizing the Holocaust, and eugenically and anthropologically trained experts like Mengele implemented Nazi genocide. Yet, within these broader categories of medically legitimated crimes, the question arises as to how many victims were maimed or killed specifically for research purposes.

We can broadly discern four types of medical research atrocities:

1. *Racial-anthropological research.* These run from the outbreak of war in September 1939, when anthropologists in Vienna took plaster face molds of stateless Polish Jews rounded up in the Vienna Sports Stadium. Josef Mengele’s experiments in Auschwitz marked an attempt to demonstrate racial factors in immune responses to infections.
2. *Brain research and neurology.* The victims were mainly German and Austrian. These experiments and research on the brains of euthanasia victims run from 1939 to the war’s end in 1945.
3. *Military medical research.* These studies evaluated the wounds caused by explosive bullets, new vaccines for diseases on the eastern front, and research on the treatment of wound infection. The majority of victims were Slav, at first male Russian prisoners of war, and then Polish women prisoners. These experiments extended mainly from 1941 until 1944. The SS dominated military medical research between 1942 and 1944, although here there were significant linkages to the German military and air force.
4. *Medical and genetic experiments and abuses, especially in 1943–44.* This was a final phase of research near the end of the war—commonly described as the era of Mengele at Auschwitz. Many of the victims were Jewish, Sinti, and Roma children.

Some of the experiments and research interventions involved deliberate killing. In other cases, the victims were regarded as disposable once the research had been completed. But the fact that research had been carried out on these victims increased the likelihood of their being killed.

Even 60 years after the close of the war, there is not a full accounting of these atrocities. More experiments and research atrocities come to light as historians comb through the research archives of organizations like the Kaiser Wilhelm Society and the DFG, which is still the main German grant-giving body for research in all branches of science.

Generally, clinical experimentation rose throughout Germany and German-controlled territory, but details of many such experiments are sparse. For example, hepatitis research on British prisoners of war in Crete is known from the scientific literature, rather than from any survivors’ accounts.⁵¹ Similarly, there has been a tendency to underestimate numbers of victims, both in terms of numbers who were killed and numbers who survived the debilitating and often traumatizing experiments.

Anatomists continued to use body parts of executed prisoners for teaching and research. Some of these prisoners were condemned for political reasons. The bodies used to create Pernkopf’s celebrated anatomical atlas were those of people executed by the Nazi judiciary, which meant that some victims were anti-Nazis. Although anatomical institutes customarily received the bodies of the executed, under Nazism the rate of executions increased and included opponents of the regime.⁵² The physiologist in Halle, Gothilft von Studnitz, dilated prisoners’ eyes and subjected them to darkness prior to execution. He claimed that he could increase the sensitivity of the eye to low intensity of illumination by using a plant extract. Some prisoners were blindfolded immediately before execution, and their eyes were extracted immediately after execution for comparison with light-adapted eyes.⁵³ Hermann Stieve, professor of anatomy in Berlin, conducted research on anxiety as manifested in the menstrual cycles of young women executed by the Nazi authorities.^{33,54}

The abuses included coercive study of racial characteristics and behavior with measurements, blood tests, casts of the face, histological and anatomical research on murdered victims, and death for dissection. Liters of blood were drained from Auschwitz prisoners for blood transfusion, and living persons incubated pathogenic microorganisms for typhus research. The question also arises as to the demarcation between legitimate and coercive, criminal forms of medical research. In some cases—such as the delivery of typhus vaccines to the Warsaw ghetto in 1941 through the Swiss Red Cross and the bacteriologist Hermann Mooser—it remains unclear whether the research was exploitive or beneficial.¹ SS doctors debated whether clinical research should be limited to naturally occurring cases, although they decided on deliberate infection.

Geneticists at the KWI for Anthropology exploited the situation. In the context of Verschuer’s “Hereditary Pathology” program, the psychologist Kurt Gottschaldt studied German twins who were sent to a special observation camp, and Nachtsheim studied epilepsy as genetically inherited in rabbits, developing a cardiazol test for inherited epilepsy. Nachtsheim and the biochemist Ruhenstroh-Bauer saw a parallel between epileptic cramps in rabbits and oxygen deficiency in high-altitude flight. In September 1943 they conducted pressure chamber experiments on at least six children from the *Landesanstalt Brandenburg-Görden*—

an institution that had a significant role in Nazi euthanasia—attempting to induce epileptic seizures in the children. It is certain that one of the six children survived, but the fate of the others remains unclear.^{55,56}

The KWI for Anthropology also supported the racial war and genocide in the East. One task was ethnic evaluation, examining individuals as specimens and deciding on their racial ancestry and worth. Nazi medical anthropologists hunted for body parts to support their grotesque views on racial history. Brains, eyes, reproductive organs, internal organs, blood samples, and skeletons were assiduously collected from persons in prisoner of war and concentration camps for comparative anatomical and histological study and teaching. Physical anthropology was an area of considerable interest in anatomy. The racial killing and experimentation had the rationale of isolating and eradicating the carriers of pathogenic genes. Genetics flourished in Nazi Germany in often gruesome research programs and as an incentive to racial policy. The Nazi obsession with race purity provided a favorable climate for genetics and experimental medicine to flourish. A successful career required support from the Nazi Party or the plethora of Nazi agencies.

The Final Phase: Mengele

Josef Mengele was born on March 16, 1911, a Roman Catholic. In 1935 he took a doctorate in anthropology in Munich, before qualifying in medicine in 1938 at Frankfurt with an M.D. thesis on the genetics of cleft palate. At the Institute for Hereditary Biology and Racial Hygiene, he worked as assistant to Otmar von Verschuer, who was interested in the genetics of twins. He joined the Nazi Party in May 1938, the SS in September 1938, and the Waffen-SS in July 1940. In November 1940, Mengele was assigned to the SS Race and Settlement Office on Ethnic German Returnees. In June 1941, he joined a combat unit as a medical officer and received the Iron Cross. From January to July 1942 he was a member of the SS's international Viking Division, and was again decorated for his frontline service. After a further period with the Race and Settlement Office, and visits to Verschuer, he was sent to Auschwitz as a camp doctor in April 1943. He combined sanitary responsibilities—supervising the “Gypsy Camp,” protecting the camp staff from infection—with undertaking racial selections of the newly arrived, sending those deemed “unfit” or simply not needed at the time to their deaths in the gas chambers. Mengele’s scientific research was an informal, spare time activity, although his facilities were extensive. He used his position in the selections to find twins and other persons of interest, such as those with growths or other anomalies. Mengele joined the medical anthropologist at Auschwitz, Siegfried Liebau, who also was associated with von Verschuer.

Mengele exemplified the scientific drive to produce outstanding data. About 900 children endured Mengele’s twin camp, and he scoured transports for additional subjects. Most but not all of his subjects were twins; children announced they were twins in the hope of surviving. They came from throughout Central and Eastern Europe: Romania, Hungary, Czechoslovakia, and Poland. Most were Jewish, although some were Sinti and Roma who were killed when the Auschwitz “Gypsy Camp” was liquidated, and their bodies were then dissected. Mengele was manipulative; he knew how to calm children when it suited him, but he was re-

lentlessly sadistic. Surviving accounts are fewer than one might expect. Some survivors have no memory; one inmate recalls just a trip to a meadow of flowers by Birkenau. Other twins remember all the procedures done to them, including painless ones, such as the taking of foot sole imprints, and painful, vicious experiments, such as incisions and operations without anesthetic, and often the killing of a beloved sibling.⁵⁷ Death was frequent.

Beginning in April 1943, Mengele built up his own research installations with a staff of prisoner pathologists, including Nyiszli and Gisella Perl, working at a number of locations within Auschwitz-Birkenau. Another contact was the physician and political prisoner Ella Lingens. Verschuer obtained a grant from the DFG for research on hereditary pathology, focusing on blood proteins, linking Mengele to the KWI for Anthropology. Mengele injected infective agents to compare their effects, and cross-injected spinal fluid. He would sometimes order the killing of a victim so that internal organs could be analyzed. He assisted in obtaining blood and body parts for Berlin colleagues who would use them for research. Under this DFG project, Mengele assisted in supplying the heterochromic eyes of a Sinto family to Karin Magnussen, a geneticist and Nazi activist in Nachtsheim’s Department of Hereditary Pathology in Berlin. Magnussen conducted serial research on iris structure of schoolchildren. When anomalies in the iris of the family of Otto Mechau from Oldenburg came to light, she examined the family members in August 1943 before their deportation to Auschwitz. She then assisted the SS anthropologist Siegfried Liebau in Auschwitz, and made strenuous efforts to secure the Mechaus’s eyes through Mengele.⁵⁸

Mengele selected the 20 children sent for TB experiments to Neuengamme camp near Hamburg. These experiments were ostensibly to determine whether there was any natural immunity to tuberculosis and to develop a vaccination serum against TB. Heissmeyer—at the SS Sanatorium of Hohenlychen, a major SS center of research involving coercive experiments—sought to disprove the popular belief that TB was an infectious disease. Heissmeyer claimed that only an “exhaustive” organism was receptive to such infection, most of all the racially “inferior organism of the Jews.”^{45,47}

Before Auschwitz was liberated on Jan. 27, 1945, Mengele vanished. He moved to the camp of Gross-Rosen, and then evaded detection in the U.S. zone of occupation. In 1948 he used International Red Cross ID to flee to South America and is believed to have died in Brazil in 1979.

The Victims Protest

In a few cases, victims resisted and sabotaged the experiments. In March 1943, some of the 74 Polish women prisoners at the women’s concentration camp of Ravensbrück protested against experiments in which the orthopedic surgeon Gebhardt wounded and then infected their legs to test the efficacy of sulphonamide in preventing tetanus. They called themselves “The Rabbits,” and they obstructed the experiments, which they also documented. They smuggled news out to Polish resistance networks, which passed the information to Red Cross societies, and—apparently—to the Vatican. The anthropologist Germaine Tillion concealed a film spool with photographs of the sulphonamide and bone transplantation experiments.^{9,59,60}

In October 1944 the International Council of Women in London demanded that the International Committee of the Red Cross (ICRC) give “all possible protection” to the women imprisoned at Ravensbrück. The council expressed horror at the “barbarous experiments under the guise of scientific research.”⁶¹ But the ICRC offered no protection and never inquired systematically as to the extent of human experiments, although it held substantial documentation.

As the war drew on, animal material—first apes and then even rabbits—was in short supply, and rabbits came to be viewed as foodstuffs. The pressure increased to use imprisoned humans for experiments. As adults resisted, the primary targets changed to “racial inferiors,” especially children, and in 1944 especially Jewish, Sinti, and Roma children. The year 1944 marked a high point of the unethical research in the basic medical sciences. This was because German scientists realized that the war was lost, but they believed they could help German science to continue by demonstrating the superiority of its research. They also hoped for academic appointments on the basis of unique research findings. Research for military purposes was rapidly overtaken by the basic medical sciences. German scientists felt that if they held unique data, it ensured continuity of employment after the war, and the survival of German science.

Investigating the Nazi Research Atrocities

After the war, survivors demanded justice, compensation, and a reconsideration of medical ethics to prevent future abuses. Allied scientific intelligence officers realized that the sacrifice of humans as experimental subjects had been widespread in Nazi Germany. One officer was John W. Thompson, an American, born in Mexico, who held an Edinburgh medical degree and conducted aviation medical research with the Royal Canadian Air Force. He demanded comprehensive documentation and ethical analysis of Nazi research. He was convinced that inaction would condone the experiments, and that “there is equally a danger that these practices may continue in Germany or spread to other countries.” British officials doubted that medical war crimes were so widespread, but conceded that there should be a special medical trial for the worst offenders. Thompson secured an inter-Allied meeting of war crimes investigators. On May 15, 1946, British, French, and U.S. representatives met “to consider evidence bearing on the commission of war crimes by German scientists believed to be guilty of inhuman experimentation on living men and women.” Thompson’s achievement was to establish an International Scientific Commission to document German medical war crimes, and he led efforts to assemble a complete databank on all medical atrocities and human experiments.⁶² Thompson considered that comprehensive documentation and ethical evaluation of all experiments was necessary because the trials brought only a select number of perpetrators to justice.

The Nuremberg Code

The Nuremberg Medical Trial was one of the war crimes trials that followed the trial of major Nazi war criminals, including Göring, before the International Military Tribunal representing the United States, Britain, France, and Russia in 1945–46. The U.S. prose-

cutors charged 23 interned Nazi medical scientists and administrators with war crimes and crimes against humanity, and brought them to trial before a panel of U.S. judges in December 1946. In August 1947, 16 of the defendants were convicted; 7 were sentenced to death and, after appeals, were hanged in June 1948 (see Table 2.2).

Survivors of experiments were key prosecution witnesses. The U.S. prosecutors selected a representative spectrum of witnesses to achieve maximum impact in court. They included four Polish women from the “Rabbits” as well as priests, Jews, and Roma.⁹ At the trial’s end, the three judges issued the Nuremberg Code, with its demand for an “enlightened consent” by human subjects of research. This provided the basis for what shortly afterward was referred to as informed consent, which eventually became the ethical prerequisite for all medical research and therapy.

The issue of an ethical code had first been raised at the International Scientific Commission in August 1946. As promulgated at the Nuremberg Medical Trial, the Code required that the experimental subject be informed of the risks and the rationale for the experiment. Its major innovation was to give the experimental subject the right to halt the experiment. The principle of informed consent and the obligations of research workers to ensure the safety and health of their subjects has had—in the long term—profound implications for clinical practice and research. The Nuremberg Code has offered guidelines for genetic counseling, genetic screening, the use of body parts, and therapeutic trials.

Only one associate of the KWI for Anthropology was a defendant at the Nuremberg Medical Trial: Helmut Poppendick of the Race and Settlement office of the SS. He had been seconded to the KWI for Anthropology for a year’s course in genetics. No other human geneticist was prosecuted at Nuremberg, and senior researchers were later de-Nazified with just a small financial penalty or wholly acquitted. Evidence against Verschuer was collected for a planned second medical trial during 1946, but this was dropped for various reasons. In 1946, Verschuer claimed that he had not known the true nature of Auschwitz, and contended that using body parts for research was permissible if a person was going to be killed.^{19,63} Mengele came to the attention of the British and U.S. war crimes investigators partly through Auschwitz survivors giving testimony at the Belsen Trial, and partly through the prisoner-physician Gisella Perl, who was keen to testify against him.^{9,64}

Despite the wave of postwar trials and Thompson’s efforts to document medical war crimes, many culpable researchers were only briefly or never interned. Robert Ritter and his assistant Eva Justin, who conducted the research into the psychology of Sinti and Roma, found a postwar niche in public health work.³³ Fritz Lenz, who had been a professor of racial hygiene in Berlin under the Nazis, became professor of human genetics in Göttingen in 1946. Verschuer initially tried to convince the Americans that his expertise was fundamental for solving problems of postwar health. Once he detected their animosity, he made headway in the British zone. Verschuer eventually obtained a chair at the University of Münster. Others who saw themselves rehabilitated included geneticists Wolfgang Lehmann at Kiel in 1948, Hans Grebe, Verschuer’s former assistant, with a teaching post in human genetics at Marburg in 1948, and Lothar Loeffler at Hannover in human genetics in 1953.⁵⁵

Karin Magnussen slipped away; she retained the eye specimens while becoming a high school biology teacher in Bremen.⁵⁸ The daughter-in-law of Carl Schneider published euthanasia

Table 2.2
Defendants at the Nuremberg Medical Trial

Name	Born	Joined Nazi Party	Role	Sentence (Reduced to)	Released
Karl Genzken	1885	1926	Chief, Medical Dept. of Waffen-SS	Life (20 yrs)	1954
Siegfried Handloser	1885	–	Chief, Armed Forces Medical Services	Life (20 yrs)	Died in custody
Georg August Weltz	1889	1937	Chief, Institute for Aviation Medicine	Acquitted	
Oskar Schröder	1891	–	Chief, Luftwaffe Medical Service	Life (15 yrs)	1954
Paul Rostock	1892	1938	Chief, Office for Medical Science and Research	Acquitted	
Kurt Blome	1894	1922/31	Deputy Reich Health Leader	Acquitted	
Adolf Pokorny	1895	–	Physician, specialist in skin and venereal diseases	Acquitted	
Gerhard Rose	1896	1922/30	Brig. Gen., Luftwaffe Medical Services	Life (15 yrs)	1955
Karl Gebhardt	1897	1933	Himmler's physician; Chief Surgeon, staff of Reich Physician SS and Police	Death	Hanged
Helmut Poppendick	1902	1932	Chief, personal staff of Reich Physician SS and Police	10 yrs	1951
Waldemar Hoven	1903	1937	Chief Doctor at Buchenwald	Death	Hanged
Viktor Brack	1904	1929	Chief Administrative Officer in Hitler's Chancellery	Death	Hanged
Karl Brandt	1904	1932	Reich Commissioner for Health and Sanitation; Hitler's Escort Surgeon	Death	Hanged
Joachim Mrugowsky	1905	1930	Chief Hygienist, Reich Physician SS and Police	Death	Hanged
Wolfram Sievers	1905	1928/9	Reich Manager, SS Ahnenerbe (Ancestral Heritage) Society	Death	Hanged
Wilhelm Beiglböck	1905	1933	Consulting physician to the Luftwaffe	15 (10 yrs)	1951
Siegfried Ruff	1907	1938	Director of Aviation Medicine, German Experimental Institute for Aviation	Acquitted	
Rudolf Brandt	1909	1932	Personal Administrative Officer to Himmler	Death	Hanged
Hermann Becker-Freyseng	1910	1933	Chief, Dept. of Aviation Medicine, Luftwaffe Medical Service	20 (10 yrs)	1952
Herta Oberheuser	1911	1937	Physician at Ravensbrück; Assistant Physician to Gebhardt at Hohenlychen	20 (10 yrs)	1952
Hans Wolfgang Romberg	1911	1933	Doctor, Dept. for Aviation Medicine, Experimental Institute for Aviation	Acquitted	
Konrad Schäfer	1912	–	Doctor, Dept. for Aviation Medicine, Experimental Institute for Aviation;	Acquitted	
Fritz Fischer	1912	1939	Assistant Physician to Gebhardt at Hohenlychen	Life (15 yrs)	1954

results from Heidelberg for her Leipzig M.D. in 1946. Peiffer calculates that of 12,000 victims' brains, at least 2,097 were examined by pathologists resulting in 37 publications after World War II.

One can cite many such cases. Barbara Uiberrak was the pathologist for the Steinhof complex from 1938 until the 1960s. In 1946, she explained to the people's court in Vienna how she found the children's euthanasia cases scientifically significant, taking pride in the 700 brains and gland specimens. Heinrich Gross began to publish in the *Morphologisches Jahrbuch* the first of a long series of neuropathological contributions, in 1952. Between 1954 and 1978 he published 34 research papers on hereditary mental defects. A coauthor, Franz Seitelberger, who had been a member of an SS unit from 1938 to 1945, became director of the Neurological Institute of the University of Vienna in 1959 and eventually was the university's rector. Gross became one of Austria's foremost psychiatrists and neurohistologists.⁴³

However, Waldemar Hoven, one of the doctors convicted at Nuremberg was found to have obtained his degree improperly, as prisoners at Buchenwald wrote his M.D. thesis.^{9,65} Only in 1961 did the Universities of Frankfurt and Munich annul the doctorates

of Mengele and the euthanasia and Auschwitz sterilization perpetrator, Horst Schumann; the annulled degrees of most Jewish physicians were never restored. The debate on the ethics of Nazi research data, which began in 1945, continues.^{66,67} In contrast, the victims of the experiments have remained marginalized, and—ironically—bioethicists have shown little concern with their welfare. The marginalization and underestimate of their numbers has meant that compensation and care have not been—and tragically never will be—adequate. It is extraordinary that 60 years on from the time of the atrocities, we still do not know their full extent or the identities of the victims. The reasons include the decline of interest in war crimes after 1947 and the protracted resistance of the Austrians and Germans to providing compensation for victims of human experiments.

The Cold War facilitated the politics of denial. West German judicial authorities did not accept the Nuremberg verdicts. Thus, SS Obergruppenführer Poppendick, convicted at Nuremberg and sentenced to 10 years imprisonment—although he was released in 1951—obtained a police report that he was free from convictions when (using the alias Poppendiek) he was awarded a doctorate

from the University of Münster in 1953.^{9,68} This indicates unwillingness of German civil police and academic authorities, as well as the professors (including Verschuer) who affirmed the academic qualities of the thesis, to recognize the Nuremberg verdicts. Judicial ineffectiveness on the part of the U.S. occupation forces and the postwar West German government explains the noncapture and nonprosecution of Mengele, and the continuing citation of Nazi research.⁶⁹ The scientific establishment closed ranks; medical leaders wished to retain specimens and to defend the reputation of celebrated teachers. Historians were interested in National Socialism only at a very general level, and failed to analyze medical atrocities.

German medical teaching and research institutes continued to hoard body parts from Holocaust and euthanasia victims until the 1990s. The pendulum swung from retention to disposal. The solution was burial. Examples include clinics in Frankfurt, Heidelberg, Munich, and Vienna, which transferred body parts for religious burial. At Frankfurt, complaints were made that relatives and the public were not invited to attend the ceremony. Neither were full efforts always made to identify the victims, nor to inform relatives. By way of contrast, the sustained efforts of Viennese anthropologists to identify victims remain exemplary.

The number of victims has been underestimated. We need to identify victims at an individual level for commemoration, compensation, and for a full understanding of the chain of tragic events involving scientific networks at the time. The high number of claims for compensation by survivors indicates how our estimates of victims need to be revised upward, taking into account not only deaths but also people who were subjected to abusive research but still survived. Given that medical research for typhus and malaria involved thousands of victims, the overall numbers of victims of atrocities conducted for scientific purposes will rise to tens of thousands. Moreover, we need to add the victims of euthanasia killed for medical research purposes, and victims (whether living or dead) of experimental methods of sterilization. No reliable account of the numbers who survived human experiments and those who were killed has ever been made. Close attention to the sources suggests that many groups—children in institutions, prisoners of war, hospital patients, as well as concentration and extermination camp prisoners—were victims of experimental and invasive research. Overall, there were many thousands of victims, possibly in the order of tens of thousands, who were killed or survived.

Victims of human experiments are very much a marginalized group in the history of the Holocaust. Once historians realized that experimental victims were generally not pilots for mass destruction, they lost interest in the often intricate rationales of researchers and their networks, and avoided critical engagement with medical texts indicating genocidal motives. Historians' attention shifted away from experimentation to euthanasia, as a key stage in the Holocaust, whereas the human experiments have been underestimated and neglected. Neither the extent of child experimentation, nor the exploitation of body parts, nor the identities of victims have been fully established. Victims and their families contributed to medical and social insurance, but survivors have never received the medical care they need, let alone adequate compensation beyond that of a single, and belated, small lump sum payment.

The journalist Hans-Joachim Lang, in *Die Namen der Nummern* ("The Names of the Numbers"), has recently identified the

victims who were killed for Hirt's skeleton collection. One victim was aged 16. She was Juli Cohen, born in 1927 in Thessaloniki, Greece. The rest of the children in her transport to Auschwitz of April 18, 1943, were killed. In 1967, the journalist Günther Schwarberg set out to identify the 20 children selected by Mengele for fatal TB experiments.⁴⁵ His pioneering study remains exemplary as regards the need to reconstruct victims' life histories.

Although Holocaust victims are commemorated on an individual basis, medical victims are often still anonymized. When victims' identities are suppressed on the basis of medical confidentiality, however, it is, in fact, the medical perpetrators who are protected from scrutiny. The identities of the victims need to be established for purposes of both commemoration and medical ethics. Only by knowing the victims can we properly comprehend the Nazi research atrocities. Only then can we unravel the networks of unscrupulous medical researchers to whom the victims fell prey, and restore a measure of justice and ethics to this dark period in the history of scientific medicine.⁷⁰

The Imperial Japanese Experiments in China

Between 1933 and the end of World War II, Japanese researchers—mostly under the aegis of the Japanese Imperial Army—killed thousands of humans in medical experiments. The experiments, which included vivisection, fell broadly into three categories: explanation of diseases, development of therapies, and research into and development of biological and chemical warfare. Most of the human experimentation took place in Japanese-occupied Manchuria and China, although the Japanese army also operated experimental centers in Southeast Asia and on the main Japanese islands. Most of the victims were Manchurian or Chinese criminals, political prisoners, or prisoners of war, although some Allied prisoners of war—such as Americans, Australians, and New Zealanders—were also used and killed in these experiments.

Because of an immunity arrangement with U.S. officials, most of the researchers involved were never brought to trial. In return, the United States got secret access to the results of Japanese biological warfare experiments that had been performed on prisoners. Many of the human experimenters went on to prestigious civilian careers, leaving both Japan and the United States with unresolved ethical issues that now date back more than half a century.

Background

Shiro Ishii, the founder and leader of Japan's network of human experimentation facilities, entered the Army in 1920 upon graduation from Kyoto Imperial University Faculty of Medicine. In 1925, Ishii began to lobby his superiors for research on biological warfare. In 1930, after a two-year trip to Europe and the United States, he became a professor in the Department of Epi-

demic Prevention of the Army Medical College (Rikugun Gun'i Gakko Boeki Bu—Boekigaku Kyoshitsu) in Tokyo. In this position he performed bacteriological studies, conducted research on and development of vaccines, and trained army surgeons. He wanted to improve the prestige of medical officers in the Japanese Army by developing a powerful biological weapons program—even though biological and chemical warfare had been prohibited by the Geneva Convention in 1925. Using the Army's authority and prestige in 1930s Japan, he also envisaged a national network for medical research that would be much more powerful and effective than the existing academic infrastructure, and that would be furnished with state-of-the-art laboratories that could freely use humans for research and development of military medicine.

The takeover of Manchuria by Japan's Kwantung Army in 1931—known as the “Manchurian Incident,” or, in China, as the “9/18 Incident”—gave Ishii his opportunity. The following year, he established a large new department specializing in biological warfare in the Army Medical College, and deceptively named it the Epidemic Prevention Laboratory (Boeki Kenkyu Shitsu). This laboratory became the headquarters of his network. Simultaneously, he built a secret facility called the Togo Unit in Beiyinhe, a small town in Manchuria about 70 km southeast of Harbin. This was Ishii's first prison-laboratory, where deadly human experimentation probably began in the fall of 1933. The subjects were mainly Chinese but included some Soviets, Mongolians, and Koreans who were arrested by the Kwantung Army Military Police as spies and resisters and who were scheduled to be executed without trial. Ishii and his colleagues thought it was better to use them as human guinea pigs than merely to execute them.

The facilities of Beiyinhe were insufficient for Ishii's project. The buildings were not strong enough to serve as a prison; in fact, in September 1934, 16 captives revolted and escaped. So Ishii and the army built a much larger, stronger prison laboratory-factory in Pingfang (sometimes written as Ping Fan), about 20 km southeast of downtown Harbin, now one of the districts of Harbin City. Construction at Pingfang began in 1935; residents of four nearby villages were forced to evacuate, and the huge complex was completed around 1938. The Togo Unit became an official unit of the Japanese army in 1936, even before construction was completed. This means that the Japanese Emperor, Hirohito, formally acknowledged Ishii's project, though it seems he was unaware of its details.

The Togo Unit was now known as the Epidemic Prevention Department (Boeki Bu) of the Kwantung Army, and as Unit 731. In addition to medical experimentation, Ishii's units were responsible for water purification for Japanese troops in China from 1937 on, and so the unit was soon renamed the Epidemic Prevention and Water Supply Department (EPWSD) (Boeki Kyusui Bu). Ishii had invented a water purification machine that could be easily carried to the battlefield. During the battles for Beijing and Shanghai, he sent teams to the front to operate it—garnering even more support from army leaders. In 1938, the Japanese army adopted Ishii's machine as standard equipment and organized 18 divisional EPWSDs (Shidan Boeki Kyusui Bu), whose directors were officers of Unit 731. By 1939, Ishii's network included some field water purification units, 18 divisional EPWSDs, and five permanent Epidemic Prevention Departments—in Harbin (Unit

731), Beijing (Unit 1855), Nanjing (Unit 1644), Guangzhou (Unit 8604), and Tokyo (Boeki Kenkyu Shitsu). Altogether, Ishii commanded more than 10,000 people. When the Japanese army occupied Singapore in 1942, another permanent EPWSD was added to the network (Unit 9420). Unit 731 had a proving ground in Anda (about 150 km northwest of Harbin) and five branches located in Mudanjiang, Linkou, Sunwu, Hailar, and Dalian.

In addition, as a leader of army surgeons, Ishii had power over army hospitals in occupied cities in China. His network also had close connections with other biological warfare departments such as the Military Animals Epidemic Prevention Department (Gunju Boeki Shou) in Changchun, Manchuria (Unit 100), and institutions for chemical warfare such as the Army Sixth Technology Institute in Tokyo, the Army Narashino School in the Tokyo suburb of Narashino, the Army Ninth Technology Institute (Noborito Institute) in Noborito, also a Tokyo suburb, and the Kwantung Army Chemical Department in Qiqihar in Manchuria (Unit 516).

Unit 731 probably moved to the new base in Pingfang in 1938. It was a 6-square-kilometer complex of secret laboratory-factories surrounded by trenches and high-voltage electric wires. The whole district became a special military area, which meant anyone approaching without permission was to be shot by the guards. The main building had two special prisons in its inner yard, so that escapees could never get outside. The captives were called *maruta*, which means "logs" in Japanese, and were identified only by numbers.

At a little-noted war crimes trial conducted by Soviet authorities at Khabarovsk in 1949, Surgeon Major General Kiyoshi

Figure 3.1. Aerial Photograph of Unit 731. Source: Seiichi Morimura. Reprinted with permission.

Kawashima, who was chief of a division of Unit 731, testified that the prisons usually held 200 to 300 captives, including some women and children, but that their maximum capacity was said to be 400.¹ The Military Police sent 400 to 600 captives to Unit 731 every year under the Special Transfer Procedure (Tokui Atsukai), a system the Japanese army developed to supply human subjects.¹ This system for procuring subjects differed from that of Nazi Germany. The Nazi transfer system was not for procuring subjects but for genocide. But in the case of the Japanese medical experiments, victims were purposely selected and sent to Ishii's network to be subjects of experiments.

At least 3,000 people were tortured to death at Unit 731 from 1940 to 1945.¹ But this number does not include victims before 1940 or at other medical experimentation sites. Allied prisoners of war (POWs) may have been subjected to experiments by Unit 731 researchers at the camp in Mukden (now Shengyang).^{2,3}

Moreover, the activities of Unit 731 researchers were only a part of the medical atrocities committed by Imperial Japan. According to a large body of testimony, deadly experiments also were performed in other permanent EPWSDs such as Units 1644 and 1855. American, Australian, and New Zealander POWs were forced to participate in experiments by Surgeon Captain Einosuke Hirano of the 24th Field EPWSD in Rabaul, Papua, New Guinea,⁴ and eight U.S. airmen were killed in surgical experiments on the Japanese home islands.⁵ Table 3.1 presents an approximate timeline of the Imperial Japanese experiments in China, along with other relevant historical dates.

Medical Atrocities

Medical atrocities performed by Imperial Japanese doctors can be classified into three categories:

1. Training of army surgeons.
2. Biological warfare maneuvers.
3. Research with humans.

Training of Army Surgeons

Surgeons at army hospitals performed many vivisections on Chinese captives, with anesthesia. For example, these doctors performed appendectomies and tracheostomies on the prisoners, shot them and took bullets from their bodies, cut open their arms and legs and sewed up the skin around the wounds, and finally killed them. This was purportedly part of training newly assigned army surgeons to treat wounded soldiers at the front lines.

Confessions by many of the surgeons involved are on record.^{6,7} At Datong Army Hospital in Datong, Shanxi, in June probably of 1941, Surgeon Major Kazuharu Tanimura and Surgeon Lieutenant Rihei Miura conducted a three-day training program that involved lectures on military surgery and exercise surgeries such as suturing of blood vessels and nerves, thoracotomy, celiotomy, craniotomy, blood transfusion, various anesthetics, appendectomy, and nephrectomy, performed serially on "six bodies of prepared materials."⁸ The trainees were army surgeon officers of the Army Medical College. Judging from confessions about similar cases, the "materials" probably were arrested Chinese resisters who probably were killed in these exercises.

In the summer of 1989, human bones from more than 100 bodies were found in the ground where the Army Medical College had been located in Tokyo from 1929 to 1945. Eleven skulls and most long bones were heavily sawed or drilled. One skull was shot and another one was stabbed. Judging from the condition and technique, they must have been the subjects of test surgeries, preserved as specimens in the Army Medical College, and finally buried when Japan surrendered.⁹ They may be the remains of vivisectioned Chinese prisoners.

Biological Warfare Maneuvers

Hundreds of confessions testify to Imperial Japanese research into the use of biological warfare. Unit 731 used biological warfare during the four-month clash between Japan and the Soviet Union over the Manchukuo-Mongol border in 1939, according to testimonies of former junior assistants of Unit 731.^{10,11} Moreover, Japanese army officers themselves wrote about biological warfare against China in their official records. According to these notes, at least three major attacks on Chinese citizens were carried out.

First, in 1940 Lieutenant Colonel Kumao Imoto, then on the general staff of the Japanese Expeditionary Force in China, wrote in his log several times about consultations with army surgeon officers of Unit 731. On October 7, 1940, he wrote that Unit 731 officers reported, "So far six attacks have been completed" on Ningpo City.¹² On October 30, an epidemic of plague suddenly occurred in Ningpo, which is now suspected to have been the result of these attacks. In the log of November 30, 1940, general officer Kaizo Yoshihashi reported, "On November 21 . . . an agreement was reached that next time Jinhua would be attacked" with Ishii's Unit.¹³ This coincides with the fact that on November 28 a Japanese bomber sprinkled on the city of Jinhua granules in which plague bacillus was found.⁷

Second, on September 16, 1941, Imoto wrote that "the Imperial Headquarters issued a direction for biological warfare."¹⁴ On November 25 it was reported that Changde was attacked in the morning of November 4 and an epidemic occurred there on November 6.¹⁵

Third, on August 28, 1942, Imoto noted how army surgeons of Unit 731 had performed biological warfare in Zhegan (Zhejiang-Jianxi) operations. In Guangxin, Guangfeng, and Yushan, plague bacillus was scattered via contaminated fleas, rats, and lice. In Jiangshan and Changshan, vibrio cholerae was thrown directly into wells or smeared on foods and injected into fruits that were left on the streets. In Quxian and Lishui, typhus and paratyphoid were distributed with corrupted fleas. On October 5, Army Surgeon Colonel Tomosada Masuda of Unit 731 told Imoto that the attacks with contaminated fleas and vibrio cholerae in the wells were probably successful.¹⁶

Fifty-five years later, in August 1997, 180 family members of Chinese victims of the biological attacks filed a complaint in Tokyo District Court demanding an apology and compensation from the Japanese government. On August 27, 2002, the court dismissed the complaint, ruling that individuals cannot sue a country for compensation for wartime suffering. On July 19, 2005, Tokyo Higher Court dismissed it again for the same reason, and so did Japanese Supreme Court on May 9, 2007. But the courts acknowledged that biological warfare had been waged, because the Japanese government never disputed the facts but rather kept silent.

Table 3.1
Timeline of the Imperial Japanese Experiments in China

<i>Date</i>	<i>Event</i>
1925	Shiro Ishii begins to lobby for research on biological warfare.
1930	Ishii becomes a professor of the Army Medical College.
Sept. 1931	Manchurian (9/18) Incident: Japanese army takes over Manchuria.
1932	Japan establishes its puppet state, "Manchukuo."
1932	Ishii establishes both the Epidemic Prevention Laboratory in the Army Medical College in Tokyo, the headquarters of his medical network, and Togo Unit in Beyinhe in Manchuria, the predecessor of Unit 731.
Autumn 1933	Deadly human experiments in Togo Unit begin.
Sept. 1934	Sixteen captives revolt and escape from a prison in Togo Unit.
1935	Construction of a huge prison laboratory-factory begins in Pingfang, near Harbin.
Circa 1935	Satoshi Sugawara of Togo Unit performs distilled water experiments on Chinese captives.
1936	The Togo Unit becomes an official unit of the Japanese army as Unit 731.
1936	Kameo Tasaki of Manchuria Medical College publishes a study of lymphogranuloma with experiments on a condemned guerrilla.
1937	Japan invades the rest of mainland China.
Circa 1938	Unit 731 moves to Pingfang.
1938	The Japanese army adopts Ishii's water purification machine as standard equipment and organizes Units 1855, 1644, and 8604.
Sept. 1939	Nazi Germany invades Poland; World War II begins in Europe.
1939	The Army Science Institute, the Kwantung Army Chemical Department, and Unit 731 appear to perform joint chemical weapon tests with human subjects.
Aug. 1939	Unit 731 conducts biological warfare against Soviet troops in the Japanese-Russian border clash over the Mongolia-Manchukuo border.
May 1940	Toyonori Yamauchi et al. perform cholera vaccine experiments on 20 Chinese captives in Unit 731.
Sept. 1940	Unit 731 performs a large human experiment of mustard gas.
Oct.–Nov. 1940	The Japanese army attacks Ningpo with biological weapons.
1941	Hisato Yoshimura gives a lecture on his frostbite studies with human subjects in Harbin.
Jan.–Feb. 1941	Kazuharu Tanimura et al. perform "winter hygiene studies" in inner Mongolia, abusing and killing 8 Chinese captives in various experiments.
May 1941	Shigeo Ban of the Army 9th Technology Institute performs poison experiments on about 15 humans at Unit 1644.
June 1941 (?)	Kazuharu Tanimura and Rihei Miura conduct a deadly training program for army surgeon officers with 6 human subjects in Datong, Shanxi.
Summer 1941	A plague flea bomb trial on humans is performed at Unit 731's Anda proving ground.
Nov. 1941	The Japanese army attacks Changde with biological weapons.
Dec. 1941	Japan attacks Pearl Harbor, Kota Bahru, and Hong Kong; The Pacific War begins.
Apr. 18, 1942	U.S. bombers launched from an aircraft carrier raid Tokyo and fly to an airbase in Zhejiang, China.
May–Aug. 1942	The Japanese army conducts biological warfare in Zhegan (Zhejiang-Jianxi) Operations.
Aug. 1942	Ishii moves the command post of Unit 731 to Masaji Kitano.
1942	Unit 9420 is established in Singapore.
1942	Naeo Ikeda performs human experiments involving epidemic hemorrhagic fever at Heihe Army Hospital.
1942	Cyanide gas is tested on human subjects, killing them.
1942–43	Vivisections are suspected to have been performed in Manchuria Medical College Anatomy Department.
End of 1943	A typhus vaccine experiment is performed on 50 Chinese prisoners in Unit 731.
End of 1943	An anthrax bomb trial on humans is performed in Anda proving ground.
1944	Kasahara, Kitano, et al. publish a study on epidemic hemorrhagic fever in "ape."
Aug.–Sept. 1944	Tsunetaka Matsui of Unit 100 performs a deadly poison experiment.
1944–45	Einosuke Hirano performs deadly experiments on American, Australian, and New Zealander POWs in Rabaul, Papua, New Guinea.
Jan. 1945	A gas gangrene bomb trial on humans is performed in Anda proving ground.
Jan. 1945	Dr. Muto of Unit 731 performs a salt overdose experiment on Chinese.
Mar. 1945	U.S. Air Force carries out huge air raids on Tokyo, Osaka, Kobe, and Nagoya.
Mar. 1945	Ishii returns as commander of Unit 731.

Table 3.1 (continued)

Date	Event
May–June 1945	Fukujiro Ishiyama et al. perform experimental surgeries on 8 U.S. airmen and kill them at Kyushu Imperial University.
Aug. 6, 1945	First atomic bomb is dropped on Hiroshima.
Aug. 8, 1945	The Soviet Union declares war against Japan: Japanese army withdraws from Manchuria, destroying evidence of medical atrocities. Ishii's network collapses, and all surviving captives are killed at Unit 731 and other facilities.
Aug. 9, 1945	Second atomic bomb is dropped on Nagasaki.
Aug. 15, 1945	Imperial Japan surrenders.
Sept.–Oct. 1945	Murray Sanders of U.S. Army Chemical Corps investigates Japanese biological warfare R&D: GHQ/SCAP grants immunity from war crime charges to Ishii and his researchers.
Jan.–Mar. 1946	A. T. Thompson of U.S. Army Chemical Corps investigates Ishii and his researchers, but cannot find evidence of deadly experiments.
Dec. 1946	Nazi Doctors Trial opens at Nuremberg Tribunal.
Jan. 1947	The Soviets demand extradition of Ishii and his researchers for investigation of their deadly experiments: U.S. learns the facts of Japanese medical atrocities.
Apr.–June 1947	N. H. Fell of U.S. Army Chemical Corps investigates details of Ishii and his researchers' deadly experiments.
Aug. 1947	The State-War-Navy Coordinating Subcommittee to the Far East approves Ishii and his researchers' immunity from war crimes charges.
Aug. 1947	Medical Trial concludes in Nuremberg: U.S. judges promulgate the Nuremberg Code.
Dec. 1949	The Soviet Union brings officers and soldiers of Units 731 and 100 to trial before a military tribunal at Khabarovsk (the Khabarovsk Trial): The United States brands it as communist propaganda.
1956	The People's Republic of China tries Japanese war criminals before military tribunals, including only one surgeon officer of Unit 731.
1959	Shiro Ishii dies of laryngeal cancer at the age of 67.

Research With Humans

The research by Japanese doctors falls into three categories:

1. Explaining diseases
2. Development of therapies
3. Development of biological and chemical weapons

Explaining Diseases

Doctors in Ishii's network performed lethal experiments on captives in order to gain new scientific knowledge. There were two major kinds of research programs. One group of experiments involved bacteriological studies, including intentional infection in order to observe how the disease occurs and progresses and to search for its pathogen. Another group involved physiological studies, which were similar to the experiments Nazi doctors performed, including observation of the body's reaction to conditions such as extremely low temperature, low pressure such as that experienced at high altitudes, salt overdose, drinking only distilled water, and intravenous air injection. Anthropological-anatomical studies with "fresh human brains" were also performed at Manchuria Medical College.

Bacteriological studies. Shiro Kasahara, a researcher at Kitasato Institute in Tokyo, worked for Unit 731 for several years. In 1944, Kasahara, Surgeon General Masaji Kitano, Commander of Unit 731 from August 1942 to March 1945, and others published a paper concerning the identification of the pathogen of epidemic hemorrhagic fever, the etiology of which was then still unknown. It reads:

We made an emulsion with 203 ground-up North Manchuria mites and salt water, and injected it into the thigh of an ape

hypodermically. This first ape became feverish with a temperature of 39.4 degrees Celsius on the 19th day after injection and moderately infected. Then we took blood of this feverish ape and injected it into the second ape, which became feverish and produced protein in its urine. Typical epidemic hemorrhagic kidney was found at its autopsy. . . . Epidemic hemorrhagic kidney was never found at autopsy in the most feverish period. . . . But kidney, liver, and spleen of this period are most infective.¹⁷

This means they vivisected the "ape," because in order for surgeons to "autopsy in the most feverish period," the subject needed to be alive. Moreover, "the ape" must have been a human being, because the normal temperature of an ape is higher than that of a human being; 39.4 degrees Celsius is normal for an ape. In another paper, Kasahara and his colleagues noted that apes do not become feverish from this disease. So it seems probable that they infected humans and vivisected them.¹⁸

Kasahara himself later confessed:

My work involved supervising the extraction of blood samples from cases previously injected; they would normally show a slight temperature rise to about 37 deg C. These samples were reinjected into a second spy by members of another section, which had nothing to do with mine, and, after the injection, the second generation of patient became infected with haemorrhagic fever. . . . From the symptoms we were able to discern the transmission of the strain. . . .

Only on rare occasions did patients die of EHF [epidemic hemorrhagic fever]; normally, they would recover. I have heard rumour that in extremely rare cases, military surgeons,

anxious to perform an autopsy, had injected critical and terminal cases with morphine. . . .

. . . when I went to the Unit for the second time in 1942 I had to participate in the experiments of Kitano and the military doctors that were already in progress, namely, injecting people, spies; this was the result of orders and simply had to be obeyed.

I feel very guilty about what I have done and I think I did wrong. There were very few instances but, when a spy did die as a result of human experiment . . . I felt terribly sad and I always arranged for a memorial service to be held in the main hall of the Ishii Unit, which was given by a Buddhist priest from among the soldiers . . . but that's how deeply I was disturbed, and I think I was the only person in the Ishii Unit to arrange such a memorial service.²

In the late 1960s former Surgeon Lieutenant Colonel Naeo Ikeda, who practiced medicine in Osaka after the war, published papers reporting his Unit 731 experiments on epidemic hemorrhagic fever, in which the “fatality rate was 15% in 1941.”¹⁹ Ikeda wrote that in 1942, at Heihe Army Hospital, he injected blood taken from a feverish patient into two “volunteers,” who became infected, in order to confirm that this disease was infectious.¹⁹ At the same time, he infected another two “healthy volunteers” with contaminated lice and four “volunteers” with contaminated fleas.²⁰ Later Ikeda said in an interview that these volunteers were “coolies” at Heihe Army Hospital, and insisted that he sent them back there after treatment at Unit 731.²¹

However, Ikeda evidently killed subjects in a study of tetanus. To measure muscle chronaxie of tetanic patients, he injected 14 with tetanus toxin or spore. All died, but before their deaths, Ikeda and Army Engineer Saburo Araki measured chronaxie of their masseter, nasal muscle, orbicular muscle of eye, papillary muscle, intercostal muscles, anterior tibial muscle, and musculus gastrocnemius.²²

Extensive data regarding the dose at which 50% of those exposed would develop various diseases, the so-called minimum infectious dose for 50% (MID50), were described in a U.S. investigator's report.²³ A determination of the MID50 was thought to be very important for the development of biological weapons. Japanese researchers infected humans to learn the MID50 of anthrax, plague, typhoid, paratyphoid A and B, dysentery, cholera, and glanders. Experiments were performed to determine the MID50 for a variety of pathogens that were introduced into humans subcutaneously, orally, and through respiration of infected air samples. Some of the infections were not fatal, but many of those exposed died.

Experiments with human captives also were performed at medical schools in Manchuria. Kameo Tasaki, a research associate of the Department of Dermatology and Urology of Manchuria Medical College, then the top medical school in Manchuria, described his “human experiment” of lymphogranuloma in a 1936 paper. Tasaki wrote that he injected emulsion of grated brain tissue of an infected mouse to the condemned “guerrilla's” prepuce. A papula grew at the focus, but the subject was executed two weeks after the injection.²⁴ Judging by other anatomical-anthropological studies, using “the condemned” for medical studies seems to have been a not uncommon practice in Manchuria.

Physiological studies. Hisato Yoshimura was a lecturer at Kyoto Imperial University Faculty of Medicine when his head professor ordered him to go to Unit 731 in 1938. He stayed there until

Unit 731 collapsed in 1945, and he used captives in studies of frostbite. At the Khabarovsk Trial, many officers and soldiers testified about the cruelty of Yoshimura's experiments. Satoru Kurakazu, a Sergeant Major of Military Police at Unit 731, testified:

I saw experiments performed on living people for the first time in December 1940. I was shown these experiments by researcher Yoshimura, a member of the 1st Division. These experiments were performed in the prison laboratory.

When I walked into the prison laboratory, five Chinese experimentees were sitting on a long form [bench]; two of these Chinese had no fingers at all, their hands were black; in those of three others the bones were visible. They had fingers, but they were only bones. Yoshimura told me that this was the result of freezing experiments.¹

Naoji Uezono, who had worked for the Printer Division of Unit 731, described another grisly scene in an interview in the 1980s: “Two naked men were put in an area 40–50 degrees below zero and researchers filmed the whole process until they died. They suffered such agony they were digging their nails into each other's flesh.”²

Yoshimura himself gave a lecture on his frostbite studies in Harbin in 1941, although he said nothing about cruel experiments.²⁵ After the war, he and his colleagues published three papers in Japanese medical journals—in English—reporting part of the studies.^{26–28} We know that these papers concern their studies at Unit 731, because they themselves wrote that outlines of the papers were read at the 21st and 22nd annual meetings of Japanese Physiological Society in 1942–43. They wrote, “The experiments were made on about 100 male subjects (laboratory workers, students, soldiers and laborers).”²⁶ They explained their methods as follows:

To examine the temperature reaction of blood vessels to cold, the authors chose the tip of the left middle finger of humans as the site of examination, and the finger was dipped in ice water of 0°C up to its base for 30 minutes. The skin temperature of the back of its tip was then measured every one minute after immersion. To determine the skin temperature, a thermopile of Lewis' type made with copper and constantan wire of 0.02 mm. [sic] diameter was applied on the tip of the finger with adhesive plaster, and protected against water with vaseline. E.M.F. of the junction on the finger was measured potentiometrically against its cold junction in ice water. The water in which the finger is [sic] immersed was stirred frequently and the room temperature was usually maintained at about 20°C.²⁶

Women, children, and even an infant were included in the experiments:

The temperature reaction in ice water was examined on about 100 Chinese coolies from 15 to 74 years old and on about 20 Chinese pupils of 7 to 14 years. . . . Though detailed studies could not be attained on children below 6 years of age, some observations were carried out on a baby. . . . [T]he reaction was detected even on the 3rd day after birth, and it increased rapidly with the lapse of days until at last it was nearly fixed after a month or so.

As to sexual difference of the reactivity, only an outlining aspect was obtained from the observation on Orochon

subjects. . . . The reactivity of the female subject was a little lower than the male's in adult age, while they were nearly the same with each other in childhood.²⁷

After the war, Yoshimura became a professor at Hyogo Prefectural School of Medicine and finally became president of Kyoto Prefectural University of Medicine. In 1978, Emperor Hirohito gave him the Order of the Rising Sun-Third Class for pioneering work in "environmental adaptation science."²⁸

Frostbite experiments with Chinese captives were also performed elsewhere. Surgeon Major Kazuharu Tanimura of Datong Army Hospital organized a detachment and went on an expedition into Inner Mongolia from January 31 to February 11, 1941, to study frostbite, field surgeries, hemostasis, blood transfusion, and other procedures.²⁹ He took eight "living bodies"—male Chinese captives—as "material" for experiments. At dawn on February 6, researchers performed frostbite experiments on six people in various conditions such as wearing wet socks or gloves, drunk, hungry, and after administration of atropine. Their report, reprinted in 1995, describes the results precisely with sketches and photographs.²⁹ The eight captives were also used in other experiments and operations, and finally were shot or vivisected to death. The report includes the names of the subjects, direction for their confinement, a log of their killing, the program of their memorial service, and Tanimura's condolences.²⁹

Sadao Koshi, a driver of Unit 731, described a shooting experiment performed in an airtight chamber designed to study gunshot wounds in low pressure conditions. When a fighter pilot was shot in a dogfight and parachuted at very high altitude, his wounds would gape in low pressure.³⁰

According to the testimony at the Chinese investigation of Japanese war criminal Masauji Hata, Dr. Muto of Yoshimura's division performed a salt overdose experiment on a Chinese captive in January 1945 in order to confirm that salt increases basal metabolism.⁷

Yoshio Kurihara, an assistant in the Togo Unit at Beiyinhe from 1935 to 1936, described a torture test with distilled water:

I was ordered to help civilian Dr. Satoshi Sugawara's experiment to learn how long man can live only on distilled water. The subject lived for 45 days with ordinary water and 33 days with distilled water. A subject forced to drink distilled water asked me, "Mister, please give me tasty water." The subject who lived for 45 days was a physician called Zuo Guangya, a very intelligent man, not a bandit.³¹

Yoshitoshi Omino, a corporal of the Shinkyo (now Changchun) Military Police, testified that Surgeon Captain Takeshi Ogasawara intravenously injected air into a Chinese worker arrested for alleged stealing. The subject did not seem to be harmed, but was decapitated with two other captives by Omino.⁷ According to the testimony by an assistant, Yataro Ueda, doctors of Unit 731 seemed to know the lethal dose of an air injection.¹⁰

Anthropological-anatomical studies. Doctors of the Department of Anatomy of Manchuria Medical College performed anthropological-anatomical studies with specimens of seemingly vivisected Chinese brain. According to an accusation by a Chinese assistant at the department, Zhang Buqing, vivisections were performed about five times from the autumn of 1942 to the spring of 1943. About 25 male captives were killed.⁷ The doctors prepared many brain tissue specimens, which have been found in China

Medical University in Shengyang, which took over the facilities of Manchuria Medical College. Zhang concluded that vivisections had been performed because he saw fresh blood on the floor of the dissection room and the color of the corpses indicated that they had recently died.

The doctors published anatomical studies of the brain experiments with figures and photographs of these specimens in academic journals. For example, Naokiti Suzuki et al. wrote: "The present work on the cytoarchitectural structure of the regio frontalis was based upon the study of serial sections of the fresh human brains. Each of them was the brain of an adult Chinese man with no history of mental or physiological disease."³² They then expressed their gratitude to army surgeons in a footnote: "We are greatly indebted to Surgeon-Colonel Dr. Kizima, the director of Mukden Garrison Hospital and Surgeon-Captain Dr. Watanabe who acted so kindly and satisfactorily [sic] in performing the delicate operations desired."³² These passages seem to confirm Zhang's accusation.

Development of Therapies

The second category of human experiments in Ishii's network was for development of therapies, including vaccines, surgical techniques both in hospital and on the battlefield, hemostasis, and transfusion of blood or its substitute.

Vaccine experiments. Yoshio Shinozuka, a former junior assistant of Unit 731 whose birth name was Yoshio Tamura, wrote in 2004:

Unit 731 was developing an envelope vaccine of plague . . . Karasawa Division, to which I belonged, also performed human experimentation and vivisection on five Chinese under the pretext of a virulence test of the germ. First we collected blood from them and measured their immunity. On the next day, we injected four kinds of plague vaccines to each of four subjects. No vaccine was given to one subject as control. A week later, vaccines were given again. A month later, we injected 1.0 cc liquid with the same number of plague germs in every subject. All five were infected with plague. . . . The man that had no vaccine was infected first. Two or three days later he became feverish and pale. On the next day he was dying and his face grew darker. He was still alive but the members of the Special Division, which administered the special prison of "Maruta" ["logs"] brought him naked on the stretcher to the dissection room where we awaited him. . . . Lieutenant Hosoda auscultated his heart-beat on his chest. At the moment the auscultation finished, Surgeon Colonel Ohyama ordered "Let's begin!"³³

Shinozuka's superiors vivisected the subject and took organs as specimens. Shinozuka testifies that even his friend, junior assistant Mitsuo Hirakawa, was vivisected when infected with plague.³³

Masauji Hata, who testified about the salt overdose experiment, also testified that in January 1945 Surgeon Major Masahiko Takahashi of the First Division of Unit 731 injected plague bacteria into three Chinese people and infected them with severe pneumonic and bubonic plague. Takahashi then tried to treat them with Japanese sulfa drug but failed. All of these subjects died.⁷

Toyonori Yamauchi, a researcher at Kanagawa Prefectural Hygiene Laboratory, and his superiors studied manufacturing

vaccine with ultrasonic devices (vaccine made with virus attenuated by exposure to ultrasound). Their study drew Ishii's attention, and Ishii hired them in 1938. One of their papers was found in the journal of Ishii's headquarters.³⁴ Yamauchi and his superiors were sent to Unit 731 in June 1939, and performed cholera vaccine experiments on 20 Chinese captives in the special prison in May 1940. He was told that the subjects were "guerrillas convicted to death." Eight people were given vaccine made with ultrasonic devices, eight were given vaccine made at the Army Medical College, and four served as controls and received nothing. They were then forced to drink milk contaminated with cholera bacteria that had been developed as a weapon. The eight subjects who received ultrasound-attenuated vaccine did not become seriously ill, but those who received the other vaccine had severe diarrhea, and one of them died. All four controls died. Ishii ordered Yamauchi and his superiors to produce ultrasound-attenuated vaccine on a large scale.⁷

Medical orderly Furuichi of Unit 731 also testified at Kharovsk about a typhus vaccine experiment:

[T]his was at the end of 1943. To test the effectiveness of vaccines 50 Chinese and Manchurians were used as experimental material. First these 50 men were given preventive inoculations, but these were differentiated inoculations—some prisoners were given one, others were given two. Furthermore, different men were inoculated with different quantities of vaccine, and some of these 50 men were not inoculated at all.

Thus, these 50 men were divided into five different groups. All these men were forced to drink water contaminated with typhoid germs and then observation was kept to see what effect these pathogenic germs had in the different cases, depending on whether preventive inoculations had been performed on the man or not, how many times, and in what quantities. . . . Most of these men contracted typhoid. Exactly what percentage I do not remember, at all events 12 or 13 of the men died. . . . I myself know of one other case of such infection, this was at the end of 1944 or beginning of 1945, when infection was caused by similar methods.¹

Human vaccine experiments were also performed at Manchuria Medical College. Masaji Kitano, then a professor of microbiology at that College and later the Commander of Unit 731, and his colleagues wrote in an unpublished paper found in China after the war, "In Linjiang area we performed human experiments with 10 volunteers and 3 condemned. . . . They were healthy men of 32–74 years old with no anamnesis of typhus and other acute fever."³⁵ Kitano and his colleagues injected Typhus bacteria into 11 people who had been vaccinated and into two condemned without vaccination as controls. The condemned subjects both developed fever and were vivisected on the 11th and 19th day, respectively. Of the 11 who were vaccinated, five became feverish, and one was vivisected.

Surgical innovation. Deadly experimental surgeries were performed on captives to develop new surgical methods, not to train beginning surgeons. At least two studies are documented. One set of experiments aimed at developing hospital techniques was performed on U.S. Army Air Force crews in mainland Japan. The other experiments, to develop field surgical procedures, were performed on Chinese captives in Inner Mongolia.

From May to June 1945, Professor Fukujiro Ishiyama of the First Department of Surgery, Apprentice Army Surgeon Taku

Komori, and other Ishiyama subordinates performed experimental surgeries on eight U.S. crewmen at Kyushu Imperial University Faculty of Medicine. The American airmen were captured when their B-29s were downed. The Japanese Western District Army decided to execute them and handed them over to Komori and Ishiyama. On May 17, 1945, Ishiyama removed a lung from two POWs. On May 22, Ishiyama and his team performed total gastric resection and heart surgery on a POW, and removed the gall bladder and half of the liver of another POW. On May 25, they performed trigeminal rhizotomy (severing the facial nerve roots) on a POW. Finally, on June 2 Ishiyama performed surgery on the mediastinum and removed the gall bladder of two of three POWs. The last POW had a blood substitute transfusion later. All eight American POWs died during these operations.⁵

After the war, GHQ/SCAP brought this case to the military tribunal in Yokohama. Komori had already died; he had been badly injured in a U.S. air raid on Fukuoka in July 1945. Ishiyama hanged himself in prison in July 1946. On August 28, 1948, the Yokohama tribunal condemned two army officers and three university doctors to death by hanging, and sentenced another officer and two doctors to life imprisonment. Five other officers, eight doctors, and a head nurse were ordered to hard labor. However, their sentences were reduced in 1950 when the Korean War broke out and none among the convicted was executed.

Surgeon Major Kazuharu Tanimura and his colleagues experimented with field surgery during their expedition to Inner Mongolia. They wrote in their log that on February 4, 1941, they performed enteroanastomosis (intestinal bypass) on "living material No. 1." On the next day, "In order to follow up wounds, using living material No. 3, we amputated the left thigh, cut and sewed right thigh skin, and cut open the skin of the left hypogastrium. Treatments of dummy perforate gunshot wounds were performed on the left arm and right thigh of living material No. 7, and on the left waist and left chest of No. 6." On February 6, they shot No. 8 to make perforate wounds, then performed transfusion and tracheostomy on him.²⁹

Hemostasis experiments. Tanimura and his colleagues also performed hemostasis experiments to develop methods to save lives of bleeding soldiers on the battlefield. On February 5, they experimented on an arm wound on subject No. 6 and a thigh wound on subject No. 7. On February 6, they cut No. 5's arteries in the leg and performed hemostasis with clamps. On February 8, they performed various experiments with tourniquets on the same person.²⁹

Transfusion experiments. Tanimura's detachment performed various transfusion experiments, also to develop battlefield treatments. On February 5, 1941, they wrote that subjects No. 1 and No. 3 had transfusions of blood and Ringer solution at room temperature. On February 7 they transfused blood kept in a thermos bottle, blood that had been frozen and then thawed, and sheep blood. On February 8, they transfused blood taken from the heart of a corpse.²⁹

At Unit 731, transfusion experiments with different blood groups were performed. Naeo Ikeda wrote:

In my experience, when A type blood 100 cc was transfused to an O type subject, whose pulse was 87 per minute and temperature was 35.4 degrees C, 30 minutes later the temperature rose to 38.6 degrees with slight trepidation. Sixty minutes later the pulse was 106 per minute and the temperature was

39.4 degrees. Two hours later the temperature was 37.7 degrees, and three hours later the subject recovered. When AB type blood 120 cc was transfused to an O type subject, an hour later the subject described malaise and psychroesthesia in both legs. When AB type blood 100 cc was transfused to a B type subject, there seemed to be no side effect.³⁶

At Kyushu Imperial University Faculty of Medicine, sterilized and diluted brine was transfused into U.S. airmen as a blood substitute in the experimental operations described above. On May 17, 1945, Professor Ishiyama and his aides transfused 2,000 cc of blood substitute into the POW whose lung was removed. On June 2, they drew about 500 cc of blood from the right thigh artery of another POW and transfused 300 cc of blood substitute.⁵

Development of Biological and Chemical Weapons

The third research category related to weapons development. The aim of those engaged in this kind of research was to find ways to kill people more effectively and efficiently. Doctors in Ishii's medical network performed both biological and chemical weapon experiments on humans.

Biological weapon experiments. U.S. investigator N. H. Fell described many biological weapon trials in his report. Regarding anthrax bomb trials he noted:

In most cases the human subjects were tied to stakes and protected with helmets and body armor. The bombs of various types were exploded either statically, or with time fuses after being dropped from aircraft. . . . The Japanese were not satisfied with the field trials with anthrax. However, in one trial with 15 subjects, 8 were killed as a result of wounds from the bombs, and 4 were infected by bomb fragments (3 of these 4 subjects died). In another trial with a more efficient bomb ("Uji"), 6 of 10 subjects developed a definite bacteremia, and 4 of these were considered to have been infected by the respiratory route; all four of these latter subjects died. However, these four subjects were only 25 meters from the nearest of the 9 bombs that were exploded in a volley.²³

Fell's description corresponds with testimony by Japanese officers and soldiers at the Khabarovsk Trial and the Chinese investigation. For example, Surgeon Major Tomio Karasawa, who was the chief of the Production Division of Unit 731, testified at Khabarovsk:

I was present on two occasions at experiments in infecting people under field conditions at the Anta [sic] Station proving ground. The first experiment was made towards the end of 1943 with anthrax bacteria. Ten persons were used for these experiments. They were brought to the proving ground and tied to stakes five metres apart from one another. A fragmentation bomb was used for the purpose, placed 50 metres from the people to be infected. The bomb was exploded by electric current. Some of the experimentees were infected as a result of these experiments. They were given certain treatments and then sent back to the detachment. I later learned from the report that the persons who had got infected with anthrax subsequently died.¹

Surgeon Major Hideo Sakakibara, who was the Chief of Lin-kou Branch of Unit 731, testified at the Chinese investigation that

he took part in a similar anthrax experiment at the Anda Proving Ground.¹⁰ Masauji Hata of Unit 731 testified that he saw a film that recorded this kind of experiment.⁷

Fell reported the following about plague trials:

d. Bomb trials

A summary of 3 or 4 of the best trials is given below (in these trials the concentration of bacilli on the ground around the subjects was measured with plates). . . . The conclusions from all the bomb trials was that plague [bacilli] were not a satisfactory B.W. weapon due to their instability but that it was much more practical to spread plague by means of fleas.

e. Spraying experiments

The results indicated that this method was highly effective, both with subjects held within a room and also exposed to bacilli spread from aircraft at low altitudes. 50–100 per cent of the subjects used in various trials became infected and the mortality was at least 60 per cent.

f. Stability

No success was attained in stabilizing plague bacilli either in suspensions or by drying.

g. Infected fleas

. . . It was found that infected fleas survived for about 30 days under the best conditions and were infective for that length of time. It was also found that one flea bite per person usually caused infection. It was also found that if subjects moved freely around a room containing a concentration of 20 fleas per square meter, 6 of 10 subjects became infected and of these 4 died. Bomb trials were carried out using the "UJI" porcelain bomb with primacord explosive. The fleas were mixed with sand before being filled into the bomb. About 50 per cent of the fleas survived the explosion which was carried out in a 10 meter square chamber with 10 subjects. 8 of the 10 subjects received flea bites and became infected and 6 of the 8 died.²³

Surgeon Major General Kiyoshi Kawashima of Unit 731 testified at Khabarovsk about an experiment in the summer of 1941:

The persons used for these experiments, fifteen in number, were brought from the detachment's inner prison to the experimental ground and tied to stakes which had been driven into the ground for the purpose. Flags and smoke signals were used to guide the planes and enable them to find the proving ground easily. A special plane took off from Pingfan [sic] Station, and when it was over the site it dropped about two dozen bombs, which burst at about 100 or 200 metres from the ground, releasing the plague fleas with which they were charged. The plague fleas dispersed all over the territory.

A long interval was allowed to pass after the bombs had been dropped in order that the fleas might spread and infect the experimentees. These people were then disinfected and taken back by plane to the inner prison at Pingfan Station, where observation was established over them to ascertain whether they had been infected with plague.¹

Fell also reported a trial of spreading glanders by bombing: "Only one trial was conducted using 10 human subjects and 10 horses. Three of the horses and one of the men became infected,

but there are no data on cloud concentration or density of the organisms on the ground."²³

Surgeon Lieutenant Colonel Toshihide Nishi, who was the chief of the Training and Education Division of Unit 731, testified at the Khabarovsk Trial about gas gangrene bomb experiments in Anda:

In January 1945, by order of the Chief of Detachment 731, I went to Anta [sic] Station. There I saw experiments in inducing gas gangrene, conducted under the direction of the chief of the 2nd Division, Ikari, and the researcher Futaki. Ten prisoners were used for the purpose. They were tied [to] facing stakes, five to ten metres apart from one another. The prisoners' heads were covered with metal helmets, and their bodies with screens.

Each man's body was fully protected, only the naked buttocks being exposed. At about 100 metres away a fragmentation bomb was exploded by electricity, this being the means of causing the infection. All ten men were wounded in the exposed part. The experiment over, the ten men were put in a special automobile and sent back to the prison at Pingfan Station. I later asked Ikari and researcher Futaki what the results had been. They told me that all ten men had been injured and died of gas gangrene.¹

Chemical weapon experiments. A report authored by unknown researcher in the Kamo Unit (Unit 731) describes a large human experiment of yperite gas (mustard gas) on September 7–10, 1940. Twenty subjects were divided into three groups and placed in combat emplacements, trenches, gazebos, and observatories. One group was clothed with Chinese underwear, no hat, and no mask, and was subjected to as much as 1,800 field gun rounds of yperite gas over 25 minutes. Another group was clothed in summer military uniform and shoes; three had masks and another three had no mask. They also were exposed to as much as 1,800 rounds of yperite gas. A third group was clothed in summer military uniform, three with masks and two without masks, and were exposed to as much as 4,800 rounds. Then their general symptoms and damage to skin, eye, respiratory organs, and digestive organs were observed at 4 hours, 24 hours, and 2, 3, and 5 days after the shots. Injecting the blister fluid from one subject into another subject and analyses of blood and soil were also performed. Five subjects were forced to drink a solution of yperite and lewisite gas in water, with or without decontamination. The report describes conditions of every subject precisely without mentioning what happened to them in the long run.³⁷

There are other documents describing similar chemical weapon experiments. In his log of April 21, 1939, Surgeon Colonel Setsuzo Kinbara wrote about a "Report of Special Tests in Manchuria" that was presented at the Department of Army by Surgeon Lieutenant Colonel Kondo of the Army Science Institute. These "tests" seem to have been performed jointly by the Army Science Institute, the Kwantung Army Chemical Department, and Unit 731. Kondo reported results as follows. About cyanide fume, he noted that "subjects became unconscious in 4–6 minutes. Since the results of human being and guinea pig are the same, we can bring latter."³⁸ About yperite and lewisite, he wrote that "treatments are effective if done in 30 seconds. Direct disinfection causes heat and burn."³⁸

Similarly, on November 19, 1942, Lieutenant Colonel Kumao Imoto wrote in his log about "A Study of 'Cha'"—meaning cyanide

gas. Imoto wrote, "50 kg blow guns were placed at 25 m intervals for 1000 m in width. When a total of 17.5 tons of cyanide fume was blown from these guns and covered the area of 4 km in depth, death rate of the subjects placed at 2 km away from the guns was 100%, while that at 4 km away was 50%. With a density of 1500 mg/m³, subjects died within two minutes."³⁹

Williams and Wallace report this description of a cyanide bomb experiment by an anonymous researcher of Unit 731 Dalian Branch:

They used a gas bomb newly developed by Unit 516 for human experiments conducted at Hailar. Nearly 100 marutas [subjects] were used and, except one, all of them were killed. Their bodies were carried by truck, ten or twenty at a time, and transported to Haruarushan where tents had been erected for a pathologist to carry out a pathological autopsy. I wasn't involved in the dissection. The person who actually did the dissection was Dr. Okamoto. I had to wait outside the tent to obtain the blood that had been recovered from various organs of the autopsies and placed in tubes, and took these to the military hospital in Hailar. There I checked the contents of cyanide in the blood. That was my job.²

At the Khabarovsk trial, Senior Sergeant Kazuo Mitomo of Unit 100 described poison experiments in which he helped researcher Tsunetaka Matsui:

Experiments on human beings were performed in August–September 1944. These experiments took the form of giving experimentees, without their knowledge, soporific drugs and poisons. The experimentees included 7–8 Russians and Chinese. Korean bindweed, heroin and castor-oil seed were among the poisons used in the experiments. These poisons were put in the food.

The poisoned food was given to the experimentees five or six times over a period of two weeks. Korean bindweed was used mostly in soups, I think heroin in porridge, while tobacco was mixed with heroin and bactal. After eating the soup mixed with Korean bindweed the experimentees dropped off into a deep five-hour sleep 30 minutes or an hour later. After two weeks the experimentees were so weak that they could no longer be used. . . .

For purposes of secrecy all the experimentees were put to death. . . . There was the case of a Russian experimentee who, on the orders of Matsui, a researcher, was put to death with an injection of one-tenth of a gram of potassium cyanide. . . . I made the injection of potassium cyanide. . . . I dissected the body at the detachment's cattle cemetery.¹

Poison experiments were also performed at other EPWSDs. Engineer Major Shigeo Ban of the Army 9th Technology Institute (Noborito Institute) confessed to performing poison experiments at Unit 1644 in Nanjing. Early in May 1941, the Army General Staff Corps ordered Ban and his eight colleagues to visit Unit 1644 to test the toxicity of a newly developed poison, acetone cyanhydrin, in humans. In 1993, Ban wrote:

Director Shinoda of Noborito Institute met Commander Shiro Ishii of Unit 731 at the General Staff Corps and asked for cooperation with this experiment. Ishii freely agreed. Unit 731 was established as the Japanese Army's secret biological warfare unit, but in its pharmacological division cyanide

compounds were also studied. . . . According to the program, the experiment would continue for about a week, the experimenter would be an army surgeon of Unit 1644, and researchers of Noborito Institute would support him. The subjects were captive soldiers of Chinese Army or the condemned for general crimes. The number of the subjects was about fifteen. . . .

The aims of the experiment were to determine lethal dose of acetone cyanhydrin, to observe symptoms, and to compare it with potassium cyanide. The results of deglutition and injection experiments demonstrated that, as had been predicted, both forms of cyanide made almost the same progress from administration to death and showed almost the same effects at dissection. Injection was most effective, hypodermic injection was enough.

The lethal dose of acetone cyanhydrin was about 1 cc (1 g), whose effect appeared in a few minutes and led to death in 30 minutes. But it depends on constitution, sex, and age, in some cases it took from several to more than ten hours to die. We could not determine it precisely. Anyway, acetone cyanhydrin begins to take effect in seconds, though it takes a little more time than potassium cyanide.⁴⁰

These passages show that the Ishii medical network had close connections with other science and technology institutes, and that the Army used Ishii's EPWSDs as laboratories for human experimentation.

Ban, who died soon after writing these passages in November 1993 at the age of 87, expressed deep remorse about this experiment:

Even though it was on captive soldiers and the condemned, inhumane and horrible human experimentation was performed. Belonging to the dark side of wartime, this fact has been passed over in silence. But now I want to disclose it. By revealing this historic fact now I want to offer my sincerest prayer for the repose of their soul and for world peace.⁴⁰

Cover-Up

Ishii's medical network suddenly collapsed in August 1945 when the Soviet Union declared war on Japan and advanced into Manchuria. The Japanese Army immediately decided to withdraw all human experimentation units from China and to destroy evidence of medical atrocities. At Unit 731, all the surviving captives were killed, cremated, and cast into the Songhuajiang River. The main building with its special prisons was totally destroyed by artillery. Its surgeon officers, researchers, workers, and soldiers were hurriedly evacuated in specially chartered trains and ships. Most succeeded in escaping and returned to Japan. In Tokyo, the Epidemic Prevention Laboratory, headquarters of Ishii's network, had already been destroyed by U.S. air raids in March and May of 1945. But Ishii and his colleagues held onto their biological warfare data.

Although the United States occupied Japan after Japan's surrender on August 15, 1945, General Headquarters/Supreme Command for the Allied Powers (GHQ/SCAP) did not investigate medical crimes. Instead, investigators from the U.S. Army Chemical Corps in Camp Detrick, Maryland, which oversaw U.S. chemical and biological warfare efforts, sought the biological warfare data that Ishii and his colleagues had accumulated—so

that the United States could catch up with the Soviet Union and other countries in biowar research and development.^{3,31,41,42} The Soviets had begun research in biological warfare in 1928, but the United States had not started it until 1942. The Cold War had already begun to emerge, and U.S. officials were under pressure to surpass Soviet capabilities in all fields.

In return for the Japanese data, Lieutenant Colonel Murray Sanders, the first Chemical Corps investigator, asked General Douglas MacArthur and General Charles Willoughby, a close MacArthur aide, to promise Ishii and his researchers immunity from war crimes charges in September 1945. Ishii and his colleagues gave up some data, but they concealed from Sanders and his successor, Lieutenant Colonel Arvo T. Thompson, that the data were from experiments with humans. The United States did not obtain evidence of deadly human experiments until 1947.

Early in January 1947, the Soviet Union sought the extradition of Ishii and his researchers for investigation of their experiments, which the Soviets had learned about from captured officers and soldiers of Ishii's network. The Soviets also wanted the biowar data and threatened to reveal the Japanese medical atrocities at the International Military Tribunal for the Far East—the Tokyo Tribunal, which conducted the war crimes trial of top Japanese leaders from 1946 to 1948—if the United States did not share the information. United States officials dismissed this threat—the United States controlled the Tokyo Tribunal—but then began to investigate the Japanese researchers more closely.

At this point, U.S. officials recognized that human experiments had occurred, and the immunity that they had granted to Ishii and others now became a problem. In Nuremberg, the United States was prosecuting Nazi doctors for their human experiments (see Chapters 2 and 12). MacArthur's headquarters discussed the dilemma repeatedly with officials in Washington, and an inter-agency task force in the U.S. capital finally concluded:

Information of Japanese BW [biological warfare] experiments will be of great value to the U.S. research program. . . . The value to the U.S. of Japanese BW data is of such importance to national security as to far outweigh the value accruing from "war crimes" prosecution. . . . The BW information obtained from Japanese sources should be retained in Intelligence channels and should not be employed as "war crimes" evidence.⁴³

This conclusion was based on close examination of the data that was finally provided by Ishii and his colleagues. The last investigator, Edwin V. Hill, reported to the chief of the U.S. Army Chemical Corps:

Evidence gathered in this investigation has greatly supplemented and amplified previous aspects of this field. It represents data which have been obtained by Japanese scientists at the expenditure of many millions of dollars and years of work. Information has accrued with respect to human susceptibility to these diseases as indicated by specific infectious doses of bacteria. Such information could not be obtained in our own laboratories because of scruples attached to human experimentation. These data were secured with a total outlay of ¥250,000 to date, a mere pittance by comparison with the actual cost of the studies.⁴⁴

Who in the United States ultimately made the decision on immunity from war crimes prosecution? The fact that the

State-War-Navy Coordinating Subcommittee to the Far East approved immunity indicates that both the armed forces and the Department of State were involved. But no documents have been found that determine how much President Harry S. Truman knew about the medical atrocities.

Most officers and researchers involved in Japan's human experimentation program, including Ishii himself, never faced war crimes charges. Ishii died of laryngeal cancer in 1959, at the age of 67. Many army surgeon officers and researchers gained positions in medical schools, national institutes, or hospitals. Some practiced in their own clinics; some others established pharmaceutical companies.²

Although failing to get custody of Ishii or access to his data, the Soviet Union brought 12 captured officers and soldiers to trial before an open military tribunal at Khabarovsk in December 1949, commonly called the Khabarovsk Trial.¹ The accused included the Captain General of the Kwantung Army, Otozo Yamada, six army surgeon officers, and two veterinarian officers. Six of the accused were from Unit 731 and two from Unit 100. They were all sentenced to confinement in a labor correction camp for sentences that ranged from 2 to 25 years, but they returned to Japan by 1956 when the Soviet Union and Japan resumed diplomatic relations.

The Soviets had intended to spread the news of the medical atrocities worldwide, but because the prosecutors, lawyers, and judges were all Russian, and there were no reporters from abroad, the proceedings drew little attention. The United States succeeded in branding the trial as communist propaganda.

The People's Republic of China also tried Japanese war criminals before military tribunals in 1956, but only one surgeon officer of Ishii's network was included. None of these defendants received a death sentence, and all returned to Japan by 1964.

Causes

Racism, ethnic prejudice, anticommunism, and lack of respect for individual rights are often blamed for creating the atmosphere in which such human experimentation could take place. But there were other causes, too.

First, Imperial Japan had become more and more dominated by the military in the 1930s. As the invasion of China grew wider and deeper, militarism became more powerful in the Japanese parliament, known as the Diet. For example, the National Mobilization Law in 1938 enabled the government to call out any resources necessary for operations without the Diet's permission. Because the Emperor officially commanded the Imperial Japanese Armed Forces, army leaders claimed to be acting with the authority of the Emperor even when they really were operating on the basis of their own judgment. In these circumstances, army surgeons might gradually have convinced themselves that everything was justifiable when it was done for the sake of the country and the Emperor.

Second, Japanese military rule in China was known to be very cruel. Chinese people who were forced to work in Japanese factories were treated violently and often killed. The murders during the experiments were only one part of a huge massacre by the Japanese army. Doctors in Ishii's network might have gotten used to treating foreigners harshly, too.

Third, because human experimentation was performed strictly behind closed doors, researchers might have lost a common sense

of humanity. The Imperial Japanese Government was in part afraid of severe international condemnation if such atrocities became widely known overseas. Therefore, the fact of deadly human experimentation was treated as the "secret of secrets." The existence of the laboratories was completely hidden from the public, making it possible for researchers to ignore the constraints of medical ethics.

Most of the doctors who performed the deadly experiments were academic researchers who had already been professors at leading medical schools. They were temporarily employed by the army. Why did they join Ishii's network? Was it impossible to avoid participation?

In Imperial Japan, pressure for their participation was high. As militarism grew powerful, cooperation with the military was common. Researchers would be considered traitors ("Hikokumin") if they refused to participate. Most accepted their fate without trying to resist, even when they knew what they would be assigned to do. Former Army Surgeon Ken Yuasa, who performed deadly surgical training at Luan Army Hospital, recalls the moment when he was ordered to perform a vivisection:

When I was told that, I felt tense and thought, "Ah, this is it." It was whispered among students in my schooldays at Jikeikai Medical University that an army surgeon sent to China risked having to perform vivisection. Students knew that most of those who became army surgeons and went to China did it. Since I became an army surgeon, I recognized that I couldn't escape from it.⁶

In addition, many researchers were ordered to go to China by their academic superiors. In Japanese medical schools, even now, head professors exercise supreme power over their staffs. Usually, there is only one professor in each "Ikyoku"—roughly speaking, a department, but with much more authority than university departments in most countries. The Ikyoku system is unique to the Japanese medical profession. The Ikyoku functions as an office of clinical practice, a faculty for graduate education, and a research laboratory. Even after earning a doctoral degree, researchers devote themselves to the Ikyoku, hoping to be nominated by the head professor as his successor. They cannot oppose their professor because refusal to follow the professor's order (for example, to go to a certain facility) would result in their excommunication from the Ikyoku and the destruction of their academic careers.

With research facilities and funding in short supply, head professors were willing to cooperate with the army and Ishii. They promised to send their best disciples to Ishii's factories; in return, the army supplied research equipment to the professors. The medical atrocities would have been impossible without the support of the leading medical professors. Therefore, not only the army but also the Japanese medical profession was guilty of the crimes.

But some researchers assigned to Unit 731 seemed to hate being there and strenuously asked their head professors for another position in Japan. In some cases, the professors accepted such appeals, probably because they valued their disciples' talents. Thus, a head professor's order seems to have been sufficient reason to go to the Ishii network, but not necessarily a strong enough reason to stay over the long term.

However, Ishii's facilities were luxurious places for the researchers. For example, the annual budget of Unit 731 was 10 million yen—equal to about 9 billion yen in modern currency

(\$80 million U.S.). Half of this budget was for research, and the other half was for labor costs for about 3,000 employees.¹ The salaries were high, and the food served there was wonderful. In fact the laboratories of Unit 731 were among the most luxurious in the Japanese Empire.

Moreover, researchers in Ishii's network could study diseases that were hardly ever observed in the Japanese homeland—such as epidemic hemorrhagic fever, plague, typhus, and severe frostbite. The researchers could thus produce brilliant scientific achievements. That's why they could gain good positions in the Japanese medical establishment after the war.

Enduring Legacy

In cooperation with the United States, Japan hid the medical atrocities from both the international and domestic public for decades. Testimony from the Khabarovsk trial was regarded as false communist propaganda. Researchers who confessed to conducting such experiments in China were considered to have been brainwashed. But in 1981, popular writer Seiichi Morimura published a bestselling book about Unit 731 that included testimony by many of its anonymous soldiers.⁴⁵ In the same year, historian Keiichi Tsuneishi published his first extensive study of Unit 731.¹⁸ Because of this, these atrocities became widely known in Japan, and historical studies have advanced greatly since then as significant documents have been found in Japan, the United States, China, and the former Soviet Union.

Outside Japan, the Imperial Japanese medical atrocities did not become widely known until even later. In Britain and the United States, the first comprehensive book in English was published at the end of the 1980s² and another essential study was published in the mid-1990s.³ Even in China, there was little modern research into the human experiments before the testimony of Japanese war criminals was published in 1989.⁷

Today, more than 60 years after the end of World War II, the U.S. government is no longer closing its eyes to the record of human experimentation. The government has refused to allow former employees of Unit 731 into the country on the ground that they are war criminals. In 1998, Yoshio Shinozuka was denied entry, and deported to Japan from Chicago's O'Hare International Airport, even though he had been invited to the country and intended to confess his Unit 731 crimes in public symposia. This attitude is hypocritical because the U.S. government must share in the responsibility for keeping these experiments secret because of its immunity deals with the researchers.

On the other hand, the Japanese government is still keeping silent on this issue. It acknowledged in the Diet in 1982 that Unit 731 surely existed, but has never explained what was done there. The government and conservative nationalists in Japan are still hiding the historical truth. Moreover, it seems they wish the truth would be forgotten. One of the most enduring legacies of these experiments is therefore the silence that continues to surround them.

Within the Japanese medical profession, the subject of *Jintai Jikken* (human experimentation) became taboo after the end of World War II. Many of the researchers who performed these experiments became prominent figures in academia. If junior researchers speak of human experimentation, they might touch on their head professors' "secret of secrets" and wreck their own academic careers. Therefore, not only Ishii's researchers them-

selves but also their disciples have hardly mentioned this issue publicly.

On the other hand, most of the public has thought it unnecessary to discuss human experimentation seriously. Because the Japanese and U.S. governments have been fairly successful in covering up the experiments, even today most people find it hard to believe that medical doctors, who devote themselves to saving lives, really treated human beings like guinea pigs. Those who found the Khabarovsk trial to be credible and who appealed for public inquiry were often sneered at.

This failure to examine history publicly permits most Japanese citizens to regard human experimentation as a barbarism performed by mad doctors—totally different from typical medical procedures carried out by normal doctors. As a matter of fact, many cases of abuse of humans in research have been reported in newspapers, journals, and TV in postwar Japan.⁴⁶ However, these were presumed to be exceptional deviations. The Japanese public has avoided reflection on human experimentation in both military and civil medicine.

These circumstances are reflected in the field of medical ethics. The failure to confront reality means that Japanese medical ethics lack a framework for critically discussing and evaluating human experimentation. Medical ethicists have seldom tried to draw from historical cases of abuse the guiding principles that should regulate medical research. There has been little discussion, publication, or teaching about protection of humans in research. Even in postwar cases of abuse, journalists and ethicists have focused discussion on a case-by-case basis and failed to derive general principles. Consequently, politicians have never proposed a blanket law to govern medical research, and the government has never articulated a general policy for the protection of humans in research. So far, Japanese guidelines for medical research are only patchworks of articles transferred from international guidelines such as the Declaration of Helsinki. They have not been derived from the lessons of history, especially of the past medical massacre performed by our own doctors.

This is a poor ethical state for a country boasting of its economic development and trying to lead world medical science. Looking into and evaluating one's own past is one of the prime imperatives of ethics. In order to be acknowledged as an ethical country, Japan must admit its past deeds, inquire into the truth, apologize to and compensate the victims for their suffering. This will surely lead to the establishment of true clinical research ethics in Japan.

Note on Translation of Sources

In this chapter, Japanese names are written in Western form, given name first and family name last. In many East Asian languages, including Japanese and Chinese, names are spoken and written in the opposite order, family name first and given name last. Some Western publications and references follow the Eastern style. All quotations from Japanese documents in this chapter were translated into English by the author.

Acknowledgments

A draft of this chapter was read at the symposium "Japanese Human Experimentation in Wartime China: Inquiries into its

Historical, Political, Cultural and Ethical Issues,” at the 22nd International Congress of History of Science in Beijing, China, on July 29, 2005. I am grateful to its participants for valuable comments. I also greatly thank the editors of this volume for advice on improving the chapter.

The Randomized Controlled Trial of Streptomycin

Background

In 1946, as word spread throughout the British Isles about a new and potentially life-saving substance called streptomycin, patients and doctors began besieging the government with requests for the drug. The vast majority of requests were for treatment of tuberculosis, which in that era was killing some 25,000 Britons each year. In July 1945, the Labour Party had swept to its first majority government, on the slogan “Fair Shares for All.” Though patients did not speak in terms of a “right to treatment,” even after the passage of the National Health Service Act establishing universal health care for the first time, the mood of the country was such that to have the old webs of influence carry too much weight in the distribution of streptomycin would have been politically intolerable. The medical authorities needed a fair and equitable means of distributing the drug. But knowledge about which patients, if any, were most likely to benefit in the long term was still very limited. And would it be worthwhile for British pharmaceutical firms, still operating under industrial controls remaining in place from the war effort, to be allowed to produce the drug?

Thus it was that the Medical Research Council (MRC) of the United Kingdom began planning in 1946 for a series of clinical trials of streptomycin. Of these experiments, by far the best known is the trial of streptomycin in pulmonary tuberculosis, published by the *British Medical Journal (BMJ)* in October 1948.¹ This trial was a model of meticulousness in design and implementation, with systematic enrollment criteria and data collection compared with the ad hoc nature of much other contemporary research, even other trials conducted under the auspices of the MRC.

A landmark because of both its methods and its findings, it conclusively confirmed streptomycin as the first effective chemotherapy for pulmonary tuberculosis, as a number of U.S. studies had been suggesting. By 1950, the MRC was trumpeting it as the first statistically controlled study of its kind.² It is generally recognized as the first randomized curative trial,³ even if subsequent historical research should some day uncover an obscure earlier trial fitting that description, the MRC’s pulmonary tuberculosis trial will remain among the most methodologically influential clinical experiments ever conducted.

It is commonly stated that because of a shortage of dollars for imports, only a small amount of U.S. streptomycin could be used in the trial, and that therefore it was ethically justifiable to provide streptomycin to only half the patients.^{2,4–10} Such a picture of the ethics of the trial is incomplete: Although the research was conducted before principles of informed consent had been fully articulated, the MRC may be criticized for withholding from patients the information that they were part of a controlled trial, and the government’s streptomycin program as a whole involved deception of the British public.

Tuberculosis and Experimental Methods

The annual rate of mortality from tuberculosis in England and Wales declined dramatically and fairly steadily from roughly 330 deaths per 100,000 population in the middle of the 19th century to roughly 60 per 100,000 just before streptomycin was introduced in the mid-20th century, aside from increased rates during the two world wars¹¹ (see Figure 4.1). The reasons for this decline have been hotly dis-

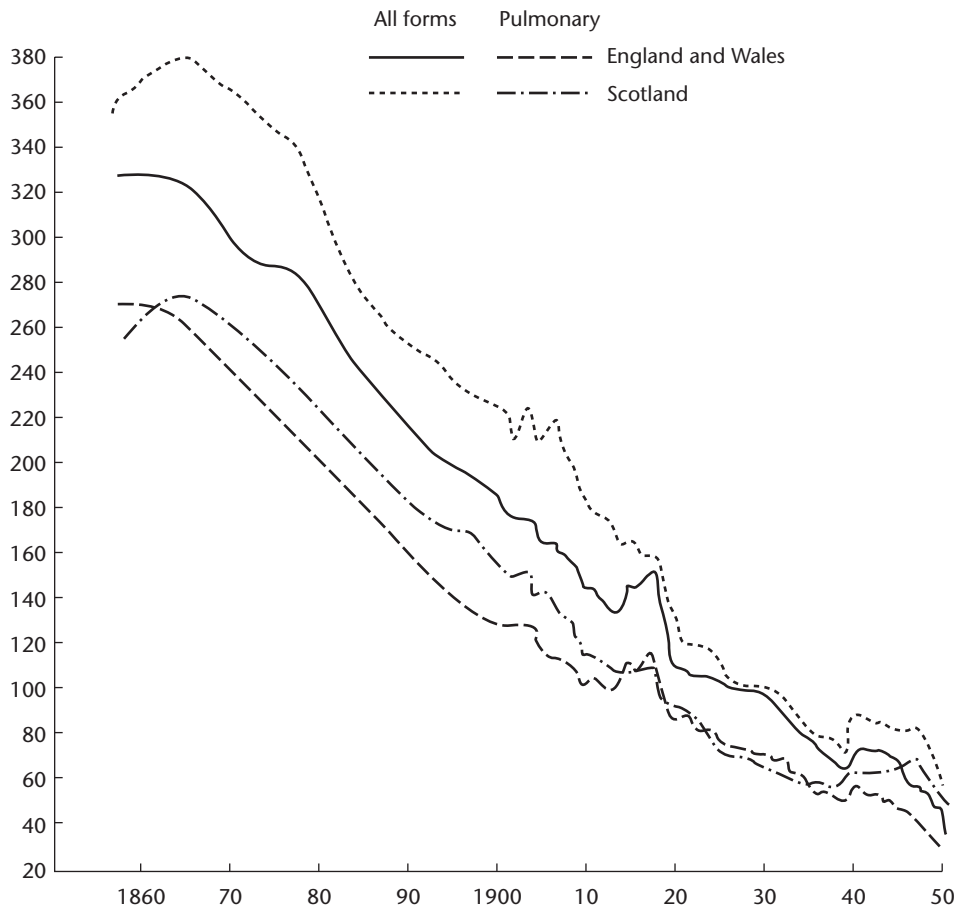

Figure 4.1. Standardized Death Rates from Tuberculosis (All Forms and Pulmonary) per 100,000 Population, England and Wales, and Scotland, 1850–1950. Source: Linda Bryder, *Below the Magic Mountain*, New York, N.Y.: Clarendon Press, 1988, p. 7. Reproduced with the permission of Linda Bryder and Oxford University Press.

puted by epidemiologists and demographers; what is clear, though, is that it occurred in the absence of effective drug treatment.

Because tuberculosis, especially in its pulmonary forms, exhibited spontaneous recoveries, numerous treatments were adopted on the basis of rather slim clinical evidence, only to be discredited later.^{12–14} Perhaps most notorious of these was sanocrysin, a gold compound discovered in 1923. In 1931, a team in Detroit, Mich., divided 24 patients into two groups, with patients paired as closely as possible according to criteria such as age and severity of disease. A single flip of a coin decided which group would receive sanocrysin and which group injections of distilled water. The control group fared better.^{12,15,16} Despite this experiment and continuing evidence of toxicity, sanocrysin remained popular until about 1935 and was still used occasionally as late as 1947. A survey published in 1940 showed some specialists continuing to use it “because one must do something” rather than because they believed in it.¹¹

Sanatorium treatment was widespread. In Britain it often involved “work therapy” along with a variety of social interventions, but bed rest was also common. The latter enjoyed greater favor in the United States. Artificial pneumothorax, one form of “collapse therapy,” consisted of collapsing one lung by the injection of air into the chest cavity outside the lung.¹¹ The theory was that without the continual movement of breathing, the lung tissue would have a better chance to heal, and there was some evidence,

albeit not conclusive, that this was effective.^{17,18} Only one lung of a patient could be treated in this way at a time, of course, so patients with tuberculosis in both lungs were considered less promising candidates for pneumothorax.¹¹

In 1944, William Feldman and Corwin Hinshaw, leading tuberculosis researchers at the Mayo Clinic in Rochester, Minn., presented numerous techniques to reduce the possibility of erroneous claims from antituberculosis trials in human patients. Their concepts of clinical trial design attempted to extend controlled laboratory conditions to the bedside. Their guidelines included careful definition of eligible cases to ensure a homogeneous group of cases, X-ray interpretation blinded as to whether patients had received treatment, and “some procedure of chance” in allocating patients¹⁹—ideas all implemented in the MRC’s trial. Feldman and Hinshaw referred to an unidentified study of their own, then under way, which used the toss of a coin to select one member from each of several pairs of patients who had been matched for clinical condition.

In Britain, meanwhile, researchers such as those involved with the MRC’s Therapeutic Trials Committee, which had been created in 1931, were likewise developing controlled clinical experiments. In 1937, *The Lancet* carried a series of articles by Professor (later Sir) Austin Bradford Hill in which he attempted to explain to medical practitioners some introductory principles of medical statistics.²⁰

Hill promoted the use of random allotment primarily to reduce bias by balancing the known and unknown characteristics of the treatment groups.²¹ This rationale was distinct from that of statistician R. A. Fisher, whose theory of randomization emphasized estimation of the uncertainty of experimental findings.²² Uncertainty is now familiar, of course, in the context of opinion polls mentioning the margin of error within which, 19 times out of 20, they are likely to be accurate. As the historian Harry Marks has emphasized, though, statistical estimation of uncertainty has taken hold only slowly and partially within clinical medicine.²²

Hill's 1937 series in *The Lancet* presents alternation—that is, alternating between treatment groups by order of admission to a trial—as simply one way of randomly allocating patients. There is no sign, in other words, of a distinction that would eventually emerge between alternation and randomization. Late in his career, Hill suggested that he had wished to avoid scaring off his audience by discussing more complicated techniques such as the random sampling numbers he would use in the streptomycin trial;⁷ contemporary evidence on this question would be welcome.²³

A procedure of alternation is theoretically open to bias. If the admitting physician knows that the next patient to be entered in the trial at his or her site would definitely fall into the control group, then a prospective patient might conceivably be encouraged to come back a few days later so as to have a better chance to receive the new treatment. Even so, during the Second World War such alternation was considered a satisfactory way of balancing the treatment groups, and indeed Peter Armitage has argued that strict alternation is no more prone to bias than randomization.²⁴ An MRC study of the antibiotic patulin in treatment of the common cold and a Royal Army Medical Corps study of a sulphonamide in bacillary dysentery used alternation; two of the organizers of those trials, Philip Hart and J. G. Scadding, went on to organize the MRC's streptomycin trials.^{3,25–28} Alternation was also used in certain streptomycin trials that followed the famous pulmonary trial.

Intriguingly, the streptomycin trial was not the first to use randomization of individual patients, as Iain Chalmers has pointed out.²¹ In a comparative trial of vitamin supplements published late in 1937, patients randomly assigned themselves to treatment groups by drawing beads from a box.²⁹ No evidence has been presented, though, that this vitamin study had any influence on the subsequent development of experimental design.

The Development of Streptomycin

The antibiotic streptomycin, like penicillin before it, was subject to extraordinary commercial and public pressures.

Penicillin was discovered in 1928 by Alexander Fleming at St. Mary's Hospital in London, England.³⁰ Its therapeutic potential lay largely unexplored, though, until a decade later, when a team of researchers at Oxford University, led by Howard Florey and Ernst Chain, tested the substance in animals and described how to produce it in significant quantities. The first clinical trial, in six patients, was completed in June 1941. At the Oxford researchers' suggestion, the U.S. government and selected U.S. pharmaceutical firms collaborated on production. Under wartime conditions, proprietary rights were set aside and competing manufacturers exchanged information freely. Production increased from 425 million units in June 1943 to about 460 billion units in March 1945, at which time the drug became generally available to civilian patients in the United States; during the same interval, the cost per

100,000 units (roughly 100 milligrams) plummeted from \$20 to less than \$1.³¹

The U.S. Committee on Medical Research rationed civilian supplies of penicillin in the name of science.^{16,32} Centralized control of research during wartime allowed some medical scientists the opportunity to try implementing innovative approaches they had long favored on methodological grounds, though cooperative trials were not without their difficulties. In a large trial of penicillin in syphilis, many of the physicians deviated from the protocol, leaving data that could not be analyzed. After extensive internal debate, the U.S. National Research Council agreed to test a new sulfonamide drug, sulfathiazole, on prison volunteers experimentally infected with gonorrhea, only to abandon the study partway through when it appeared that technical problems would keep it from yielding sound conclusions.¹⁶ Chester Keefer of the U.S. Committee on Chemotherapeutics initially ruled that penicillin should not be used in subacute bacterial endocarditis, in which long-term treatment at high dosages would be required—supposing that the drug was effective at all. Some clinicians disregarded this restriction and showed that penicillin did often control this previously fatal infection, as was also later confirmed by one of the MRC's penicillin studies;³¹ MRC insiders have pointed to this study as a methodologically sound use of historical controls.^{6,33}

In the late 1930s, Selman Waksman's microbiology laboratory at Rutgers University in New Brunswick, N.J., began systematically screening antibiotic substances for possible therapeutic activity. A large manufacturer of pharmaceuticals and fine chemicals, George Merck and Company, based in nearby Rahway, N.J., agreed with Waksman in 1940 to develop any promising substances. Streptomycin was isolated around November 1943 by Albert Schatz, a Ph.D. student in Waksman's department^{34,35} (see Figure 4.2). (A bitter dispute over royalties and scientific credit for the discovery broke out in 1949 between Schatz and Waksman and was fully resolved only after several decades.) On the strength of clinical findings in tularemia (rabbit fever), influenzal meningitis, and gram-negative urinary tract infections, the U.S. War Production Board decided in June 1945 to permit Merck to proceed with a new plant in Elkton, Va., in which the company invested \$3.5 million³⁶ (see Figures 4.3 and 4.4). In the month of October 1945, before this plant became operational, Merck made three kilograms of streptomycin. A year later, it was making 100 kilograms per month. Some 10 or 12 other firms belonging to the U.S. streptomycin consortium tried to produce the drug—most with reportedly little success.³⁷

In December 1944, Feldman and Hinshaw showed “striking” results of streptomycin in tuberculosis in experimentally infected guinea pigs, the animal model of choice. A subsequent study, published in October 1945, examined 20 animals treated with streptomycin and 10 untreated controls and showed the drug to effectively resolve or suppress established experimental infections in guinea pigs.³⁸ In September 1945, the Mayo Clinic reported preliminary clinical trials in tuberculosis, with cautiously optimistic conclusions.³⁹

Meanwhile, research elsewhere in the United States was proceeding apace. In September 1946, Keefer and his colleagues from the Committee on Chemotherapeutics published their findings from 1,000 cases of disease treated with streptomycin.^{40,41} In the summer of 1946, the U.S. Veterans Administration, with 9,000 tuberculosis patients in its hospitals, began a large trial of streptomycin in treatment of men with pulmonary tuberculosis.⁴² Fearful of the political repercussions of using an untreated control

group, the researchers proceeded without one. In contrast, the U.S. Public Health Service agreed in May 1947 that patients in its study would be randomly allocated to the streptomycin treatment group or a control group without the drug.¹⁶

Early in 1946, two British pharmaceutical firms were hoping to begin large-scale manufacture of streptomycin: Glaxo Laboratories, based in Ware, north of London, and the Boots Pure Drug Company, based in Nottingham in the Midlands. They approached the Ministry of Supply, the wartime ministry that continued to oversee virtually all industrial activity in the country. Only if the Ministry of Supply granted them “priorities” would the companies be permitted to allocate to the project the necessary building materials, steel tanks, industrial solvents, and skilled laborers, all of which were in short supply. There was thus a key industrial

incentive to know how effective streptomycin was. Then, between July 15 and 20, William Feldman’s lecture tour through London and Oxford stirred up medical interest—much to the consternation of the Ministry of Health, which foresaw a public demand that could not be met. The Mayo Clinic experimentalist’s presentation included a highly persuasive graphic illustration of the laboratory evidence of the effectiveness of streptomycin in tuberculosis in guinea pigs³⁸ (see Figure 4.5).

The Planning of the British Program of Streptomycin Research

The MRC first became involved with streptomycin in September 1945, when one of the members of its Penicillin Clinical Trials Committee, L. P. Garrod, read of the first clinical use of streptomycin, in a typhoid outbreak in Philadelphia. The mortality in streptomycin-treated patients was 40%, considerably higher than the 9% in untreated patients.⁴³ Garrod remarked dryly, “The evidence of curative action is not wholly convincing,”⁴⁴ but he nonetheless requested a supply of streptomycin to try treating a patient of his who was described as an intractable typhoid carrier. At the time, though, the drug was not to be found in the United Kingdom, and Garrod’s request was deferred.

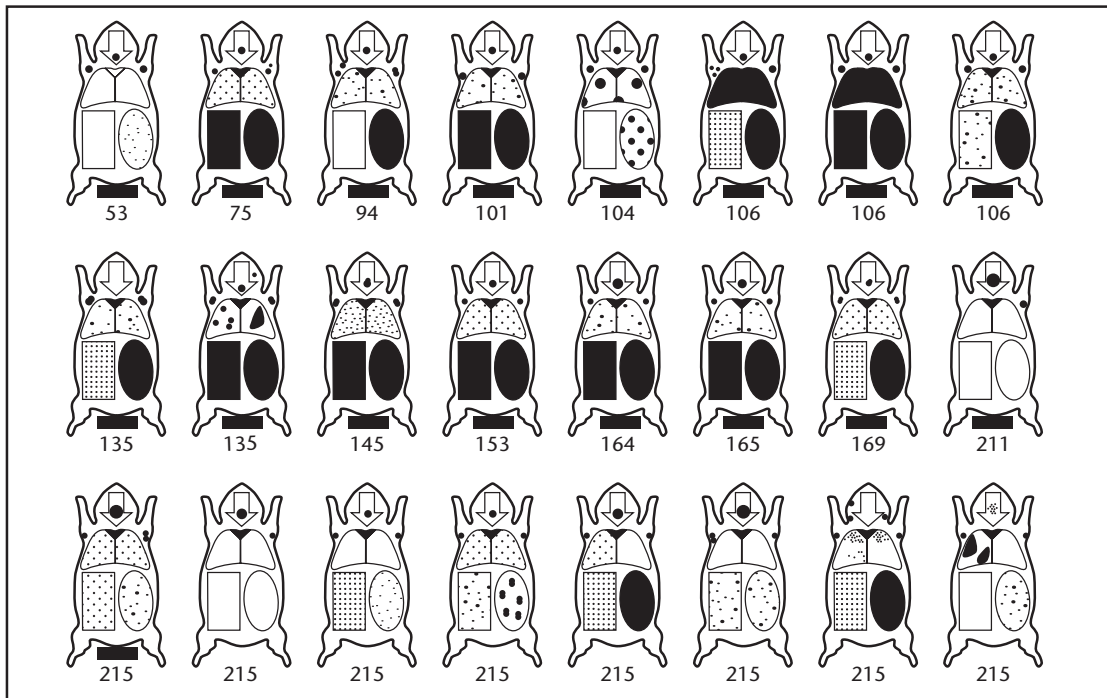

In March 1946 the MRC Secretary, Sir Edward Mellanby, tried to procure streptomycin for one of his close relatives, himself a medical man. He asked pharmacologist A. N. Richards at the University of Pennsylvania, who was an adviser to Merck. Richards at first agreed to help Mellanby but then was forced to retract his offer because of the restrictions imposed on streptomycin distribution in the United States.⁴⁵

The Ministry of Supply and Ministry of Health decided in June 1946 that clinical trials of British streptomycin needed to be run, but the health official in charge dawdled for weeks, until finally Harold Raistrick, the Ministry of Supply representative, took action himself. Four days after Feldman’s final lecture in Oxford, Raistrick collared the MRC Secretary. Suddenly under pressure to say how much of the drug would be needed, Mellanby came up with the idea of using 100 patients. To treat that many patients for six months, he told Raistrick, 75 kilograms of streptomycin would suffice.⁴⁶ Boots, Glaxo, and a third manufacturer, the Distillers Company (which had been brought into the British penicillin project because of its expertise in fermentation technology), were expected to have the drug ready soon for clinical testing.

Geoffrey Marshall (Figure 4.6), a respected consultant at the Brompton Hospital, Britain’s most prestigious institution for the treatment of tuberculosis, chaired a hastily assembled conference of clinicians, all of them with experience in the treatment of tuberculosis. Not surprisingly, they decided that the main trial would focus on pulmonary tuberculosis, though consideration was also given to leprosy.⁴⁷ Hill was not present at this conference, nor at a meeting of a few physicians a few days later at Marshall’s home, at which time it was suggested that control cases were “highly desirable, if not essential, for the main group of broncho-pneumonic cases.”⁴⁸ A few more men, including Hill, were invited to a second streptomycin conference, which was held on August 27.⁴⁹

The Streptomycin Clinical Trials (Tuberculosis) Committee, as it was formally known, was created in October 1946,⁵⁰ with Marshall as chairman and Philip Hart, who later directed the MRC’s tuberculosis research unit, as secretary.⁵¹ Marc Daniels, as the “registrar,” coordinated the clinicians at participating hospitals.

CONTROLS

STREPTOMYCIN SERIES

TREATED AFTER 49 DAYS

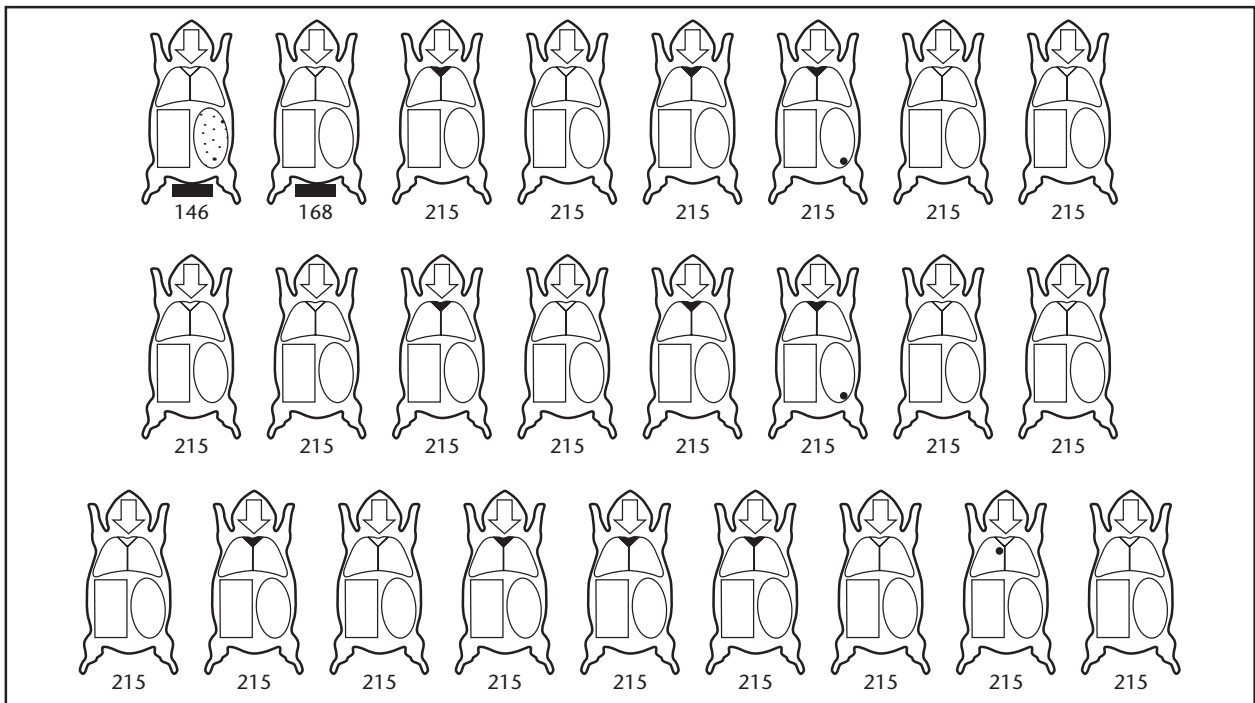

Figure 4.5. Controlled Study of Streptomycin Treatment of Tuberculous Guinea Pigs. Amount of tuberculosis, shown schematically, noted grossly at necropsy in treated and untreated groups of guinea pigs. The number beneath an animal represents the length of life in days after inoculation. A black bar above a numeral indicates that the animal died (third experiment). British regulations permitted the importation of streptomycin for private use, so unknown quantities of the drug circulated around the country. A black market emerged.⁵² In addition, the BBC began broadcasting a series of appeals to the public for streptomycin to be used in medical emergencies it highlighted—typically, cases of tuberculous meningitis in children.⁵³ In the first of many such incidents, in November 1946, one company donated a tiny amount of the drug in the vain hope of saving a young boy who was critically ill in hospital.

In order to manage public demand, MRC officials wanted their research program to absorb any supplies that would be entering the country. The MRC's staff repeatedly told the public that supplies had to be fully restricted to the clinical trials.⁵⁴ These officials reasoned that the scarce and potentially life-saving drug would be used inefficiently if allowed into untrained hands, and they had ample reason to be wary. For example, in one of many poignant cases, a prominent banker had sought the MRC's help in procuring the antibiotic to treat his young grandson, who was dying of leukemia⁵⁵—an indication for which there was no laboratory or clinical evidence to suggest the drug would be effective.⁴⁶

Streptomycin was difficult to manufacture, even more so than penicillin. The process was quite complex and demanded huge amounts of raw materials (see Figure 4.7). Also, contamination from airborne organisms could reduce the yield. The British firms experienced continual production delays, so when a large U.S. shipment became available in mid-November 1946, the MRC leapt at the chance to purchase it.⁴⁶

Research Study Events

The trial was designed “to give a negative or affirmative answer to the question, is streptomycin of value in the treatment of pulmonary tuberculosis?”¹ That is, as the *BMJ* paper emphasizes, it

was not meant to find the ideal dosage or to find the best treatment regimen. Later the tuberculosis committee would investigate, for example, whether pulsed treatment, with several weeks on and several weeks off, in alternation, might help to avoid the development of resistant strains of bacteria.¹ Hill subsequently made a point of recommending that clinical trials test the efficacy (as it has now come to be called) of a strictly controlled treatment regimen, rather than the effectiveness of a treatment in a wide variety of less easily compared circumstances.^{56,57}

The duration of treatment was originally set up to be six months. Once the trial got underway, however, evidence from the Mayo Clinic and from the trial clinicians themselves suggested that the greatest benefit would result during four months of treatment. A shorter course of treatment was therefore implemented as of July 1947. Patients remained in hospital under observation for their final two months in the study.¹

One of the Committee's most important decisions was to restrict admission to a homogeneous set of cases: “acute progressive bilateral pulmonary tuberculosis of presumably recent origin, bacteriologically proved, unsuitable for collapse therapy, age group 15 to 25 (later extended to 30).”¹ Previous clinical evidence suggested that such patients would be more likely to benefit than those with long-established disease, and the similarity of cases meeting these criteria lent credibility to the comparison between the treatment and control group. As it happened, the initial entry criteria were loosened because not enough eligible patients could be found.

The enrollment of control patients who did not receive streptomycin was justified explicitly in the study paper, on the ground that there was not enough of the drug to go around. The control patients did receive bed rest, the then standard treatment.

The story is often repeated that a controlled trial could be run because there were not enough U.S. dollars to import streptomycin.^{2,6–9} The evidence does not really support this after-the-fact explanation. Although supplies of streptomycin in the United Kingdom fell short of demand until 1949, the British government's problems with its balance of payments did not become serious until the MRC's controlled trial was well underway. Export quotas set by the U.S. government, not limits imposed by the British Treasury, determined the quantity of streptomycin that the MRC could obtain. A substantial 50 kilograms (enough to fully treat more than 135 patients) were offered to the British government in November 1946, at a cost of \$320,000, for which the spending of dollars was not an obstacle. It was in April 1947, months after the trial had begun, that the Treasury first implemented procedures requiring high-level approval of the spending of dollars, and even then, the import of a further 50 kilograms of streptomycin was approved with little delay.⁴⁶

The clinicians in the pulmonary tuberculosis trial were not blinded as to the treatment assignment. Patients were not told they were in an experiment at all.⁵⁶ Use of placebo injections was considered at the meeting at Marshall's home but was ruled out by the Committee at its first meeting in November.^{48,51} The Committee's rationale for considering placebos unnecessary was that four-times-daily injections of saline would cause too much discomfort relative to the value they would provide in safeguarding the validity of the study, in that the main comparisons relied upon objective measures: deaths and changes in radiological condition. Patients' X-rays were assessed independently by two radiologists

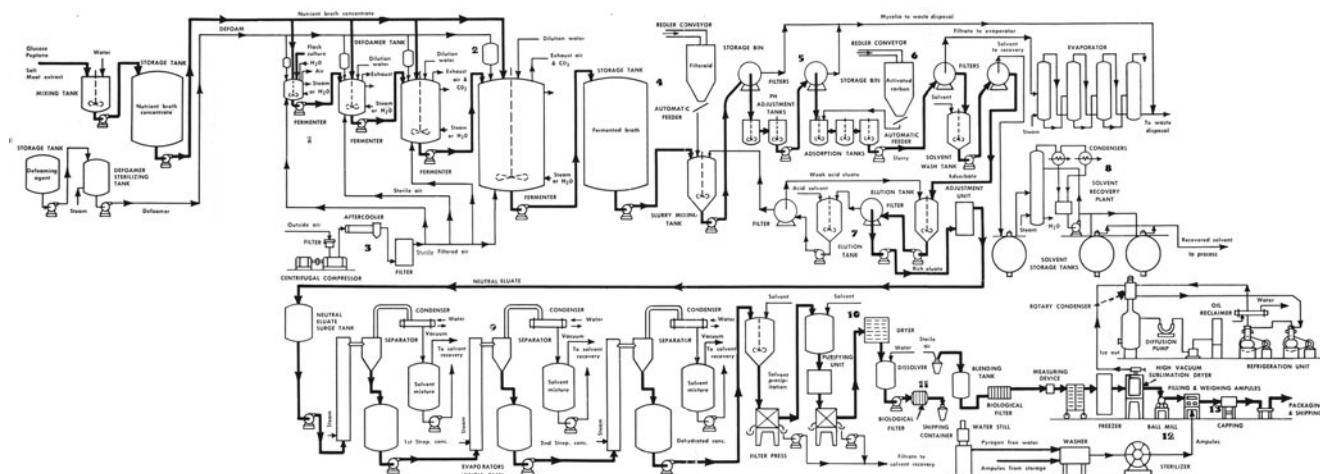

Figure 4.7. Schematic Diagram of the Streptomycin Manufacturing Process. Source: Porter RW. Streptomycin: Engineered into commercial production. *Chemical Engineering* 1946;53(10)94–8, 142–5. Reproduced with permission.

and a clinician, all of whom were blinded with regard to the treatment assignment.

Randomization Versus Alternation

As is well known, Hill instituted a new method in the pulmonary trial, which the tuberculosis committee's report in the *BMJ* describes in detail:

Determination of whether a patient would be treated by streptomycin and bed-rest (S case) or by bed-rest alone (C case) was made by reference to a statistical series based on random sampling numbers drawn up for each sex at each centre by Professor Bradford Hill; the details of the series were unknown to any of the investigators or to the co-ordinator and were contained in a set of sealed envelopes, each bearing on the outside only the name of the hospital and a number. After acceptance of a patient by the panel, and before admission to the streptomycin centre, the appropriate numbered envelope was opened at the central office: the card inside told if the patient was to be an S or C case, and this information was then given to the medical officer of the centre. Patients were not told before admission that they were to get special treatment; C patients did not know throughout their stay in hospital that they were control patients in a special study; they were in fact treated as they would have been in the past, the sole difference being that they had been admitted to the centre more rapidly than was normal. Usually they were not in the same wards as S patients, but the same regimen was maintained.¹

Subsequent accounts have differed somewhat in their characterizations of what was novel about this system.^{6,8,9,33,58–60} Chalmers praises Hart for making clear that a key advantage of Hill's system over alternation was "allocation concealment" at the time patients entered the study.^{3,21,28} That is, randomization permitted, though it did not ensure, concealment from the admitting physician of the treatment group to which a prospective patient entering the

study would be assigned. Marks, following Chalmers, suggests that this was intended "to prevent physicians from cream skimming—selectively assigning healthier patients to the experimental drug."²²

There is room for further research and reflection on the topic, but, given that access to treatment was such a sensitive issue, it may be that the key issue was centralization of the experimental "decision"—impersonal as it had become—to assign any individual patient to the control group. Surely some observers would have seen this as consigning some patients in the trial to inferior care, despite the existing uncertainties about the value of the new drug and despite the point, brought out in the *BMJ* report, that most control patients were admitted to hospital within a week. Thus it may be that the main significance of Hill's scheme lay in keeping treatment allocation out of the hands of those who came face to face with patients and were responsible for their care. In the words of the *BMJ* leading article that introduced the report, the new method of random allocation "removed personal responsibility from the clinician."⁶¹

Conduct of the Trial

By September 1947, when admission to the pulmonary trial was closed, 109 patients had been accepted. Two died during a preliminary observation week during which all patients received only standard clinical care. Of the 107 patients analyzed, 52 were in the control group (21 men and 31 women), and 55 in the group receiving streptomycin (22 men and 33 women).¹

When the condition of some patients deteriorated, they received collapse therapy if this was judged medically advisable. With such pressure on the resources of the trial, it made sense to restrict admission to those patients who were least likely to benefit from the alternative of collapse therapy. Even so, it did happen that 11 patients from the control group (5 during the first four months of the trial and 6 during the last two months of observation) were judged to require collapse therapy, which was duly applied. Another 11 patients in the streptomycin group also were treated with collapse therapy, all during the two-month observation period

in hospital that followed active treatment under the revised treatment schedule.¹

Though there were a number of what would now be called protocol amendments, the fundamental design of the trial was adhered to remarkably closely, which was no minor accomplishment.⁶²

Study Drug Supplies and the Other Streptomycin Trials

It is all but forgotten that two other streptomycin trials began under the same MRC committee around the same time. One was in acute miliary tuberculosis; the other, tuberculous meningitis. Both trials are mentioned as examples in which it would have been unethical to use a control group.^{6,8} With essentially 100% mortality to that point (for example, in tuberculous meningitis, only some 60 recoveries had ever been recorded worldwide, and not all of these cases had been diagnosed conclusively),⁶³ there was no need for a concurrent control group. All of the MRC researchers' patients who had these conditions were given streptomycin. Hospitals in the MRC scheme admitted 25 patients with miliary tuberculosis between March and September 1947,⁶⁴ and 105 patients with proven tuberculous meningitis before August 18, 1947.⁶⁵

The pulmonary tuberculosis paper justified the control group partly through "the fact that all the streptomycin available in the country was in any case being used," the rest of the supply being taken up for these two hitherto fatal conditions.¹ This was a convenient gloss: The Committee's decision to run a controlled trial was made before the trials in miliary tuberculosis and tuberculous meningitis were approved. And although the Committee decided to treat all the patients in these other trials with streptomycin—and hindsight has declared that to do otherwise would have been unjustifiable⁶—remarkably, the MRC's second streptomycin conference during the summer of 1946 had not been equally definite, declaring only that the use of a control group in miliary and meningeal tuberculosis was "possibly not" essential.⁴⁹

Still more obscure was the trial of streptomycin in nontuberculous conditions. A few weeks after the MRC set up the tuberculosis committee, it created a committee to conduct clinical trials of streptomycin in nontuberculous conditions. Sir Alexander Fleming, who enjoyed great scientific prestige because of his discovery of penicillin, chaired this body, which had no statistical representative. This lesser-known committee tested streptomycin in *Haemophilus influenzae* meningitis, whooping cough, and several other conditions including—satisfying L. P. Garrod's request at last—typhoid fever (see Table 4.1). It allowed the participating clinicians to gain experience in treating patients with the drug. And in this trial, as with the others run by the MRC, careful bacteriological testing examined the development of resistance.

The trial in nontuberculous conditions illustrates a different style of research from that of the tuberculosis trials—similar in fact to what Hill's lectures on clinical trial design would criticize in the years to come. For most of the conditions studied, the small numbers of cases made it difficult to draw firm conclusions. The minutes from the meetings during the committee's first year make no mention at all of the possibility of using control groups for any of the diseases; in 1948 a trial using alternating controls was approved for infantile gastroenteritis.⁶⁶ Initially the record keeping was left to the discretion of investigators,⁶⁷ though after several months a standard clinical report form was adopted, at least for the meningitis cases.⁶⁸

Among the reasons for setting up this committee was to help ensure that all of the MRC's supplies were allocated to research. For uniformity, all the streptomycin given to patients with pulmonary or meningeal tuberculosis came from a single manufacturer, Merck, whereas all of the streptomycin given to patients with miliary tuberculosis came from another firm. The nontuberculous conditions trial was crucial to the success of the three tuberculosis trials, in that it used up allotments of streptomycin for which the latter had no use, for example an initial 540 grams in December 1946.⁶⁷ Courses of treatment sometimes involved much smaller quantities of the drug than were needed for pulmonary tuberculosis; for example, in March 1947, several centers for influenzal meningitis each received a 50-gram supply that was expected to treat 5 to 10 cases.⁶⁹ In May 1947, Fleming's committee requested an additional 20 kilograms over the next year.⁷⁰ Streptomycin could not be released to the general public without causing chaos, so the committee quietly treated more than 227 patients by September 1948 and gained some useful knowledge along the way.

Outcomes

The Streptomycin Clinical Trials (Tuberculosis) Committee told the Ministry of Health in April 1947 that streptomycin definitely prolonged the lives of patients with tuberculous meningitis.⁷¹ The ministry hastened to make streptomycin treatment available for this condition (and also, as of June 1947, for miliary tuberculosis) throughout the country through a network of teaching hospitals.⁷² Its scheme was running by September. The MRC's tuberculous meningitis report was published in *The Lancet* in April 1948. Of 105 proved cases admitted between early January and August 18, 1947, there were 38 patients surviving as of December 15, 1947, after 120 or more days' treatment and observation. Of these, 30 (28% of the original total) were said to be making good progress.⁶⁵

An interim report on streptomycin in nontuberculous conditions⁷³ was summarized in both the *BMJ* and *The Lancet* in September 1948.^{74,75} It described some success in controlling infections due to gram-negative bacteria such as *H. influenzae*. In 1950, though, when Fleming's committee was concluding its work, MRC headquarters advised its secretary not to go to the trouble of publishing a final report if there was "nothing very fresh to say."⁷⁶

The landmark report on pulmonary tuberculosis was published in the *BMJ* on October 30, 1948. In this trial, four of the 55 patients in the S group (7%) and 14 of the 52 patients in the C group (27%) died by the end of the sixth month. The probability that this difference between groups would occur by chance was said to be less than one in a hundred.¹ The report documented the emergence of streptomycin-resistant strains of the tubercle bacillus, a phenomenon that Mayo researchers had first described in a clinical setting in 1946.⁷⁷

The Ministry of Health scheme for treating meningeal and miliary tuberculosis progressively widened to cover other tuberculous conditions, and the MRC began testing streptomycin in conjunction with surgical procedures and the new drug para-aminosalicylic acid. The report on the miliary tuberculosis trial was not published until 1950, by which time of course many other studies had appeared, though the MRC paper did provide lengthier follow-up than the others cited: By October 1949, at the end of at least 24 months of observation, there were 14 survivors (56%) out of the original 25 patients.⁶⁴

Table 4.1
Features of the Initial MRC Clinical Trials of Streptomycin

Committee		Streptomycin Clinical Trials (Tuberculosis) Committee		Streptomycin Clinical Trials (Non-Tuberculous Conditions) Committee
Chair		Geoffrey Marshall		Sir Alexander Fleming
Disease(s) (number of cases)	Pulmonary tuberculosis (109) ¹	Tuberculous meningitis (138) ⁶⁵	Acute miliary tuberculosis (25) ⁶⁴	<i>H. influenzae</i> meningitis (43), other meningitis (14), septicæmias with or without subacute bacterial endocarditis (8), urinary tract infection (61), local sepsis (45), chronic lung infection due to bronchiectasis and lung abscess (14), whooping cough (not stated), infantile diarrhea (42), ulcerative colitis or typhoid fever (not stated) ^{71,72}
Admission criteria	Predefined	Predefined	Predefined	Generally not specified—subject to the restriction that, in most of the conditions studied, the infection should be resistant to penicillin and sulphonamides
Record keeping	Standard case record forms	Standard case record forms	Standard case record forms	Discretionary at first, ⁶⁷ then standardized for at least meningitis ⁶⁸
Controls	Randomized	Historical, due to near 100% mortality	Historical, due to near 100% mortality	None for most conditions; alternating for a 1948 study of infantile gastroenteritis
Duration of treatment	6 months initially (changed to 4 months treatment followed by 2 months observation in hospital)	Initially planned as 3 months or more	Initially planned as 3 months or more	Dependent on the condition; many patients for between 4 and 14 days, and very few patients for as many as 28 days
Dosage in treatment group	2 g daily, given in four intramuscular injections at 6-hour intervals	Some combination of intramuscular injections of up to 2 g daily (depending on age and body weight), and intrathecal injections of between 50 mg and 100 mg daily	Intramuscular injections of up to 2 g daily (depending on age and body weight), given as four intramuscular injections at 6-hour intervals; plus intrathecal injections if showing evidence of meningitis	Depending on age, body weight, and disease category; intrathecal injections of between 50 and 100 mg daily in meningitis
Form of drug	Streptomycin hydrochloride	Streptomycin hydrochloride	Streptomycin sulphate	Not stated

Once Glaxo's large new plant at Ulverston began producing the drug, the supply of streptomycin ceased to be a problem. On November 1, 1949, the drug became available to anyone in the United Kingdom with a valid prescription (see Table 4.2).⁷⁸

Ethical Issues

Discussion of the ethics of the MRC's streptomycin research has remained curiously one-sided. More than half a century after the publication of the pulmonary tuberculosis paper, there is no shortage of literature reiterating the Committee's rationale for using a control group without streptomycin.^{2,4–10} Sir Richard Doll, who worked closely with Hill for decades, has written, "No one has questioned the Committee's contention that it would have been unethical not to conduct the trial, nor the way the trial was carried out."⁸ Yet this seems surprising: It is hard to imagine that anyone would put forward the MRC's arguments so explicitly and so per-

sistently if the ethical objections they answered had remained purely hypothetical.

One can only wonder where any contrary views, or even any questioning views, are expressed. A symposium at Oxford in 2002 represents a rare published dialogue touching on the subject.⁷⁹ As researchers continue their recent foray into the archives, the "official story" may finally receive the scrutiny and debate it deserves.

According to several members of the MRC committee for streptomycin in tuberculosis, the greatest contribution of its chairman, Geoffrey Marshall, lay in persuading the clinicians around the country that the pulmonary tuberculosis trial was a respectable venture.⁸⁰ The MRC files do not spell out, though, quite which clinicians had to be won over or from what positions. Here the MRC's archival records stand in contrast to those of, for example, the U.S. Committee on Medical Research and the U.S. National Research Council, in which frank methodological and ethical exchanges are amply documented, as Marks describes.¹⁶

Table 4.2**Timeline of the Context of British Clinical Trials of Streptomycin**

1918–19	The Medical Research Committee (later Medical Research Council) is formed.
1925–35	The “gold decade.” The gold compound sanocrysin is used frequently to treat tuberculosis, despite evidence of toxicity.
1929	Fleming publishes first paper on penicillin, describing its bactericidal properties.
1931	Amberson discredits sanocrysin through a controlled trial with group assigned to treatment by a single flip of a coin.
1935	Domagk publishes paper on the antibacterial action of prontosil, the first of the sulphonamides.
1937	<i>The Lancet</i> publishes Hill’s series on medical statistics.
1940–41	Florey and Chain demonstrate chemotherapeutic potential of penicillin.
Aug. 1940	Merck and Rutgers sign agreement on commercialization of substances derived from Waksman’s research program.
Nov. 1943	Schatz isolates streptomycin.
Jan. 1944	Schatz, Bugie, and Waksman publish first paper on streptomycin.
1944	Merck begins manufacturing streptomycin on a pilot scale using surface-culture process.
Dec. 27, 1944	Feldman and Hinshaw prove that streptomycin arrests tuberculosis in guinea pigs.
Mar. 1945	Penicillin becomes commercially available in United States.
June 20, 1945	Civilian and military researchers at streptomycin conference conclude that it is effective against tularemia, influenzal meningitis, and gram-negative urinary tract infections.
July 1945	Labour Party wins British general election with a majority. Aneurin Bevan becomes Minister of Health.
Aug. 1945	U.S. War Production Board approves large-scale production of streptomycin.
Sept. 1945	MRC receives its first proposal for streptomycin research from Garrod.
Sept. 1945	Feldman and Hinshaw publish first clinical report on streptomycin in tuberculosis.
Dec. 1945	Fleming, Florey, and Chain win Nobel Prize for discovery of penicillin.
Jan. 1946	Glaxo decides to invest in streptomycin production plant.
Jan. 1946	MRC first tries to procure streptomycin for clinical trial, in treatment of plague.
Jan. 5, 1946	Lehmann publishes paper in <i>The Lancet</i> on para-aminosalicylic acid (PAS) against clinical tuberculosis.
Mar. 1946	Ministry of Supply consults with MRC about streptomycin manufacture.
Mar. 1946	U.S. Committee on Chemotherapeutics decides that no further patients should be started on streptomycin therapy until supplies increase.
Mar. 1946	Bevan introduces National Health Service Bill in Parliament.
June 1946	Penicillin becomes available by prescription in the United Kingdom.
July 1946	Feldman’s lectures stir up medical interest in streptomycin in the United Kingdom.
July 29, 1946	MRC convenes First Streptomycin Conference, which agrees to study streptomycin in tuberculosis.
Aug. 27, 1946	MRC convenes Second Streptomycin Conference, which decides to run a pilot trial using streptomycin to be manufactured in the United Kingdom by surface culture.
Sept. 1, 1946	Streptomycin becomes commercially available in the United States. Export restrictions remain in effect.
Oct. 1946	MRC creates its Streptomycin Clinical Trials (Tuberculosis) Committee under chairmanship of Geoffrey Marshall.
Oct. 1946	Feldman and Hinshaw demonstrate recovery of four patients with tuberculous meningitis treated with streptomycin.
Nov. 1946	MRC creates its Streptomycin Clinical Trials (Non-Tuberculous Conditions) Committee under chairmanship of Fleming.
Nov. 12–15, 1946	British Treasury approves import of 50 kg of streptomycin at a cost of \$320,000.
Nov. 21, 1946	MRC Streptomycin in Tuberculosis Committee holds first meeting, approves randomized design, abandons idea of pilot trial.
Dec. 14, 1946	<i>BMJ</i> publishes statement on danger of streptomycin treatment.
Jan. 1947	MRC streptomycin trials admit first patients.
April 1947	Early findings from the MRC tuberculous meningitis trial justify making treatment more widely available. Treasury approves import of a further 50 kg of streptomycin for the MRC’s research and subsequently allocates \$500,000, which is sufficient for about 160 kg.
May 1947	Bevan and other key cabinet ministers agree to grant highest possible priority for the development of streptomycin, including the Ulverston plant.
July 1947	MRC committee shortens course of treatment in pulmonary tuberculosis to four months.
Apr. 17, 1948	MRC committee publishes paper in <i>The Lancet</i> on streptomycin treatment of tuberculous meningitis.
Sept. 18, 1948	MRC Streptomycin Clinical Trials (Non-Tuberculous Conditions) Committee publishes interim report in <i>The Lancet</i> and <i>BMJ</i> .
Oct. 30, 1948	MRC publishes landmark paper in <i>BMJ</i> on streptomycin treatment of pulmonary tuberculosis.
1949	Glaxo’s streptomycin plant at Ulverston begins producing enough streptomycin to supply the United Kingdom’s needs.
Nov. 1949	MRC officially establishes the long-awaited Tuberculosis Research Unit, with Philip D’Arcy Hart as director.
Nov. 1, 1949	Streptomycin becomes available by prescription throughout the United Kingdom.
1950	MRC committee publishes paper in <i>The Lancet</i> on streptomycin treatment of acute military tuberculosis.
1952	Robitzek and Selikoff publish paper on isoniazid against tuberculosis.
1952	Waksman wins the Nobel Prize for discovery of streptomycin.

Marks has coined the term *therapeutic reformers* for “individuals who sought to use the science of controlled experiments to direct medical practice.”¹⁶ He points out that such therapeutic reformers were indeed driven by an ethical concern: that physicians be guided rationally by evidence from properly controlled trials.¹⁶ Thus first and foremost the MRC hoped to obtain reliable evidence of whether the new drug was of value. Looking back in 1963 on the circumstances of the streptomycin trial, Hill wrote, “It would, the Committee believed, have been unethical *not* to have seized the opportunity to design a strictly controlled trial which could speedily and effectively reveal the value of the treatment.”⁵

Access to Treatment

The pulmonary tuberculosis report took pains to defend the use of a control group, a familiar but still ethically contentious research design. It argued, understandably, that the effectiveness of the drug was still uncertain, no controlled trial in pulmonary tuberculosis having been conducted in the United States as of 1946.¹ Marks has rightly pointed out that there was great concern about the clinical variability and unpredictability of pulmonary tuberculosis.⁷⁹ Even so, a condition of equipoise, as it later came to be called by ethicists, did not really exist at the time of the trial, in that a rational, informed person would have had good grounds for preferring to receive streptomycin relative to bed rest alone. But it has been argued, quite independently of the streptomycin scenario, that randomization in the absence of personal equipoise is “permissible, indeed desirable, when access to treatment is in any case limited as a result of inadequate resources.”⁸¹ Given the shortage that existed, then, a requirement for equipoise does not stand as a barrier to the use of a control group.

“Additional justification,” the MRC report said, “lay in the fact that all the streptomycin available in the country was in any case being used, the rest of the supply being taken up for two rapidly fatal forms of the disease, miliary and meningeal tuberculosis.”¹ As explained above, this glossed over a substantial program in non-tuberculous conditions. The MRC steadfastly told external inquirers that all of its supplies were being devoted to large-scale clinical trials and that requests for individual allocations could not be entertained. Quietly, though, MRC officials made exceptions for certain insiders. It has been reported, for instance, that a senior physician fell ill with tuberculosis and was provided with streptomycin outside the MRC’s trial so as not to compromise the allocation scheme.⁵² It should be noted that the MRC did not have a complete monopoly but controlled only the supplies in government hands: Because of private imports, which were quite legal, others could and did use streptomycin outside the MRC trials. In February 1948, for example, the U.S. royalties from *Animal Farm* provided the dollars to import a supply of the drug for author George Orwell, in an unsuccessful attempt to treat the pulmonary tuberculosis that would eventually take his life.⁸² In April 1948 the U.S. Red Cross donated supplies for 10 patients who were treated in an uncontrolled case series.⁸³

Informed Consent

Some instances of attention to informed consent have been identified from before the Second World War—for example, an MRC policy dating from 1933,⁸⁴ as well as German guidelines enacted in

1931 and U.S. case law from early in the 20th century.⁸⁵ It is not altogether clear, though, how successful these examples were in identifying a standard against which we, looking back, might judge researchers who simply took their ethical cues from prevailing practice. Overall, it is probably fair to characterize the dominant ethos of the British medical profession at the time of the streptomycin research as a duty of beneficence toward patients rather than respect for patient autonomy.⁸⁵ Whatever the circumstances, it was remarked only briefly in the pulmonary tuberculosis paper that control patients were not made aware that they were being enrolled in a trial.¹ The study files do not document what, if anything, the streptomycin patients were told about the identity of their injections or about the risks their treatment entailed. Strikingly, Hill wrote in 1951 that precautions were taken to keep both groups of patients in ignorance of their participation in a controlled trial.⁵⁶

The U.S. Public Health Service trial, begun around the same time as the MRC’s, likewise did not inform control patients that they were part of an experiment.¹⁶ Hill later acknowledged the value of having an independent ethical committee oversee the experimenting doctors (which was not a consideration in the 1940s), but he continued to view it as wrong to shift onto patients the responsibility of giving informed consent.⁷

Transparency

Arguably the greatest ethical lapse in the MRC’s streptomycin program lay in the handling of public relations. In statements to the British public, the MRC repeatedly framed the current state of knowledge in terms so pessimistic as to be deliberately deceptive.⁸⁶ Although evidence continued to accumulate from the United States to the effect that streptomycin was effective in a number of conditions and fairly safe,⁸⁷ the British authorities left inquirers to imagine that brain damage in patients who survived tuberculous meningitis might be the result of the drug rather than an effect of the disease itself. In the face of overwhelming public demand for the drug, the MRC’s press officer, Frank Green, and the Ministry of Health arranged for alarming statements to appear in the *BMJ* and *The Times*.^{88–90} The latter warned in January 1947, “In the very small number of patients with tubercular meningitis whose life has been prolonged by the treatment there has nearly always been permanent derangement, blindness or deafness.”⁹⁰ *The Lancet*, however, did not cooperate with this campaign.⁹¹ One paper published by *The Lancet* presented evidence that toxicity was inversely proportional to purity; noting that the purity of streptomycin preparations had been steadily improving over time, the authors declared themselves convinced that the drug could be used safely at the dose levels they had adopted.⁹² Waksman, writing from New Jersey, objected to the scare. Green explained unrepentantly to the British Foreign Office in April 1947 that the statement “was intended to discourage broadcast appeals for the drug, by indicating these cannot be met from British sources at the present time.”⁹³

The adverse publicity evidently left many British medical practitioners confused about the true benefit of streptomycin.^{11,94} In 1950 the Ministry of Health belatedly (and disingenuously) tried to correct the apparently common belief that the treatment did no more than “prolong life or produce ‘recovery’ as a physical and mental wreck.”⁹⁵

Given the lack of transparency with which information was presented to the public, readers of the MRC's publications on the streptomycin program may be excused for wondering whether other statements should be accepted at face value.

Enduring Legacy

The MRC's trial of streptomycin in pulmonary tuberculosis is significant in several ways. In terms of tuberculosis treatment, it was one of several studies that established the efficacy of streptomycin. The MRC study supported other observations of the rather rapid emergence of drug resistance. Together these findings led to the investigation of pulsed treatment and the continued push to develop new therapies that, alone or in combination, would minimize acquired resistance. Along with these other newer drugs, streptomycin contributed greatly to the declining prevalence of tuberculosis in developed countries over the next several decades and the shortening of stays in hospitals and sanatoria. As for the initial industrial question the research program had been intended to settle, it was mainly evidence from the United States (though also the British interim findings in meningitis early in 1947) that would guide decisions about production priorities.⁹⁶

As founding director of the MRC's Tuberculosis Research Unit, which was formally established in 1949,⁹⁷ Hart went on to organize much important research, ably assisted by Daniels until the latter's untimely death in 1953. Notably the unit demonstrated that vaccines substantially reduced the incidence of tuberculosis and, later, that chemotherapy could be effective against tuberculosis even in outpatients living in very difficult circumstances in developing countries.^{98,99}

The greatest influence of the pulmonary tuberculosis trial, though, lay in its methods, which have affected virtually every area of clinical medicine. The trial quickly came to be recognized as a model of design and implementation.¹⁰⁰ Hill was invited to the United States to lecture on clinical trials and became a great popularizer of randomized controlled trials.^{5,56,57} Daniels also wrote on clinical trial methods.⁶² Over the years, as the discipline of controlled clinical trials grew in sophistication and influence, the streptomycin trial continued to be referred to as ground-breaking.^{101–103} Two notable features were the concealment of the allocation schedule and the use of objective measures such as interpretation of X-ray films by experts who were not aware of patients' treatment assignment.

Advocates of randomized controlled trials have had considerable success in changing the culture and policies of medical journals and regulatory agencies.^{104,105} A now vast body of evidence gathered from randomized controlled trials is disseminated globally by The Cochrane Collaboration, named in honor of a leading promoter of such trials, British health-care researcher Archie Cochrane.¹⁰⁶

To some observers, however, the push for greater methodological rigor has come at a price. In the 1980s, for example, AIDS activists objected to the use of placebo controls when treatments for life-threatening conditions were being tested.¹⁰⁷ Placebo controls—which were not used in the MRC study—have continued to evoke controversy.

The MRC's trials illustrate a recurring quandary about how to allocate treatment fairly under conditions of uncertain knowledge

and short supply. To their credit, the MRC researchers answered their main clinical questions conclusively, and health officials then extended treatment as broadly and quickly as resources allowed. Ethical reservations may remain, though, about the approach that scientists and government officials took to the sharing of information with experimental patients and members of the public.

The Salk Polio Vaccine Field Trial of 1954

Epidemiology of Polio

In the first half of the 20th century, poliomyelitis meant long summers of fear and suffering for families living in the United States. The disease, hardly recognized before the 20th century, had become a significant danger to children and to general quality of life, especially in the post–World War II era. The epidemiological work of John Paul, Thomas Francis, Dorothy Horstmann, and others had only recently shown that the apparent increased danger of the infection was directly related to modern American affluence. In less prosperous, less sanitized times and places, babies usually contracted the polio, or infantile paralysis, virus early in life, while still protected by their mother’s immune system. In the postwar United States, a whole generation was growing up healthy, well nourished and often bottle-fed, protected from infection until they began nursery school. But these practices left them defenseless against polio virus.¹ Although the incidence of the paralytic form of the disease was quite low, it was disproportionately high among young, middle-class children. As prosperity increased, so did crippling and death; for Americans, polio took on the face of a fearful plague. In 1948, polio incidence had risen to 19 per 100,000 people in the population, the highest since the horrible epidemic of 1916. In 1949, it rose again to 28.3 per 100,000.²

Early Research on Vaccines

The most famous polio victim had been Franklin D. Roosevelt, who contracted the disease in the 1920s, before becoming president. In the mid-1930s, he had launched an annual Birthday Ball

to raise funds for his favorite rehabilitation resort in Warm Springs, Ga., and recruited his former law partner, Basil O’Connor, to head the effort. The Birthday Ball Commission proved far more successful than anticipated; in 1934, the event brought in more than \$1 million, much more than was needed for Warm Springs. O’Connor recruited some scientific advisers to help disburse the surplus. Some of the windfall funds were given to William H. Park, the respected director of the Bureau of Laboratories of the New York Health Department, and his young associate Maurice Brodie, for development of a killed-virus poliomyelitis vaccine—even though the virus had not been fully identified and cultured at this time.^{3,4}

Park and Brodie produced their vaccine by exposing infected monkey tissue to formalin to inactivate its pathogenicity. In 1935, it was tested on more than 7,000 children without ill effects, except for some localized reactions to the injection.⁵ In the same year, another experimenter, John Kolmer of Temple University, referred to his polio vaccine as “attenuated.” He chopped the monkey tissue very fine and treated it with what some called a chemical “witch’s brew.”⁶ At the same meeting of the American Public Health Association where Brodie presented his data, Kolmer reported on the vaccination of 10,725 people, mostly children. He stated that the vaccine was “probably safe.” Yet 10 of the children given his preparation had contracted polio and 5 had died, an incidence higher than that of the natural disease.⁷

Both Brodie and Kolmer met with scathing attacks from the small community of U.S. virologists, led by Thomas Rivers of the Rockefeller Institute and James Leake of the U.S. Public Health Service (PHS). In their view, killed-virus polio vaccine was scientifically impossible. Any such preparation would either be

“reasonably safe but ineffective,” as Rivers described the Park-Brodie product, or itself pathogenic, as Kolmer’s appeared to be.^{8,9} As Rivers’ Rockefeller colleagues, Peter Olitsky and Herald Cox, had reported, “If these chemicals did not act a sufficient time, the vaccine by itself could produce polio in monkeys; if they . . . killed the virus, no immunity, except rarely, was induced.”⁴

Despite these discouraging events, O’Connor did not stop supporting research, but he shifted the focus away from vaccines. In 1938, the Birthday Ball Commission was reorganized as the National Foundation for Infantile Paralysis (NFIP), popularly nicknamed the March of Dimes, “to lead, direct, and unify the fight on every phase of this sickness,” Roosevelt announced.^{3,10} Volunteer chapters, established in each of the nation’s 3,608 counties, organized the annual “Mothers’ March” to collect dimes and quarters from their neighbors. Half of the funds raised were returned to the chapters to be used primarily for the care of polio victims.³ The emphasis on grass roots organization built strong loyalties to the NFIP. The volunteers said of it, “It’s always the little people” and “you have the feeling of belonging . . . that it’s *our* organization.”¹¹

Foundation Sponsorship of Basic Research

What funds were left, after the costs of medical care, publicity, and administration were covered, were given to research. O’Connor set up a new Committee on Scientific Research in 1938, later the Committee on Virus Research and Epidemiology, with Rivers at its head. Under his leadership, the Committee emphasized gradual progress through basic virological research. Rivers said later:

We actually knew very little about the nature of poliovirus. . . . [O]ften we didn’t know what questions to ask. . . . [I]f we wanted answers to problems in polio and they were not forthcoming, it might be to our advantage to study related viruses where we had better information and techniques. . . . I never minded broad gauged grants if they in any way furthered our knowledge of virus disease.⁴

The NFIP was the only major sponsor of poliomyelitis research in the 1940s and 1950s, although never able to offer more than \$1 million in one year before 1949. This crucial funding made possible several major achievements.¹² One of these was the demonstration, by David Bodian of Johns Hopkins University, that there were in fact three distinct types, or strains, of polio virus. In the late 1940s, the Foundation supported the painstaking type identification of each of the several hundred polio cultures maintained in various laboratories around the country.⁴

A few years later, in 1949, John Enders, Thomas Weller, and Frederick Robbins at Harvard University cultured polio virus for the first time in nonnervous tissue; if the virus could grow outside the nervous system, then a vaccine that generated antibodies in the blood prior to infection could theoretically prevent the disease from reaching the brain and causing paralysis.¹³ At the same time, Isabel Morgan of Johns Hopkins reported to the NFIP Research Committee that she had inactivated all three types of polio virus with formalin and successfully immunized monkeys against a pathogenic dose injected directly into the brain.¹⁴ About Morgan’s results Rivers said, “Most virologists believed that you couldn’t immunize against poliomyelitis with a formalin-inactivated poliovirus. She converted us, and that was quite a feat.”⁴

The subject of polio vaccines had now been reopened at the Committee’s regular round table conferences. By 1951, a number of experiments were in progress: inactivation with formalin and ultraviolet light; passive immunization through the use of gamma globulin prepared from the blood of convalescent cases, urged by William Hammon of the University of Pittsburgh; and culturing of live virus to try to isolate an “attenuated” mutant that, in a vaccine preparation, would confer lasting immunity through a subclinical infection. This live-virus work was pursued by Hilary Koprowski and Herald Cox, then at Lederle Laboratories, and by Albert Sabin at the University of Cincinnati.¹⁵ The Foundation created a special Immunization Committee, with the immediate objective of advising O’Connor on Hammon’s trials of gamma globulin.^{4,16,17} The year that followed, 1952, was the worst polio year in a series of “worsts.” The disease struck 57,879 people, an incidence of 37.2 per 100,000, and 2,500 people died.²

Jonas Salk’s Killed-Virus Vaccine

Jonas Salk had been supported by NFIP grants since completing his medical residency, first working on influenza with Thomas Francis at the University of Michigan, then in his own lab at Pittsburgh, where he had participated in the exacting and tedious “scut work” of poliovirus typing.^{4,11} He had become convinced that rigorous treatment with heat and formalin could produce a viral culture that was no longer pathogenic but still triggered the production of antibodies, which he argued were not just the by-products, but the agents of immunity.¹⁸ During 1952, he tested an inactivated vaccine on 161 children: first on paralyzed polio survivors living at the Watson Home near Pittsburgh, then on mentally retarded children at the Polk State School. These tests were done with parental and institutional consent; all the children’s guardians thought it appropriate for the unfortunates to make their small contribution to society. “We just enjoyed being part of the project,” said the Watson Home administrator.¹⁹ Salk had given injections to himself, his staff, and his own young sons as well (see Figure 5.1). On January 23, 1953, he presented his results to the NFIP’s Immunization Committee. The vaccinated children had shown no ill effects; their antibody titers had risen demonstrably.²⁰

Events then moved swiftly. On January 26, 1953, the Foundation announced to the press and public that it would conduct field trials of this new vaccine within a year.²¹ On February 26, a special meeting chaired by Rivers recommended as a first step that Salk begin safety trials on another 500 to 600 children in the Pittsburgh area.²² On May 25, O’Connor appointed a new seven-member Vaccine Advisory Committee to take over supervision of the field trial project; it included only three members of the Immunization Committee and only two virologists, Rivers and Joseph Smadel of Walter Reed Army Medical Center.⁴

The decision to proceed to a national field trial was considered precipitous by many members of the Immunization Committee, particularly Enders and Sabin.²³ Enders called Salk’s work “most encouraging” but argued that “the ideal immunizing agent against any virus infection should consist of a living agent exhibiting a degree of virulence so low that it may be inoculated without risk.”²⁴ Cox agreed: “The most logical and practical way to immunize infants and children against poliomyelitis is to follow the pattern that seems to take place so universally under natural conditions.”²⁵ In their view, Salk should continue with limited

Figure 5.1. Donna Salk, Jonas Salk's wife (at left), and an unidentified nurse, help as Jonas Salk administers his polio vaccine to their son, Jonathan, on May 16, 1953. Source: © The March of Dimes. Reproduced with permission.

tests that would contribute to the growing fund of knowledge on polio vaccine. But only an attenuated or live-virus preparation, developed through natural mutation, would possess the essential attributes of safety and lasting efficacy for use in a mass vaccination program.

Salk, his mentor Francis, and Bodian, among others, disagreed. Killed-virus vaccine stimulated antibody production and, if there were no remaining trace of live virus, it was clearly safer than any natural variant that could mutate in succeeding generations. The live-virus advocates were arguing, Francis said, for "some undesignated advantage derived from apparently harmless infection" that they could not define.²⁶ To his biographer, Richard Carter, Salk spoke with more passion: "What had once been skepticism about attempts to develop an effective killed vaccine was now becoming ideological conflict. . . . How could a killed vaccine contain the magical life force of the natural disease—its *élan vital*?"¹⁹ But proof that killed-virus vaccine would be both safe and effective would require what Isabel Morgan had called "a vast human experiment" in which "no risk whatsoever would be justified."²⁷

O'Connor and Rivers recognized that they were in fact taking a significant risk, against the counsel of many of their own expert advisers. But by June 30, 1953, the World Health Organization had reported that polio incidence in the United States was 17% above the 1952 figure.²⁸ The National Foundation was answerable first to its grass roots base, its volunteers and small contributors. They wanted their children protected against polio and they did not care if killed-virus vaccine was not "the ideal immunizing agent." If Salk's further tests provided sufficient evidence of safety, then the gamble had to be taken.^{4,19}

Debates Over the Field Trial Design

The National Foundation faced many hurdles in designing its massive field trial. The major tasks involved were: (1) selection of the trial design; (2) selection of the field trial population; (3) obtaining parental consent; (4) production of a consistently safe vaccine product in sufficient quantity; (5) recruitment and coordination

of the volunteers needed to vaccinate the children, screen for signs of polio, and maintain records; and, (6) systematic collection and accurate tabulation of the outcome data. Of these, the trial design was the most crucial and problematic.

The NFIP's Vaccine Advisory Committee supported a randomized and blinded clinical trial with a control group receiving an injection of placebo.⁴ However, both Salk and O'Connor thought that such a trial would be too complicated and risky. Salk wrote an emotional letter to O'Connor on October 16, 1953: "The use of a placebo control, I am afraid, is a fetish of orthodoxy and would serve to create a 'beautiful epidemiologic' experiment over which the epidemiologist could become quite ecstatic but would make the humanitarian shudder."¹⁹ No such trial had ever been carried out on healthy children and there were no government regulations prescribing the methodology. The first large-scale, randomized, placebo-controlled trial had been carried out with streptomycin in British tuberculosis patients in 1947, and the relative scarcity of the drug in the United Kingdom at that time had forestalled ethical concerns over the design^{29,30} (see Chapter 4). A placebo-controlled trial on many thousands of children was considered to be difficult to administer and to present to anxious parents.

O'Connor announced on November 9, 1953, that the vaccine would be given to second grade children, whereas their first and third grade schoolmates would serve as unvaccinated "observed-controls."^{31,32} Ten days later, Hart van Riper, the NFIP medical director, wrote to the chief public health officers in every state, requesting information on the numbers of children, of schools, and of recent polio cases by age in counties of historic high incidence.³³ By December 9, he had received enthusiastic responses from 38 states and the District of Columbia, as well as "a large volume of unsolicited offers of assistance."³⁴ Through January 1954, the plan continued to call for the use of observed controls.

However, Rivers and the Vaccine Advisory Committee knew that this study design would not achieve their goal. Such a trial might establish that the Salk vaccine was *safe*, but not that it was definitely effective against polio. The disease might be light among second-graders that year, or physicians might misdiagnose doubtful cases, based on their knowledge that the child had or had not

Table 5.1
Salk Polio Vaccine Field Trial Timeline

<i>Date</i>	<i>Event</i>
1789	First clinical description of polio by British physician Michael Underwood
1894	First small epidemic in the United States, in Vermont
1908	Polio virus isolated by Karl Landsteiner and Erwin Popper
1916	Major epidemic kills several thousand in United States
1921	Franklin D. Roosevelt stricken and left paralyzed
1934	First “President’s Birthday Ball” for Polio
1935	Kolmer and Park-Brodie vaccines fail to prevent paralysis
1938	National Foundation for Infantile Paralysis established, led by Basil O’Connor; Research Committee chaired by Thomas Rivers
1948	Polio incidence is 19/100,000
1948	Isabel Morgan first reports immunization of monkeys with killed-poliovirus vaccine
1949	Polio incidence is 28.3/100,000
1949	Enders, Weller and Robbins culture poliovirus in non-nervous human tissue
1951	Polio incidence is 18.5/100,000
1951–52	Gamma globulin field trials carried out by William Hammon
1952	Polio incidence is 37.2/100,000; 2500 die
1952	Jonas Salk tests his killed-virus vaccine at Watson Home and Polk State School
1953	Polio incidence is 22.5/100,000
Jan. 1953	Salk reports his tests to NFIP Immunization Committee
Jan. 1953	Foundation announces plans for national field trial of new vaccine
May 1953	Foundation creates new Vaccine Advisory Committee
Oct. 1953	Target counties selected for field trial
Nov. 1953	Foundation announces field trial will take place in spring 1954
Jan. 1954	Thomas Francis meets with state health officers
Feb. 1954	Francis appointed to head Vaccine Evaluation Center
Feb. 1954	Salk begins testing commercial vaccine in Pittsburgh
Mar. 1954	“Manual of Suggested Procedures” goes out to state health departments and to Foundation volunteers
Mar. 1954	Parents receive request form and O’Connor letter
Apr. 4 1954	Walter Winchell broadcast warns that vaccine may <i>cause</i> polio
Apr. 25 1954	Vaccine Advisory Committee recommends that field trial proceed
Apr. 26 1954	Vaccinations begin in first 8 states
June 1954	Vaccinations end and observation period begins
Jan. 1955	Codes broken at VEC
Mar. 9 1955	Last completed report on suspected polio case arrives at VEC
Apr. 12 1955	Francis presents summary report and announces vaccine is 80–90% effective against paralytic polio; Public Health Service immediately licenses vaccine
Apr. 25 1955	First child falls ill after receiving Cutter-manufactured vaccine
May 7 1955	Vaccination programs suspended
May 14 1955	Vaccinations resume with Parke-Davis vaccine
June 7 1955	Surgeon General Leonard Scheele appears on national television to announce new manufacturing standards and continuation of vaccinations
1956	Polio incidence is 9.1/100,000 (15,140 cases)
Late 1956	75% of children ages 5–12 have received injections of Salk vaccine
1958–59	Albert Sabin’s attenuated-virus vaccine in field trials outside the United States
1961	Sabin vaccine licensed and quickly replaces Salk in clinical practice
2000	CDC recommends return to sole use of improved killed-virus vaccine

been vaccinated. Only a placebo-controlled trial would be strong enough evidence to pacify the scientific critics and to get the vaccine licensed and widely distributed. Several state health officers were supportive of a placebo-control design, but they were also doubtful of the Foundation's ability to evaluate its own field trial objectively.

On November 16, 1953, O'Connor and van Riper asked Francis, a highly respected virologist and backer of the killed-virus concept, to direct an independent evaluation of the field trial, supported by NFIP funds.^{35,36} "I think I shall do it," Francis wrote in a letter on Dec. 29, but before he took the job, he recruited the support of key state health officers for a randomized, placebo-controlled study.³⁷ He identified those states that had well-organized and professionally respected health departments. In January 1954, he convened a series of crucial meetings in which leading officials of these health departments endorsed a placebo-control plan in 12 states and agreed that those areas would have "priority on available vaccine" if supplies should run short.^{38,39} He was formally appointed director of the Vaccine Evaluation Center (VEC) to be established at the University of Michigan, on February 9, 1954.⁴⁰ Five days later, the Foundation announced that both observed-control and placebo-control trials would be conducted, and that "a combination of the two procedures [would] assure a valid evaluation of the trial vaccine."⁴¹ "The best Departments are committed to this [placebo-control] plan," Francis noted.⁴² The placebo-control study remained his primary focus throughout the three years that followed.

The Field Trial Protocol

But the observed-control trials were not a sideshow to the main event. Thirty-six states were tied to that plan, and they, too, were necessary to the field trial. To succeed in legitimizing killed-virus vaccine, the Foundation needed both scientific evidence and widespread public support. It was essential that the trial be a massive national event, ensuring a high level of public participation and commitment.

The field trial population had to be large and demographically diverse, to ensure a representative sample. Moreover, because natural polio incidence was quite low but disproportionately high in children aged 6 to 11, these were the only individuals in whom a trial was likely to be statistically valid. In October 1953, Gabriel Stickle, the Foundation's statistician, and medical consultant Thomas Dublin had made a careful selection of those U.S. counties with total populations above 50,000 that had the highest case rates (at least 2.6 cases per 10,000) for the previous five years. These 272 counties, at least 1 in every state, were targeted as trial areas.^{43,44}

To be eligible for the trial, the targeted children in the selected counties would have to be identified, recruited, and delivered to central locations for vaccination; the most efficient way to accomplish this was through the primary schools. Consequently, Van Riper excluded preschool children from the study, although they were a higher risk group than their older siblings. He may also have thought the younger children would entail a higher emotional cost.⁴⁵

In the observed-control areas, only those in the second grade would be recruited for vaccination; parents of first- and third-graders would be asked to sign forms requesting that their chil-

dren participate as controls. In the placebo-control areas, parents of children in all three grades would be asked to allow their children to participate. This arm of the trial was to be double-blinded. Enrolled children would receive injections of vaccine or placebo from one of a pair of coded vials on "V-Day," and follow-up shots at one and five weeks. None of the teachers leading the children, the physicians giving the shots, nor the NFIP volunteers checking off the names, would know which vials contained vaccine.⁴⁶ The codes were not broken at the VEC until January 1955.⁴⁷

The health officers at the January meetings had drawn up the full protocol with the guidance of Francis and statisticians William Cochran and Hugo Muench. A randomly chosen 2% of each group, including the observed-controls, would have blood samples drawn before and after the injections, and again in the fall, to check antibody levels. The health departments, with Foundation assistance, would keep track of suspected polio cases among all the different groups of children. Because many illnesses could resemble a nonparalytic case of polio, each small patient was to be evaluated by a complex set of diagnostic procedures, including blood samples for antibody titers, fecal testing for virus, and muscle evaluation for paralysis. Ten regional laboratories were enlisted to conduct the blinded analyses of the blood and stool samples.^{39,47}

Volunteer Collaborators in the Vaccine Field Trial

The National Foundation had been built on volunteer contributions and public support; these were O'Connor's greatest assets and he intended to capitalize on them to ensure the success of the field trial. Foundation staff lavished the same concern on the observed-control trials as on the placebo-control series, which Francis preferred. Planning and publicity endlessly highlighted the importance of the local volunteer chapters, local schools, local parents' groups, and local health departments. The "Manual of Suggested Procedures," issued to the local NFIP chapters and health departments in March 1954, stressed that "the Local Health Officer who wisely utilizes the many volunteers [sic] services [of the chapters] will not only relieve himself and his staff of many burdens but . . . make it possible for many devoted chapter volunteers to have a rewarding satisfaction that comes from taking an intimate part in this great scientific undertaking."⁴⁶

Similarly, when Foundation staff met with state chapter representatives that month, they emphasized that the volunteers' role was to defer to and assist the health officers as needed, while working "to ensure maximum public acceptance and participation in the test areas."⁴⁸ The volunteers were to coordinate all the local publicity, the distribution and collection of patient permission forms, and the organization of vaccination centers at the schools. The health departments would give the injections, collect the blood samples, and oversee the evaluation of possible polio cases in the study population.^{39,47}

O'Connor's Letter to Parents

The most crucial support needed for the field trials was the consent of the children's parents. Each child brought home from

school, four to five weeks before “V-Day,” a request form with a carefully worded one-page message from Basil O’Connor. “A vaccine which may protect children against polio is now being tested by your National Foundation for Infantile Paralysis,” the letter to the observed-control areas began. “Thousands of children in selected communities will be given the chance of receiving this vaccine. . . . Your child and his classmates have been selected to take part in this great scientific test.”⁴⁸ O’Connor’s letter explained that some children would be vaccinated, whereas others would simply be observed, and that some blood samples would be taken; that the choice of children for each part of the trial “will conform to a nation-wide plan”; and that all roles were “equally important to the study.” The strongest emphasis was laid on the fact that “THE VACCINE WILL BE GIVEN ONLY ON REQUEST OF PARENTS”; but the letter also stated that parental request did not guarantee that a child would receive any vaccine. No specific risks or benefits of participation were mentioned. “This is one of the most important projects in medical history. . . . We feel sure you will want your child to take part.”⁴⁶ The request form itself briefly outlined the procedures again and emphasized the importance of all participants. It described the vaccine as “chemically killed poliomyelitis virus of all three known types.” Parents were asked to request that their child “be vaccinated if selected, or otherwise be permitted to participate in the procedures described above without cost to me.”⁴⁶

Vaccine Supply Issues

The remaining major concern for the organizers was an adequate supply of safe vaccine. Vaccine produced in Salk’s own laboratory had been tested by this time on many people without ill effect. Albert Milzer and Sidney Levinson of the University of Chicago, however, reported that they were unable to inactivate polio virus using Salk’s guidelines. NFIP Medical Director van Riper, speaking for the Foundation, said that Milzer and Levinson could not have been using Salk’s “exact methods.”⁴⁹ But the five commercial firms chosen to manufacture vaccine for the field trial also found it difficult to replicate his results, particularly as Salk kept revising his process to get a better balance between safety and antigenicity. Each commercial batch was tested on monkeys three times for live virus: at the manufacturing plant, at Salk’s Pittsburgh lab, and by the PHS.⁵⁰ Several animals sickened and died after injection with commercial vaccine in these tests. Only Parke–Davis and Eli Lilly had managed to produce several consecutive batches that passed the safety screenings before the trials began. The other firms selected were Cutter, Pitman-Moore, and Wyeth.⁴

The Vaccine Advisory Committee insisted that Salk test the commercial products on a pilot group of 5,000 Pittsburgh children, causing further delays. The trials were postponed until late March and then to late April.^{4,51} Anxieties persisted until the day before the field trials began; some state health officers wavered about the risks, whereas others were unsure whether there would be sufficient vaccine supplies.⁵²

April 1954: The Acid Test

On April 4, 1954, citing the reports of live virus found in the commercial batches, Walter Winchell made his famous announcement

on nationwide radio that the Salk vaccine “may be a killer!” Anxious letters and telegrams arrived in Ann Arbor and in Washington from one state health department and medical society after another.^{53–55} Salk, O’Connor, and Francis did their best to placate the fearful. The PHS laboratory insisted indignantly that it would never release any batch of vaccine if live virus were found. Minnesota was the only state to withdraw from the trials as a result of this incident; some individual counties also declined. North Carolina tried to withdraw, but public pressure forced state officials to re-enlist. Most of the states and counties, and all the NFIP volunteer chapters, remained committed to proceed.^{52,56–59}

On Sunday, April 25, 1954, the NFIP’s Vaccine Advisory Committee met in Washington and nervously but unanimously approved the Salk vaccine for “carefully controlled vaccine studies,” noting that it was the result of “a broad program of scientific research . . . supported financially by the American people.” The Vaccine Advisory Committee also recommended that the National Foundation “assume the administrative and financial responsibility for the trials.”^{4,60} The following day, April 26, 1954, Dublin confirmed to Francis by telegram that vaccinations had begun in 4 observed-control sites and 10 placebo-control areas.⁶¹ Arizona, Maryland, and the District of Columbia had to withdraw when early school closings ended easy access to the student population. Georgia also left the ranks when polio broke out there before vaccinations could begin. The remaining 44 states, with 84 placebo-control and 127 observed-control areas, stayed with the research design, namely, three injections at zero, one, and five weeks, with blood samples drawn from 2% of both test subjects and consenting controls for antibody titers.⁶²

Overall, as calculated and detailed in Francis’s Summary Report, the field trials also passed the acid test of parent support for participation. The eligible population of the first three grades in the 11 placebo-control states was 749,236. The parents of 455,474, or 60.8%, returned the request forms, asking that their children participate as “Polio Pioneers.” A small percentage of these did not attend the first clinic, missed follow-up injections, or received in error a mixed series of vaccine and placebo. Ultimately, 401,974 children, or 53.7% of the study population, completed the full series of coded injections, divided almost precisely between vaccine (200,745) and placebo (201,229).⁴⁷

The study population in the 33 observed-control states was 1,080,260 in the first three grades; 355,527 were in the second grade, the group designated for vaccination. The parents of this group requested participation at a higher rate, 69.2%, or 245,895 children, than did those in the placebo-control study. Of those whose parents made the request, 221,998 children, 62.4% of the second graders in the 33 areas, and 20.5% of the total observed-control population, received the full three injections of vaccine.⁴⁷

Collecting the Data

As the trials continued into June, momentum and morale seemed to build. Several states arranged for special school openings for the second and third shots.⁶³ Health officers were impressed by “the remarkable cooperation of the public”; the willingness of so many to participate “instilled complete confidence in the field trial.”⁶⁴ Press reports noted that the children themselves were enjoying their important role: “They were glad to be shot as pioneers.”⁶⁵

THE NATIONAL FOUNDATION FOR INFANTILE PARALYSIS
FRANKLIN D. ROOSEVELT, FOUNDER

120 BROADWAY
NEW YORK 5, N.Y.

BASIL O'CONNOR
PRESIDENT

BEEKMAN 3-0500

A MESSAGE TO PARENTS:

A vaccine which may protect children against polio is now being tested by your National Foundation for Infantile Paralysis with the cooperation of local health and educational authorities and of the medical profession.

Thousands of children in selected communities will be given the chance of receiving this vaccine to test its effectiveness. At least an equal number of children who do not receive the vaccine will be observed so that a comparison can be made between the two groups.

In certain instances it will be necessary to test small samples of blood before and after the vaccine is given to determine its effect. Samples from some of the children who are not vaccinated will also be necessary for comparison.

Your child and his classmates have been selected to take part in this great scientific test.

After the next polio season, records of all the children will be studied to determine whether those who received the vaccine were protected against infantile paralysis.

The choice of the children in your community who are to be vaccinated will conform to a nation-wide plan. Some children will receive the vaccine and some will not. The children in each group, those who receive the vaccine and those who do not, are equally important to the study.

Please read and sign the enclosed request form and return it promptly to your child's teacher. If you request participation, your child may be among those receiving the vaccine.

THE VACCINE WILL BE GIVEN ONLY ON REQUEST OF PARENTS.
Remember that the vaccine must be given three times. One or two doses will not be enough to test its effectiveness.

This is one of the most important projects in medical history. Its success depends on the cooperation of parents. We feel sure you will want your child to take part.

Sincerely yours,

Basil O'Connor
President

Figure 5.2. Letter From Basil O'Connor to Parents. Source: Thomas Francis Papers, Manual of Suggested Procedures for the Conduct of the Vaccine Field Trial in 1954, Bentley Historical Library, University of Michigan. Reproduced with permission of the March of Dimes, White Plains, N.Y.

The enthusiasm of the volunteers and participants did not ensure complete and accurate data. Despite visits of Francis and his VEC statistical staff to 32 states during the trials and numerous instructional memoranda, the completed vaccination and blood sampling schedules were late in arriving in Ann Arbor.^{47,66} By the end of September, 8,000 schedules were still outstanding and many that had been submitted were sketchily and erratically completed, necessitating revisits to 35 field trial areas.^{47,48}

Collection of data on the 1,013 cases of suspected poliomyelitis that occurred among the study population during the relevant period also proved troublesome. Children diagnosed with polio were to be reported weekly to the VEC as of May 1, 1954. However, not every case was reported promptly or even at all. The staff was forced to check its lists against the Foundation’s hospitalization reports and to insist on immediate notification by collect telegram. Once a case was identified, the protocol required that the diagnosis be verified by physical examination, blood, and fecal tests.⁴⁷ Only after all records of vaccinations, blood samplings, and polio case evaluations for a field trial area had been submitted to the VEC could the evaluation begin. Head statistician Robert Voight wrote plaintively in mid-October, “We have received only six completed areas. . . . Without a flow of completed tabulations, our personnel will be out of work in the very near future.”⁶⁸

Some data were never collected or were unusable for analysis. Records were very nearly complete for the children whose parents requested participation and who were inoculated; more than 96% of these reported and received three injections. In addition, strict randomization and blinding had been well maintained in the placebo-controlled study population.^{47,67} Randomized selection of children for blood sampling, particularly among the observed-controls, however, had proven impossible.⁶⁷ “The actual collections were made pretty much as the local areas saw fit. The ideal distribution was not achieved in most areas.”⁶⁹ Antibody levels in the field trial population were therefore difficult to compare with accuracy.

Another element of uncertainty was the history of previous polio infection among the children. This information was requested on the schedules but the answers “were so inadequately filled out in the field that we believe the data are highly unreliable.”⁶⁹ And the NFIP itself introduced a possible major element of bias through free administration of gamma globulin to areas with high polio incidence during the summer of 1954. The health officers’ group had endorsed the withholding of the blood serum from the study population when they met in January 1954.³⁹ But the policy proved to be difficult to adhere to as the summer wore on, according to reports from local doctors in Virginia, Florida, Ohio, Utah, and many other states that were both placebo and observed-control sites.⁷⁰ “We are having a terrible time withholding gamma globulin in the field trial areas,” Mason Romaine of Richmond told Francis;⁷¹ his colleague L. L. Parks of Jacksonville added in a plaintive letter that, “[T]he poor health officer is placed in a difficult spot.”⁷² Francis and his staff pleaded with them to “hold the line,” but were not always successful.⁷³

The long-anticipated results of the trial were announced in a much publicized ceremony at the University of Michigan on April 12, 1955, and reported in print in a special supplement to the May issue of the *American Journal of Public Health*. As summarized in Tables 5.2 and 5.3, the vaccine was shown to be 80%–90% effective

Table 5.2
Poliomyelitis in the Placebo-Control Trial

<i>Experimental Group</i>	<i>Paralytic Polio Cases (rate/10,000)</i>	<i>Nonparalytic Polio Cases (rate/10,000)</i>
Vaccinated (series of 3)	33 (1.6)	24 (1.2)
Placebo (series of 3)	115 (5.7)	27 (1.3)
Incomplete vaccine series	1 (1.2)	1 (1.2)
Not vaccinated*	121 (3.6)	36 (1.1)

*Includes children whose parents refused to allow participation, children not present on V-Day, or children who received one or two injections of placebo only. Children who received one or two injections of vaccine or a mixed series of vaccine and placebo are listed under “Incomplete series of vaccine.” (Table adapted from Francis 1955.)⁷⁴

in preventing the paralytic form of the disease in the placebo-controlled study population. Francis did not minimize the procedural and statistical problems noted above, nor did he try to draw unwarranted generalizations from the data in these or later reports.⁴⁷ About cases of polio among nonvaccinated children in the placebo-control areas, for example, he stated in an article for *JAMA*: “The populations receiving vaccine or placebo are strictly comparable in every characteristic; they are equal parts of one population, while those who refused participation are distinctly different. . . . The nonparticipating portions of the populations . . . are not additional controls.”⁷⁴

Francis was similarly candid in his Summary Report: “From these data it is not possible to select a single value giving numerical expression . . . to the effectiveness of vaccine as a total experience.”⁴⁷ The rates of nonparalytic polio in vaccinated children and placebo children were almost identical. There appeared to be a significant difference in rates of paralytic polio between the vaccinated children and the large group of controls in the observed-control population, but the latter was so ill-defined that it was not possible to interpret these results. Whatever the observed-control trials had contributed to the Foundation’s goals, they did not provide the needed statistical verification of efficacy. But the painstakingly confirmed rates of diagnosed paralytic polio in the placebo-control groups showed striking differences between the vaccinees and the controls. “It may be suggested,” Francis concluded, on the basis of “the results obtained from the strictly controlled and almost identical test populations of the placebo areas,” that the vaccine was indeed highly effective against paralytic poliomyelitis.⁴⁷

Poliomyelitis in the Observed-Control Trial

<i>Experimental Group</i>	<i>Paralytic Polio Cases (rate/10,000)</i>	<i>Nonparalytic Polio Cases (rate/10,000)</i>
Vaccinated (series of 3)	38 (1.7)	18 (.8)
Controls*	330 (4.6)	61 (.8)
Incomplete vaccine series	4 (4.0)	—
Second-graders not vaccinated	43 (3.5)	11 (.9)

*Total population of first and third grades. (Table adapted from Francis 1955.)⁷⁴

From Research Protocol to Clinical Practice

The PHS, with the approval of Oveta Culp Hobby, secretary of the new Department of Health, Education, and Welfare, immediately licensed the vaccine on the strength of the April 12, 1955, report, and mass vaccinations began under NFIP auspices.⁷⁵ On April 25, 1955, a child who had received some of the new vaccine made by Cutter Laboratories fell ill with what appeared to be polio. Other cases followed; 11 deaths and 153 cases of paralysis were eventually attributed to “the Cutter crisis.” Surgeon General Leonard Scheele stopped the vaccination programs and appointed a Technical Advisory Committee, which met for many hours and released multiple reports.⁷⁶ Sabin and Enders, testifying before a House Subcommittee in June, again raised serious doubts that killed-virus vaccine could ever be both harmless and effective.⁷⁷ As the technical data eventually made clear, and as Paul Meier would later explain, neither Salk’s very precise inactivation procedures nor tissue-culture tests guaranteed that any batch of the vaccine was free of live virus. The PHS found that such batches could still infect cortisone-treated monkeys, and presumably susceptible humans, with the paralytic disease. All the batches released for the field trials had undergone triple testing, including monkey trials; no such requirement had been imposed on the commercial firms when the PHS licensed the vaccine.⁷⁸

Vaccinations, however, resumed almost immediately, under new manufacturing and testing standards that Scheele asserted would ensure “negligible” risk.⁷⁹ Public support had been shaken but in large part recovered. By late 1956, 75% of American children aged 5–12 had received Salk vaccine, although only 40% of the nation’s teenagers and fewer than 12% of adults had followed suit.⁸⁰ The following year, polio incidence had diminished to 3 per 100,000 in the United States.² The summers of fear and suffering had ended.

Ethical Issues

The Salk vaccine field trials pose a number of interrelated ethical questions: issues of adequate pretesting, full informed consent, and the social versus the scientific justification for seeking clarity in therapeutic choice. In an era when ethical decisions were normally entrusted to the wisdom of investigators, and medical progress was considered an unquestioned social good, the National Foundation, as a lay volunteer group, invited an unusual amount of consultation and debate—from its scientific advisers, the state health officers, and the PHS—in formulating the trial design and procedures. Yet core issues remained unresolved and are still debated today. Did the Foundation act precipitately and without adequate scientific justification in deciding to hold a sizable field trial? Were the organizers justified in claiming safety for the experimental vaccine? Given that the final evaluation rested on the findings of the placebo-control trials, involving just over 400,000 children, was it ethical to expose the additional children in the observed-control areas to the possible risks of vaccination? Were the children’s parents fully informed of the risks of the trial? Was their consent based on a rational assessment of the situation or did the trial organizers rely on their fear of polio, their faith in the Foundation, and the national excitement fueled by constant publicity?

The Foundation throughout this period used the press and its volunteer network to build the idea of an alliance between scientists and laypeople, to stress the importance of the trials, and to describe participation as a special privilege earned by the participants through their long-term financial support of polio research. The letter accompanying the request (not consent) form conveyed this idea of an earned reward: “Your child and his classmates have been selected to take part in this great scientific test.” O’Connor’s editorial in *Today’s Health* in 1954 struck a similar note: “If an effective vaccine emerges from these studies . . . the layman—who furnished the original impetus for this effort—will have been instrumental in dealing the disease its final blow.”⁸¹

It was this idea of a nationwide alliance that mandated the continuance of the observed-control plan, so that there would be at least one trial area in every possible state, and that impelled the blitz of publicity which surrounded the advance planning, the trials themselves, and the announcement of the results. O’Connor, Francis, and their colleagues also relied on the fear of the disease to maintain public support, deciding, for example, that the placebo-control plan “would not be difficult to sell as there is a high attack rate in the three grades.”³⁹

The confidence and enthusiasm with which participating families responded is evident in the statistics, as well as the many letters sent to the Foundation and the VEC. The letters make clear that many, perhaps most, of the parents in the placebo-control areas were informed about trial procedures. They understood the 50% chance that their children had not received “the real shot” and that they were participating in a test of the efficacy of an experimental vaccine.⁸² “No one is more anxious for the success of your venture than [nine-year-old son] and I,” wrote one physician from Detroit. “It was with that idea that we decided on the trial of the vaccine.”⁸³

What the parents probably did not understand, and what neither the Foundation nor the PHS made clear, was the risk-benefit ratio entailed in exposure to the experimental vaccine. They did not realize, in all probability, the tenuousness of Salk’s hypothesis of a steady inactivation rate linked to the time of exposure to formalin;⁷⁸ the likelihood of persistence of live virus in any batch; the extent of the manufacturers’ failure to produce virus-free batches; and the uncertainty as to whether a decisively killed-virus vaccine could confer lasting immunity. Experimental risks were not commonly outlined for experimental subjects in 1954, as is the standard today.

What the parents knew was that Salk had given his vaccine to many children without ill effect. They had faith in the National Foundation and they had faith in modern science, which had already given them insulin, penicillin, streptomycin, and cortisone. On the basis of that past experience and of the rhetoric that described medical advances emerging from research, they anticipated a “breakthrough.” That confidence and anticipation persisted, despite Winchell’s warning broadcast, through a year of waiting, and even through the frightening “Cutter crisis.”

O’Connor and Rivers certainly recognized, as did their scientific advisers, that they were taking a calculated gamble. The trial participants were taking some risk in receiving an experimental vaccine, but this could be balanced against their existing risk of contracting paralytic polio. The Foundation was staking its reputation, its solvency, and its very existence, which depended on public confidence. Salk himself could make a safe vaccine; there was a triple-testing procedure in place for all batches to be used;

but Rivers and O'Connor knew that the margin of safety of the commercial products was relatively narrow. If the live-virus advocates were correct, moreover, and the vaccine did not prove to be very effective, the field trial would be seen as a great waste of time and money. Worse, even a few vaccine-associated cases of polio would be seen as a great waste of lives.

Against these risks, O'Connor and Rivers had to set the likelihood of several more summers of fear and an unknown additional number of paralyzed and dead children, while the work on an "ideal immunizing agent" continued. Yet the natural incidence of this frightening disease was still quite low. Their impetus to act rather than wait was a function of the Foundation's philanthropic bias toward activism, rather than the result of a systematic assessment of risk versus benefit. The decision may be considered as socially, if not scientifically, justified.

Caught between its volunteer constituency and its scientific advisers, and in an era when research ethics were less well-defined and regulated than they are today, the Foundation may be considered culpable on several counts. The field trial organizers failed to inform parents fully of the potential risks of the vaccine; exposed children in the observed-control areas to some risk for political, not scientific, reasons; publicized every aspect of the great experiment, but glossed over the difficulty of manufacturing safe, but antigenic, vaccine; and moved into a national field trial without fully adequate scientific justification. On the positive side, the organizers chose to use a rigorous experimental design in the placebo-control areas, one of which parents were fully informed, and to employ a screening process that proved to be effective in producing safe experimental vaccine. The Foundation also provided financial and emotional support for all U.S. polio victims that year, within the trial areas or elsewhere.

The most serious ethical lapse was an error not in research procedures but in translating research results into practice. The PHS was cognizant of all the risks and caveats, including the evidence produced by its own laboratories of manufacturing failures. But in the excitement of the public announcement of the field trial results, Hobby, Scheele, and their advisers failed to accurately assess the risks of blanket licensing and mass vaccinations with the commercial product, versus a phased-in and prescreened program. The PHS had no authority at that time to regulate research ethics, but the agency was responsible for the safety of U.S. vaccines.

Enduring Legacy

The 1954 Salk polio vaccine trials, despite the many scientific and ethical criticisms leveled at the time and in the half-century since, were a masterpiece of trial design and organization. They proved that a randomized and blinded design could be effectively used on a large scale to provide a rigorous demonstration of therapeutic efficacy. Most large-scale, multisite randomized, controlled trials since 1954 probably owe some debt to the polio vaccine trials.

Although the statistical results of the trials made possible a mass vaccination program with killed-virus vaccine, the virological community continued to support the idea of a live-virus preparation as "the ideal agent." The Sabin oral live-virus vaccine, after being tested in the Soviet Union, Mexico, and Czechoslovakia, was introduced into the United States in 1961 and remained

the standard for polio prevention for more than 30 years. There were 8 to 10 cases of polio each year associated with the use of this virus, however; and as the wild virus was gradually eliminated from the U.S. population, the live-virus vaccine presented a greater threat than the disease to most Americans. In 1997, the Centers for Disease Control and Prevention (CDC) approved a mixed vaccination schedule of two killed-virus injections and two live-virus doses, and in 2000, the CDC recommended the sole use of killed-virus vaccination (an improved preparation with greater antigenic content than Salk's original vaccine was developed in 1978).⁸⁴

The ethical choice at the heart of the Salk field trials confronts the researcher in every such case; at some point, he or she must choose action over caution, must decide to take a calculated risk. The polio vaccine story throws into high relief the interests and concerns surrounding many experimental innovations today—the researcher's interest in clear and replicable results; the manufacturer's concern for production efficiency, costs, and profit; and the desperation and hope of the individuals and families at risk—and it reminds us how easily those interests can be conflated or misrepresented. That the outcome proved to justify the decision the National Foundation made should not obscure the dimensions of the risk taken or the ethical complexities of the choice.

The Jewish Chronic Disease Hospital Case

During the summer of 1963, Chester M. Southam and Deogracias B. Custodio together injected live, cultured cancer cells into the bodies of 22 debilitated patients at the Jewish Chronic Disease Hospital (JCDH) in Brooklyn, New York. Custodio, a Philippine-born, unlicensed medical resident at JCDH, was participating in a medical experiment designed by Southam, a distinguished physician-researcher at the Sloan-Kettering Institute for Cancer Research, an attending physician at Memorial Hospital in New York City, and associate professor of medicine at Cornell University Medical College. The purpose of the research was to determine whether the previously established immune deficiency of cancer patients was caused by their cancer or, alternatively, by their debilitated condition. Southam thus looked to a group of noncancerous but highly debilitated elderly patients who might bear out his guiding hypothesis that cancer, not old age, was the cause of the previously witnessed immune deficiency. Importantly, he believed on the basis of long experience that the injection of cultured cancer cells posed no risk to these patients, and that all of the cells would eventually be rejected by their immune systems. Although Southam's professional credentials were impeccable, and although his work was deemed by his peers to be of the utmost scientific importance, the JCDH experiment soon erupted in a major public controversy. Critics denounced Southam's methods as being morally comparable to those of the Nazi physicians tried at Nuremberg, whereas his defenders countered that he was a distinguished physician-researcher, and by all accounts an honorable man, who merely had the bad luck to be caught in the shifting rip tides of history.

Curiously, although the JCDH case has gone down in history as one of the most important milestones in the development of

contemporary ethical and regulatory approaches to biomedical research, the case is not nearly as well known as similar scandals, such as the Willowbrook hepatitis experiments or the Tuskegee syphilis study (see Chapters 7 and 8). And although the JCDH case is almost always briefly mentioned in published litanies of important research scandals, including Henry Beecher's landmark study of medical science run amok,¹ it has never been the exclusive subject of any full-length scholarly paper, let alone a book. (It has, however, been the focus of two very helpful short papers in recent years, on which I have been happy to draw.)^{2,3}

Basic Chronology

Southam's research project focused on the relationship between the body's immune system and cancer. Beginning in 1954, Southam had performed numerous studies on more than 300 cancer patients at Memorial Hospital and on hundreds of healthy prison volunteers at the Ohio State Penitentiary. Southam had noticed that cancer patients exhibit a delayed immunological response to injected cancer cells. He had chosen cultured cancer cells for these experiments because they possessed the necessary uniformity, reproducibility, comparability, and growth potential to cause a measurable reaction in patients. Whereas the immune systems of healthy volunteers would normally reject such foreign tissue completely and promptly in roughly 4 to 6 weeks, it took cancer patients much longer, often 12 weeks or longer, to finally reject the injected cells. Southam worried about a gap in his data. Was the delayed immune response in cancer patients due to their cancer, or was it due instead to the fact that most such patients

were elderly, debilitated, and chronically ill? In order to fill this gap in knowledge, Southam proposed to repeat his immunological study on a group of noncancerous but elderly and debilitated patients. He hypothesized that this study population would reject the injected material at the same rate as normal, healthy volunteers. He hoped that studies such as this would ultimately lead to progress in our ability to boost the human immune system's defenses against cancer, but he was also aware of possible applications in the area of transplant immunology. This, then, was important research.

To test his hypothesis, Southam contacted Emanuel Mandel, who was then director of the department of medicine at the JCDH. Eager to affiliate his modest hospital with the work of a famous doctor at a prestigious medical institution, Mandel immediately agreed to provide the requisite number of chronically ill patients for Southam's study. Like many of the studies criticized in Henry Beecher's famous whistle-blowing exposé in the *New England Journal of Medicine*, this project was to be funded by eminently respectable sources, including the American Cancer Society and the U.S. Public Health Service. At their first meeting to discuss the study, Southam explained to Mandel that his proposal was not related to the care and treatment of patients; that it was, in other words, a pure example of "nontherapeutic" research. Southam also informed Mandel that it would not be necessary to obtain the written informed consent of patients at JCDH, because these immunological studies had become "routine" at Memorial Hospital. He also noted that there was no need to inform these elderly patients that the injected material consisted of live, cultured cancer cells, because that would be of "no consequence" to them. On the basis of his considerable prior experience of such studies with patients and prisoners, which easily included more than 600 subjects, Southam was convinced that the injection of cultured cancer cells from another person posed no discernible risk of transmitting cancer. In his opinion, it would simply be a question of when, not whether, such injected cells would eventually be rejected by the patients' immune systems. Because in his view the subjects would not be placed at risk by his study, Southam saw no need to inform them specifically that live cancer cells would be injected into their bodies. The whole point of using cancer cells had to do with their special properties within the context of his research project; no one, he opined, was actually at risk of getting cancer.

Prior to initiating the study at JCDH, Mandel hit a snag. He had asked three young staff physicians at the hospital—Avir Kagan, David Leichter, and Perry Fersko—to help with the injections of live cancer cells into the hospital's debilitated patients. All three had refused to cooperate on the ground that, in their view, informed consent could not be obtained from the potential subjects that Mandel and Southam had in mind for the study. Undeterred, Mandel and Southam forged ahead, eventually settling upon the unlicensed and comparatively vulnerable house officer, Custodio, to help with the injections.

On July 16, 1963, Custodio, Southam, and Mandel met at the JCDH to initiate the study. Custodio and Mandel had already selected the 22 chronically ill patients to be asked to participate. Southam demonstrated the injection procedure on the first three patients, and then Custodio proceeded to inject the remaining 19 with two separate doses of tissue-cultured cells. According to Southam and Custodio, each patient was told that the injections were being given to test their immune capacity—there was no mention of research—and that a small nodule would likely form at

the site of the injections but would eventually disappear. In the investigators' view, this constituted sufficient "oral consent" to participate in the study. At the end of just two hours, 22 elderly and debilitated patients on six floors of two separate hospital buildings had received injections, and this first crucial phase of the research was complete.⁴ With the passage of a few weeks, Southam's hypothesis would be fully vindicated: With the exception of patients who had died shortly after receiving their injections, all of the JCDH patients rejected the foreign tissue as completely and at the same rate as the prior group of physically healthy individuals. The gap in the data was thus filled: It was cancer, not debilitation and chronic illness, that was responsible for the impaired immune reaction of Southam's patients at Memorial Hospital. None of the JCDH patients, moreover, experienced any long-lasting physical harms attributable to the study.

The Battle Within the JCDH

News of the Southam-Mandel study spread quickly along the corridors of the JCDH. Samuel Rosenfeld, chief of medicine at the Blumberg Pavilion of JCDH for the previous seven years, was outraged both by the nature of the study, which he regarded as immoral and illegal, and by the fact that he had not even been consulted about it.⁵ The three young physicians who had rebuffed Southam and Mandel—Kagan, Fersko, and Leichter—fearing that their silence might be construed as condoning the research, resigned en bloc on August 27, 1963, less than six weeks after the injections.^{2,5} All three were Jewish; Leichter was a Holocaust survivor, and the other two had lost many family members to Nazi violence during the catastrophe of World War II. Each subsequently attributed his negative response to this study to a visceral revulsion at the thought of using such debilitated and helpless patients in experiments without their consent. None had had any training in ethics or law during their medical studies, and Kagan subsequently admitted that none of them had even heard of the Nuremberg Code.²

In order to quiet the gathering storm, authorities at the JCDH assembled the hospital's Grievance Committee on September 7, 1963. After hearing testimony from the hospital's executive director, Solomon Siegel, and Southam, the Committee judged that the resignations of Kagan, Fersko, and Leichter were "irresponsible" and should therefore be accepted by the hospital. The Committee then fully and enthusiastically endorsed the scientific and medical importance of Southam's research and concluded that the allegations of the three young doctors and of the medical director, Rosenfeld, against Mandel and Southam were baseless.⁵ Later that month, the JCDH's Board of Directors approved the Grievance Committee's report, and four months later the hospital's Research Committee approved the continuation of Southam's study at the JCDH, but only on the condition that he obtain the written consent of all subjects in the study.

Growing increasingly desperate, the three young doctors turned to William A. Hyman, an internationally recognized lawyer who had helped to found JCDH in 1926 and had sat on its Board ever since. Hyman had many reasons to be furious with his fellow Board members and with the medical authorities at the hospital, who, in his view, had aided, abetted, and then whitewashed this sordid story of human experimentation. One reason for his fury was, however, based upon the erroneous belief that the purpose of

Southam's research was to determine whether cancer could be induced by the injection of live cancer cells.⁵ Against the backdrop of this factual misunderstanding, it's no wonder that Hyman promptly accused Southam, Mandel, and Custodio of acting like Nazi doctors: "I don't want Nazi concentration camps in America. I don't want Nazi practices of using human beings as experimental guinea pigs."²

Fearing that the JCDH could be subject to legal liability for providing Southam with patients for his experiment, Hyman, in his capacity as Board member, sought the minutes of the Grievance Committee meeting of September 9, 1963, as well as the medical records of all the patients enlisted in the study. Rebuffed by the hospital authorities and ignored by the New York State Department of Education, Hyman then took his case to the Supreme Court of Brooklyn (a terminological oddity, because this is a *trial* court, not in appeals court in New York State), where he argued that, as a member of the JCDH Board of Directors, he had a legal right and responsibility to inspect committee minutes and patient records in response to allegations of wrongdoing and threats of potential legal liability. It is important to note at this point in the story that Hyman's quixotic legal quest was actually directed at a very narrowly focused topic. His case, *Hyman v. Jewish Chronic Disease Hospital*,⁶ was not an investigation into the substantive moral or legal issues raised by Southam's research. That would come later. The case was, rather, focused exclusively on the narrowly construed procedural question bearing on a Board member's right to see certain documents and patients' countervailing rights to the privacy of their medical records. Hyman's procedural claims were ultimately vindicated at the level of the state's highest court,⁵ but the real significance of his legal odyssey lay elsewhere. Although the New York State Department of Education, whose Board of Regents controlled medical licensure, had dithered and effectively ignored Hyman's original allegations, it was finally drawn into this case by the high public visibility and news accounts of the legal proceedings in Brooklyn. The Grievance Committee of the Board of Regents would henceforth provide the crucible for the ethical and legal implications of Southam's research at the JCDH.

Arguments in the Case of Chester Southam

In its 1965 inquiry into the JCDH case, the Grievance Committee of the Board of Regents focused on two major issues: the assessment of risk and the quality of informed consent. Southam offered strong arguments on both fronts, at least when viewed in the context of social and medical assumptions of the time.

The Inquiry Into Risk

With regard to the presence or absence of risk in this study, Southam argued that the injection of cultured cancer cells from an extraneous source into the human body posed no appreciable risk. His 10 years of prior experience with more than 600 subjects—including cancer patients at Memorial Hospital in New York and healthy prison volunteers in Ohio—had led him to conclude that "it is biologically and medically impossible to induce cancer by this means."⁵ The Regents concurred in this conclusion. As reported in the *New York Times*, the Regents established to their own

satisfaction that prior to the JCDH study in July 1963, "medical opinion was unanimous that the patients were running no risk of contracting cancer and hence need not be cautioned that there was any such risk."⁷

Medical opinion at the time was not, however, entirely unanimous on the question of risk, as it hardly ever is on any question worthy of public debate. One reputable physician, Bernard Pisani, past president of the Medical Society of the County of New York and director of obstetrics and gynecology at St. Vincent's Hospital, testified during the Supreme Court hearing that "the known hazards of such experiments include growth of nodules and tumors and may result in metastases of cancer if the patient does not reject these cells."⁵ In addition, according to a recent account based upon an interview with Kagan many years after the fact, "Kagan, Leichter, and Fersko . . . disagreed with Southam's contention that the injections posed no risk to the patients involved."²

Another reason to doubt Southam's unequivocal denial of any risk in this experiment is the fact that in one of his own previous studies, the injected cancer cells had migrated 10 inches up the arm of a subject from the injection site to a nearby lymph node. The patient in question had died shortly thereafter, but there was some speculation at the time that, had the patient lived, cancer cells that had migrated that far might then have been subsequently disseminated throughout the body via the lymphatic system. Although Southam claimed that the cells would not have traveled beyond the lymph node if the patient had lived, he admitted that he could not settle the matter with a "statement based on fact."⁵

But perhaps the most telling and unintentionally humorous admission that Southam made regarding the possibility of risk came during his cross-examination before the Board of Regents. Mr. Calanese, an attorney for the Regents, was quizzing Southam about an apparent contradiction in an article based upon an interview with him in the journal *Science*.⁸ Although emphasizing Southam's confidence that there was "no theoretical likelihood" that the injections of live cancer cells would cause cancer, the article also noted Southam's unwillingness to inject himself or his colleagues. Calanese then quoted the following line from the interview: "But, let's face it, there are relatively few skilled cancer researchers, and it seemed stupid to take even the little risk." To which Southam responded: "I deny the quote. I am sure I didn't say, 'Let's face it.'"⁵ In retrospect, we can grant Southam the objective truth of the proposition that those live cancer cells posed zero appreciable risk to the residents of the JCDH. But we can also question his assertion that any right-minded physician *at the time* would have corroborated this claim. This doubt, plus Southam's own admission that the injections posed "little risk"—which suggests at least *some* risk—to himself and his staff, leads me to conclude that the doctor was being somewhat disingenuous and misleading in his outright denials of risk. Even if he believed that the likelihood of those injections causing cancer was vanishingly small, it is not obvious, even judging by the louche standards of informed consent operative at the time, that Southam did not owe these elderly residents of the JCDH some mention of the possibility of risk.

Informed Consent and Professional Norms

The historical importance and personal poignancy of Southam's story are both due in large measure to the fact that his case played out against a backdrop of changing societal and professional mores with regard to the physician-patient relationship. Southam

was obviously brought up and trained within a system of medical education that was deeply and pervasively paternalistic. In those days, there were no “strangers at the bedside,”⁹ no institutional review boards, lawyers, bioethicists, patient advocates, or hospital risk managers to second-guess the experienced judgments of physicians. Although the nascent doctrine of informed consent was beginning to percolate through the medical and research establishments, at the time of the JCDH case in 1963 most physician-researchers believed that obtaining the subject’s consent was a matter of individual professional discretion. If one were doing research on healthy subjects in nontherapeutic experiments, then one might well ask for the subjects’ written informed consent, as Southam did in his trials with state prisoners in Ohio. But research on sick patients was another matter, and here researchers were more likely to cloak themselves in the mantle of the traditional ethic governing relationships between patients and physicians.

In the clinical setting, truthful information regarding risks was regarded less as an ethical or legal matter and more as a matter of therapeutics. If the risks were small, physicians would likely conclude that informed consent was not necessary, especially if they believed that the information in question would upset or depress the patient. But if the risks were great, or if physicians needed the patient to be informed in order to better collaborate on recovery, then information would be “medically indicated.” According to this paternalistic physician ethic, information regarding risks was viewed as essentially one more tool in the physician’s black bag. Truth-telling was a matter of individual physician discretion, and the relevant yardstick for disclosure was the perceived benefit or harm of disclosing information bearing on the patient’s medical condition. Even though medical researchers were primarily interested in producing knowledge rather than in the traditional physician’s goal of advancing the best interests of particular patients, they felt free to avail themselves of this traditional physician ethic in their research.

Against the background of this professional practice, Southam’s duty seemed clear. The risk of injecting cancer cells into the bodies of frail, elderly patients was, in his view, infinitesimally small, perhaps even nonexistent. Were he to announce to these patients that he was about to inject them with *live cancer cells*, such a disclosure would have advanced no legitimate medical purpose while only serving to make the elderly residents very upset and anxious. In those days, physicians tended to avoid the dreaded word *cancer* when talking to their patients, preferring instead to speak cryptically of *nodes*, *cysts*, or *growths*.¹⁰ It was standard medical practice to envelop patients in a conspiracy of silence in order to shield them from information that was perceived to be alarming, depressing, or otherwise harmful.¹¹ Contrary to Board member Hyman’s misguided allegation, Southam was not trying to determine if cancer could be induced through the injection of live, foreign cancer cells; his choice of live, cultured cancer cells was dictated solely by methodological and comparative purposes. So, because using the word *cancer* was irrelevant to the actual state of affairs, because there was little to no risk, and because the dreaded word would only serve needlessly to alarm patients, Southam believed disclosure of the cells’ derivation to be medically “contraindicated.” In reaching this conclusion, Southam insisted that he was merely acting in the “best tradition of responsible clinical practice.”⁵ It is important to note that the notion of medical relevance advanced here by Southam was purportedly “objective” and scientific rather than subjective, and that the arbiter of what

counts as medically relevant, objective information was, in his view, the physician (who also just happens to be a researcher), not the individual patient-subject.

Southam’s paternalistic view of researchers’ obligations to subjects was confirmed by a parade of distinguished witnesses on his behalf before the tribunal of the Board of Regents. High-ranking medical officers and practitioners at such prestigious institutions as Memorial Hospital, Cornell University, West Virginia Medical Center, the University of Pennsylvania, and the Roswell Park Memorial Institute of Buffalo, New York, a cancer research center, all expressed their complete agreement with Southam’s central contentions: specifically that his research was of high scientific and social merit; that there was no appreciable risk to subjects; that informed consent was a matter for individual physician discretion; that disclosure of information should be “titrated” according to the level of risk posed by research; that the word *cancer* was generally avoided so as not to upset patients, and would in any case not accurately and objectively represent the true nature of the injected materials; and, finally, that Southam’s conduct toward the subjects in the JCDH trial was in complete conformity with the prevailing standards of medical practice. As one of Southam’s lawyers remarked at the time, “If the whole profession is doing it, how can you call it ‘unprofessional conduct?’”⁵

Even journalists chimed in on behalf of the beleaguered Southam. At a time when the authority of the legal and medical professions was still largely unchallenged, the press tended to echo the larger society’s unbridled enthusiasm for medical progress while ignoring, if not denigrating, what we today would call the rights of patients and research subjects. Thus, journalist Earl Ubell, writing in the *New York Herald Tribune*, conjured images of “enormous pay-offs” from Southam’s research, including a possible vaccine against cancer, in dismissing the controversy over the JCDH case as a mere “brouhaha.” He concluded, “It would be a shame if a squabble over who-told-what-to-whom should destroy a thrilling lead in cancer research.”⁵

The Judgment of the New York State Board of Regents

The ultimate arbiters of professional medical norms in New York, the State Board of Regents, did not view Southam’s case as a mere squabble over who-told-what-to-whom. On the contrary, the Board summoned Southam before its Grievance Committee as it heard evidence and eventually passed judgment on whether his license to practice medicine should be revoked. The Regents considered two related charges: (1) that Southam was guilty of fraud or deceit in the practice of medicine, and (2) that he was guilty of unprofessional conduct. The first charge focused on Southam’s alleged failure to obtain informed consent from the patients at the JCDH, while the second implied that violating patient-subjects’ rights of informed consent constituted a violation of professional norms.

Consent at the JCDH

The charge bearing on informed consent had two distinct components: the competency of the research subjects and the extent of information disclosure. Before discussing the adequacy of consent

obtained at JCDH on these two indicia, let us recall what transpired on that day in the summer of 1963. Twenty-two residents were selected for this experiment. All were frail elderly residents of a long-term care hospital, and many were Holocaust survivors whose primary language was Yiddish. Following Southam's initial demonstration of the injection procedure on the first 3 subjects, Custodio proceeded during the next two hours to obtain "consent" from the remaining 19 residents in two separate buildings and to inject them all with the cancer cells. None of the residents was told the purpose of the injections or that they were about to participate in a research project having nothing to do with their own health and well-being. Each was told, however, that they were about to receive an injection designed to test their immune capacity, and that soon a nodule would form that would go away in a short time.

The first question, then, is whether all of these frail, debilitated elderly were "competent" to make an informed decision whether or not to hold out their arms to Southam and Custodio—that is, were they of "sound mind," capable of understanding complex medical information and coming to a decision on whether or not to participate? The evidence and testimony on this question were mixed. Custodio testified that all the patients were fully competent to make their own decisions, and that he had no trouble communicating with any of them. On the other hand, Samuel Rosenfeld, chief of medicine at the Blumberg Pavilion of the JCDH for many years, testified that many of the 18 patients injected on his ward were mentally incapable of giving consent.⁵ Mendel Jacobi, the consultant pathologist at JCDH, added considerable specificity to this charge through an examination of the charts of 5 of the 22 patients. He painted the following picture: Chart No. K-14397 described a 67-year-old patient with "poor cerebration" who had been in a depressive state for a year. Chart No. 2290 showed a 63-year-old patient with advanced Parkinson's disease, low mentality, and lack of insight and judgment. Patient No. 8183 had a history of depressive psychosis and had been diagnosed at JCDH as suffering from dementia praecox and unsound judgment. And the chart of patient No. 3762 recorded a diagnosis of postencephalitic Parkinson's, difficulty in communicating, constant falling, suicidal ideation, and considerable sedation throughout the years. Although it's at least theoretically conceivable that each one of these debilitated patients was lucid during his or her brief interview with Custodio on that summer day, Saul Heller, one of the Regents who heard testimony and rendered a judgment in the case, concluded that under such conditions these debilitated patients could not possibly have understood such complex matters in a mere one- to five-minute encounter.⁵

The Regents' deliberations on the nature and extent of disclosure required for genuine consent were of far greater philosophical, legal, and historic importance than their findings on the issue of competency; indeed, the Board's deliberations on this subject take us to the heart of the matter. Whereas Mandel, Custodio, and Southam were entirely satisfied with the amount of information disclosed to the residents, the Regents concluded that the patients' consent was woefully inadequate. In the first place, none of the residents was told that they were about to participate in a research project. The Regents reasoned that in order for consent to be valid, it had to be informed; and for consent to be adequately informed, subjects had to understand that they were being asked to participate in nontherapeutic research. For all these patients knew, the good doctors in white coats were merely run-

ning routine tests on their immune responses; they had every reason to think that the nature of the impending injections was entirely therapeutic and had nothing to do with research. A mere signature, mere verbal assent, or, worse yet, the resigned nod of a confused patient's head, were not enough. In the Regents' judgment, "[d]eliberate nondisclosure of the material fact [i.e., that the injections were done for research purposes] is no different from deliberate misrepresentation of such a fact."⁵ They concluded that such misrepresentation constituted a serious deception and fraud perpetrated upon the JCDH subjects.

Secondly, the Regents were genuinely scandalized by Southam's deliberate omission of the word *cancer*. Gauging his duties to research subjects through the lens of a paternalistic medical ethic, Southam had claimed that disclosure of the nature of the cells would have been both medically, objectively irrelevant and needlessly upsetting to frail, elderly patients. The Regents concluded, by contrast, that physician-researchers had a legal duty to disclose all information "material" to a patient-subject's decision whether or not to participate. In contrast to Southam's belief that any negative reaction on the part of potential subjects to the word *cancer* would have been irrational, the Regents held that "any fact which might influence the giving or withholding of consent is material," whether or not physicians might consider such influence to be irrational. The bottom line for the Regents was that *the decision is the patient's to make*, not the physician's.⁵ The patient's subjectivity (or at least that of a "reasonable person") was henceforth to be the touchstone of researchers' duty of disclosure, not physicians' estimates of objective truth. In taking this step, the Regents explicitly repudiated the entrenched paternalism of the traditional Hippocratic ethic in the domain of research on which Southam and his supporters had relied.

In response to Southam's additional claim that withholding the word *cancer* was dictated by a genuine concern for patients' well-being—a concern in keeping with "the best tradition of responsible clinical practice"—the Regents pointed out the obvious fact that in this particular case there was no preexisting doctor-patient relationship. Southam may well have professed a concern to shield these patients from any undue emotional distress during a time when doctors often shielded patients from bad news, particularly about cancer; but they were not *his* patients. He was essentially an interloper at the JCDH who had never previously met the 22 injected residents, let alone had a long-standing professional relationship with them. The Regents concluded that, at least with regard to the kind of nontherapeutic research involved at the JCDH, Southam, Custodio, and Mandel were acting primarily as researchers who also just happened to be physicians. They thus had no right to help themselves to the wide-ranging discretion normally allowed at that time to physicians charged with pursuing the best interests of their patients.

Viewing the charges against them through the lens of traditional (paternalistic) medical ethics, Custodio, Mandel, and Southam had focused narrowly on the question of physical harm. They contended that in the absence of a serious risk of harm, failure to disclose the experimental nature of the injections or the true nature of the cells injected could not possibly constitute a valid reason to reproach their behavior. As we currently say with good humor in the rough and tumble world of U.S. professional basketball, "No harm, no foul." The Regents concluded, however, that Southam and colleagues, although not physically harming anyone, had robbed the JCDH residents of their "basic human

right” to make their own decisions whether or not to participate in research.⁵ In the language of the law of torts, under which violations of informed consent would soon be subsumed,¹¹ Southam’s failure adequately to inform his subjects constituted a “dignitary insult” and a legal wrong, quite apart from the question whether anyone was physically harmed.

After considering and sharply rejecting all of Southam’s and Mandel’s justifications for withholding vital information bearing on the nature, rationale, and conduct of the JCDH trial, the Board of Regents issued its final verdict in the case: Both physicians were guilty of fraud, deceit, and unprofessional conduct in the practice of medicine. They had allowed their zeal for research to override “the basic rights and immunities of a human person.”⁵ Having rendered their verdict, the Regents then considered the nature and severity of the punishment for the physicians’ misdeeds. Fifteen of the 17 members of the Regents’ Grievance Committee, meeting on June 10, 1965, voted for censure and reprimand, whereas the remaining 2 members, apparently believing that being dragged before that tribunal was punishment enough, voted for no further action. In its final action in this case, the Board voted to suspend the medical licenses of both Southam and Mandel for one year, a stinging rebuke especially to Southam, who was at the time a prominent leader of the New York and national communities of cancer researchers. The Regents softened this punishment considerably, however, by staying the license suspensions on the condition that the physicians stayed out of trouble for the next year, during which time they would remain on probation.

Dénouement

Events subsequent to the resolution of the JCDH case proved just as freighted with ambiguity as the evidence presented before the Regents’ tribunal. Kagan and Fersko, two of the three courageous young residents who had refused to cooperate, were rewarded for their efforts with exclusion from the American College of Physicians. As Preminger reports, their exclusion was doubtless prompted by their refusal to cooperate in the experiment and their subsequent “irresponsible” resignations from the staff of the JCDH. They appealed, and their exclusion was eventually reversed on the ground that their “overreaction” to Southam’s experiment was excusable in light of their families’ “Holocaust situations.”² These all-too-rare profiles in courage were thus trivialized by the governors of the American College of Physicians, reduced to the status of merely exculpatory psychological pathology. The three dissenters had refused to cooperate in wrongdoing, apparently, not because of any allegiance to an ethical principle or the “basic rights of the human person,” but rather because Mandel’s proposal had triggered their memories of the Holocaust, which, in turn, caused their “irresponsible” behavior.

William Hyman, the founding Board member of the JCDH whose protracted lawsuit to view the subjects’ charts eventually brought the Regents into the case, was refused perfunctory reelection to the hospital’s Board of Trustees in 1966. Even though he had won his narrowly focused lawsuit, and even though the larger issues for which he fought were eventually vindicated by the Regents, his fellow trustees of the JCDH expelled him from the Board of a hospital he helped to found.

But the most remarkable historical irony was reserved for Southam himself. Having been publicly humiliated by an inqui-

sition before the New York State Board of Regents; having been found guilty of fraud, deceit, and the unprofessional conduct of medicine, and having had his medical license suspended and been placed on probation, as his lawyer put it, like some “low-brow scoundrel,” Chester M. Southam was elected president of the American Association for Cancer Research in 1968.⁵ Although his case both reflected and helped to bring about profound changes in the ethos and rules governing biomedical research, those changes had not yet percolated down into the rank and file of the research community, which still clung to its paternalistic ways and duly rewarded Southam with one of its greatest honors. In most researchers’ view, apparently, the JCDH case was nothing more than a mere “brouhaha,” a mere “squabble over who-told-what-to-whom.” For them, there were no lessons to be learned, but as we know now, history was on the side of Hyman and the brave young residents. The days of untrammelled physician discretion in research ethics were numbered, and strangers were indeed gathering at the bedside. It would not be long before the revelations at Tuskegee would explode once and for all any lingering doubts about the desirability and necessity of imposing strict rules on the practice of biomedical research.

Ethical Legacy

What is the legacy and verdict of history on Chester Southam? In his own eyes, Southam might well have considered himself the victim of a cruel historical joke. In the process of doing important research in the usual way according to the regnant Hippocratic canons of medical ethics, he became enmeshed in a wrenching chapter in the development of contemporary research ethics. At one moment he was nobly pursuing research that promised “enormous pay-offs” for millions of future patients, the next he was accused of fraudulent actions befitting a Nazi doctor in the dock at Nuremberg. Indeed, the fact that Southam could muster so many distinguished physicians and researchers in his defense, and that he was subsequently given high honors by his peers in the cancer research establishment, suggests that the verdict in his case had a certain *ex post facto* quality about it. Many years later his daughter reported that Southam viewed his election to the presidency of the American Association of Cancer Research as vindication for his having been unfairly singled out by the Board of Regents.³

However, it would be an exaggeration to say that Southam’s perspective on the obligations of researchers was the only one available at the time, and that he was therefore completely blindsided by history. Several physicians at the JCDH—and not just Kagan, Leichter, and Fersko—strenuously objected to the terms of Southam’s proposed research. It says something that Mandel had to settle for an unlicensed and highly vulnerable Philippine medical resident to do his bidding in facilitating Southam’s study. It should be noted, moreover, that Southam’s cavalier attitude toward informed consent directly contradicted contemporary standards as articulated by one of the study’s sponsors, the U.S. National Institutes of Health (NIH). As the attorney general of New York pointed out in his charges, the NIH’s Clinical Center had explicitly required principal investigators to “personally provide the assigned volunteer, in lay language and at the level of his comprehension, with information about the proposed research project. He outlines its purpose, method,

demands, inconveniences and discomforts, to enable the volunteer to make a mature judgment as to his willingness and ability to participate.”³

Clearly, Southam’s behavior does not measure up very well to this contemporaneous standard. He basically left the selection of subjects to Mandel and Custodio, an unlicensed physician, whom he then left to their own devices in dealing with the remaining 19 resident-subjects. True, there may well be some ambiguity regarding the official reach of the NIH regulations. It is unclear whether they governed only intramural research within the NIH’s Clinical Center in Bethesda, Maryland, or also extended to all extramural research funded by the NIH, such as the JCDH case. Similarly, those regulations may only have applied to competent volunteers, whom they surely covered, and not to hospitalized patients, a more doubtful category. It should nevertheless be obvious that there were other, more demanding interpretations of the researcher’s duties in play at the time this case transpired.

The ethical assessment of Southam’s behavior in this case should also take note of the fact that he was unwilling to expose himself and his colleagues to the same, admittedly small risks to which he was willing to subject the residents of the JCDH. Whether or not he uttered or wrote the words, “Let’s face it,” Southam admitted on cross-examination before the Board of Regents that there might after all be a small risk associated with the injection of live cancer cells into one’s body, and that he was unwilling to subject himself to that small risk. In refusing on principle to share the fate of his elderly, debilitated subjects at the JCDH, Southam appears to be a man who, because of his exalted status as a medical researcher, believed himself to exist on a higher plane than the human beings whom he conscripted into his studies. However, it should be noted that Southam and colleagues were not physically debilitated and therefore would not have been suitable subjects, given the aim of the research.

This last point touches on what for many is perhaps the most galling aspect of Southam’s behavior in this case. This man apparently believed that because he was a medical researcher whose study aimed at truth and posed no lasting harm to subjects, *he was thereby entitled to a special dispensation from ordinary morality to conscript the bodies and lives of whomever he pleased.* Although this

must have seemed to Southam to be a most natural assumption to make, it is in actuality a presumption exhibiting remarkable, albeit all-too-common hubris. Writing in 1970, just four years after the Regents’ judgment in the JCDH case, one of the great forerunners of contemporary bioethics, the distinguished moral theologian Paul Ramsey offered a new bioethical gloss on Lincoln’s famous proclamation that “no man is good enough to govern another without his consent.” Referring explicitly to then-recent scandals in research ethics, Ramsey wrote that “[n]o man is good enough to experiment upon another without his consent.”¹² In 1972, the public reaction to the Tuskegee syphilis study would finally put a decisive end to the freewheeling discretion enjoyed by Southam and his peers in the medical establishment. The era of heavily regulated biomedical research was about to begin.

The Hepatitis Experiments at the Willowbrook State School

The hepatitis experiments performed at the Willowbrook State School are routinely cited as one of the most serious breaches of research ethics of the post–World War II period.^{1–3} This determination is principally due to the inclusion of the experiments in Henry K. Beecher’s 1966 article “Ethics and Clinical Research” in the *New England Journal of Medicine*.⁴ Beecher’s criticism set off a decade of debate about the ethics of clinical research at Willowbrook, with sharply differing opinions from leaders in the field.^{5,6} Beecher extended his critique of the experiments at Willowbrook in his book *Research and the Individual* in 1970.⁷

Willowbrook was an institution for the mentally retarded operated in Staten Island, New York, from 1947 to 1987. For many, Willowbrook is seen today as a symbol of both the improper institutionalization of the retarded and the successful use of the legal system to force state governments to improve the conditions for retarded citizens under their care.⁸ For the research ethics community, Willowbrook has become a potent symbol of unethical research. The experiments are often referred to in the same litany as the Jewish Chronic Disease Hospital case and the Tuskegee syphilis experiments (see Chapters 6 and 8). Indeed, Willowbrook is seen by many as the “pediatric Tuskegee,” and the principal scientist involved in the studies, Saul Krugman, is routinely vilified.

The reality of the experiments at Willowbrook is more complicated. What really happened at Willowbrook? What are the real lessons of Willowbrook for contemporary research ethics?

Hepatitis Before Willowbrook

Krugman began his work at Willowbrook in 1954. At the time, the causative agent for hepatitis was thought to be a virus and the

disease was characterized by two related clinical patterns. The first pattern was *infectious* hepatitis, thought to be transmitted by the ingestion of infectious material from feces. Transmission of infectious hepatitis by food workers through inadequate sanitation facilities, or by person-to-person contact without good hand-washing, had been documented. The second pattern was *serum* hepatitis, in which the infection was transmitted through inadequately sterilized needles or blood transfusions.

The diagnosis of hepatitis was made by observation of a clinical pattern of vomiting, anorexia, jaundice, and liver tenderness. Blood enzyme assays to detect liver damage were just being introduced. Reliance on the clinical symptoms alone for diagnosis meant that the infection might go undetected or be misdiagnosed. In the mid-1950s, it was unclear whether these “subclinical” cases of hepatitis could still lead to the spread of the infection.^{9,10}

Previous research by Joseph Stokes at the University of Pennsylvania had demonstrated that injections of gamma globulin, an antibody-rich distillate of human serum, could modulate the clinical course of hepatitis by means of “passive” immunity. Stokes theorized that if hepatitis infection occurred during the period of passive immunity produced by gamma globulin, the clinical disease would be mild and long-lasting immunity to future infection might result.¹¹ He called this theory “passive-active” immunity.

The Initial Studies at Willowbrook

Krugman came to the Willowbrook State School as a consultant in infectious disease from New York University and Bellevue Hospital. He described his intentions at Willowbrook in the *New England Journal of Medicine* in February of 1958:

Figure 7.1. Saul Krugman (1911–1995). Source: Ehrman Medical Library Archives, New York University School of Medicine. Reproduced with permission.

The present report is concerned with an attempt to control the high prevalence of infectious hepatitis in an institution for mentally defective patients. Its purpose is threefold: to describe the circumstances under which the disease occurred, and the effect of gamma globulin in reducing its occurrence; an attempt to induce “passive-active immunity” by feeding virus to persons protected by gamma globulin; and [to describe the] excretion of virus during the incubation period of the disease.¹²

The investigations, funded in part by the Armed Forces Epidemiology section of the U.S. Surgeon General’s Office, began with an epidemiologic survey of hepatitis at the school. Krugman demonstrated that the majority of hepatitis cases were acquired while at the institution, rather than as the result of infection prior to admission. By surveying the sewer and water systems, the growth and preparation of food, and the clinical histories of those who prepared and served the food, he also demonstrated that the source of hepatitis at the school was contact among infected students rather than infection from the food supply.

The Willowbrook strain of hepatitis was mild compared with other reported cases. Indeed, there were no deaths from hepatitis either in the patient population or in the attendants from 1953 to 1957. Krugman documented the rate of clinically apparent hepatitis among children and attendants at the school. The rate of acquisition of hepatitis among children at the school was to become a source of much contention, but Krugman’s estimate at the time was that 40 to 50 patients per 1,000 per year contracted hepatitis.

Krugman and his coinvestigators set out to explore the protective effects of gamma globulin on the children at Willowbrook. After an initial trial with what was shown to be an inadequate dose, a second trial compared hepatitis rates between two groups of recently admitted students, only one of which was given gamma globulin injections. The results were startling. The children given gamma globulin appeared to be protected against clinical hepatitis for 39 weeks. The duration of the protection against infection was unexpected, because in the work by Stokes and others the pro-

TECTIVE effects of gamma globulin had lasted only 6 weeks. In order to explain the difference, Krugman asked whether the prolonged protection against hepatitis in persons injected with gamma globulin might be due to Stokes’ passive-active immunity: “If so, it might be induced artificially by feeding virus to patients protected by an injection of gamma globulin.”¹²

This hypothesis is the essential aspect of Krugman’s experimental program, namely, that infection of children with a mild form of hepatitis could be an effective strategy to confer long-lasting immunity. In a report in 1957, Krugman wondered,

Would gamma-globulin prevent [the] spread [of hepatitis], and if prevention occurred, would the effect be transitory or would it be prolonged in such a way as to suggest “passive-active” immunity (Stokes)? Could “passive-active” immunity be induced experimentally in small isolated groups by injecting gamma-globulin and then feeding hepatitis virus?¹³

The idea that infection with a mild form of a viral agent could induce immunity was well established by the time of Krugman’s work, and in 1957 Krugman directly refers to his research as “immunization.”¹³ Much of the work on infectious diseases of childhood focused on just this approach. The polio trials¹⁴ are perhaps the most famous example, but the work to induce immunity to measles also followed a similar pattern at precisely the same time, the mid-1950s¹⁵ (see Chapter 5).

Ethical Issues Considered Before Beginning the Research

In outlining their intention to initiate the research, Krugman and colleagues wrote that “[t]he decision to feed hepatitis virus to patients at Willowbrook was not undertaken lightly.”¹² The depth of planning for the trial and the lengthy list of ethical considerations prior to beginning the research are clearly enumerated in the 1958 *New England Journal of Medicine* article:

It is well recognized that infectious hepatitis is a much milder disease in young children. Hepatitis was especially mild at Willowbrook; it was even benign in adults and there were no deaths. . . . Only the local strain or strains of virus already disseminated at Willowbrook would be used. . . . Since the annual attack rates of jaundice were high, for example 20 to 25 per 1000, and since in all probability cases of hepatitis without jaundice were occurring with the frequency equal to overt forms, it was apparent that most of the patients at Willowbrook were naturally exposed to hepatitis virus. . . . The advantages were considered of inducing the infection under the most favorable circumstances such as special isolation quarters with special medical and nursing personnel to provide close observation and extra care. . . . The study was planned so as to begin with very small and obviously ineffective doses of virus and to increase the dosage level gradually, in accordance with the results obtained. . . . The study group would contain only patients whose parents gave consent. . . . A serious uncontrolled endemic situation existed in the institution, and knowledge obtained from a series of suitable studies could lead to its control. . . . These factors were instrumental in the decision to proceed with the plan for titrating virus and inducing so-called passive active immunity.

The plan was sanctioned by the authorities of the New York State [D]epartment of Mental Hygiene, by the Armed Forces Epidemiologic Board of the [O]ffice of [S]urgeon [G]eneral.¹²

From today's perspective, this list of considerations mimics those presented in protocol applications to an institutional review board. Krugman designed an experiment that presented the least risk possible to those enrolled. He began with a low dose to observe side effects, created a specialized system for monitoring the children, and used an agent known to produce a mild form of the disease. He took into account the risks that the children faced in the absence of participating in the research. He considered the benefit to those enrolled as well as to other children facing the same circumstances. He obtained consent from the parents of every child who participated. And he obtained an independent review of the study design from experts in the field.

One result of the research program at Willowbrook was a reduction in the incidence of hepatitis among patients and employees by "80 to 85 percent."¹⁶ Yet a beneficial outcome does not justify unethical research.

Criticisms of the Willowbrook Studies

Criticism of the Willowbrook experiments was first published in the *New England Journal of Medicine* in 1966 by Beecher, who continued his attack in 1970 in his *Research and the Individual*. Beecher set the tone for all subsequent condemnations of the experiments, and the legacy of his errors can be seen not only in the literature^{2,3} but also in a brief unsuccessful attempt to outlaw all pediatric research in New York.¹⁷ Beecher and later critics have made seven interlocking charges against the experiment.

1. Research that is done not for the benefit of the children involved in the study, but for others, is unacceptable. One of Beecher's primary concerns in writing the 1966 article was to criticize experimentation on one group of individuals solely to benefit another group. He cites the World Medical Association's draft code on ethics—which was to become known as the Declaration of Helsinki—and concludes, "[t]here is no right to risk injury to one person for the benefit of others."⁴

Beecher's criticism misses the mark at Willowbrook. Krugman had been clear in each report of the Willowbrook research that the goal of the research was to induce immunity in the children participating in the research so as to afford them protection against future infection.^{12,13} Hepatitis was a problem at Willowbrook. Were Krugman to have performed the experiments on children who were not in an institution, and therefore not at an increased risk of acquiring hepatitis, then a case could be made that the experiment would place the children at risk only to benefit other children or adults. In the modern parlance, there was a "prospect of a direct benefit" to the children participating in the study, although this wording was unavailable to either Beecher or Krugman.

This is, of course, not to say that only the children at Willowbrook would benefit from the experiment; if Krugman were correct, then the induction of "passive-active" immunity might provide a boon to others who lived in crowded conditions with an increased potential for acquiring hepatitis. It is likely that the prospect of effective immunization against hepatitis that might be used with military recruits was the reason for the funding provided for the experiments. But the prospect of benefiting others

does not exclude the prospect of benefit to the children at Willowbrook.

2. Deliberate infection of a person with an infectious agent as a part of research is unacceptable. Beecher's argument is that the intentional induction of an infectious disease is an unacceptable practice as part of research, regardless of the reason or the potential benefits of the research. Although he does not elaborate his concern, it appears that he has a principled objection to making someone sick when they are part of an experiment.

Beecher's objection is not very persuasive. There is no ethical weight that should be attached to the use of an infectious agent in a study independent of the effect that the infectious agent has on the study's risk. Beecher's rhetoric of "infection" carries with it undertones of dirt or pestilence when none is reasonably present. Beecher's argument appears to rest on a view of the human body as being irrevocably damaged by contact with infectious agents, and this is simply not the case, as the history of immunization programs amply demonstrates. The ethical issue is the harm done by the infection, not the mere fact of infection itself.

3. The parents who consented were unaware of the risks of participation. Beecher's claim is not that parents did not consent, but that there was inadequate disclosure of the details of the trial to the parents. His argument is that the research was so risky that no reasonably informed parent ought to have consented, and he takes the fact that the parents did consent as evidence that the consent process must have been inadequate.

Not much is known about the specific information provided to parents of children approached to participate in the Willowbrook experiments. In 1967, Joan Giles, Krugman's longtime collaborator in the hepatitis studies, described the consent process in the following way:

I explain that there is no vaccine against infectious hepatitis, that the disease is always present here, and that their child is quite likely to come in contact with it by the intestinal-oral route common to a close quartered group of this type. I also tell them that we can modify the disease with gamma globulin but we can't provide lasting immunity without letting them get the disease. I explain that we use blood serum taken from Willowbrook patients who had hepatitis and that experience has shown a minimum dosage that can induce the disease in a form even less severe than occurs naturally in patients outside the hepatitis unit.²⁰

In *Research and the Individual* Beecher responds to Giles' comments by arguing that "it was not clear whether any or all of the parents were told that hepatitis sometimes progresses to fatal liver destruction or that there is a possibility that cirrhosis developing later in life may have had its origin in earlier hepatitis."⁷ Beecher's criticism boils down to a concern that there was a failure to focus on the serious but small risk of death due to hepatitis with liver failure. His criticism ignores that this complication had not been seen during the survey of hepatitis carried out at Willowbrook before the studies began: "Hepatitis was especially mild at Willowbrook; it was even benign in adults and there were no deaths."¹² In considering the overall quality of the consent process described by Giles, and acknowledging that she may have been explaining it in the best possible light considering Beecher's criticism, it is hard to argue convincingly that the parental consent was so insufficiently informed as to make the entire process unethical and the consents invalid.

4. *Parents were coerced into enrolling their children in the research by the lack of available space at the school.* Beecher's criticism is based on events that were reported in 1967 but that occurred in 1964. Admissions to Willowbrook were halted due to overcrowding, yet space remained for additional children in the separate hepatitis research building. At that time, letters were sent by Dr. Jack Hammond, the medical director of Willowbrook and a coauthor on several reports of the hepatitis experiments, to the parents of children who were on the waiting list informing them that there was space in the research building.²⁰ Beecher's conclusion was that the investigators could not ethically be allowed to benefit, in the form of new children in their trial, from the lack of space at the school, and that enrollment should have ceased once parents had only the option of enrolling their children in the study or of not placing their children in Willowbrook at all.

The grounds for Beecher calling this letter unacceptably coercive are unclear: Parents clearly did want to admit their children in the school before they heard of the hepatitis experiments, and there is no evidence that the clinical standards for admission to the school were manipulated for those parents willing to enroll their children in the experiments. Parents were offered a set of options, neither of which was by itself unethical. There was no evidence of monetary or other incentives that induced the parents to choose enrollment in the studies. It is not *prima facie* unacceptable to require consent to research participation as a prerequisite for entry into a specialized care facility. Under such a reading of coercion, one might conclude that all institutions such as the NIH Clinical Center, where patients are admitted by agreeing to participate in a research program, systematically engage in unacceptable coercion. Such a reading abuses the meaning of the term coercion.²¹

5. *Infection with hepatitis was not "inevitable" for children admitted to Willowbrook as Krugman had argued.* The rate of hepatitis infection among the children at Willowbrook has been the subject of enduring debate. Krugman and others argued that if infection with hepatitis were "inevitable" for children admitted to Willowbrook, then it would be acceptable to infect them under controlled conditions.

It is now clear that Krugman's rhetoric inflated the risk of infection with hepatitis. He reported in 1958 that the rate of hepatitis with jaundice was 25 per 1,000 per year, and that the rate of infection without jaundice was likely to be twice that, or 50 per 1,000 per year. Yet a recent best estimate using data available to Krugman at the time concludes that between 30 and 53% of the children admitted to Willowbrook would have acquired hepatitis during a childhood spent at the institution.²³ These estimates are below the claim of "inevitability" cited by Krugman and his supporters. Although all children in the experiments would contract hepatitis, only half—using a "generous" estimate²³—of the children not participating in the trial would contract the disease. There may have been a subpopulation of children in whom the risk of infection was greater—perhaps those with a greater degree of disability or those exhibiting specific behaviors—and if so, then there may have been a subset of children for whom infection was "inevitable." But as these characteristics were not used in selecting children for the trial, the claim that infection was "inevitable" for the children in the general population does not withstand close scrutiny.

How much does this matter to the overall assessment of the experiment? If the goal of the trial were to study the effects of infection *per se*—or if the goal were, as Beecher suggests, simply to

determine the period of infectivity—then the lack of "inevitability" damns the trial, because the risk to the children not enrolled in the trial is less than that to those enrolled. Yet this was not the case, because there was the prospect of direct benefit to the children participating in the experiments.

If we correctly recognize that the experiments were done in an attempt to confer long-lasting immunity, then we can ask at what threshold of risk for an infectious illness in a given population should we begin immunization trials. We can get a sense of the acceptable threshold at the time by comparing Krugman's work to the other immunization research of his era. Using the 30% figure, the risk of contracting hepatitis as a child at Willowbrook was substantially greater than the risk of contracting polio as a child in the general population.¹⁴ The point is that we ought to use a threshold risk in the population substantially lower than "inevitable" for the comparison of the risks of trial participation. Compared to other trials at the time, a risk of 30% was certainly over the acceptable threshold.

6. *The experiments were unacceptable "experiments in nature."* Some have criticized Krugman for participating in a problematic "experiment in nature," a situation in which something bad is known to be happening to a group of people, and rather than preventing the bad event, a researcher exploits the situation by studying those negatively affected by it.³ Rather than study hepatitis in children, the argument goes, Krugman had a moral duty to change the institutional conditions that led to the infection.

Calling the research at Willowbrook an "experiment in nature" rests on a mistaken idea that infection of the children was done in a convenient population simply to understand the consequences of infection. As Krugman explained in 1967, "Willowbrook was not chosen because its population is mentally retarded, but because it had endemic infectious hepatitis and a sufficiently open population so that the disease [hepatitis] could never be quieted by exhausting the supply of susceptibles."²⁰ Krugman was intervening in an epidemic situation, not simply standing by and observing. More importantly, his goal was to help those afflicted or likely to be afflicted by the illness in the very institution where the study was being done. Krugman's aim was to remedy the situation he found, not just to use it for an experiment. Again, the criticism that the studies were "experiments in nature" rests on a failure to see them as a program of immunization designed to address the problem of hepatitis in the institution.

7. *The researchers should have cleaned up the conditions that led to the increased risk of infection rather than studied how to protect the children via immunization.* At Willowbrook, the increased hepatitis risk faced by the children was a consequence of the decision to gather children with mental disabilities and incontinence together in an institution, rather than a consequence of the children's disabilities *per se*. It can thus be argued that the conditions leading to the increased risk of hepatitis at Willowbrook were artificially created, because they were a result of a policy of institutionalization, and that by halting the institutionalization of children, the risk of hepatitis would be greatly reduced without the children having to undergo the risk of participation in research. If so, did the investigators have a moral duty to change the policy and to thereby decrease the risk of hepatitis faced by the children?

In order to answer this question, we must first know whether there were steps short of closing the institution (and not involving

immunization) that might have prevented the risk of hepatitis infection. Preventing the fecal-oral spread of infectious agents among incontinent children in an institution is not a simple matter, even in a resource-rich environment. Control of hepatitis A outbreaks in neonatal intensive care units remain difficult even today.^{23,24} Effective cohorting of children to prevent cross infection takes strict measures, with quarantining of all infectious children. Prior to the work of Krugman and his colleagues, such cohorting within the institution would have proven ineffective, because identification of those who were infectious was not possible. Nor would it have been clear what the duration of quarantine should be. In the context of a long-term residential program, physical measures to prevent infection would likely have meant the end of interactions among the children, with the indefinite closing of play groups and other measures thought to be therapeutic. Faced with those options, an attempt to discover an effective means of conferring immunity seems an appropriate means to address the medical risk to the children while preserving their ability to participate in the life of the institution.

So, were the investigators ethically bound to close the institution, or was it ethically viable instead to study how to make the institution safer? At the time of the hepatitis experiments, parents and physicians were eager to get children admitted to Willowbrook because institutionalization was thought to be the best thing for the children and for their families.²⁵ Placement in Willowbrook—that is, placement in a specialized school where retarded children could have access to the services of experts—was at the time seen by many as a symbol of an enlightened approach to the plight of retarded children.²⁶ Objecting to the institutionalization of children at Willowbrook in the 1950s and early 1960s, based on our contemporary approach to mental retardation in children, is open to a charge of anachronism, as well as of a certain arrogance that we are more ethically evolved than those who preceded us. Given the view that institutionalization was a beneficial policy for children and their families, Krugman and colleagues did what they could to improve the chances that institutions were safer for their child residents. Accusing Krugman of ignoring the suffering of the children at Willowbrook only to further his own agenda makes no sense in this context.

Correcting the Distorted Legacy

Because of the mistaken views of Beecher and others about the scientific objectives of the hepatitis research, Krugman's studies at Willowbrook are persistently cited as an example of unethical pediatric research. Yet many in the medical community who correctly understood the scientific and social context of the research have honored Krugman's work at Willowbrook, as have many of the families of the children in the research.

The mistakes of Beecher's analysis should be held to account for much of the continued misunderstanding. The errors are not simply of historical interest, because Willowbrook continues to be invoked in order to cast doubt on the ethics of researching the medical and social problems of retarded or otherwise socially vulnerable children. The use of Willowbrook in such a manner dangerously discourages research as a means to ameliorate health conditions for vulnerable populations of children.

Participation in medical research can be a powerful vehicle by which we devote social resources toward understanding the med-

ical problems of specific populations, as the parallel example of women in clinical research makes clear. Excluded from participating in research, in part by misplaced ethical concerns over the effect of research on a possible pregnancy, women were assumed to benefit from the products of research if men were shown to have benefited from this research. The result was twofold: The unique medical issues of women were ignored, and different physiological responses of women to standard care were rendered invisible. It is a similar mistake to continue to allow the experiments at Willowbrook to cast a restrictive ethical pall over the participation of vulnerable children in medical research.

The Tuskegee Syphilis Experiment

The Tuskegee Syphilis Experiment, commonly called The Tuskegee Study, was a peculiarly American tragedy, and it ultimately played a key role in creating the institutions and practices that today govern the use of human volunteers in U.S. biomedical research.¹⁻³ From 1932 until 1972, the U.S. Public Health Service (PHS), aided and abetted by a number of partners, conducted a nontherapeutic study of the effects of untreated syphilis on more than 400 black men in Macon County, Alabama, in and around the county seat of Tuskegee. Although PHS officers and other participating physicians performed a variety of tests and medical examinations on the men over the years, the Tuskegee Study in essence was a 40-year deathwatch. Only men with advanced cases of syphilis were selected for study, and the men were left largely untreated. Instead, the Tuskegee Study's basic procedures called for periodic blood tests and routine autopsies to supplement the information obtained through regular clinical examinations. The fact that only men with advanced syphilis were selected for the study indicated that the PHS officers were eager to learn more about the serious complications that the disease inflicts on its victims. To comprehend the magnitude of the risks to the men from denying them adequate treatment, it is useful to know a few basic facts about the disease.

Syphilis

Syphilis is a highly contagious disease caused by the *Treponema pallidum*, a delicate bacterium that is microscopic in size and resembles a corkscrew in shape. The disease may be acquired or congenital. In acquired syphilis, the spirochete (as the *Treponema*

pallidum is also called) enters the body through the skin or mucous membrane, usually during sexual intercourse, though infection may also occur from other forms of bodily contact, such as kissing. Congenital syphilis is transmitted to the fetus from the infected mother when the spirochete penetrates the placental barrier.

From the onset of infection, syphilis is a generalized disease involving tissues throughout the entire body. Once they wiggle their way through the skin or mucous membrane, the spirochetes enter the lymph capillaries, where they are hurried along to the nearest lymph gland. There they multiply at a rapid rate and work their way into the bloodstream. Within days the spirochetes invade every part of the body.

Three stages mark the natural history of the disease: primary, secondary, and tertiary. The primary stage lasts from 10 to 60 days starting from the time of infection. During this first incubation period, the primary lesion of syphilis, the chancre, appears at the point of contact, usually on the genitals. The chancre, typically a slightly elevated, round ulcer, rarely causes personal discomfort and may be so small as to go unnoticed. If it does not become secondarily infected, the chancre will heal without treatment within a month or two, leaving a scar that persists for several months.

While the chancre is healing, the second stage begins. Within six weeks to six months, a rash appears, signaling the onset of secondary syphilis. The rash may resemble measles, chicken pox, or any number of skin eruptions, though occasionally it is so mild as to evade notice. Bones and joints often become painful, and circulatory disturbances, such as cardiac palpitations, may develop. Fever, indigestion, headaches, or other nonspecific symptoms may accompany the rash. In some cases skin lesions develop into moist ulcers teeming with spirochetes, a condition that is

especially severe when the rash appears in the mouth and causes open sores that are viciously infectious. Scalp hair may drop out in patches, creating a “moth-eaten” appearance. The greatest proliferation and most widespread distribution of spirochetes throughout the body occur in secondary syphilis.

Secondary syphilis gives way in most cases, with or without treatment, to a period of latency that may last as little as a few weeks or as long as 30 years. As if by magic, all symptoms of the disease seem to disappear, and the syphilitic patient does not associate the disease’s early symptoms with the occasional skin infections, periodic chest pains, eye disorders, and vague discomforts that may follow. But the spirochetes do not vanish once the disease falls silent. They bore into the bone marrow, lymph glands, vital organs, and central nervous systems of their victims. In some cases the disease seems to follow a policy of peaceful coexistence, and its hosts are able to enjoy full and long lives. Even so, autopsies in such cases often reveal syphilitic lesions in vital organs as contributing causes of death. For many syphilitic patients, however, the disease remains latent only 2 or 3 years. Then the illusion of a truce is shattered by the appearance of signs and symptoms that denote tertiary syphilis, the disease’s final and most deadly stage.

It is during late syphilis, as the tertiary stage is also called, that the disease erupts into a merciless killer. Gummy or rubbery tumors (so-called gummas), the characteristic lesion of late syphilis, appear. They are the stigmata from the concentration of spirochetes in the body’s tissues, with deadly destruction of vital structures. The tumors often coalesce on the skin, forming large ulcers covered with crust consisting of several layers of exuded matter. Their assaults on bone structure produce deteriorations resembling osteomyelitis or bone tuberculosis. The small tumors may be absorbed, leaving slight scarred depressions, or they may cause wholesale destruction of the bone, such as the horrible mutilation that occurs when nasal and palate bones are eaten away. The liver may also be attacked; here the results are scarring and deformity of the organ that impede circulation from the intestines.

The cardiovascular and central nervous systems are frequent (and often fatal) targets of late syphilis. The tumors may attack the walls of the heart or the blood vessels. When the aorta is involved, the walls become weakened, scar tissue forms over the lesion, the artery dilates, and the valves of the heart no longer open and close properly. Instead, they start to leak. Then the stretching of the vessel walls often produces an aneurysm, a balloon-like bulge in the aorta. If the bulge bursts, the result is sudden death.

The results of neurosyphilis are equally devastating. Syphilis spreads to the brain through the blood vessels, and while the disease can take several forms, the best known is paresis, a general softening of the brain that produces progressive paralysis and, eventually, insanity. *Tabes dorsalis*, another form of neurosyphilis, produces a stumbling, foot-slapping gait in its victims due to the destruction of nerve cells in the spinal cord. Syphilis can also attack the optic nerve, causing blindness, or can invade the eight cranial nerves, inflicting deafness. Because nerve cells lack regenerative power, all such damage is permanent.

The Social Context

The germ that causes syphilis, the stages of the disease’s development, and the complications that can result from untreated syphilis

were all known to medical science in 1932, the year the Tuskegee Study began. Indeed, among the many diseases that plagued mankind, syphilis was the most exhaustively studied, the most richly documented, the most elegantly described, and the best understood. So why would the U.S. PHS decide to launch a study of the effects of untreated syphilis in 1932, and why would PHS officials limit the study to black males?

The South in the 1930s was the section of the United States that most resembled the underdeveloped nations of the world. Its people, white and black, remained mostly rural; they were less educated than other Americans; and they made decidedly less money.

As a group, black Americans in the South were among the poorest of the poor. Indeed, they were virtual paupers—chronically unemployed or underemployed, many living in shacks without benefit of sanitation, adequate diet, or the rudiments of hygiene. As a group, they did not enjoy good health. Many suffered from a host of diseases, including tuberculosis, syphilis, hookworm, pellagra, rickets, and rotting teeth, and their death rate far exceeded that of whites.

Despite their chronic need, few blacks received proper medical care. In fact, many blacks lived outside the world of modern medicine, going from cradle to grave without ever seeing a physician. There was a severe shortage of black physicians throughout the South, and many white physicians refused to treat black patients. In addition, there were only a handful of black hospitals in the South, and most white hospitals either denied blacks admission or assigned them to segregated wings that were often overcrowded and understaffed.

But poverty was as much to blame as racism for the medical neglect of black Americans during the 1930s. The United States was in the depths of a bleak economic depression, and blacks, always the last to be hired and the first to be fired, were especially hard hit by the collapse of the economy. Medical care in the United States was offered on a fee-for-service basis, and the truth was that many black Americans simply did not have the money to pay for health care.

The Rise and Role of the PHS

During the Progressive Era, that period of social, economic, and political reform in the United States that began around 1890 and ended around 1920, the federal government took steps to ease the hardships on the poor, and part of these efforts centered on medical care. In 1912 the federal government united all its health-related activities under the PHS. Over the next few decades, the PHS distinguished itself by launching attacks on hookworm, pellagra, and a host of other illnesses. In no field was the PHS more active than in its efforts to combat venereal diseases.

Health reformers knew that syphilis, in particular, was a killer, and that the disease was capable of inflicting blindness, deafness, and insanity on its victims. Furthermore, they regarded syphilis as a serious threat to the family because they associated it with prostitution and with loose morals in general, adding a moral dimension to their medical concerns.

Taking advantage of the emergency atmosphere of World War I, progressive reformers pushed through Congress in 1918 a bill to create a special Division of Venereal Diseases within the PHS. The PHS officers who worked in the VD Division called themselves

“syphilis men,” so great was their personal identification with their vocations. They were crusaders, true believers. Safeguarding the public’s health was their mission and, as zealots, they had a tendency to overstate the challenges they confronted. Labeling syphilis “the great killer,” they proclaimed the gospels of prophylaxis, prompt diagnosis, and early treatment. To them syphilis was the most insidious of diseases, and they worked night and day to drive it from the land. The offensive they launched began with high hopes, and their initial successes were impressive. By 1919, they had established over 200 health clinics, which treated over 64,000 patients who otherwise could not have afforded health care.

To their credit, PHS officers did not ignore the health of black Americans. In the late 1920s, the PHS joined forces with the Rosenwald Fund, a private, philanthropic foundation in Chicago named in honor of its benefactor, Julius Rosenwald, who had made a fortune as one of the founders of Sears, Roebuck and Co. Together, the PHS and the Rosenwald Fund developed a syphilis control program for blacks in the South. In 1929, Michael M. Davis, the director of the Rosenwald Fund’s Medical Division, asked the PHS to assign one of its officers to the Fund in order to advise the Fund on health issues that would benefit blacks living in the South. Julius Rosenwald had a special interest in uplifting blacks, and he was eager to see his foundation’s medical division develop programs that would improve their health. In response, the PHS seconded a physician named Taliaferro Clark to the Rosenwald Fund, with instructions to provide advice and assistance in the Fund’s efforts to develop new programs to improve the health of blacks living in the South. Clark, who had served as the director of the PHS Division of Venereal Diseases, immediately recommended that the Rosenwald Fund develop a syphilis control program for blacks in the South.

Most white physicians believed the racial stereotypes that permeated white society, including the notion the blacks were libidinous creatures who could not control their sexual behavior. As a result, many white physicians assumed that blacks suffered a much higher infection rate than whites because blacks abandoned themselves to sexual promiscuity. And once infected, the argument held, blacks remained infected because they were too poor and too ignorant to seek medical care. In short, many physicians despaired of being able to treat syphilis in the black community, creating a powerful rationale for inactivity in the face of a health crisis that public health officials and private physicians alike agreed had reached epidemic portions.

Armed with money from the Rosenwald Fund, the PHS devised a health study designed to establish the incidence of syphilis in blacks and to learn whether blacks could be treated successfully for syphilis if treatment programs were made available to them. To answer these questions, the PHS selected communities in six different southern states, each chosen because of the different demographic profiles it offered for representing a continuum of the living conditions and circumstances of blacks in the South. In each of the six communities, the PHS dispatched health professionals into the field to ascertain the incidence of syphilis by administering Wassermann tests to a representative sample of the local black residents and then to offer free treatment to those who tested positive and were found to be infected.

The results of this pilot program were at once informative and impressive. Based on the data from the six southern communities, the PHS learned that the rate of infection varied greatly from community to community, ranging from a low of roughly 7% in

Albemarle County, Virginia, to a high of 36% in Macon County, Alabama. In large measure, PHS officers pointed to different socioeconomic conditions to explain the jarring variations they discovered among the communities. In communities where blacks enjoyed higher incomes, better housing, and affordable health care, the incidence of syphilis was relatively low, whereas blacks who suffered higher rates of infection were much more likely to live in communities where living wages, decent housing, and affordable health care were rare. In addition, the data from this pilot program demonstrated conclusively that black patients not only wanted medical treatment for syphilis but returned to the clinics in large numbers to complete the extended program of therapy required to cure the disease.

This program had to be abandoned, however, soon after the stock market collapse of 1929 forced the Rosenwald Fund to terminate its support, leaving the PHS without sufficient funds to follow up its syphilis control work among blacks in the South.

The Tuskegee Syphilis Study

The PHS was reluctant to take leave of one of its pilot programs in particular, the one in Macon County, Alabama. Its county seat, Tuskegee, was the home of the Tuskegee Institute, the famed school founded by Booker T. Washington in 1882 to uplift blacks in the South. It was in and around Tuskegee that the PHS discovered an infection rate of 36%, the highest incidence in the six communities studied. In fact, despite the presence of the Tuskegee Institute, which boasted a well-equipped hospital that might have provided low-cost health care to blacks in the region, Macon County was home to the worst poverty and the most sickly residents that the PHS uncovered anywhere in the South.

It was precisely this ready-made laboratory of human suffering that prompted the PHS to return to Macon County in 1932. Because the PHS could not afford to treat syphilis, Clark decided to document the disease’s damages on its victims by launching a scientific study of the effects of untreated syphilis on black males. (The reason he decided to limit the study to males was his belief that it was easier to get a reliable clinical history from males than it was from females because men were more likely to observe and remember the date of the appearance of the primary chancre, a crucial piece of data for pinpointing how long each person had suffered from the disease.) Many white Southerners, including many white physicians, believed that although syphilis was widespread among blacks, the disease did not harm them as severely as it did whites. PHS officials thought that this was nonsense because they knew that syphilis was a serious threat to the health of black Americans, and they intended to use the results of the study to pressure Southern state legislatures into appropriating funds for syphilis control work among rural blacks. By denying the men treatment, the PHS intended to document the ravages of the disease in black people, build a case for treatment programs sponsored by state governments, and force state health officials to develop and fund treatment programs for Southern blacks modeled after the recently completed Rosenwald Fund syphilis control demonstrations. Here, the irony was palpable: By withholding treatment from the men in Tuskegee, the PHS hoped to secure treatment for blacks throughout the South.

Still, whatever social value might accrue from encouraging state legislatures to appropriate funds to diagnose and treat syphilis

in their black citizens, the fact remains that these “hoped for” benefits in no way justified withholding treatment for a deadly disease from people who believed they were being helped.

There was another motive for the proposed study. For decades medical scientists and clinical physicians alike had accepted as an article of faith the notion that advanced syphilis affected whites and blacks differently. Blacks were believed to suffer a much higher incidence of cardiovascular syphilis, whereas whites were thought to suffer a higher incidence of brain damage and related neuro-

logical disease. The Oslo Study of untreated syphilis in a select group of Caucasians, a retrospective study that dated back to the 1890s, had provided medical science with a controlled experiment on whites, and the PHS officers wanted to develop comparable data on blacks. In other words, the Tuskegee Study was intended to provide a black counterpoint to the Oslo Study, supplying data that would permit scientists to test the notion that advanced syphilis affected blacks and whites differently. Here again, the social value of determining whether the disease affected the races differently

Table 8.1
Tuskegee Syphilis Study Timeline

<i>Date</i>	<i>Event</i>
Nov. 1929	The Rosenwald Fund, a private philanthropic foundation, appropriates \$50,000 to finance syphilis control demonstrations by the U.S. Public Health Service (PHS) with African Americans in six different communities in six different southern states, one of which is the town of Tuskegee, the county seat of Macon County, Ala.
Jan. 1930	The PHS begins its syphilis control demonstrations in Tuskegee and other communities in the South.
Oct. 1932	The PHS returns to Tuskegee, where it previously uncovered an infection rate of 35% among those tested, to study the effects of untreated syphilis in a select group of African American males. The men are not told the purpose of the study nor the effects of syphilis on human beings.
May 1933	Spinal taps are performed on the subjects of the study without the procedure or its effects being explained to them.
June 1933	Taliaferro Clark, who originated the study, retires from the PHS. Raymond Vonderlehr, who is intent on continuing the study, succeeds him.
Nov. 1933–Mar. 1934	PHS officers return to Tuskegee and add a group of approximately 200 African American men to serve as controls for the study, again without explaining the study to them.
May 1935	The Milbank Memorial Fund, another private philanthropic foundation, gives the PHS a grant of \$500 to pay burial stipends to the men as an incentive for them and their families to consent to autopsies on the men when they die. The grant is extended in subsequent years.
1937–1938	The PHS sends mobile units into Macon County to treat people for syphilis, but treatment is withheld from the men in the study.
1942–1943	The PHS intervenes with the local draft boards in and around Macon County to secure deferments for the men in the study in order to prevent them from receiving treatment from the armed services upon induction into military service.
1943	The PHS starts treating patients who have syphilis with penicillin in several medical centers in the United States.
1947	The Nuremberg Code is articulated to protect human subjects from unethical and illegal medical experiments and studies.
1952	The PHS attempts to improve its record keeping and diagnostic standards for the study.
1958	The PHS distributes certificates of appreciation and small cash payments to the men in the study.
1964	The Declaration of Helsinki, which stipulates that researchers must obtain informed consent from their subjects, is issued by the World Medical Association.
1966, 1968	Peter Buxtun, a PHS employee in San Francisco, Calif., raises strong moral objections to the Tuskegee Study.
Feb. 1969	The PHS convenes a blue-ribbon panel to review the Tuskegee Study, and the panel recommends that the study be continued, with one panelist in dissent.
July 1972	Peter Buxtun tells a newspaper reporter about the Tuskegee Study and the press breaks the story.
Aug. 1972	In response to public outrage, the Department of Health, Education and Welfare (HEW) appoints a panel to investigate the Tuskegee Study.
Feb./Mar. 1972	The U.S. Senate holds hearings on human experimentation; the Tuskegee Study is given prominent attention.
Mar. 1973	HEW officially ends the Tuskegee Study by authorizing treatment for the survivors.
July 1973	Attorney Fred Gray files a \$1.8 billion class action lawsuit against the United States, HEW, the State of Alabama, the State Board of Health of Alabama, and the Milbank Fund, as well as certain individuals in their private capacity.
Dec. 1974	A settlement is reached in the lawsuit.
1975	The U.S. government agrees to treat the wives and children of the men in the Tuskegee Study.
1997	President Bill Clinton apologizes for the Tuskegee Study.

must be weighed against the risks to the men from lack of treatment for a disease that medical authorities agreed was a killer.

The Design of the Tuskegee Study

In 1932, Clark dispatched two of his best officers from the Division of Venereal Disease, Oscar C. Wenger and Raymond Vonderlehr, to Alabama to conduct the study. As part of their preparations, Wenger and Vonderlehr briefed state health officials, the chief administrators and medical officials at the Tuskegee Institute, local doctors in the region, and other concerned parties on the proposed study and secured their full cooperation and support. In addition, they hired a black nurse, Eunice Rivers, to help with the study. Once these preparations were completed, the PHS officers went through Macon County and the surrounding counties with a Wassermann dragnet. Based on the test results of the men they examined, the PHS officers selected approximately 400 men who would serve as subjects in the study group. In 1933 and 1934, the PHS officers selected an additional 200 men who were free of the disease to serve as controls.

From the outset, the Tuskegee Study was a nontherapeutic scientific experiment. It had nothing to do with treatment; its overriding purpose was to document the natural history of disease in black males. In order to secure their cooperation, Wenger and Vonderlehr told the local residents and the men who were selected for study that the PHS had returned to Macon County to resume the treatment program that had been started under the Rosenwald Fund syphilis control demonstrations. The PHS did not inform the men that they had syphilis. Instead, the men were told only that they had “bad blood,” a catchall phrase that rural blacks used to describe a host of ailments. In short, the PHS did not obtain informed consent from the men in study. Rather, the PHS deceived them by withholding critical information about the nature of their illness and the true purpose of the study.

Although the PHS had no intention of treating the men, J. N. Baker, the ranking state health officer, demanded as the price for the Alabama Health Department’s cooperation that the men in the study be given treatment—not enough to cure them, to be sure, but enough to render them noninfectious. Consequently, all of the men in the study received at least some treatment with arsphenamine by injection and mercury by inunction—the drugs and treatment methods of choice in the 1930s.

No one worried much at the time about the glaring contradiction of treating subjects in a study of untreated syphilis because the men did not receive enough treatment to cure them. Treatments against syphilis did exist at the time, although they were not as effective as current therapies. Any amount of treatment, however, was fatal to the scientific integrity of the experiment. Flawed beyond redemption, the Tuskegee Study had no scientific validity because it was hopelessly contaminated from the outset. In addition to being morally bankrupt, it was bad science.

The original plan called for the Tuskegee Study to last from six months to a year. After Vonderlehr started examining the men, however, he was fascinated by the high incidence of cardiovascular syphilis he believed he had discovered in the subjects. He urged Clark to extend the study for several more years so that science could learn more about the effects of untreated syphilis. Clark refused his request, explaining that the Division of Venereal Diseases did not have enough money to continue the study. Within

the year, however, Clark retired and Vonderlehr succeeded him as the director of the Division. Vonderlehr’s promotion settled the matter. He decided to continue the Tuskegee Study, stipulating that its time frame would be open-ended.

Vonderlehr’s decision to continue the study anticipated one of the most important reasons why the Tuskegee Study would last for 40 years. Over and over again during the next four decades, the PHS policy of promoting from within would bring to the directorship of the Division of Venereal Diseases officers who had worked in one capacity or another on the Tuskegee Study earlier in their careers. Often they had been sent to Tuskegee as young PHS recruits to sharpen their diagnostic skills by examining the men, and over the years they became not only knowledgeable about the study but comfortable with it. On those rare occasions when questions were asked regarding the study, these officers found it difficult to be objective. Time after time, they brushed aside scientific challenges and moral objections to continuing the study. In effect, they were co-opted by familiarity and they found it impossible to bring an unbiased assessment to the study.

The Tuskegee Study was not a difficult experiment to run. The PHS officers had only to monitor the progress of the disease in the subjects and perform autopsies on them when they died. To accomplish these tasks, the PHS sent teams of officers back to Tuskegee at regular intervals to perform what they called “annual round-ups.” Nurse Rivers was responsible for transporting the men in her automobile from their homes either to the Andrews Hospital on the campus of the Tuskegee Institute or to the nearby Veterans Hospital, the two facilities where most of the clinical examinations were performed. Men who were discovered to be in poor or declining health were followed closely until they died, at which time Nurse Rivers negotiated with their families to secure permission for doctors to perform autopsies.

The PHS offered the families of the deceased men a powerful incentive to allow the autopsies. Because most of these families did not have any kind of burial insurance, they were hard pressed to come up with the money for decent burials. The PHS offered the families burial stipends if they would consent to autopsies. Most did. To finance the burial stipends, the PHS turned directly to the Milbank Memorial Fund, a medical philanthropic foundation. Over the years, the Milbank Memorial Fund provided a series of grants to the PHS for the explicit purpose of providing burial stipends to the families that permitted autopsies.

Burial stipends were not the only incentives offered by the PHS. In order to make the men think they were being treated for their “bad blood,” Wenger, at the beginning of the study, started handing out pink-colored aspirin tablets to them. This “pink medicine,” as the doctors dubbed the aspirin, became an instant hit. Most of the men had never taken aspirin before and they marveled at how quickly it relieved their aches and pains. From then on, the “government doctors” routinely dispensed little bottles of “pink medicine” every time they examined the men. A few years later, the “government doctors” also started dispensing iron tonic to the men. It, too, became much in demand. Perhaps no better placebos could have been used.

It is striking how little the PHS offered the men. Indeed, it is difficult to imagine a risk-benefit ratio that was more lopsided. Small amounts of syphilis therapy at the beginning of the study, aspirin, iron tonics, and burial stipends were the only benefits the men received in the early years of the study. In the 1950s, the PHS sweetened the deal by giving the men official-looking certificates

Figure 8.1. Nurse Eunice Rivers in the cotton fields with an unidentified man. Source: Centers for Disease Control Papers, Tuskegee Syphilis Study Administrative Records, National Archives—Southeast Region.

of appreciation and a dollar a year for every year they had remained in the study (see Figure 8.2). Added together, the benefits can only be described as paltry. As a group, the men saw their life expectancy decline by 20%, and one estimate placed the number of men who died from complications from syphilis at 100, fully a quarter of the men with the disease. Meager as the benefits were, they had their intended effect. They kept the men in the study, illustrating to perfection two crucial factors that the PHS counted on to keep the study going: deception and inducements to the poor.

Originally, the Tuskegee Study was supposed to last for only six months to a year. But because there was no formal protocol at the beginning, the time frame proved to be remarkably elastic. As the years passed, it became open-ended, and PHS officials simply assumed that the study would continue until the last man had died. It was as though the PHS had converted Macon County and the surrounding areas into its own private laboratory—in effect, a “sick farm”—where diseased and dying subjects could be maintained without further treatment and herded together for inspection at the yearly roundups. One of the health officers who conducted an “annual roundup” even spoke of “corralling” the men, as though they were so many sheep or cattle. In truth, the Tuskegee Study made no emotional demands on the PHS officers who conducted it because the little contact they had with the subjects did not require them to develop person-to-person relationships. They never got to know the men as patients or as people.

Instead, the PHS officers behaved like absentee landlords, issuing orders from afar, demanding strict accountings for day-to-day affairs, and appearing in Tuskegee only when needed. From their standpoint, the operation of their sick farm in Alabama was ideal. They were free to analyze data and to write scientific papers about the effects of untreated syphilis in black males; a few weeks of frantic work each year during the roundups was all they had to do in Alabama. Time, disease, and Nurse Rivers took care of the rest.

Potential Challenges to the Tuskegee Study

During the first few years of the experiment, there was no real danger that the men would receive medical treatment; poverty and ignorance decreed that they would remain untreated. That situation changed dramatically in 1937. In that year, the Rosenwald Fund decided to renew its support of syphilis control programs in the South and sent a black physician, William B. Perry of the Harvard School of Public Health, to Macon County. Fearing that the resumption of treatment activities might endanger the experiment and aware that Perry badly needed help, Vonderlehr shrewdly arranged to have Nurse Rivers assigned as his assistant. Perry agreed to cooperate fully with the experiment by not treating any of the subjects. Nurse Rivers worked closely with him to make certain that none of the subjects, all of whom she knew by name and on sight, received treatment.

Although withholding treatment from the subjects had always been standard operating procedure, this episode marked a sea change. Before the study began, the men were in no real danger of being treated because they were too poor and too ignorant to seek medical care. In a sense, then, all the Tuskegee Study did was to take a de facto situation and place it under a microscope so that science could compile data from the men’s plights. By denying the subjects in the study therapy when treatment became widely available in the late 1930s and early 1940s, however, the PHS actually prevented the men from benefiting from therapy that they otherwise would have received.

Nor was this the only time when the PHS took steps to deny the men treatment. Until World War II erupted, Nurse Rivers, with the aid of local and state health authorities, had successfully cut the men off from treatment programs, but the war created a situation in which representatives of the lay public were making certain that syphilitic men in Macon County received treatment. Approximately 250 of the syphilitic subjects were under 45 years

U. S. PUBLIC HEALTH SERVICE

This certificate is awarded to

In grateful recognition of 25 years
of active participation in the
Tuskegee medical research study.

of age (the cutoff age for the draft) in 1941, and they became “1-A” registrants, the group first in line for induction into the armed services. Once their physical examinations revealed syphilis, the men in the study started receiving letters from their local draft boards ordering them to take treatment. To prevent them from being treated and from being inducted into the armed services, the PHS intervened with the local drafts and obtained deferments for all of the men in the study. Thanks to the PHS intervention, a significant number of the subjects were denied treatment once again, for the PHS had no intention of losing men from the study. If the men were to be placed in harm’s way, the PHS meant for them to do so as “soldiers of science,” not as soldiers who fought the nation’s enemies on foreign battlefields.

Preventing the men from receiving treatment had always been a violation of Alabama’s public health statutes requiring public reporting and prompt treatment of venereal disease cases. In 1943 these regulations were superseded by the Henderson Act, an extremely stringent public health law inspired by the wartime emergency. The law pertained to tuberculosis as well as venereal diseases and required state and local health officials to test everyone in the state between the ages of 14 and 50 and to treat those who were found to be infected. Under the auspices of the law, health officials conducted the largest state-level testing and treatment program in the history of the nation. But just as the men in the Tuskegee Study were cut off from earlier treatment programs, the Henderson Act was never applied to them. State and local health officials deferred to the PHS policy of keeping the men untreated and continued to cooperate with the study.

The Tuskegee Syphilis Study After World War II

Two developments associated with World War II might have impinged on the study, but did not do so. The first was the discovery of penicillin and the drug’s mass production during the last part of the war. Yet penicillin did not produce any soul searching or second thoughts within the PHS. It was withheld for the same reason that other drugs had been denied to the men from the beginning of the experiment: Treatment would have ended the Tuskegee Study. In the view of the PHS, the men were subjects, not patients; clinical material, not sick people.

The other development associated with World War II that might have given the PHS officers pause was the Nuremberg trials and the Nuremberg Code, the 10 basic conclusions or principles on human experimentation that emerged from the trials (see Chapter 12). The PHS officers associated with the Tuskegee Study during and immediately after World War II saw no connection whatsoever between the atrocities committed by Nazi scientists and their own actions in the Tuskegee Study. Indeed, there is no evidence that the Tuskegee Study was ever discussed in light of the Nuremberg Code.

And yet there was a similarity between the Nazi experiments and the Tuskegee Study, one that transcended their racist and medical natures. Just as the chain of command within the military hierarchy of Nazi Germany blunted individual responsibility and failed to frame moral issues, the Tuskegee Study’s firm entrenchment within the PHS bureaucracy reduced the sense of personal responsibility and ethical concerns. Like the Nazi doctors who pleaded that they were simply following orders, the PHS

officers, state health officials, the medical staff of the Tuskegee Institute, and the staff from the Veterans Hospital in Tuskegee all felt that they were simply doing their jobs. Some spoke of merely “following orders,” whereas others insisted that they had worked to advance science.

Black professionals in and around Tuskegee showed no more concern for the men than did the white doctors and health officials who launched and sustained the experiment. Over the decades, a procession of black doctors, health officials, educators, and nurses all lent their support, knowing full well the details of the study and its goals. Robert Russa Moton, who succeeded Booker T. Washington as the principal of the Tuskegee Institute; Eugene Dibble, the head of the Andrews Hospital at the Tuskegee Institute; William B. Perry, who conducted the second Rosenwald Fund syphilis treatment program in Macon County; Jerome J. Peters, who performed many of the autopsies at the Veterans Hospital in Tuskegee, all cooperated with the Tuskegee Study. Indeed, they and other black professionals lent a powerful element of biracial support to the Tuskegee Study. For at every stage of the study, the black professionals worked side-by-side with their white counterparts, and their very presence served to reassure the subjects that they were being helped by their participation in the Tuskegee Study. Indeed, it seems doubtful that the Tuskegee Study could have kept going without the black professionals. Yet as a group, they went largely unnoticed by the later pundits who saw the experiment as a simple morality play that cast white people in the familiar role of exploiters and oppressors of black people. It was far easier to keep things simple than to explore class divisions, based largely on education and income, within the black community, or to ponder how those same class divisions and professional identities could ally black professionals with white professionals.

Exposing the Tuskegee Study

Despite its powerful element of biracial support, the Tuskegee Study was a bellwether for race relations in the United States. Only 35 miles from Tuskegee, Rosa Parks and Martin Luther King were launching historic protests against racial injustice in the United States.

At one level, the civil rights movement made it difficult for the PHS to conduct business as usual with regard to the Tuskegee Study. Previously, PHS officers had always published their scientific reports on the experiment like scientists who had nothing to hide. By the 1960s and early 1970s, however, the self-confidence of their predecessors had been replaced by self-consciousness. For beneath the façade of “business as usual” there was a growing uneasiness, a perception that things had changed. It was not that the PHS officers had come to the conclusion that the Tuskegee Study was morally wrong. Rather, they feared dire consequences if the experiment became known. In other words, they regarded the Tuskegee Study as a potential public relations disaster waiting to happen. The day had passed when medical researchers could ignore the public’s concern over the protection of human subjects, and they knew it. They understood, at least at some level, that race added a volatile issue.

In the years following the appearance of the Nuremberg Code and the Declaration of Helsinki (see Chapter 13), pressure gradually grew within the United States for the government to regulate

human experimentation. In 1966, the Surgeon General's office issued Policy and Procedure Order Number 129, outlining the PHS's first guidelines on grants for clinical research and training. The guidelines established a system of peer review conducted by a standing panel of colleagues at an investigator's institution. Members of the committee had the responsibility of reviewing all proposals from their institution and submitting an "assurance of compliance" to the PHS.

Significantly, none of the guidelines contained provisions that applied to the PHS's own research programs. And nothing in the guidelines—except, of course, their spirit—obliged the PHS to meet the same standards as its grantees. Thus, none of the PHS health officers connected with the Tuskegee Study felt bound by these guidelines, and none expressed any ethical concern about the experiment in the light of these guidelines.

Peter Buxtun was different. He thought the Tuskegee Study was a moral disaster, and he said as much to anyone within the PHS who would listen. In the mid-1960s, Buxtun, a psychiatric social worker by training, was employed by the PHS at the Hunt Street Clinic in San Francisco, California, where he worked as a venereal disease interviewer and investigator. Buxtun learned about the Tuskegee Study from discussions with coworkers, and he researched the topic for a short paper he was required to prepare as part of his training. Disturbed by what he learned from his research, Buxtun launched a one-man crusade within the PHS to protest the bankrupt morality of the Tuskegee Study. He wrote letters, met with officials, and did everything in his power to persuade them to end the study.

As a result of Buxtun's protests, the PHS conducted a full-scale review of the Tuskegee Study in 1969. The review was held at the Communicable Disease Center (now the Centers for Disease Control and Prevention, or CDC) in Atlanta, Georgia, and the committee consisted of several high-ranking PHS officials, three medical professors, the state health officer of Alabama, and a senior representative of the Milbank Memorial Fund, the philanthropic foundation that had provided the money to pay small stipends to cover the burial expenses of deceased subjects in exchange for their families' permission to perform autopsies. No one with training in medical ethics was invited to the meeting, none of the participants was black, and at no point during the discussions did anyone mention the PHS's own guidelines on human experimentation or those of other federal agencies. Equally noteworthy, all the members of the committee except one had been directly involved with the Tuskegee Study in one capacity or another in the past. And precisely because all of them but one had been implicated by familiarity, it was difficult for them to bring an objective, fresh perspective to their task. Instead, as group, they were hostages of the same attitudes and values that had allowed them to work on the study for years.

During the course of the review, the committee members discussed whether to stop the study and offer the surviving subjects treatment. In the end, however, they decided to continue the study and recommended steps to improve it scientifically. In addition, they concluded that it would be an excellent idea to seek some type of "informed consent" for the study. Following a discussion, they agreed that the subjects were incapable of giving "informed consent" due to their meager educations and advanced ages. In place of the subjects, the committee members recommended that the PHS consult with state health authorities and the

members of the local medical societies in and around Tuskegee, explain the study to these officials, and seek their cooperation and approval—obtaining, as it were, a kind of "surrogate informed consent" from the local medical establishment.

The committee's recommendation settled the fate of the Tuskegee Study, at least for the time being. It would continue. All of the committee members were physicians, and they approached the experiment as a medical matter. And once a medical judgment had been made against treating the men, the members of the committee saw no point in stopping the study. As a group, they did not perceive a conflict between their own scientific interests in continuing the experiment and attempting to decide what was best for the subjects. As physicians and men of science, they felt fully capable of deciding both. In their professional judgment, the Tuskegee Study was important to science, and they agreed that much remained to be learned from its continuation. Therefore, they decided to follow the men until the last subject had died and all the data had been analyzed and reported in scientific articles.

The members of the committee obviously felt comfortable deciding the fate of the men as a group, without bothering to examining a single subject. For although they expressed concern for the men and discussed whether any might benefit from treatment, they did not recommend that the PHS monitor the men and care for their well-being.

The PHS paid more attention to building alliances with medical groups in Alabama than it did to the subjects. In 1970, the PHS followed up on its plans to meet with state and county health officials in Alabama and with the membership of the local medical societies in and around Tuskegee. During those conferences the PHS officials reviewed the history of the Tuskegee Study, outlined their plans for continuing the study, asked for suggestions, and requested the cooperation of the health officials and private physicians with whom they met. In each instance, the PHS officials were pushing against an open door. Not only did the state health authorities and the local doctors fail to question or criticize the experiment, they offered to help in any way they could. Their response was all the more noteworthy for the fact that the Macon County Medical Society included many black physicians among its members. Thus, from beginning to end, the Tuskegee Study enjoyed the support of white and black doctors and health officials alike.

The Final Disclosure of Tuskegee

Had the PHS been left to its own devices, there is no doubt that the Tuskegee Study would have continued until the last subject had died, all the data had been analyzed, and the final article had been published. Instead, Peter Buxtun suddenly reappeared on the scene. Aided by the press, he moved with dispatch and purpose to end the experiment. Buxtun had resigned from the PHS in 1967 to attend law school, and during his years as a law student, he had attempted to interest several different law professors in the Tuskegee Study, all to no avail. After finishing law school, he finally told his story early in 1972 to someone who was willing to do something more than listen politely—Edith Lederer, a longtime friend who worked as an international affairs reporter for the Associated Press. After Buxtun showed her published articles and

copies of his correspondence with PHS officials regarding the experiment. Lederer forwarded these materials to her superiors at the Associated Press, asking to be assigned to the story. Instead, the Associated Press gave the story to a highly regarded young reporter named Jean Heller, largely because she was based in Washington, D.C., and was familiar with government agencies.

A little digging on Heller's part uncovered additional medical articles on the experiment, but her best source proved to be the officials at the CDC. Heller recalls that in numerous telephone interviews, she received straightforward, matter-of-fact answers to her questions—however sensitive or potentially damaging to the PHS. Spokesmen there even provided estimates of the number of men who had died from the various complications of late syphilis, placing the figure between 28 and 100.

True to their goal of pursuing the study until the last subject had died, PHS officers were still conducting the experiment when Heller broke the story on July 25, 1972. In a series of hard-hitting articles that followed in rapid succession, Heller did a brilliant job of laying out the bare facts of the study. Her articles were only the beginning. All across the country television news shows and newspapers bombarded the public with facts and commentary on the Tuskegee Study. At first PHS officials tried to defend the experiment, but public outrage quickly silenced them, and the PHS officials announced that they had given orders for the experiment to be ended—effective immediately.

Fallout

Suddenly, the 40-year deathwatch was over, but the fallout from the experiment continued unabated. In the wake of the experiment's abrupt ending, Fred Gray, a black attorney and civil rights leader in Tuskegee, brought a class action lawsuit on behalf of the Tuskegee Study's surviving subjects and the estates of the deceased subjects. Rather than go to trial, the government settled the case. As part of the out-of-court settlement, the surviving subjects were finally treated with penicillin for syphilis. In addition, the men and the families of the deceased subjects received small cash payments.

In 1973, Senator Edward Kennedy of Massachusetts held hearings on the Tuskegee Study and other human experiments, and the next year the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research was created to explore the full range of issues involved in the use of humans in biomedical research. In response to the public uproar and the National Commission's recommendations, the government issued new guidelines for research projects that used federal funds in the United States. Drafted for the explicit purpose of protecting human subjects in scientific and medical experiments, these guidelines established and strengthened institutional review boards in universities and hospitals throughout the United States (see Chapter 14).

The Tuskegee Legacy

But the Tuskegee Study's troubled legacy did not end there. No scientific experiment in history inflicted more damage on the collective psyche of black Americans than the Tuskegee Study. In the

years after the experiment's disclosure, news of the tragedy spread in the black community. In addition to what they read in newspapers and magazines or heard on the radio and television, many blacks learned about the study by word of mouth, replete with the sorts of embellishments and distortions that usually attend oral traditions. Many blacks and whites were told that the federal government deliberately inoculated black sharecroppers with syphilis, whereas others were given to understand that the experiment was conducted on black prisoners.

Despite such errors, most black Americans got the gist of the story right: They understood that for 40 years, an agency of the federal government had withheld treatment from men with syphilis so science could learn what the disease, if left untreated, would do to people. Many of the men, the black public learned, had died from syphilis, whereas others had gone blind or insane. Confronted with the experiment's moral bankruptcy, many blacks lost faith in the government and in the medical establishment and no longer trusted health officials who spoke to them on matters of public concern.

This problem came into stark relief when the HIV epidemic struck the United States. Predisposed to distrust health authorities, many black Americans believed the rumors that circulated in the black community charging that HIV was a man-made virus created to perpetrate genocide on African Americans. Although these charges had no scientific basis, many of the people who heard them believed that they were true. And many of these same people did not believe the government's official explanations and theories about the causes of HIV. Suspicious and mistrustful of the government's reports on HIV, they felt deeply alienated from the experts who purported to have their best interests at heart.

Not surprisingly, then, many health officials encountered opposition when they tried to study HIV in black communities. In 1988, federal health authorities were forced to abandon a planned study of HIV infections in the District of Columbia. As designed, the scrapped project proposed to ask the residents of a black neighborhood to submit to household blood tests and complete a questionnaire to determine the feasibility of a national survey to gather data on the incidence of HIV. According to the *New York Times*, city officials "expressed concern that Washington's black community was being used as a 'guinea pig' in a project that would stigmatize the city and its minority communities."⁴ The meaning of this and similar episodes across the country was clear: The legacy of the Tuskegee Study was hampering the government's efforts to control HIV in the black community.

In an effort to address this problem, President Bill Clinton held a public ceremony at the White House on May 16, 1997, and officially apologized for the Tuskegee Study. Speaking to the handful of Tuskegee Study survivors who had been brought to the White House at government expense to hear the apology—and speaking, by extension, to the nation—Clinton delivered an apology that constituted a masterly performance of the politics of symbolism. Aware that blacks have long placed great faith in symbols to express their hopes that they would one day enjoy true freedom and equality in the "land of the free," Clinton used the moral authority of his office to attempt to make amends for the Tuskegee Study and to begin the healing process within the black community.

Despite Clinton's best efforts, however, the Tuskegee Study remains today what it has been ever since the public became aware of it in 1972: a symbol of research malfeasance in which virtually every principle underlying the ethical treatment of human subjects of research was violated.

HIV Research

In the 26 years since its first recognition, the AIDS epidemic has had a profound impact on human history. The Joint United Nations Programme on HIV/AIDS estimates that in 2006 there were 39.5 million people worldwide living with HIV, 4.3 million became newly infected, and 2.9 million died. “In addition to the untold grief and human misery caused by AIDS, the epidemic is wiping out development gains, decreasing life expectancy, increasing child mortality, orphaning millions, setting back the situation of women and children, and threatening to undermine national security in highly-affected societies.”¹

Since 1981, an enormous, worldwide biomedical research response has been mounted. For example, U.S. government funding of AIDS research by the National Institutes of Health (NIH) totaled \$2.902 billion in fiscal year 2006, an amount representing over 10% of the total NIH budget.² Although much remains to be accomplished, the output of that investment has been spectacular. Indeed, as Anthony Fauci has written, “the extraordinary research effort devoted to AIDS during the first two decades of the pandemic and the rapidity with which advances have been realized surpass those associated with any other life-threatening infectious disease in history and certainly any newly recognized disease.”³

The epidemic has also had a profound impact on virtually every facet of research ethics. I will examine just one of those facets in this chapter—how activism and other events in the early history of the HIV epidemic in the United States have caused the field to look anew at the principles of autonomy and justice, as they were articulated in the Belmont Report and implemented in regulation and policy that followed from it. In particular, I will focus on the following:

1. How advocacy for access to promising experimental therapy and clinical trials has:
 - Broadened the concept of autonomy to include the notion that humans with life-threatening diseases are entitled to an important role in assessing the potential risks and benefits of their participation in clinical research.
 - Broadened the concept of justice by giving specific form to the notion that the potential benefits of participation in research must be fairly and equitably shared.
2. How extensive involvement of the HIV/AIDS community has shaped scientific progress and altered the general landscape of clinical biomedical research.

Other facets of the epidemic will be considered in detail in other chapters. Of necessity, this examination is neither chronological nor comprehensive. More complete historical assessments are available.^{3–7} Furthermore, because the epidemic continues to unfold at this writing and is likely to do so for many years to come, the story and its legacy for research ethics are both works in progress. Table 9.1 presents a timeline of selected events in HIV/AIDS treatment research.

Overview: The HIV/AIDS Epidemic in the United States

The disease that was to become known as AIDS was first identified in 1981 in the form of independent outbreaks of Kaposi’s sarcoma (KS) and *Pneumocystis carinii* pneumonia (PcP) in homosexual

Table 9.1
Timeline of Selected Events in HIV/AIDS Treatment Research

<i>Date</i>	<i>Event</i>
1981	Recognition of AIDS (initially known as GRID) in homosexual men
1982	Identification of AIDS in intravenous drug users, hemophiliacs, women, transfusion recipients, and children
1983	Identification of causative virus Identification of AIDS cases in Africa
1984	Recognition of pre-AIDS conditions (AIDS-related complex) Establishment of relationship between high-risk sex and HIV transmission
1985	Licensure of diagnostic test for HIV Initiation of routine HIV screening and heat treatment of blood products
1986	AZT enhances survival of patients with advanced AIDS Establishment of AIDS Clinical Trials Group AZT treatment IND provides AZT to 4,000 patients in four months
1987	Approval/licensure of AZT
1988	Association between cervical dysplasia and HIV infection in women established Enactment of Health Omnibus Programs Extension (HOPE) Act
1989	AZT delays disease progression in patients with early HIV infection ACTG Community Constituency Group
1990	First guidelines for use of antiretroviral therapy Initiation of first trials of combinations of antiretroviral chemotherapy National Conference on Women and HIV Infection Demonstration: "Storm the NIH"
1991	Start of ACTG 076, a study of AZT to prevent mother-to-infant transmission of HIV
1992	FDA announces Parallel Track and Accelerated Approval Initiatives Start of first clinical trial testing a protease inhibitor
1993	Establishment of Women's Interagency Health Study
1994	AZT reduces mother-to-infant transmission of HIV by 70% (ACTG 076)
1995	First demonstration of effectiveness of combinations of highly active antiretroviral therapy (HAART) in treating HIV-infected patients at various stages of disease Licensure and approval of first protease inhibitor
1996	AZT dramatically reduces mother-to-infant transmission in the general population Combination HAART dramatically reduces morbidity and mortality in clinical trials
1997	Huge decreases in U.S. AIDS mortality, attributed to HAART
1998	Identification of lipodystrophy and other long-term complications of HAART Treatment Action Campaign launched by AIDS activists in South Africa to promote greater access to effective treatment
1999	Interruption of HAART explored as strategy for reducing long-term side effects
2000	13th International AIDS Conference ("Break the Silence") in Durban, South Africa, focuses attention on the unavailability of state-of-the-art HIV/AIDS care in the developing world World Medical Association revises Declaration of Helsinki, endorsing the concept that clinical trial participants everywhere must receive worldwide best standard of care
2002	Global Fund to Fight AIDS, Tuberculosis, and Malaria established to fund locally driven strategies to combat the three pandemics World Health Organization releases guidelines for antiretroviral therapy in resource-poor settings
2004	15th International AIDS Conference in Bangkok, Thailand, under the theme "Access for All," includes major activist protests highlighting global disparities in availability of care and heavy emphasis on programs to deliver care in resource-poor settings

men in New York and Los Angeles. Prior to these reports, the two diseases were virtually unknown in healthy young adults. Immunological evaluation of the affected individuals revealed severely compromised immune systems. The syndrome was initially referred to as gay related immune deficiency (GRID). In 1982, the identification of new cases among people with hemophilia, re-

cipients of blood transfusions, and intravenous drug users (IV-DUs) and their children confirmed the presence of an epidemic. The term GRID was soon replaced by the term acquired immunodeficiency syndrome (AIDS).

AIDS was initially defined by the coexistence of certain clinical conditions (e.g., Pcp or KS) and specific laboratory findings in-

Figure 9.1. Estimated Number of AIDS Cases and Deaths Among Adults and Adolescents With AIDS in the United States, 1985–2003. Note: Data adjusted for reporting delays. Source: U.S. Department of Health and Human Services, Centers for Disease Control and Prevention.

dicative of immune deficiency. Further epidemiological investigation led to the identification of various pre-AIDS conditions and with that, the understanding that progressive deterioration of immune function occurred over a number of years. Thus, it became clear that the clinical disease known as “AIDS” was only the tip of the iceberg of an epidemic of unknown size. Gay and bisexual men remained the most heavily affected group. The cause remained unknown until 1983 when investigators in France and the United States independently isolated a previously unknown retrovirus from affected individuals. Although scientific disputes regarding their respective discoveries continued for years, the virus they identified became known as human immunodeficiency virus 1 (HIV-1). This pivotal discovery led directly to the licensure of the first diagnostic test for HIV two years later, in turn paving the way for better elucidation of the course of infection, as well as for routine screening and securing of the safety of blood and blood products. It also connected HIV-1 with “slims disease,” a fatal AIDS-like syndrome characterized by wasting and bouts of severe infection that had been recognized among eastern and central Africans for a number of years before.

In 1986, five years and thousands of U.S. deaths after the first cases of AIDS were identified, the first major advance in treatment occurred. A placebo-controlled clinical trial sponsored by the Burroughs Wellcome Company demonstrated the effectiveness of azidothymidine (AZT), a drug that had been explored but abandoned years earlier as a potential treatment for cancer, in reducing mortality among patients with AIDS.⁸ Over the ensuing decade,

advances in pathogenesis and treatment research led to dramatic improvements in morbidity and mortality through development of potent, multidrug chemotherapy regimens, and strategies for their use.⁹ Striking evidence of the public health impact of these advances in the United States, which parallel those seen in many developed countries, is seen in Figures 9.1 and 9.2.

The Emergence of U.S. HIV/AIDS Activism

The history of HIV/AIDS research is bound together with the story of AIDS activism, which arose in the peculiar social and political milieu of the gay communities of several major metropolitan areas of the United States. Much has been written about the tactics, mechanisms, dynamics and sociopolitical factors involved.^{4,6} The essential point here is that AIDS first appeared in a community that was simultaneously and rapidly emerging, through social and political activism, from a long history of persecution, repression, and marginalization by government, society, and medicine. As a consequence, there existed strong, highly motivated, and politically savvy leadership, with grass roots organizational abilities and powerful communication networks. Unfortunately, the concomitant sexual freedom of the time in general, and of gay liberation in particular, created conditions that permitted the epidemic to spread silently for years. This convergence of biology and sociology was hugely important in shaping the U.S. epidemic and the scientific and activist responses to it.

Figure 9.2. Estimated Number of AIDS Cases Resulting From Mother-to-Infant Transmission, 1985–2003.

Note: Data adjusted for reporting delays and for estimated proportional redistribution of cases in persons initially reported without an identified risk factor. Source: U.S. Department of Health and Human Services, Centers for Disease Control and Prevention.

In this context, AIDS activism was fueled by anger and fear, which grew with scientific insights into the epidemic that included the following: (1) the understanding that there was an initial phase of clinically silent infection that spanned years or decades; (2) estimates that the true scope of the epidemic of viral infection (as opposed to clinical illness manifest as AIDS) included 5 to 10 times as many asymptomatic as symptomatic individuals; (3) proof that transmission of virus from infected to uninfected could occur throughout the asymptomatic phase; (4) an inability to quantify the risk of specific sexual practices known to place gay and bisexual men at increased risk of infection; (5) the rapidly escalating numbers of deaths among friends and sexual partners; (6) frustration and desperation at the lack of effective treatment; and (7) the perceived (often real) indifference of government and the biomedical research establishment to the rights and welfare of gay people.

From this milieu during the mid-1980s emerged a vocal and effective AIDS activist movement that, in the United States, encompassed “a wide range of grassroots activists, lobbying groups, service providers, and community-based organizations [representing] the diverse interests of people of various races, ethnicities, genders, sexual preferences, and HIV ‘risk behaviors.’”⁴ The movement employed all manner of classic and novel activist tactics. The initial focus was on expediting the development of promising experimental AIDS therapies and increasing access to clinical trials in which they were being studied.

Activism and Advocacy for Access

Access to Experimental Therapy

Immediately upon release of the results of the Burroughs Wellcome clinical trial showing effectiveness of AZT, activists demanded that the thousands of people with AIDS in the United States be given access to the drug. This created difficult scientific and regulatory problems because the trial was the first and only controlled study of the drug.¹⁰ Furthermore, it was a relatively small study, its eligibility criteria defined a small subset of infected individuals with advanced disease, the improvement in mortality was short term, side effects were significant, and long-term efficacy and safety were unknown.

Nonetheless, because of the desperate situation at hand and the lack of proven therapeutic options, the U.S. Food and Drug Administration (FDA) followed the advice of its Anti-Infective Advisory Committee and quickly granted approval for marketing of AZT for use by individuals with disease similar to that of the clinical trial population. In the interval between trial results and marketing, the U.S. Department of Health and Human Services and the Burroughs Wellcome Company jointly launched a massive and creative access program, utilizing the regulatory mechanism known as a “treatment IND.” Until that time, access to experimental drugs outside of clinical trials by terminally ill patients was limited, typically entailing case-by-case review by the

FDA. In contrast, under the AZT treatment IND, physicians registered with the FDA as investigators on a protocol designed to collect safety data. Once registered, they submitted information documenting the eligibility of each patient for participation in the program. Drugs for patients deemed eligible were shipped to a registered pharmacy to be administered under the physician's care in accordance with and according to the protocol.

The AZT treatment IND marked the beginning of a major shift in attitude about access to and regulation of experimental drugs for life-threatening diseases that was quite remarkable, given the uncertainties inherent in the results of the relatively small, short-term clinical trial on which it was based and the massive scale of expedited access that resulted. AZT was provided to more than 4,000 people during the six months between advisory committee recommendation and ultimate licensure for marketing by the FDA.¹¹ As other new drugs began to move through the early clinical pipeline of development, activist testimony and advocacy contributed substantially to other important access initiatives that became known as the parallel track policy and accelerated approval.

The parallel track policy permitted limited access to certain investigational drugs by patients with HIV/AIDS who could not participate in clinical trials by virtue of ineligibility or lack of geographic proximity to a clinical trial site.¹² Like the treatment IND, it required that there be substantive preliminary evidence of efficacy from earlier studies, and that research toward ultimate marketing approval be underway. Drugs were supplied free of charge by the pharmaceutical company sponsor to patients.

More sweeping change was seen in the accelerated approval initiative, designed to expedite the approval of a new drug for serious and life-threatening diseases when the drug provides meaningful therapeutic benefit over existing products.¹² Until that time approval by the FDA for marketing required proof of significant improvement in one or more important clinical endpoints such as increased survival or disease-free interval, or shortened duration of clinical illness. (AIDS activists referred to such studies as "body count trials."¹³) Accelerated approval effectively lowered this threshold and allowed sponsors to seek marketing approval on the basis of changes in surrogate measures that reasonably predict clinical benefit (e.g., decreases in tumor size in cancer or increases in measures of immune function in HIV infection). Again, the policy required that research to establish clinical efficacy be continued after marketing approval was granted. It also contained provisions for removal of the drug from the market if those studies failed to confirm clinical benefit.

Access to Clinical Trials

Although it originated in the gay community, the agenda of the U.S. AIDS activist movement was diverse and inclusive from the start. Thus, access to promising experimental therapies also included demands for fair and equitable access to clinical trials by *all* individuals affected by the epidemic. Activists worked diligently to diminish scientific, logistical, and ethical barriers to participation in clinical trials by women and minorities. This focus coincided and was synergistic with parallel emerging government initiatives on a number of fronts to address underrepresentation of women and minorities in clinical research, a problem that compromised the amount and quality of health information available to them.¹⁴

For example, the routes of access to cutting-edge experimental treatment led mainly to clinical trials at academic research centers. These, of course, were not evenly distributed among the U.S. population. AIDS activists demanded that special efforts be taken to ensure opportunities for access to clinical trials among minority communities affected by AIDS. Although it seemed to many a confusion between the goals of research and access to care, clinical research sites (with variable enthusiasm) devoted increased resources to minority community outreach, and progress in accruing underrepresented populations became an important benchmark for evaluation of the performance of clinical trial sites.

AIDS activists also demanded an end to exclusion of women of childbearing potential from participation in experimental drug trials, which had become routine practice following the thalidomide tragedy of the 1960s. Instead they helped bring about regulatory change by the FDA, as well as a general shift in ethical review toward more inclusive approaches such as allowing participation by women if pregnancy testing was negative, and encouragement for all research participants enrolled in a clinical trial to utilize effective birth control measures.¹⁵

Problems with serious adverse events have occurred under these access initiatives but fortunately have been infrequent. For instance, pancreatitis emerged as a severe toxicity of unexpectedly high frequency when the antiretroviral drug didanosine (ddI) was made available under the parallel track mechanism.¹⁶ In retrospect it became clear that patients who received the drug under expanded access had, on average, more advanced disease than those who had been included earlier clinical trials. Surveillance detected the problem quickly, and appropriate changes in labeling were instituted. For other important scientific and ethical concerns with expanded access in interesting and informative analyses, consult discussions by Rebecca Dresser, David Rothman, and Harold Edgar.^{17,18} Of particular importance for research ethics is the potential to exacerbate the therapeutic misconception (see Chapter 58).

Legacy for Research Ethics

The scientific and ethical debate behind these sweeping changes in social attitude, policy, and regulation was intense. The activist argument for change was passionate and straightforward. For example, Martin Delaney, a leader of the AIDS movement from San Francisco, stated the case before the 26th annual meeting of the Infectious Diseases Society of America, and also in the pages of the *Journal of Infectious Diseases*.¹⁹ First, he summarized the three main arguments made by those opposing change: "(1) that patients must be protected from their own desperation, (2) that the experimental drugs might do more harm than good, and (3) that public access to experimental drugs would render it impossible to conduct clinical studies, since no one would bother participating if they could have the drugs any other way."

Focusing on the first two points, he argued that in the "broad gray area" between no evidence for efficacy and "fully proven to FDA standards," there comes a time when evidence of effectiveness, although not conclusive, emerges. "[It] is in this area that we believe life-threatened patients and their physicians must have the handcuffs removed." He went on to acknowledge that the multiphase steps of clinical research were a proven way to quantify the effects of a drug, but questioned "whether those steps should be equally required when seeking to restrain a contagious,

world-wide epidemic as when judging a new cold tablet or pain remedy.” He also asked, “Who gets to decide what risks are acceptable: the bureaucracy in Washington or the patient whose life is on the line?” With similar lucidity he dismissed the concern that easier access during the development phase might slow the drug development process by “siphoning off” potential research participants.¹⁹ Such arguments, emanating from the community of people most affected, were powerful and compelling forces in the scientific and regulatory debate, and since that time proponents for expanded access and accelerated approval have prevailed, repeatedly, and on the fronts of many life-threatening conditions in addition to AIDS.¹²

In the process, they have challenged the manner in which principles articulated in the Belmont Report had been translated into clinical practice in the United States. Given the context of scandal and abuse from which Belmont and its offspring arose, it is not surprising that there existed a more-or-less explicit assumption that researchers and participation in research (and therefore access to investigational drugs) should be considered dangerous to patients, who must be protected from them. Thus the regulation and practice of ethical review—including institutional review board (IRB) oversight and FDA regulation of investigational drug research—erected substantial protective barriers around all human experimentation. In this context, autonomy was regarded largely a matter of ensuring fully informed consent and voluntary participation throughout the course of the study. Similarly, justice was considered largely in terms of ensuring that burdens of research were not unfairly carried by the vulnerable of society.

AIDS activists, on the other hand, did not see protection from uncertain and unacceptable risk. Instead, they saw insurmountable barriers blocking access to their only source of medical hope and potential survival, with no opportunity for discussion or appeal. Their argument was poignantly and succinctly summarized on an activist poster that read, “Stop Protecting Us to Death.” In effect, they asserted that paternalistic protectionism did not constitute respect in the case of persons whose lives were in imminent jeopardy and who had available to them no known effective alternative interventions. Instead, respect required that those persons be permitted a substantial role in autonomous and informed choice regarding the interpretation and meaning of the potential risks and benefits of participation in experimental drug trials.

Furthermore, AIDS activists viewed access to clinical trials as a matter of social privilege. The AIDS Coalition to Unleash Power (ACT UP) used the phrase *medical apartheid* to describe “the routine exclusion of women, children, people of color, and IV drug users from most AIDS research.”²⁰ Rhetoric aside, they argued in effect that the principle of justice required equitable distribution of the opportunity to benefit from participation in experimental drug research as well as protection of the vulnerable from exploitation.

In summary, the realities of the AIDS epidemic presented the field of research ethics with an entirely new set of issues and concerns regarding access to experimental interventions. It demanded a new look at and added new depth to the meaning of basic principles. This legacy is clearly etched in sweeping U.S. regulatory reform regarding human experimentation in the case of treatments for life-threatening conditions and in the processes of ethical review of clinical research that is integral to research and development of new therapy for them.

Community Involvement in the Research Enterprise

Perhaps even more far-reaching than the legacy of expanded access and accelerated approval has been the legacy of involvement of the community of people affected by AIDS in more “upstream” aspects of the biomedical research enterprise. Elements of this involvement, which has truly altered the entire landscape of clinical biomedical research, include the following:

1. The establishment of numerous formal and informal opportunities for direct involvement of people with or affected by HIV/AIDS in all aspects of the federal HIV/AIDS research program.
2. Important involvement of the community in shaping the science that has been carried out under those programs.
3. Use of the political process to change important aspects of oversight, management, administration, and funding of the federal HIV/AIDS research effort.

A few highly selected examples illustrate these three themes.

Direct Involvement in the Research Enterprise

The AIDS Clinical Trials Group (ACTG) is a national multicenter clinical research network that was established in 1987 by the U.S. National Institute of Allergy and Infectious Diseases (NIAID), a part of the NIH, to study treatments for the disease.²¹ AZT had just been approved by the FDA for marketing as the ACTG began work, and the Group’s initial scientific efforts focused on research aimed at extending knowledge of the usefulness and toxicity of the drug for other AIDS-related indications, for example, in earlier stages of infection than the original Burroughs Wellcome study. Because AZT was the only proven treatment option and research was synonymous with state-of-the-art care, many observers and AIDS patients viewed the ACTG as a key route of access to AIDS treatment. For the ACTG’s first several years, the number of people entered in trials was the benchmark by which many activists and congressional observers judged the Group’s progress and success.

Others, however, grew increasingly critical of the ACTG’s science and its scientific leadership, “in part because of growing concerns about the ethics of clinical research, and in part because activists recognized that it was no good fighting for faster approval of drugs if there were few such drugs to be approved.”⁴ Rapidly mounting criticism focused on the slow pace of progress in treatment research; the small number of new drugs that were being studied; the methodology used to study them (e.g., placebo-controlled trials); the heavy emphasis on studies of AZT-based antiretroviral therapy; the inadequacy of research on treatments for opportunistic complications of the disease; the failure to study a variety of “underground” alternative treatments that were not approved by the FDA but were nonetheless being used in the community by people with HIV; the organizational structure put in place to administer the Group and carry out the trials; and the seemingly secretive processes of prioritization, study development, and execution.

Scientists were in the bull’s eye of activist frustration and anger. The leadership of the ACTG—internationally prominent researchers in infectious diseases, virology, microbiology, and immunology—became known to many as “the Gang of Five,” a

phrase borrowed from Chinese political activists, referring to their “control of most U.S. AIDS research.” A flier from a chapter of the activist organization ACT UP stated: “They are not the sole source of all the ACTG’s problems, but they symbolize and embody them: obsession with AZT, excessive ties with the large pharmaceutical companies, conflicts of interests, disdain for community concerns, lack of interest in opportunistic infections, opposition to expanded access, and love of secrecy, decision-making behind closed doors.” The flier concluded with the statement: “These are the people who are killing us!”²²

Scientists in general were surprised and bewildered. Accustomed to less incendiary approaches to discourse and debate, they were ill-equipped and unprepared for protest, demonstrations, and ad hominem attacks. They were also stunned and hurt by accusations of greed, selfishness, or that they were working for any goal other than the best interests of their patients and people with AIDS in general. For example, virologist Martin Hirsch described a 1988 activist protest during a presentation he was giving at a national medical conference in Boston. An activist carried a sign which read, “Marty Hirsch and Clinical Trials = Jim Jones and Jamestown.” Another sign read, “The blood of 19 is on your hands” (referring to the 19 placebo recipients in the trial he was describing). He recalled:

What was even more troubling was that one of my own patients was carrying the sign. When asked about it later by one of my colleagues, the patient responded casually, “Hirsch shouldn’t take it personally.” What was seen by the medical community as a major triumph . . . was seen by some in the patient advocate community as a needless waste of life. Where had these different perceptions arisen? Clearly, the protesters and I came from different backgrounds and had different expectations concerning the proper conduct of clinical investigation. We had failed to communicate with each other concerning our different expectations.²³

Anthony Fauci, Director of NIAID and a frequent activist target, borrowed from Mario Puzo in counseling scientists and staff who became the subject of such attacks: “It’s nothing personal; it’s strictly business.”²⁴ Many, however, had a difficult time distancing themselves from the rhetoric, and there was talk at the time of researchers leaving the field because of it all. The activist-science relationship hit a low point during the 1990 International AIDS Conference in San Francisco, when leading government scientists were provided with bodyguards because of anonymous threats.

In the midst of such turmoil, a group of activists demanded admittance to and participation in ACTG meetings.²⁵ They asserted a right to be directly involved in a publicly funded program that directly affected them and their communities, with which they had many disagreements and which they could neither understand nor influence from the “outside.” Not surprisingly, most ACTG scientists and NIH staff resisted, arguing that open and healthy scientific debate would be either misinterpreted or stifled by the presence of scientifically naive and hostile “outsiders”; that the inherently difficult and deliberative process of establishing research priorities and implementing studies to address them would be slowed even further by the need to explain complex matters of science to lay people; and that proprietary, privileged, or preliminary scientific data would be “leaked” to the public

inappropriately or before it was adequately reviewed and analyzed. In retrospect it is easy to see that raw emotions were just beneath the surface of such rational arguments.

To the chagrin of many of his staff and scientists in the field, Fauci was moved by the substance of the activists’ arguments. He listened carefully and at length to both sides of the debate, determined that more good than bad would come from openness, and assigned to his Division of AIDS the task of working with ACTG researchers and activists to implement his decision to open the ACTG to participation by the HIV/AIDS community.

During the next several years, avenues were created for membership and participation in all aspects of the ACTG by people with HIV and representatives of their communities. The centerpiece of the process was the Community Constituency Group (CCG), a new permanent ACTG committee.²⁶ The job of the CCG and its members was to bring direct community perspective and expertise to all aspects of the ACTG. Over time, individual CCG members and the CCG as a whole have developed and contributed indispensable expertise in many areas including science as well as community relations, information dissemination, advocacy, and inclusion. From the beginning, the CCG aspired to a level of diversity in representation that reflected the full scope of the HIV epidemic and the communities affected by it. Members of the CCG choose their peers and successors, and they sit as full members on every ACTG scientific operational committee, task force, and governing body. Together with the Group’s scientists and operational staff, they participate directly in the establishment of research priorities, plan and implement studies, and analyze and disseminate study results. NIAID and the ACTG leadership also mandated the establishment of Community Advisory Boards (CABs) at each clinical trial site.²¹ CABs play a role analogous to the CCG at the locations where the clinical trials actually take place. Many CAB members are also part of the CCG.

This paradigm of ongoing, direct community involvement has become a feature of virtually all other NIH-sponsored HIV/AIDS clinical research programs, scientific meetings and workshops, and both formal and informal HIV/AIDS advisory bodies of the NIH. Analogous types of involvement have also become standard practice in much pharmaceutical company-sponsored HIV/AIDS research.

This is not to say that the process was easy for either scientists or activists. Scientists’ hopes that such involvement would end protest were quickly dashed when, only six months following the first meeting of the newly “opened” ACTG, more than 1,000 demonstrators descended on the NIH in Bethesda, Md., in a protest called “STORM THE NIH.” They demanded that President George H. W. Bush and Congress increase funding for AIDS research and that the NIH “study the whole disease, test all AIDS treatments immediately, and end medical apartheid.”²⁰ *The Washington Post* reported that 83 demonstrators were arrested for trespassing or resisting arrest as they occupied offices, hung red streamers in the trees to symbolize bureaucratic red tape, and left mock gravestones around the campus²⁷ (see Figure 9.3).

The CCG members, too, faced challenges reconciling their role with their activist roots. Their more militant counterparts charged that CCG members were being co-opted and did not really represent people with AIDS. In addition, there were several bitter disputes within the CCG on important scientific and policy directions, such as the design of studies to prevent mother-to-infant transmission of HIV. Several CCG members were also

Figure 9.3. Protesters “storm the NIH” and conduct a “die-in” in front of the Office of the Director of the NIH, May 21, 1990. “Storm” demonstrators as well as parties to a consensus statement endorsed by an ad hoc coalition of 25 AIDS-related organizations released only four days before the demonstration.²⁸ Its critically thoughtful approach to the same issues stood in stark counterpoint to the tactics and rhetoric of the demonstration.

Shaping Science From Within and Without

Over time, however, this new and important perspective has been assimilated at the table of science and has evolved to a more stable, collegial partnership. Epstein provides an insightful, detailed, and well-balanced account in which he posits that AIDS activists were effective because they established credibility by studying and understanding the science, and speaking with scientists on scientific terms.⁴

Activist Publications, Studies, and Reports

AIDS activists have subjected virtually all aspects of the research enterprise to independent scientific analysis. Their critiques, conclusions, and recommendations are contained in innumerable reports such as those listed in Table 9.2. Far from activist diatribe, these were important sources of AIDS activists’ credibility. First, they staked out clear positions that could be debated and discussed. Second, they were often informed by, or facilitated alignments with, the agenda of subsets of scientists within the research enterprise. Such activist-scientist alliances were critical in facilitating change toward mutual objectives. Third, the scope of topics goes far beyond the immediate, specific, and applied interests in treatment research of the community of people with HIV. Finally, they served as an important resource for a virtual industry of periodical publications written by or for people with HIV/AIDS. Such pub-

lications served an invaluable role in building an informed constituency of unprecedented scientific sophistication.

Engaging Science on Science's Terms

An illustrative, early example is "Countdown 18 Months," a well-researched, thoughtful, and passionate critique of the state of clinical research on treatment of opportunistic infections (OIs). Released in late 1990 by a group associated with chapters of ACT UP, the report challenged prevailing scientific priorities that focused on the long-term goal of controlling the underlying cause of AIDS through antiretroviral drug development. It argued that such research must be balanced by research addressing the immediate needs of thousands of patients with life-threatening complications of the disease. The report contained a detailed scientific agenda for OI research and drug development, recommendations aimed at multiple federal agencies and the pharmaceutical industry for specific new research and policy/regulatory initiatives, benchmarks for measuring progress during its 18-month timeline, and

explicit notice that progress would be scrutinized closely and regularly. The report, in turn, triggered a congressional investigation which, not surprisingly, came to many of the same conclusions.²⁹

Many of the report's arguments resonated with groups of scientists within the research enterprise. The resulting activist-scientist alliance advocated successfully for increased attention to OI treatment and prevention research within the ACTG and industry—although the same activists continued to criticize the pace. Their efforts contributed directly to the fact that by 2005, at least 30 drugs had been approved for marketing by the FDA specifically for treatment or prevention of AIDS-related OIs and other complications. Several of the activists responsible for the report became important and highly respected contributors to the efforts of the ACTG OI Committee.

Activists became increasingly important participants in complex deliberations about significant matters of science, such as acceptance of the validity of "surrogate markers" as endpoints in antiretroviral drug research and development.³⁰ In a somewhat ironic convergence of interests, activists found themselves aligned with scientists in the pharmaceutical industry who advocated use of CD4+ cell counts as more efficient routes to licensure through quicker answers in studies with fewer research participants. Advocacy from this activist-scientist coalition led to a large, coordinated, retrospective analysis of clinical trial data from previously completed studies. This analysis established that changes in CD4+ cell counts following treatment correlated well with subsequent morbidity and mortality. In turn, subsequent clinical trials relied increasingly on CD4+ cell count and other surrogate endpoints as primary measures of treatment effect. There can be no doubt that answers to clinical trials accrued more quickly as a result. However, there was intense debate for years about the wisdom of this scientific leap of faith. Scientifically conservative opponents argued that it would create a "house of cards" of short-term data that then would become the standard by which the next intervention was judged, a concern that subsequently gained traction for a number of years. In fact, a subset of the same activists who were instrumental in the push for surrogate markers reversed course several years later and argued for larger clinical endpoint studies because, in their judgment, pharmaceutical companies failed to follow through on their obligation to pursue postlicensing research documenting clinical benefit.³¹

To a large degree, this concern has been mitigated as highly effective antiretroviral chemotherapy and better surrogate markers, such as precise, reliable quantitative measures of viral load, have been validated and become more widely available. However, such phenomenal advances have brought with them complex management decisions for people with HIV and their care providers. As people with HIV live longer, new complications of the disease or long-term side effects of therapy have emerged, engendering complex management problems for patients and their health-care providers. Activists have kept these matters squarely on the table of problems requiring scientific attention. More importantly, they have become parties to the process of grappling with vexing methodological challenges and clinical dilemmas of research to address them, such as the following:

- Management of a syndrome of metabolic dysfunction causing disfiguring changes in body fat distribution
- When, in the course of HIV infection, to begin antiretroviral therapy

- Indications and optimal strategies for antiretroviral therapy when relapse appears
- The possibility that effective treatment can be safely interrupted for periods of time as a way of decreasing unacceptable long-term side effects

HIV/AIDS Research Addressing the Needs of Women

Activism of a different sort played a pivotal role in increasing the attention of the research enterprise to the specific problems of women infected with HIV. Because the early epidemic in the United States was overwhelmingly among men, specific manifestations of the disease in women went unrecognized and were not included in the Centers for Disease Control (CDC) case definition of AIDS. As a result, women were undercounted in national case figures that provided the basis for many AIDS service programs around the country. Furthermore, most research involving women with HIV addressed the problem of mother-to-infant transmission. Activists banded together with concerned scientists and spearheaded the first National Conference on Women and HIV Infection, held in 1990. Research and other presentations at that conference led directly to changes in the national case definition of AIDS to include conditions that specifically affected women.³² The conference also led to federal funding in 1993 of a national multicenter cohort study of women with HIV, and to a number of more specific clinical and basic research studies addressing pathogenesis, prevention, and care of HIV infection in women.³³

Engaging the Political Process: The HOPE Act

AIDS activists have been widely recognized for their success in lobbying for increased federal funding for prevention, care, and research. They have also used the legislative process in other ways to directly influence science and science policy.

A particularly far-reaching example was the Health Omnibus Programs Extension (the “HOPE” Act, PL 100–607), signed into law by President Ronald Reagan on November 4, 1988.³⁴ Among its provisions, Title II contained language that affected the structure and design of the federal HIV/AIDS research enterprise. Of particular note for the purposes of this discussion were requirements that NIH do the following:

- Establish a clinical research review committee within NIAID.
- Establish community-based clinical trials.
- Provide the public with information on HIV/AIDS treatments and options for participating in clinical trials.
- Expedite the review process for all AIDS-related grants.
- Create an Office of AIDS Research within the Office of the Director of NIH.

Establishing a Clinical Research Review Committee

This legislative requirement was notable for several reasons. First was the striking level of detail in the Clinical Research Review Committee’s mandate—a virtual charter addressing specific concerns of the activist community at the time. Second was the unusual requirement that NIH develop what amounted to treatment guidelines—essentially recognition of the need for intimate connection between such an important national resource and the

rapidly changing state of science. Finally, was a requirement to provide recommendations to FDA regarding drugs that should be made available under the parallel track policy, clearly indicating explicit congressional intent to facilitate access to promising experimental therapies.

Establishing Community-Based Clinical Trials

The community-based clinical trial “movement” was borne of the frustration of many activists and primary care providers. It rested on impressions that mainstream clinical trials programs were isolated in academia and skewed toward populations that did not fully represent the epidemic; addressed the scientific questions and needs of academic researchers rather than the everyday issues confronted by physicians and patients in the course of routine primary care; and utilized study designs with restrictive and narrowly defined eligibility requirements that led to results of limited or uncertain generalizability. In at least some activist and clinician circles there existed the attitude that “If they can’t do research that has meaning to us, we’ll do it ourselves.”

Thus, community-based HIV/AIDS research was strongly shaped by activist initiatives. Perhaps the boldest was the establishment of independent research networks based in primary care settings. Two prominent examples were the County Community Consortium in San Francisco and the Community Research Initiative in New York City. An explicit goal of both was to carry out community-relevant research on potential new AIDS treatments in community settings as an alternative to the academic base of most clinical research at the time.

In this context, the HOPE Act articulated specific congressional direction for NIAID’s then-emerging Community Programs for Clinical Research on AIDS (CPCRA).³⁵ The objectives of the CPCRA, indicative of those of the community-based research movement in general, are to do the following:

- Conduct research in HIV primary-care settings.
- Reach underserved populations.
- Conduct clinical studies that answer questions about the day-to-day medical management of HIV disease.
- Generate data about therapies and treatment strategies that can be used in a wide range of patients.
- Provide research results concerning new therapies and treatment strategies to clinicians, clinical researchers, pharmaceutical companies, and patient advocates.

It is beyond the scope of this chapter to assess either the validity of the assumptions behind the community-based research movement or the ultimate impact of such organizations on the current state of HIV/AIDS research and care. It is fair to say that novel and alternative models for clinical research were created and tested, and that important, useful, and interesting studies have been carried out. For example, an early trial established the efficacy of aerosolized pentamidine in preventing PCP, an approach first advocated by prominent community practitioners³⁶; and a recently published study demonstrated that intermittent administration of antiretroviral treatment (with the hope of diminishing side effects) results in increased morbidity and mortality and does not reduce adverse events compared to standard continuous administration.³⁷ It is also fair to say that community-based research programs have faced many challenges, including the involvement of critical masses of creative scientific talent and the development

of systems for data collection and quality control in primary care medical practices. The important point for this discussion is that these networks were, in part, activist-inspired and driven alternatives to mainstream clinical research.

Providing Public Information on AIDS Clinical Trials

With an explicit goal of facilitating access to experimental treatment by people with HIV, the HOPE legislation mandated that NIH create a publicly available resource of information on NIH-sponsored clinical trials. In the process, Congress signaled support for the regulatory reform concerning investigational drug access already underway at the time and discussed above, as well as for a nascent, joint NIH-CDC initiative to establish the AIDS Clinical Trials Information Service (ACTIS).³⁸ ACTIS began as a toll-free telephone-based service. It has since expanded in scope and sponsorship to become AIDSinfo, a federally supported, authoritative and comprehensive source for information on HIV prevention and treatment. It contains tools for locating federally and privately supported clinical trials, trial results, educational resources, treatment guidelines, and extensive data on HIV/AIDS drugs and vaccines. (ACTIS later served as a prototype for www.clinicaltrials.gov, a congressionally mandated “registry of clinical trials for federally and privately funded trials of experimental treatments for serious or life-threatening diseases or conditions.”)

Expediting the Review of Grants

Two other provisions of the HOPE legislation related to the management and organization of the NIH itself. One specifically mandated that NIH expedite peer review and award of HIV-related grant applications, a process that typically takes nine months or more from grant submission to award (if successful). Activists joined many scientists who argued that “business as usual” was unacceptable in a public health emergency. The HOPE legislation reduced review and processing time to six months, concerns about cost, logistics, and perceived unfairness by other scientists of such “AIDS exceptionalism” notwithstanding. The legislative mandate stands intact as of this writing.

Creating an Office of AIDS Research

The final provision affecting the organization of the NIH established an Office of AIDS Research (OAR) within the Office of the NIH Director. The OAR was charged with coordinating the AIDS activities of the various NIH Institutes and Centers supporting HIV research. Many activists and scientists were critical of the traditional decentralized and primarily investigator-initiated research grant activities that constituted a substantial proportion of the basic HIV research portfolio. Some even called for an AIDS “Manhattan Project.”^{39,40} The HOPE legislation compromised on this matter and created a locus of accountability toward a more directed program, but stopped short of central government direction of science. The OAR quickly became the focal point for heated debate between proponents of centralized management on the one hand, and decentralized management on the other. The culmination was a massive independent review of the entire NIH AIDS research effort and a report, released in 1996.⁴¹ One of the most hotly contested of the many recommendations of the “Levine Report”—named for the cochair of the panel that produced it,

Arnold Levine of Princeton University—led directly to additional congressional legislation that took another step toward centralization. It significantly increased the authority of the Director of the OAR over the establishment of overall NIH AIDS research priorities, the creation and submission of the NIH AIDS budget to Congress, and the allocation of the appropriated NIH AIDS budget.

Legacy for Research Ethics

Even from this limited overview, it should be evident that the field of HIV research has been shaped to an unprecedented degree by involvement of the community of people directly affected by the disease. It should also be evident, as Epstein notes, that it has usually been the case that movement on specific issues has been the result of alliances involving activists and groups of scientists within the research or political establishments. Rarely, if ever, has it been the case that the entire scientific establishment was completely on one side of an issue whereas the entire activist community was on the other. Epstein correctly notes, “This is a complicated history in which no party has had all the answers. All players have revised their claims and shifted their positions over time; all have had to wrestle with the unintended consequences of their own actions.”⁴

Thus, the almost overwhelming temptation to look in these events for heroes and villains diminishes the real story and its larger lessons. Clearly, the enduring legacy of this fascinating history is the extraordinary scientific progress that has occurred, almost in spite of the extreme mistrust, anger, fear, and divisiveness that characterized the early relationship between science and the community of people affected by HIV. To the mutual credit of both activists and scientists, a relatively stable and productive democracy has evolved and made this scientific progress possible. Through diligent advocacy from their perspective as the people most directly affected by the disease, and in coming to understand the scientific method and the complexities of the scientific challenge posed by HIV, activists have become essential partners in the scientific enterprise. Similarly, most scientists have come to value understanding of the priorities and perspectives of the people most directly affected by HIV, and they acknowledge that better studies are launched that involve well-educated and savvy participants. Most important, to a vastly greater extent than any could have imagined in 1989, most activists and scientists have, in general, come to see each other as allies who know they share the same goals, even if they sometimes disagree on the path to pursue them. It is impossible to overstate just how remarkable the transformation has been.

Indeed, Lo views the events associated with AIDS activism as a stringent and highly successful test of the concept of partnership between community and science.⁴² In that vein, another enormously important legacy of these events lies in the contribution of this paradigm of partnership in the sometimes difficult matter of determining whether research has social and scientific value. In other words the perspectives of the community have become an integral part of the scientific process. Although it does not prevent disagreement, it helps ensure that a richer variety of practical and immediate perspectives on social and scientific relevance are in the forefront of discussion about the science that is planned and undertaken.

One might question whether this paradigm has relevance to other situations, given the unique milieu in which it arose. The model of U.S. AIDS activism has been adopted in other countries with vastly different social and cultural contexts, most notably South Africa. Advocates for conditions as diverse as breast cancer, Alzheimer's disease, and Parkinson's disease frequently credit the model of AIDS activism.^{17,24,43–45} Furthermore, increasing attention is being devoted on a variety of fronts to the importance of including a public perspective in scientific processes.⁴⁶ Although neither necessary nor sufficient, the AIDS model surely represents a proven approach to contentious situations that should bolster confidence that the first requirement for ethical research—social and scientific relevance⁴⁷—is satisfied.

Epilogue

The very limited history discussed here mainly concerns events in the early years of the HIV epidemic in the United States, and focuses on sentinel events of particular relevance to one enduring legacy of the U.S. HIV epidemic on research ethics—activism and community involvement in science. The focus on this aspect of the story also lays a foundation for better understanding of another enduring and more troubling legacy—some of the ethical controversies concerning exploitation, considered at length elsewhere in this volume, that have come to dominate the arena of international research ethics for more than a decade. At the core of those controversies is the juxtaposition of tremendous progress in treatment that has occurred in wealthier countries of the world (in association with activism and community involvement) on the one hand, and the fact that this progress is beyond the reach of most people with HIV infection, who live in the developing world, on the other (see Part X). Two practical and vexing questions related to this problem have fueled the current environment of suspicion and mistrust:

1. Are researchers obligated to ensure that study participants receive state-of-the-art care, regardless of the objectives of the study or the level of care available in the setting in which the study is carried out?
2. What are the obligations of researchers to study participants after a study is completed?

That this ethical controversy has persisted for so long suggests that answers cannot be derived solely from either the fundamental principles of research ethics or in the abundance of existing guidelines and frameworks. One must hope that creative attempts to apply the HIV/AIDS partnership paradigm to this global health research issue⁴⁸ might bring about movement toward solutions that help identify research that is important and fair to the communities concerned, and has impact on the broadest possible global scale.

The Gelsinger Case

Background

The death of Jesse Gelsinger in September 1999 is one of the defining cases in the recent history of research with humans. Gelsinger, 18, died during a gene transfer experiment at the University of Pennsylvania School of Medicine.¹ His death—the first directly attributed to gene transfer—raised profound questions about the protection of patients in this high-profile research field, as well as in other clinical studies. It also raised questions about adherence to research protocols, the reporting of adverse events, informed consent, and financial conflicts of interest. It shook the confidence of the public and the federal government in the competence and ethics of clinical researchers and the institutions where they work, and led to efforts to improve the protection of research participants.

Although the terms gene transfer and gene therapy are often used interchangeably, gene transfer is more precise. Gene transfer refers to the transfer to a person of recombinant DNA, or the transfer of DNA or RNA derived from recombinant DNA. The aim is to modify or manipulate the expression of a gene in the body or to change the biological properties of cells. Although the promise of gene transfer is great, progress has been slow. A 1995 review of the investment in the field by the National Institutes of Health (NIH) advocated caution: “Significant problems remain in all basic aspects of gene therapy. Major difficulties at the basic level include shortcomings in all current gene transfer vectors and inadequate understanding of the biological interaction of these vectors with the host.”²

As of February 2000, several months after Gelsinger’s death, more than 4,000 patients had participated in gene transfer studies.

Of the 372 clinical trials that were registered with the NIH, 89% were Phase I studies of safety and toxicity.³ For many years, the public and scientists have been concerned about the potential environmental and infectious disease risks of recombinant DNA technology. This is one reason that the federal government has treated gene transfer studies differently from other clinical research. Extensive data about all trials registered with the NIH are publicly available—far more than for most other studies. Investigators who are funded by the NIH or who conduct their work at institutions that receive NIH support for any type of recombinant DNA research must comply with specific NIH guidelines. In addition to this, a Recombinant DNA Advisory Committee (RAC) was established within the NIH in 1974. The RAC is a public forum for discussion of novel and substantial issues related to gene transfer trials, including the review of specific protocols. Although the guidelines and the specific duties of the RAC have changed over time, it has a critical role in the oversight of this research.⁴ The Food and Drug Administration (FDA) also regulates clinical gene transfer trials.

Gene Transfer for Ornithine Transcarbamylase Deficiency

Ornithine transcarbamylase (OTC) deficiency is a recessive X-linked autosomal genetic defect that interferes with the metabolism of ammonia by the liver. Although the mutations that lead to this enzyme deficiency are rare—affecting 1 in 40,000 to 1 in 80,000 people—they are the most common of the inborn errors of urea synthesis. Correction of this single gene enzyme deficiency

has been viewed as a model for gene transfer directed at the liver.⁵ The reason is that restoration of the enzyme activity should treat the disorder, as has been demonstrated by treatment with liver transplantation.⁶ Gene transfer for OTC deficiency has been studied in the sparse fur mouse, which is deficient in the enzyme. Studies in this animal model suggest that the gene defect can be corrected.¹

People with OTC deficiency can develop profound hyperammonemia. Excessive levels of ammonium ion in the brain can lead to life-threatening encephalopathy, coma, and brain damage. Complete deficiency usually leads to death during infancy. Without a liver transplant, only about half of those born with OTC deficiency will survive to age 5, and many survivors have profound mental impairment. For people with partial enzyme deficiency, a low protein diet supplemented with oral medications (sodium benzoate and sodium phenylacetate/sodium phenylbutyrate) can be used to minimize the risk of complications or death. Such treatment eliminates excess urea and precursors of ammonia. However, adherence to diet and medical therapy is difficult, and only partially effective.

Background to the Research Study at the University of Pennsylvania

A chronology of events leading up to and following Gelsinger's death is shown in Table 10.1. In 1993, James M. Wilson was recruited to the University of Pennsylvania from the University of Michigan. At the time of Gelsinger's death, Wilson was widely considered to be one of the leading gene transfer researchers in the world. He was director of the Institute for Human Gene Therapy and professor and chair of the Department of Molecular and Cellular Engineering in the university's School of Medicine. In 1992, while working in Michigan, Wilson was a founder of Genovo, Inc., which had the rights to market his discoveries related to gene transfer. Wilson held patents related to the use of vectors derived from the adenovirus for gene transfer.

There were many financial links between Genovo, whose principal offices were in a Philadelphia suburb, Wilson, the Institute for Human Gene Therapy, and the University of Pennsylvania. By 1999, Genovo provided more than \$4 million a year to the institute, a substantial portion of its budget. Wilson and his immediate family had a 30% nonvoting equity stake in Genovo, and the University of Pennsylvania had a 3.2% equity stake.⁷ Other shareholders included past and present employees of the university and the institute. In the late 1990s, Penn was aggressively seeking to profit from the discoveries of its professors. The *Philadelphia Inquirer* quoted the managing director of Penn's Center for Technology Transfer: "For years, Penn wasn't even in the game. Now we're in the game and we're looking for some home runs"⁸ (see Chapters 68–71).

In December 1994, Penn's Center for Technology Transfer had officially requested that the Conflict of Interest Standing Committee at the University of Pennsylvania Medical Center review Wilson's involvement with Genovo. The committee had the authority to review the case and to make recommendations for managing potential conflicts of interest. The committee considered the case of great importance and conducted a detailed review. For example, according to the minutes of the committee's February 6, 1995, meeting, many comments and questions were considered.

Members were concerned that Wilson's multiple roles would "conflict" with his responsibilities at Penn and "create conflicts" for the medical school in allocating resources or implementing ethical and academic policies. According to the minutes, "Since Dr. Wilson's research efforts will be directed towards the solution of a problem in which he has a financial interest in the outcome, how can Dr. Wilson assure the University that he will not be conflicted when making decisions that could have an impact on either Genovo, Biogen [another biotechnology company that had invested in Genovo], or the further development of his intellectual property?" Another question appeared in the draft version of the minutes, but not in the final version: "How can Dr. Wilson and the University avoid liability for damages if a patient died from any products produced or studied at the University?"

The Conflict of Interest Standing Committee recognized the potential conflicts of interest involving Wilson's commitments to Genovo and to the University of Pennsylvania. It also recognized that his research program could lead to important medical advances that might benefit the public. In 1995, it did not seek to end his financial arrangements with the company. Instead, it recommended actions to manage the conflicts by reducing his managerial and scientific control. These included making Wilson's stock nonvoting and prohibiting him from being a member of the company's scientific advisory board.

The Research Study

Between 1997 and 1999, Gelsinger and 17 other subjects participated in the clinical protocol, "Recombinant Adenovirus Gene Transfer in Adults With Partial Ornithine Transcarbamylase Deficiency."^{5,9} Wilson was a coinvestigator and the sponsor of the research. His main collaborators were Steven E. Raper, a surgeon at the University of Pennsylvania, who was the principal investigator, and Mark L. Batshaw of the Children's National Medical Center in Washington, D.C., who was the coprincipal investigator. Batshaw had pioneered the drug and diet treatment that was widely used for OTC deficiency. On June 21, 1997, Wilson signed FDA form 1572, in which he agreed to conduct the study in accordance with the investigational plan and applicable federal regulations.

The adenovirus-derived vector contained a functional OTC gene. The vector was rendered incapable of replicating by the deletion of two adenoviral genes; it was designed to be safer than earlier versions of the vector. The purpose of the research was "to establish a safe dose of recombinant adenovirus to serve as a treatment for adults with partial OTC [deficiency]."⁵ Like most gene transfer studies at the time, the trial was a Phase I safety study of escalating doses of the vector, not a study of the effectiveness of the treatment. Thus, subjects were not expected to benefit directly from their participation. The protocol was reviewed and approved by many oversight bodies, including the RAC, the FDA, and human subjects review boards at the University of Pennsylvania Medical Center and the Children's Hospital of Philadelphia. The NIH and Genovo, the company that Wilson had helped to found and in which he held equity, were the major funders of the research and of Wilson's laboratory.

The protocol called for groups of three or four participants to be assigned to one of six dosing regimens; each group received a progressively higher dose of the vector, with adjustment for their body weight. The genetically altered adenovirus was administered

Table 10.1
Timeline of Events Leading Up To and Following the Death of Jesse Gelsinger

Date	Event	Date	Event
1992	While at the University of Michigan, James M. Wilson is a founder of Genovo, Inc., a company involved in gene transfer research and development. The company has rights to market Wilson's discoveries related to gene transfer.	Apr. 2000	An independent, external panel appointed by the president of the University of Pennsylvania reports on the Institute for Human Gene Therapy.
1993	Wilson is recruited to the University of Pennsylvania to be the director of the Institute for Human Gene Therapy.	May 2000	The University of Pennsylvania announces that the Institute for Human Gene Therapy will stop conducting clinical studies and sponsoring clinical trials.
1995	The Recombinant DNA Advisory Committee (RAC) at the National Institutes of Health approves a clinical protocol from the Institute for Human Gene Therapy, "Recombinant Adenovirus Gene Transfer in Adults With Partial Ornithine Transcarbamylase [OTC] Deficiency." The principal investigator is Steven E. Raper, also of the University of Pennsylvania. The coprincipal investigator is Mark L. Batshaw of the Children's National Medical Center in Washington, D.C. Wilson is a coinvestigator.	Aug. 2000	Targeted Genetics Corp. of Seattle agrees to acquire Genovo, Inc. Wilson receives stock valued at about \$13.5 million and the University of Pennsylvania stock valued at about \$1.4 million.
1997	Enrollment of patients in the gene transfer protocol begins. The informed consent document includes a one-sentence statement about the financial interest of the University of Pennsylvania, Wilson, and Genovo, Inc., in "a successful outcome of the research involved in this study."	Sept. 2000	Gelsinger's family files a civil lawsuit against Wilson, other researchers, and the University of Pennsylvania.
1998	Jesse Gelsinger, an 18-year-old man with partial OTC deficiency and a resident of Tucson, Ariz., learns about the Penn study from his physician.	Nov. 2000	The lawsuit is settled out of court; details are not disclosed.
June 1999	Gelsinger and his father go to the Institute for Human Gene Therapy. Blood tests to determine his eligibility for the gene transfer trial are performed.	Nov. 2000	The FDA, citing six violations of federal regulations, begins proceedings to disqualify Wilson from performing clinical research with investigational drugs.
Sept. 9, 1999	Gelsinger returns to Philadelphia to begin the trial.	Sept. 2001	The Office for Human Research Protections, in the Department of Health and Human Services, accepts Penn's corrective actions with regard to the OTC deficiency protocol and the University's system for protecting human subjects.
Sept. 13, 1999	Gelsinger receives an infusion of 3.8×10^{13} particles of the adenoviral vector through a femoral catheter into the right hepatic artery. He is the 18th, and last, subject in the study.	Feb. 2002	The FDA concludes that Wilson's explanations "fail to adequately address the violations."
Sept. 17, 1999	Gelsinger dies. After his death, the study is halted.	Apr. 2002	Wilson announces that he will step down as director of the Institute for Human Gene Therapy.
Sept. 29, 1999	<i>The Washington Post</i> reports on Gelsinger's death. Serious problems with the conduct of the OTC deficiency trial and the financial relationships between Wilson, Penn, and Genovo subsequently become widely known.	Summer 2002	The Institute for Human Gene Therapy closes.
Dec. 1999	The RAC considers Gelsinger's death at a public meeting.	Apr. 2003	The University of Pennsylvania revises its conflict of interest policies for faculty participating in clinical trials.
Jan. 2000	After conducting multiple inspections at Penn, the FDA closes down all clinical trials at the Institute for Human Gene Therapy.	Oct. 2003	A report on Gelsinger's death, "Fatal Systemic Inflammatory Response Syndrome in a Ornithine Transcarbamylase Deficient Patient Following Adenoviral Gene Transfer," is published in the medical literature. ¹
		Feb. 2005	Resolving investigations by the Office of Criminal Investigations at the FDA and the Office of Inspector General of the Department of Health and Human Services, the Department of Justice reaches civil settlements with the University of Pennsylvania, the Children's National Medical Center, Wilson, Raper, and Batshaw.

as a single two-hour infusion of one ounce of fluid through a femoral catheter into the right hepatic artery. Participants were not compensated.

The informed consent document cited three major risks:

1. The possibility that the adenovirus would inflame the liver. "It is even possible that this inflammation could lead to liver toxicity or failure and be life-threatening," the consent document stated.

2. The possibility that the adenovirus would provoke an immune response that would damage the liver.
3. The possibility that receiving the vector would prevent the research participants from receiving it as part of a therapy in the future. If used again, the vector would likely trigger an immune response and the body would eliminate it.

The consent document also stated that if a subject developed liver failure, "a liver transplant could be required." Participants were to

undergo a liver biopsy; the document stated that this procedure was associated with a “very small risk (1 in 10,000) of serious unpredicted complications which can include death.”¹⁰

A particularly controversial aspect of the study was the decision to enroll adults with mild disease, rather than children with severe disease. The investigators had initially planned to use dying newborn infants as subjects but changed their minds.¹¹ According to the informed consent document, “Because this is a study of safety and long-term metabolic improvement is not expected, we felt it most appropriate to study adults (ages 18–65) who have a mild deficiency of OTC rather than children.”¹⁰

One reason for the switch was that adults without mental impairment were better able to provide informed consent than the parents of children with terminal illness. Another was that it would be difficult to recognize adverse or life-threatening events in children who were already dying from their disease. Arthur L. Caplan, a leading bioethicist, a professor of bioethics at Penn, and a member of Wilson’s department, advocated this approach.¹¹ Wilson has stated that the decision to use adults “was based on the collective input and recommendations from the University of Pennsylvania’s own bioethicists, as well as from families of diseased children and other metabolic disease experts not associated with the study.”¹² In some ways, the choice between enrolling adults with mild disease or children with severe disease represented a no-win situation for the investigators. Although this was a Phase I safety study, terminally ill newborns potentially had the most to gain.¹³ Both positions can be justified, and both can be criticized.

The enrollment of subjects with only mild disease was criticized before and after Gelsinger’s death. The RAC (which at the time had to approve gene transfer studies) had approved the protocol in December 1995.¹⁴ The approval, by a vote of 12 to 1, with 4 abstentions, followed a lengthy discussion during which some members questioned the safety and wisdom of the proposed experiment. One concern was the enrollment of patients with mild disease. Another was the infusion of large quantities of the vector directly into the blood supply of the liver. For example, one reviewer of the protocol said that it would “be more acceptable if the vector can be repeatedly delivered by the less invasive intravenous route” and if the treatment was “given to affected children with life threatening OTC deficiency.”¹⁴ At the time, the researchers agreed to infuse the vector into the bloodstream, not directly into the liver. This decision was subsequently reversed, as the FDA requested when it approved the protocol in 1997. The rationale was that because the vector would travel through the circulation to the liver anyway, it was safer to put it directly where it was needed with the hope that it would not travel elsewhere. The RAC was not informed of this change.¹⁵

The informed consent document also included a one-sentence statement about the financial interests of the sponsors: “Please be aware that the University of Pennsylvania, Dr. James M. Wilson (the Director of the Institute for Human Gene Therapy), and Genovo, Inc. (a gene therapy company in which Dr. Wilson holds an interest), have a financial interest in a successful outcome from the research involved in this study.”¹⁰ Such a statement was highly unusual at the time. The form did not specify what the financial interests were, or their potential magnitude. According to the University, Wilson had no role in recruiting patients, obtaining informed consent, or treating patients, including Gelsinger. Wilson, however, was a coinvestigator. As the director of the Institute for Human Gene Therapy, he was the sponsor of the study. It was

his gene transfer research that made the trial possible. Wilson was extensively involved in activities such as the preclinical animal work, the development of the gene transfer vector and its mode of delivery, the design of the trial, protocol modifications, laboratory work during the trial, and the analysis of the results.

Jesse Gelsinger

Jesse Gelsinger was diagnosed with partial OTC deficiency when he was a young child. He was subsequently found to have a unique mutation. Some of his cells had a defective OTC gene with a large deletion, whereas others had a normal gene—a condition known as mosaicism.¹⁶ Despite diet and drug therapy, he developed serious hyperammonemia many times, including an episode of hyperammonemic coma in December 1998 that required treatment with mechanical ventilation. He recovered from this episode without apparent adverse effects. In 1999, his disease was considered generally controlled.

Gelsinger lived in Tucson, Arizona. He was the 18th subject in the study and, at age 18, the youngest person enrolled. He had learned about the trial in 1998 from his physician. His father said after his death that he “was doing this for other people.”¹⁷ Jesse Gelsinger set aside his personal life to participate, and took an unpaid leave from his job.¹⁸ According to his father, “One night he even said, ‘The worst that could happen is that I could die and maybe help doctors figure out a way to save sick babies.’ I’ve never been more proud of my son than the moment he decided to do this experiment.”¹⁷

The doses of the vector in the study ranged from 2×10^9 to 6×10^{11} particles/kg of body weight. (The second-highest dose was 2×10^{11} particles/kg.) On September 13, 1999, Gelsinger became the second subject to receive the highest dose of 6×10^{11} particles/kg; his total dose, based on his weight, was 3.8×10^{13} particles. In the other study participants, including the first to receive the highest dose, the adverse effects were transient muscle aches and fevers and laboratory abnormalities such as thrombocytopenia, anemia, hypophosphatemia, and elevated levels of the liver enzymes known as transaminases. The adverse events in other study participants, however, were not life threatening.

About 18 hours following infusion of the adenovirus vector, Gelsinger developed altered mental status and jaundice—neither of which had been seen in the first 17 study participants. He subsequently developed the systemic inflammatory response syndrome, disseminated intravascular coagulation and multiple organ system failure, and the acute respiratory distress syndrome.¹ Gelsinger died on September 17, 1999, 98 hours following gene transfer.

An autopsy and subsequent studies indicated that his death was caused by a fulminant immune reaction (with high serum levels of the cytokines interleukin-6 and interleukin-10) to the adenoviral vector.¹ Substantial amounts of the vector were found not only in his liver (as expected) but also in his spleen, lymph nodes, and bone marrow. According to an NIH report on adenoviral safety and toxicity that was prompted by Gelsinger’s death, “The data suggested that the high dose of Ad [adenoviral] vector, delivered by infusion directly to the liver, quickly saturated available receptors . . . within that organ and then spilled into the circulatory and other organ systems including the bone marrow, thus inducing the systemic immune response.”¹⁹ The report added, “Although the Ad vector used in the OTC trial was incapable of replicating, the capsid

Figure 10.1. Jesse Gelsinger, June 22, 1999. “Having just been screened for participation in the Ornithine Transcarbamylase Deficiency clinical trial, Jesse Gelsinger was ready, just like Rocky Balboa was ready for battle, to help advance treatments for his disease,” says Jesse’s father, Paul Gelsinger. “Jesse had no real idea of the concealed dangers involved in what he was about to do, nor of the ethical awareness his death would bring.” Source: Mickie Gelsinger and Paul Gelsinger. Reproduced with permission.

proteins encoating the vector [the shell of the vector] likely contributed to the participant’s immune response.”

In October 2003, the research team published a report on “the unexpected and tragic consequences of Jesse Gelsinger’s participation in this trial.”¹ They concluded that his death pointed to “the limitations of animal studies in predicting human responses, the steep toxicity curve for replication defective adenovirus vectors, substantial subject-to-subject variation in host responses to systemically administered vectors, and the need for further study of the immune response to these vectors.”¹

Subsequent Developments at Penn

After Gelsinger’s death, the study was halted. Although a Tucson newspaper had reported on his death a few days earlier, the events

were not widely known until an article appeared in the *Washington Post* on September 29, 1999.^{20,21} The FDA, the NIH, and the Office for Protection from Research Risks at NIH began intensive reviews of the protocol and other gene transfer research.

Serious deficiencies in the conduct of the study soon became widely known.²² One was that Gelsinger should not have been allowed into the study, because his liver was not functioning at the minimal level required for inclusion on the day he received the infusion. Another was that the researchers failed to immediately notify the FDA when earlier participants had “Grade III” liver toxicity. Their liver enzyme abnormalities were sufficiently severe that the study should have been put on hold, as the research protocol required. Still another was that the FDA was not promptly informed about the results of tests in laboratory animals that suggested a significant risk of the adenoviral vector for human subjects. When given higher doses of the vector (1×10^{13} particles/kg), rhesus monkeys developed disseminated intravascular coagulation and liver failure; some died. However, at the dose administered to Gelsinger (6×10^{11} particles/kg), which was about 15-fold less, only minor toxicities to the liver were observed in the monkeys. Yet another deficiency was that the researchers had changed the protocol multiple times without notifying the FDA, and failed to make changes they had agreed to make. These included tightening the exclusion criteria in a way that would have made more potential subjects ineligible, because they were at risk for liver toxicity on the basis of their medical histories. Other questions had to do with Wilson’s and Penn’s financial interest in the study’s success, deficiencies in the informed consent process, including downplaying the risks by failing to give potential participants all the relevant safety information, such as the monkey deaths and the serious side effects in other subjects, failure to follow the protocol, failure to maintain complete and accurate records, and the adequacy of the review of the trial by Penn’s institutional review board (IRB).^{22–29}

In January 2000, after conducting multiple inspections at Penn, the FDA issued a “list of inspectional observations” and closed down all clinical trials at the Institute for Human Gene Therapy.²⁵ Neither the FDA nor the Office for Protection from Research Risks sought to halt all clinical research at Penn.

Although acknowledging mistakes and extending its sympathy to the Gelsinger family, the research team vigorously defended its work, and Penn defended its researchers.³⁰ According to Wilson, “the alleged lure of potential financial gain played no role in any clinical decisions.”¹² Penn’s position has been that “as deeply regrettable as Gelsinger’s death was, it was simply not foreseeable based on informed medical judgment and the best scientific information available at the time,” according to a written statement in October 2003 by Rebecca Harmon, the chief public affairs officer for the University’s School of Medicine.

After Gelsinger’s death, Penn initially sought to reopen its gene transfer program. Soon, however, it changed its mind. In early 2000, Judith Rodin, then the president of the university, appointed an independent, external panel to evaluate the issues. William H. Danforth, former chancellor of Washington University in St. Louis, chaired the panel. In April 2000, the panel recommended that the university do a better job of evaluating and monitoring clinical trials and ensuring that informed consent is properly obtained.³¹ The panel also recommended that Penn review its policies on conflict of interest, especially with regard to clinical trials. For clinical trials, the panel found that

[E]quity positions by an investigator and/or the University may be ill advised, even if, in reality, there is no practical effect whatsoever. Given that the overriding responsibility of the University and its investigators is to the welfare of patients, the avoidance of conflict of interest that even remotely might detract from putting the needs of patients first becomes paramount. In that regard, investments in new therapies differ from those in other ventures, such as computer technology, which involve no responsibility for patient care.

The panel also questioned whether it made sense “to have an entire Institute devoted to gene therapy.”

Rodin also requested a second report, an internal review by Penn faculty of all aspects of research involving human subjects at the university. In an interim report, also in April 2000, the internal Committee on Research Using Humans recommended that Rodin carry out a comprehensive review of the university’s IRB system, and develop formal monitoring mechanisms for clinical trials as well as “standard operating procedures” that apply to human subjects research.³² At the time, Penn had more than 3,900 ongoing research protocols involving humans, of which more than 750 involved the use of investigational drugs. The committee also recommended that the IRB “act expeditiously to require that principal investigators and coinvestigators disclose on the forms requesting IRB approval any proprietary interest in the product or procedure under investigation, including potential future compensation both for themselves and their immediate family. The IRB should then determine on a case-by-case basis whether disclosures in the patient consent document or other protections are required.”³² The committee never issued a final report, as the university quickly implemented changes.

In May 2000, the University of Pennsylvania announced that the Institute for Human Gene Therapy would stop conducting clinical studies and sponsoring clinical trials. Instead, it would conduct animal experiments and preclinical research. The university also announced other changes, including reforms in its IRB system, educational programs for researchers, and a more comprehensive infrastructure to protect research subjects.³³ According to a university publication, the work of the internal review committee and other efforts by faculty and administrators “have generated unprecedented change in Penn’s research infrastructure and culture.”³⁴

In August 2000, Targeted Genetics Corp. of Seattle agreed to acquire Genovo, the company that Wilson had helped to found.³⁵ The acquisition enriched Wilson and the University of Pennsylvania. Under the agreement, Wilson was to receive Targeted Genetics stock that was then valued at about \$13.5 million. The University of Pennsylvania was to receive stock valued at about \$1.4 million.⁷ Although the actual amount of money that Wilson and the university received is not known, it may have been considerably less, because the value of the stock plummeted.

In September 2001, the Office for Human Research Protections of the Department of Health and Human Services (DHHS), which had replaced the Office for Protection from Research Risks at the NIH, accepted Penn’s corrective actions with regard to the OTC deficiency protocol and the University’s system for protecting research participants.³⁶ In April 2002, Wilson announced that he would step down as director of the Institute for Human Gene

Therapy. He continued as chairman and professor of the Molecular and Cellular Engineering Department. The institute closed in the summer of 2002.

The University of Pennsylvania also revised its conflict of interest policies. In April 2003, a policy on “financial disclosure and presumptively prohibited conflicts for faculty participating in clinical trials” became effective.³⁷ An earlier version had been used as an interim policy. The policy prohibited clinical investigators from maintaining certain “significant financial interests” such as service on the board of directors or as an officer of a company or entity that sponsors a clinical trial, significant equity interest in the sponsor, or ownership of a proprietary interest in the tested product. The policy defined “significant equity interest” as

[A]ny ownership interest, stock options, or other financial interest whose value cannot be readily determined through reference to public prices (generally, interests in a non-publicly traded corporation), or any equity interest in a publicly traded corporation that exceeds \$10,000 (or exceeds 5% ownership) during the time the clinical investigator is carrying out the study and for 1 year following the completion of the study. Interest in any publicly traded mutual fund is excluded.

Like policies at many academic medical centers, Penn’s policy allowed for exceptions on a case-by-case basis when there are “compelling circumstances.” The policy defined “compelling circumstances” as “facts that convince the [Conflict of Interest Standing Committee] that an investigator should be permitted to participate in a specific trial in spite of a Significant Financial Interest.” Relevant information “includes the nature of the research; the magnitude of the financial interest; the extent to which the financial interest could be influenced by the research; the degree of risk to human subjects; and whether the interest is amenable to management.”³⁷

The Response of Gelsinger’s Family

Following his son’s death, Paul Gelsinger became an outspoken advocate of improved protection for research participants. In the first months after the death, he continued to support his son’s doctors—“believing that their intent was nearly as pure as Jesse’s”—even as the news media exposed the flaws in their work.¹⁸ However, while attending the discussion of his son’s death at a RAC meeting in December 1999, he became convinced that he and his son had not been given all the relevant information. He changed his mind. “It wasn’t until that three-day meeting that I discovered that there was never any efficacy in humans,” he later wrote. “I believed this was working based on my conversations with Mark Batshaw and that is why I defended Penn for so long.” At a meeting with FDA and NIH officials and the Penn doctors during the RAC meeting, “after touching on many issues I let them know that I had not to this point even spoken to a lawyer, but would be in the near future. Too many mistakes had been made and unfortunately, because of our litigious society, it was the only way to correct these problems.”¹⁸ In September 2000, Gelsinger’s family filed a civil lawsuit against the lead researchers, the University of Pennsylvania, and others.³⁸ In November 2000, the suit was settled out of court; details have not been disclosed.^{39,40}

The Response of the Federal Government

At the time of Gelsinger's death, adenoviral vectors were used in one quarter of the 372 gene transfer trials that were registered with the NIH. After reviewing safety and toxicity data from these trials, the RAC recommended that human gene transfer research with adenoviral vectors continue, but with greater caution.¹⁹ The committee also recommended a centralized data base for collecting and organizing safety and toxicity data on gene transfer vectors, greater standardization of the experimental data collected during trials, improved informed consent documents, and more extensive monitoring of research participants.

Prompt and complete reporting of serious adverse events was a particular concern. After Gelsinger died, the NIH and the FDA both reminded researchers of their obligations to report adverse events in gene transfer trials. The NIH soon received nearly 700 such reports, including reports of deaths that occurred before Gelsinger's.⁴¹ For example, the NIH learned that a gene transfer trial at another academic medical center had been suspended in June 1999 after three of the first six participants died and a seventh became seriously ill. The study participants were terminally ill cancer patients. The NIH also had not been promptly notified of two deaths at a third institution during trials involving genes for a vascular endothelial growth factor aimed at growing new blood vessels in patients with coronary or peripheral artery disease. In 2000, the FDA halted the experiments.⁴² The FDA and the NIH subsequently tightened the monitoring procedures for gene transfer trials, increased federal oversight and public access to information about the trials, increased inspections of gene transfer clinical investigators, and improved the reporting of serious adverse events. In March 2004, the agencies launched the Genetic Modification Clinical Research Information System, known as GeMCRIS. This Web-accessible database on human gene transfer (<http://www.gemcris.od.nih.gov>) provides information about clinical gene transfer trials. It also allows investigators and sponsors to report adverse events using a secure electronic interface, thus improving and centralizing reporting procedures.

In March and July 2000, the FDA sent warning letters to Wilson, outlining what the agency viewed as widespread deficiencies in the conduct of the research.^{26,27} In November 2000, the FDA sent warning letters to Batsaw⁴³ and Raper⁴⁴ and began proceedings to disqualify Wilson from performing clinical research with investigational drugs.²⁸ It is unusual for the FDA to seek such a disqualification. In a 15-page letter, the FDA detailed the evidence that Wilson had "repeatedly or deliberately violated regulations governing the proper conduct of clinical studies involving investigational new drugs."²⁸ It cited six violations: failure to fulfill the general responsibilities of investigators; failure to ensure that an investigation was conducted according to the investigational plan; failure to submit accurate reports about the safety of the study to the University of Pennsylvania IRB; failure to accurately and completely identify changes in the research for review and evaluation by the review board; failure to properly obtain informed consent; and failure to maintain accurate case histories of the research subjects. Wilson contested many of the allegations.

In February 2002, the FDA concluded that Wilson's written explanations failed "to adequately address the violations."⁴⁵ The agency told Wilson that, although he was assisted by "several subinvestigators," as "the clinical investigator you were responsi-

ble for all aspects of the study." It added, "While you assert that you delegated many aspects of the subject recruitment and subject management to others, you were the responsible leader of the investigational team. Indeed, you were present when prospective subjects' cases were discussed, and when protocol modifications were considered at the OTCD team meetings."⁴⁵

Following investigations by the Office of Criminal Investigations at the FDA and the Office of Inspector General at the DHHS, the Department of Justice brought civil charges against the University of Pennsylvania, the Children's National Medical Center, Wilson, Batshaw, and Raper. The government alleged that the investigators and their institutions violated the federal False Claims Act by making false statements and claims in connection with grant applications and progress reports to the NIH, submissions to the FDA, information supplied to the IRBs that had oversight over the research, and by failing to obtain proper informed consent.

In February 2005, the government reached civil settlements with the investigators and institutions.⁴⁰ The institutions and investigators did not acknowledge the government's allegations and maintained that they acted appropriately and within the law at all times. The investigators did not take responsibility for Gelsinger's death. The University of Pennsylvania agreed to pay a fine of \$517,496 and to increase IRB oversight of clinical research and training for investigators and clinical coordinators. The settlement agreement outlined the steps the university had taken to promote safety in clinical research. For example, between fiscal years 1998 and 2005, the number of full-time employees of the University's Office of Regulatory Affairs, which is responsible for staffing the IRBs, increased from 5 to 23. In a written statement, the university said, "Out of this tragedy has come a renewed national effort to protect the safety of those who help to advance new treatments and cure through clinical research." The Children's National Medical Center agreed to pay \$514,622 and to increase its IRB budget and staff.

Wilson continued to work at the University of Pennsylvania. The agreement terminated the FDA's administrative proceedings against him. Wilson agreed not to serve as a sponsor of a clinical trial regulated by the FDA or to participate without restriction in research with humans until February 2010. (He already had not been involved with human research participants since January 2000.) Wilson also agreed to meet specified educational, training, and monitoring requirements related to his research and to lecture and write an article on the lessons of human research participants protections learned from the OTC deficiency trial. In a written statement released by Penn, Wilson said, "In the last few years, I have focused my research on the discovery and design of new gene-transfer vectors for gene therapy and genetic vaccines. Reaching this agreement means that I may continue to devote myself fully and without restriction to my laboratory and that I may conduct clinical research when it would be appropriate for scientific advancement." Batshaw and Raper agreed to lesser restrictions.

Enduring Legacy

More than eight years after Gelsinger's death, the case remained sensitive for the University of Pennsylvania. Despite repeated requests, neither Wilson nor any of the university officials with

extensive knowledge of the case were willing to speak about it; Wilson has granted no interviews for many years.

According to Donna Shalala, Secretary of DHHS during the Clinton administration, “The tragic death of Jesse Gelsinger focused national attention on the inadequacies in the current system of protections for human research subjects.”⁴⁶ In a better world, improved protection for research subjects would be less dependent on responses to tragedy. Nonetheless, the protection of research subjects has often improved after crises, such as the Tuskegee syphilis experiment in the 1970s (see Chapter 8). In an article in the *New England Journal of Medicine* in 2000, Shalala wrote that “the American people expect that clinical researchers will never compromise or neglect the safety of human subjects.” She also cited practical considerations: “To put it simply, if we cannot guarantee sound research in general—and patients’ safety in particular—public support for gene therapy and other potentially lifesaving treatments will evaporate.”⁴⁶

Reports from the DHHS Office of Inspector General, some of which were completed before Gelsinger’s death, documented problems with IRBs in the United States. The review boards have been criticized for reviewing too many protocols, working too quickly, having insufficient expertise, and providing too little training for investigators and board members.⁴⁷ The National Bioethics Advisory Commission and the Institute of Medicine examined these and additional problems with assuring the safety of subjects.^{48,49} A common theme was that broader and more effective federal oversight of clinical research was needed.

In 2000, DHHS established the Office for Human Research Protections. The office replaced the NIH Office for Protection from Research Risks, which had less visibility and stature. In 2001, the FDA established the Office for Good Clinical Practice to coordinate its efforts to protect research subjects. As indicated above, in 2004, the NIH and the FDA launched the GeMCRIS to provide information about clinical gene-transfer trials and allow prompt reporting of adverse events. Institutions that have corrected serious problems with their programs for protecting subjects, such as Johns Hopkins University and Duke University as well as Penn, have markedly increased their spending for these programs, and have increased the number of review boards.⁴⁷

Lawsuits against investigators, IRBs, and academic institutions are increasingly common.⁵⁰ Traditionally, litigation in clinical research was based on allegations about failure to obtain informed consent. For example, investigators may not have given research participants sufficient information to permit meaningful consent. In the Gelsinger case and other recent actions, new types of claims have been made. These include product liability claims against a drug manufacturer and fraud claims against investigators for not revealing their financial ties or problems encountered by previous subjects. The number and types of defendants have also expanded.

The allegations in the civil lawsuit filed by Gelsinger’s family included wrongful death, product liability, lack of informed consent, and fraud. The initial defendants included William N. Kelly, the former dean of the School of Medicine and the chief executive of its health system, who had recruited Wilson to Penn and had patent interests related to gene transfer research. They also included Caplan, who had been consulted about the trial, the trustees of the University, the main investigators, and Genovo, the company that Wilson had helped to found.³⁸ When the lawsuit was settled, Kelly and Caplan were dismissed from the suit.⁴⁰ According to an analysis of these trends by Mello, Studdert, and

Brennan, litigation may help injured subjects obtain compensation. However, it is also likely to lead IRBs to adopt “a more legalistic, mechanistic approach to ethical review that does not further the interests of human subjects or scientific progress.”⁵⁰

In response to the Gelsinger case, the American Society of Gene Therapy revised its conflict of interest policies.⁵¹ The Association of American Medical Colleges issued guidelines for oversight of both individual and institutional financial interests in human subjects research.^{52,53} In 2004, after years of consideration, DHHS issued guidance on financial relationships and interests and human subject protection.⁵⁴ The department recommended that “IRBs, institutions, and investigators consider whether specific financial relationships create financial interests in research studies that may adversely affect the rights and welfare of subjects.” Among the questions to be addressed were, “What financial relationships and resulting financial interests could cause potential or actual conflicts of interest?” and “At what levels should those potential or actual financial conflicts of interest be managed or eliminated?”⁵⁴

Despite the various reports and institutional changes following Gelsinger’s death, it can be argued that nothing has really changed. Review boards and other oversight mechanisms can do only so much. As of 2007, Congress had enacted no legislation to make the system for protecting research participants more efficient and effective. There had been no new federal regulations. For example, according to David Blumenthal, the guidance from DHHS about financial relationships is “notable for the qualified nature of its recommendations, which are not backed by any regulatory authority.”⁵⁵ In addition, improvements in the federal oversight of research primarily affect federally funded programs. With the exception of research involving new drugs and medical devices that is under the jurisdiction of the FDA, there is no requirement that participants in privately sponsored research receive the same protection that federal regulations provide.⁴⁷ The National Bioethics Advisory Commission concluded in 2001 that the difference in protection was “ethically indefensible” and “a fundamental flaw in the current oversight system.”⁴⁸ This situation remains unchanged. Although it might seem that that research subjects should be safer than they were before Gelsinger’s death, there is no way to know for sure.

Ethical Issues

The issues raised by the Gelsinger case have a common theme. In their zeal to help patients with a life-threatening disease, leading researchers at one of the premier academic medical centers in the United States lost their focus. They overlooked warning signals that the experimental intervention was not safe, with tragic, fatal consequences. The ethical issues relate to the selection of the research subjects, informed consent, adherence to the research protocol, and financial conflicts of interest.

The concerns about the selection of research subjects are discussed earlier in this chapter. Although adults with mild OTC deficiency and no mental impairment could provide informed consent, participation in the trial may have placed them at unnecessary risk. New treatments for OTC deficiency were urgently needed for patients with severe disease, not mild disease. Both the enrollment of adults with mild disease or newborns with the lethal form of the disease can be justified, and both positions can be

criticized. As a Phase I study of dosage and safety, the Penn experiment was not intended to evaluate the therapeutic effectiveness of gene transfer for OTC deficiency. It is easy to criticize decisions after a tragedy. There was a rationale for the enrollment criteria, and many oversight groups approved the protocol.

The case underscores the responsibilities of investigators to properly obtain informed consent, to clearly disclose all the risks of research, to adhere to the research protocol, to keep good records, and to communicate promptly and completely with IRBs and regulatory agencies.¹³ It also underscores the obligations of review boards and regulatory agencies to provide effective oversight of research.

There is no evidence that the financial interests of the University of Pennsylvania and Wilson in the success of the research had any relation to Gelsinger's death. Nonetheless, the existence of their financial interests inherently created uncertainty about their motives. Even if their motives had nothing to do with making money and their financial incentives had nothing to do with the conduct of the study, there was no way that either Penn or Wilson could effectively respond to the charge that the research was pursued for financial gain. The informed consent document included a statement about the financial interests of Penn, Wilson, and Genovo "in a successful outcome from the research involved in this study," although it did not indicate what the financial interests were, or their magnitude.¹⁰ It can be argued that although disclosing this information to subjects was preferable to not disclosing it, the conflicts did not have to exist in the first place. A key question is whether Penn or Wilson should have been allowed to have these financial interests at all, or if the clinical trial should have been conducted by other investigators or at another institution. An IRB or a conflict of interest committee could require that financial conflicts be eliminated.

Cooperation between academic medical centers and industry can advance medical knowledge and speed the development of new treatments and technologies. Financial relations, however, complicate this cooperation. Some experts consider a presumption that financial conflicts should be eliminated, not managed, to be too draconian because it will impede vital research. Others argue that less radical approaches are doomed to fail. According to Marcia Angell, a former editor-in-chief of the *New England Journal of Medicine*,

[O]ur society is now so drenched in market ideology that any resistance is considered quixotic. But medicine and clinical research are special, and I believe we have to protect their timeless values of service and disinterestedness. Patients should not have to wonder whether an investigator is motivated by financial gain, and the public should not have to wonder whether medical research can be believed. The only way to deal with the problem is to eliminate it as much as possible.⁵⁶

Gene transfer is still in its infancy. It continues to hold great promise, but the risks and benefits are still being discovered. For example, encouraging results with gene transfer in the treatment of X-linked severe combined immunodeficiency (X-SCID), a devastating disease of young children, were followed by reports of a leukemia-like disorder in some of the research participants. One of these children died in 2004. According to Philip Noguchi of the FDA, the developments are a reminder that "the manipulations needed to create gene therapy add enormous complexity to con-

siderations of safety and preclinical toxicity testing, and for every intended consequence of a complex biological product, there are unintended consequences."⁵⁷ In March 2005, an advisory committee to the FDA recommended that gene transfer for X-SCID be restricted to children who have no alternative. As of that month, the FDA had received 472 investigational new drug applications for gene transfer; 123 had been withdrawn, 92 were inactive, 14 had been terminated, and 243 remained active. As of October 18, 2007, the FDA had received 562 applications; 150 had been withdrawn, 101 were inactive, 15 had been terminated, and 296 remained active. The agency had approved no gene therapies.

The death of Jesse Gelsinger has taught the medical community and society about how to make clinical research safer. Research, however, is still research. Only a minority of clinical trials will show benefit. Adverse events are inevitable. Some will continue to be unexpected, and tragic.

Codes, Declarations, and Other Ethical Guidance for Research With Humans

This page intentionally left blank

An Ethical Framework for Biomedical Research

Over the last 60 years or so, there has been myriad guidance on the ethical conduct of research with humans¹⁻¹³ (see Table 11.1). Despite the profusion, the extant guidance seems flawed in several respects. First, most guidance was “born in scandal.”¹⁴ That is, the guidelines or reports were a response to a specific controversy, and therefore tend to focus on what was perceived to be the transgression of that scandal. The Nuremberg Code directly addressed the atrocities of the Nazi physicians;² the Belmont Report was a response to the Tuskegee Syphilis Study and other scandals;⁴ and the Advisory Committee on Human Radiation Experiments responded to covert radiation experiments during the Cold War and therefore emphasized deception.¹⁵ Second, regulatory guidance tends not to examine the overall ethics of research but to have a specific practical purpose. For instance, the International Conference on Harmonisation has the purpose of creating common rules across developed countries for the “registration of pharmaceuticals for human use.”⁸ The aim is more to enhance the efficiency of drug approval than to protect research participants, for which it defers to the Declaration of Helsinki.³ In general, these regulatory guidelines emphasize the procedural safeguards of informed consent and independent review by an institutional review board or research ethics committee because these leave “paper trails” that can subsequently be audited.

Both of these deficiencies contribute to a third: existing guidance is neither comprehensive nor systematic. The guidelines tend to be lists of claims or principles. For instance, the Nuremberg Code with its 10 statements and the Declaration of Helsinki, originally with 22 principles subsequently expanded to 32, contain no elaboration.^{2,3} Such sparse, oracular statements lack an overarching framework to ensure that all relevant ethical issues are

addressed. They also lack justifications for their claims, implying that the ethical guidance is either self-evident or beyond debate. Consequently, when controversies arise about whether the principle itself is valid or how a principle should be applied to a case, there is nothing to appeal to other than the authority of these documents. Agreement can frequently be secured on the broad principles, but this often hides deep disagreements about how they should be interpreted and applied to specific situations.¹⁶

Finally, and maybe most important, the existing guidance seems mistaken on some important issues. For instance, the Nuremberg Code’s strong statement that “the voluntary consent of the human subject is absolutely essential” seems to prohibit all pediatric research.² Yet this seems wrong. Similarly, the 1993 Council for International Organizations of Medical Sciences (CIOMS) guidelines recommended that Phase I or II studies of drugs and vaccines should be conducted first in sponsoring countries before being done in developing countries.¹⁷ Because of strong objections, especially by developing countries, a decade later this was deleted from the revision.⁶ The most recent version of the Declaration of Helsinki addresses conflicts of interest through disclosure, requiring that potential research participants be adequately informed about “any possible conflict of interest” and that these “should be declared in the publication.”³ The value and importance of disclosing conflicts of interest to research participants is controversial.¹⁸ More important, exclusive reliance on disclosure in the absence of prohibitions on certain conflicts of interest seems inadequate.^{19,20}

Because of the deficiencies of existing research ethics guidance, there is a need for a broader, systematic, and comprehensive framework that includes an ethical justification and specification

for how each principle is to be fulfilled in practice.^{21,22} Among other goals, this framework should incorporate those concerns that overlap in the existing guidance and organize them into a coherent whole.

Fundamental Ethical Purpose

Informing this overarching framework is the understanding that the fundamental ethical challenge of all research with humans is to avoid exploitation.^{21,22} Research aims at obtaining generalizable knowledge that can be used to improve health and health care. Participants in research are a necessary means to obtaining this knowledge. Consequently, participants are used in the research process for the benefit of others and are at risk of being exploited. The fundamental purpose of research guidelines is to minimize the possibility of exploitation in clinical research.

There are two distinct conceptions of exploitation. Both are important in protecting research participants. One is the traditional, Kantian notion of exploitation as using an individual merely as a means and not simultaneously as an end in itself.^{23,24} This Kantian conception of exploitation is grounded in the use of individuals for an end they do not agree with or to which they have not consented. Using individuals without their consent violates their autonomy.²⁵ The remedy for the Kantian type of exploitation is obtaining informed consent and sometimes ensuring collaborative partnership with a larger community that agrees to the research.

A second conception of exploitation elaborated by Alan Wertheimer rests on the unfair distribution of the benefits and burdens of an interaction.^{26,27} This is distinct from the Kantian conception because it concerns the distribution of benefits—how much they benefit—rather than autonomy. Importantly, this type of exploitation can occur even when the interacting parties provide valid consent.²⁶ Minimizing this type of exploitation is more complex, requiring the fulfillment of multiple principles.²⁷

Principles and Benchmarks of Ethical Clinical Research

The following eight ethical principles provide a comprehensive and systematic framework to guide the ethical conduct of clinical research and thereby minimize the possibility of exploitation^{21,22} (see Table 11.2). These principles are general and identify considerations necessary to justify research as ethical. They are conceptually included in most of the previously mentioned guidance, although existing guidelines do not necessarily include all of them. In addition, they are presented sequentially, going from the development of research proposals to the conduct of research to monitoring during research.

Each principle is specified by benchmarks that offer a specific elaboration and understanding of each principle.²² The benchmarks are practical interpretations of what is required to fulfill each principle.^{22,28,29} In this sense, the benchmarks should clarify and focus the kinds of values and considerations at stake in fulfilling each principle. No matter how specific and detailed, the benchmarks cannot eliminate all controversy over the principles.^{16,22} However, by specifying and clarifying the eight princi-

ples, these benchmarks should help to narrow any disagreement related to specific cases, making it easier to focus on the substance of the disagreement, assess the importance of the problems and concerns, and even identify potential solutions.²²

Collaborative Partnership

Clinical research is meant to serve a social good, to enhance the health and health care of people. It is part of the way people collectively improve their well-being. Clinical research is not meant to be done *to* people but done *with* people.³⁰ The principle of collaborative partnership recognizes that the community in which research is conducted should collaborate in the research endeavor.^{22,27} Seeking the community's agreement and input helps ensure that the particular community will not be exploited.²⁷ In addition, collaboration helps ensure—although it does not guarantee—that the community will receive fair benefits from the conduct of the research.^{27,31} Collaborative partnership helps ensure that the community determines for itself whether the research is acceptable and responsive to its health problems. Finally, collaborative partnership is practically important. Without the engagement of researchers and community members, research is unlikely to have any lasting impact. Without the investment of health policy makers, the research results are unlikely to influence policy making and the allocation of scarce health-care resources.²²

Collaborative partnership can be fulfilled through myriad formal and informal mechanisms. For instance, establishment of community advisory boards, consultations with advocacy groups, public meetings with community members, and advocacy for funding of research are approaches to developing collaborative partnerships.^{30,32} Which method is preferred depends upon the nature of the particular research study. Because many of these mechanisms exist in the background without the need to launch explicit initiatives or are just part of “doing business,” collaborative partnership has infrequently been included as an explicit ethical requirement of clinical research.²¹ One example of research that fails on collaborative partnership grounds includes “helicopter research” in which researchers arrive in a community, take samples, and leave, never to return.

Several benchmarks are essential to fulfilling the principle of collaborative partnership.²² First, collaborative partnership obviously requires partners. This means identifying representatives of the target community to be involved in the research. Second, it requires collaboration. This entails sharing responsibility for assessing the importance of the health problem and the value of the research to the community, as well as for planning and conducting the study, disseminating the results, and ensuring that the results are used for health improvements.

Third, a collaborative partnership requires mutual respect. This entails recognition of and respect for a community's distinctive values, circumstances, culture, and social practices.³⁰ Importantly, respect does not mean uncritical acceptance of practices that might be oppressive or coercive. Indeed, some of these practices may be challenged in research. A true collaborative partnership based on respect also aspires toward equality between the partners. In this sense, collaborative partnership aspires to minimize the deprived circumstances of the involved community. Research aims to ameliorate deprivations usually of disease and sometimes of social circumstances. This could occur through a number of interventions directly related to the goals of the research

Table 11.2
Principles and Benchmarks for Ethical Clinical Research

<i>Principles</i>	<i>Benchmarks</i>
Collaborative partnership	<ul style="list-style-type: none"> • Which community representatives will be partners, involved in helping to plan and conduct the research, disseminate the results and use the results to improve health? • How will responsibility be shared with these partners for planning and conducting the research, disseminating the results and using the results to improve health? • How will respect for the community's values, circumstances, culture, social practices, and so forth, be demonstrated? • How will fair benefits for the community from the conduct and results of the research be assured? • How will the tangible benefits of the research, such as authorship credit and intellectual property rights, be distributed to ensure fairness?
Social value	<ul style="list-style-type: none"> • Who will benefit from the conduct and results of research? • What is the potential value of the research for each of the prospective beneficiaries? • How will the social value of the research be enhanced? • How can adverse impacts, if any, of conducting the research be minimized?
Scientific validity	<ul style="list-style-type: none"> • Do the scientific and statistical design and methods satisfy generally accepted standards and achieve the objectives of the study? If not, is there clear justification for the deviations? • Will the research results be interpretable and useful in the context of the health problem? • Does the study design ensure participants health-care services they are entitled to? If not, are there methodologically compelling reasons and are participants protected from serious harm? • Is the research design practically feasible given the social, political, economic, and cultural environment?
Fair participant selection	<ul style="list-style-type: none"> • Is the research population selected to ensure that the research complies with scientific norms and will generate valid and reliable data? • Is the research population selected to minimize risks to the participants? • Are the individual research participants selected to maximize social value and enhance the possibility of benefits to the participants? • Are the participants vulnerable based on age, clinical status, social marginalization, economic deprivation, and so forth? If so, what safeguards are included to protect the participants?
Favorable risk-benefit ratio	<ul style="list-style-type: none"> • Are the potential physical, psychological, social, and economic risks of the research for the individual participants delineated and their probability and magnitude quantified to the extent possible given the available data? • Are the potential physical, psychological, social, and economic benefits of the research for the individual participants delineated and their probability and magnitude quantified to the extent possible given the available data? • When compared, do the potential benefits to the individual participants outweigh the risks? If not, does the knowledge gained from the study for society justify the net risks to the individual participants?
Independent review	<ul style="list-style-type: none"> • Are the procedures for independent review established by law and regulation being properly followed? • Is the review body both independent and competent? • Is the review process transparent, and are reasons given for the review committee's decisions? • Are multiple reviews minimized and reconciled if they conflict?
Informed consent	<ul style="list-style-type: none"> • Are recruitment procedures and incentives consistent with cultural, political and social practices of the potential participants and their community? • Are disclosure forms and verbal disclosure procedures sensitive to participants' culture, language, and context? • Is the information presented to participants complete, accurate, and not overwhelming? • Are there appropriate plans in place for obtaining permission from legally authorized representatives for individuals unable to consent for themselves? • Are supplementary consents or permissions, for example, from spouses or community leaders, obtained? If so, are there ways to ensure that the individual participant can still decide whether to participate independent of the spouse or community leader? • Are the mechanisms to symbolize consent consistent with participants' culture and context? • How will individual participants be made aware of their right to refuse to participate and are they actually be free to refuse?
Respect for participants	<ul style="list-style-type: none"> • How will the health and well-being of participants be monitored to minimize harms? Are the criteria for changing doses or procedures for stopping the study for the health of participants adequate? • How will the confidentiality procedures actually be implemented? • How will it be ensured that participants who want to withdraw can withdraw without penalty? • How will results of the research be disseminated? • What are the plans for care of the participants after the research is completed?

project or ancillary mechanisms such as developing the general infrastructure necessary to actually conducting ethical research.

Fourth, the community in which the research is being conducted should receive fair benefits from the conduct and/or results of the research.^{27,31} What level of benefits is fair depends upon the burdens the community bears for the conduct of the research.²⁶ Such benefits might include direct benefits to the research participants as well as more indirect benefits such as employment and training for community members to augment health care services for the entire community.^{27,31}

Finally, collaborative partnership requires a fair distribution of the tangible and intangible rewards of research among the partners. Very little can generate more resentment, mistrust, and sense of exploitation than an unfair distribution of the benefits of collaboration. This may require agreements regarding sharing intellectual property rights, royalties, and other sources of financial profit as well as appropriate authorship and other credit for contributions to the research.^{27,31}

Social Value

Clinical research is not an end in itself. It has instrumental value because it generates knowledge that leads to improvement in health or health care.^{33,34} It is such improvements in health that ultimately constitute the social value of research. Unfortunately, the emphasis on protection of research participants has displaced the importance of assessing research's social value. Without social value, research exposes participants to risks for no good reason and wastes resources.^{21,22,33–35} However, the process of translating research results into health improvements is complex, incremental, and haphazard.³⁶ Typically, early studies are valuable because the data they generate informs additional research that ultimately could improve health. Priorities may change while a study is being conducted, and the cooperation of diverse groups is often needed to make changes based on research results. This makes the process of going from research to health improvement uncertain and arduous. Assessment of the value of research is made prospectively before any data are collected. Consequently, determinations of social value are uncertain and probabilistic, entailing judgments about the usefulness of a sequence of research and chances of implementing the results.^{35,36} Even in wealthy countries with well-established research studies and health system infrastructures, research results are imperfectly incorporated into clinical practice.

Certain kinds of research clearly lack social value: for example, research that is nongeneralizable, that addresses a problem of little relevance to anyone, that will not enroll sufficient numbers of patients, that assesses proven or empirically well-established results, and research that could never be practically implemented to improve health or health care even if effective in the research setting.^{37,38}

Consideration of four benchmarks helps to ensure fulfillment of the principle of social value.^{21,22} First, to whom will the research be valuable? It is important to delineate both the short-term and long-term prospective beneficiaries of the research study, specifying whether they include a specific group, similarly situated groups, a larger community from which research participants will be recruited, the country hosting the research, or people outside the host country.²²

Second, what is the potential value of the research for each of the prospective beneficiaries? Potential beneficiaries may rank the health problem's importance differently and may receive different benefits from the research results. Factors to be considered might include how widespread the disease or condition is, the impact of the disease on individuals and communities, and the extent to which the research is likely to offer an intervention or information useful to the beneficiaries. For example, because malaria is a substantially greater health problem for certain developing countries than for developed countries, research on cerebral malaria may be of substantial value to people in developing countries. Conversely, research on prophylactic medications for malaria is likely to be more valuable for tourists, whereas research on a malaria vaccine may be perceived as valuable to everyone, but to a different degree. Similarly, research on new HIV/AIDS medications in a developing country, although needed in that country, could benefit those outside the host country more than the community in which the research is being conducted if the ultimate cost of the medication is high.

Third, it is important to develop mechanisms to enhance the social value of research. Through collaborative partnerships, strategies should be devised to disseminate results in appropriate ways to key stakeholders including people with the disease, practicing clinicians, advocacy groups, health policy makers, and sometimes international health-care organizations.^{22,30} In addition to presentations at scientific conferences and journal publications, this may require novel forms of dissemination such as letters to patients, articles in advocacy publications, presentations at community gatherings, public service announcements in the media, or letters to clinicians. Social value can also be enhanced when research is integrated into a long-term collaborative strategy, so that one research project forms part of a more comprehensive research and health delivery strategy to address significant health problems.²⁷

Finally, consideration should be given to the impact of the research on the existing health-care infrastructure. The conduct of the research should not undermine a community's existing health-care services or social structures and leave it worse off at the end of the research. Supplementing the existing system and contributing to sustainable improvements in health through the provision of additional resources, equipment, medications, or training appropriate to the research can enhance value.

Scientific Validity

Contrary to many claims, in research, science and ethics do not conflict.^{21,22,34} Valid science is a fundamental ethical requirement.^{21,22,35} Unless research generates reliable and valid data that can be interpreted and used by the specified beneficiaries of the research, it will have no social value and participants may be exposed to risks for no benefits.^{39,40} Research must be designed in a way that provides valid and reliable data.

Four benchmarks are important in fulfilling the principle of scientific validity. First, the scientific and statistical design and methods of the research must plausibly realize the objectives of the research and must also satisfy the generally accepted norms of research. Research must have clear, justifiable objectives, an adequate sample size, and unbiased and reliable outcome measures and statistical analyses. Deviations from such standards, such as innovative designs, must be plausibly justifiable to the research community.

Second, a research study must be designed to generate results that will be interpretable and useful in the context of the health problem.¹⁵ Interventions should be selected to ensure that the design is useful in identifying ineffective or appropriate interventions; implementing socially, culturally, and economically appropriate changes in the health-care system; or providing a reliable foundation for conducting subsequent research. Interventions should be selected to ensure that the design will realize social value and that the data are generalizable.^{21,22,41}

Third, the study design must realize the research objectives while neither denying health-care services that participants are otherwise entitled to nor requiring services that are not feasible to deliver in the context.^{37,38,42} However, studies can be ethically designed yet not provide a service or intervention individuals are entitled to under certain, restrictive conditions.^{41,43–45} Specifically, it is ethical to use placebo or less than the diagnostic tests or treatments to which individuals are entitled when two conditions are fulfilled: (1) there is a methodologically compelling reason to do so, and (2) there is only minimal chance of serious harm—such as suffering irreversible morbidity or disability, or reversible but serious injury.^{41,43–45}

Determining entitlement to medical services in studies is challenging because entitlements differ among countries, and may differ among groups within a country.^{46,47} Even in wealthy countries, participants are not entitled to every available or effective medical service, because justice necessitates establishing priorities for the distribution of scarce resources.^{46,48} For instance, some developed countries may not guarantee expensive drugs when inexpensive but more inconvenient yet effective drugs are available. Similarly, it is widely accepted that cardiac research conducted in developing countries need not be designed to require a coronary care unit because participants would not necessarily be entitled to this service under a just distribution of scarce resources in those countries.^{37,38,42,46,49} Conversely, in a study evaluating interventions to reduce mortality from cerebral malaria conducted in rural settings in which travel to hospitals is impracticable, provision of bed nets may be part of a valid design even if participants may not otherwise have them.⁵⁰ However, even if the study's objective is deemed socially valuable, especially to the enrolled participants' community, it is not ethically necessary to provide more comprehensive interventions beyond those to which participants are entitled, especially interventions that may not be feasible and sustainable. Doing so may even be unethical if it undermines the scientific objectives or makes the results irrelevant to the enrolled participants' community.

Finally, the study must be designed in a way that is practically feasible given the social, political, and cultural environment in which it is being conducted.⁵¹ Ensuring feasibility might require extensive community education and outreach as well as sustainable improvements to the health-care infrastructure, such as training of personnel, construction of additional facilities, or provision of an affordable drug. Feasibility also requires that it be possible to achieve the sample size in a reasonable time frame.

Fair Participant Selection

Historically, populations that were poor, uneducated, or powerless to defend their own interests were targeted for high-risk re-

search, whereas promising research was offered to more privileged individuals.^{15,34,52} Fair selection of participants requires that the research objectives be the primary basis for determining eligibility.^{4,15,21,22,34} Once a target group is identified based on scientific objectives, considerations of minimizing risk, enhancing benefits, minimizing vulnerability, feasibility, as well as facilitating collaborative partnership, become determinative.²² Factors extraneous to the objectives, risks, benefits, and feasibility of conducting the research should not be the basis for selecting target communities or excluding individuals or communities.^{4,15,22,34}

Four benchmarks are necessary to fulfill the principle of fair participant selection. First, the study population should be selected to ensure valid science.^{21,22,34,53} Scientific reasons for choosing a particular group of individuals or a community might be high prevalence or incidence of a disease, the magnitude of harms caused by the disease, high transmission rates of an infection, special drug resistance patterns, deprived social circumstances that increase susceptibility to a disease, or particular combinations of diseases. Social status that is irrelevant to the research objectives should not influence selection. Scientific considerations alone, however, will usually underdetermine which community or individuals are selected.

Second, selecting participants in a way that minimizes risk is essential.⁵⁴ For instance, in selecting a target population for an HIV vaccine study, the extent to which a community protects HIV-infected persons against discrimination and provides treatment for opportunistic infections are important considerations to minimize risk. Similarly, individuals with high creatinine clearance may be appropriately excluded from a trial of a potentially renal toxic drug in order to reduce risk.

Third, individuals should be selected in order to enhance both the social value of the research and the possibility of benefits to participants.^{22,55–57} For example, assuring an adequate number of women in a study of a disease largely affecting women enhances benefits to women. Selecting individuals who are able to comply with the study's requirements will enhance the chances that they will benefit from the intervention and that the study will yield valid data. Communities should be selected in which a collaborative partnership can be developed and in which social value can be realized. Consequently, it is preferable to select communities that have, or can establish, a system for identifying legitimate representatives and that will share responsibility for planning and conducting the study and ensuring that results are implemented through health system improvements or additional research.

Finally, factors such as cognitive ability, age, clinical status, familial relationships, social marginalization, political powerlessness, and economic deprivation should be considered in order to determine the vulnerability of individuals or groups.⁵⁸ For instance, if health policy makers suggest a particular group for research participation, the researchers should determine whether the group has been selected for good reasons, such as a high incidence of disease, or because of social subjugation. If scientifically appropriate individuals or groups are identified as vulnerable, specific safeguards to protect the population should be implemented, such as consent monitoring or independent capacity assessment, independent clinical monitoring, ensuring confidentiality, and ensuring that potential research participants are free to decline joining the study.

Favorable Risk-Benefit Ratio

Like life itself, all research entails some risks. However, clinical research typically should offer individual participants a favorable net risk-benefit ratio.^{21,22,34} In cases in which potential risks outweigh benefits to individual participants, the social value of the study must be sufficient to justify these net risks.^{4,59} Because clinical research involves drugs, devices, and procedures about which there is limited knowledge, uncertainty about the degree of risks and benefits is inherent. And the uncertainty is greater in early phase research.

The principle of a favorable net risk-benefit ratio requires fulfilling three benchmarks. First, the risks of the research should be delineated and minimized. Researchers should identify the type, probability, and magnitude of the risks of the research. The risks are not limited to physical risks, but should also encompass potential psychological, social, and economic risks. To the extent possible, the assessment of risks should be based on available empirical data, not intuition or speculation. Within the context of good clinical practice, these risks should be minimized “by using procedures which are consistent with sound research design and which do not unnecessarily expose subjects to risk, and whenever appropriate, by using procedures already being performed on the subjects for diagnostic or treatment purposes.”⁵ In addition, research procedures should be performed by trained and competent individuals who adhere to the standards of clinical practice.³

Second, the type, probability, and magnitude of the benefits of the research should be identified. The benefits to individual participants, such as health improvements, are relevant. The specification of potential benefits to individual participants should consider only health-related potential benefits derived from the research intervention itself.^{21,22,34} The benefits to society through the generation of knowledge are assumed if the research is deemed to be of social value and scientifically valid. Secondary benefits, such as payment, or adjunct medical services, such as the possibility of receiving a hepatitis vaccine not related to the research, should *not* be considered in the risk-benefit evaluation; otherwise simply increasing payment or adding more unrelated services could allow the benefits to justify even the riskiest research.^{22,60} Furthermore, although participants in clinical research often receive some health services and benefits, the purpose of clinical research is not the provision of health services. Services directly related to clinical research are necessary to ensure scientific validity and to protect the well-being of the individual participants.

As a matter of general beneficence, consideration should be given to enhancing benefits to participants and their community, especially when such benefits can be provided easily and will not compromise the scientific validity of the study. However, such enhancements of benefits are not to be considered in the assessment of the risk-benefit ratio—or even of the social value—of the research study itself.

Third, the risks and potential benefits of the clinical research interventions to individual participants should be compared. In general, the more likely and/or more severe the potential risks, the greater in likelihood and/or magnitude the prospective benefits must be; conversely, research entailing potential risks that are less likely and/or of lower severity can have more uncertain and/or circumscribed potential benefits. Importantly, this comparison of

risks and benefits should take into account the context in which the participants live and the risks they actually face. The underlying risks of a particular disease can vary because of differences in incidence, drug resistance, genetic susceptibility, or social or environmental factors. When participants confront a higher risk of disease, riskier research may be justifiable.⁶¹ Similarly, the net risk-benefit ratio for a particular study may be favorable in communities in which the social value of the research is high, yet may be unfavorable in communities in which the potential value is lower.

When potential benefits to participants from the research are proportional to the risks they face, then the additional social value of the research, assured by the fulfillment of the value and validity requirements, implies that the cumulative benefits of the research outweigh its net risks.

The notions of “proportionality” and potential benefits “outweighing” risks are metaphorical.⁴ Yet the absence of a mathematical formula to determine when the balance of risks and potential benefits is proportionate does not connote that such judgments are inherently haphazard or subjective. Instead, assessments of risks and potential benefits to the same individuals can appeal to explicit standards, informed by existing data on the potential types of harms and benefits, their likelihood of occurring, and their long-term consequences.⁴ Evaluations of the quality of books are not quantifiable either, but neither are they merely matters of subjective taste; comparing the quality of Shakespeare or Dostoevsky with Danielle Steel entails judgments based on shared standards that can be justified to others. Similarly, people routinely make discursively justifiable intrapersonal comparisons of risks and benefits for themselves, and even for others, such as children, friends, and employees without the aid of mathematical formulae.⁶²

Finally, a more complex evaluation is necessary when clinical research presents no or few potential benefits to individual participants, such as in Phase I safety and pharmacokinetic studies, and even in some epidemiology research, or when the risks outweigh the potential benefits to individual participants. In this case, a more complex evaluation, what Charles Weijer calls a “‘risk-knowledge’ calculus,” is necessary.⁵⁷ This calculus assesses whether the societal benefits in terms of knowledge gained justify the “excess” risks to individual participants.⁶³ Determining when potential social benefits outweigh net risks to individual participants requires interpersonal comparisons that are conceptually and practically more difficult than intrapersonal comparisons.⁶² However, policy makers are often required to make these kinds of comparisons, for example, when considering whether pollution and its attendant harms to some people are worth the potential benefits of higher employment and tax revenues to others. There is no settled framework for how potential social benefits should be “balanced” against individual risks. Indeed, the appeal to a utilitarian approach of maximization, as in cost-benefit analysis, is quite controversial both morally and because many risks and benefits of research are not readily quantifiable on commensurable scales.^{64–66} Nevertheless, these comparisons are made,⁶⁷ and regulations mandate that investigators and research review committees make them with respect to clinical research.^{4,5} When research risks exceed the combination of potential medical benefits to individuals and the benefit of useful knowledge to society, clinical research is not justifiable.

Independent Review

Independent ethical review of all clinical research protocols is necessary for two reasons: (1) to minimize concerns regarding researchers' conflicts of interest and (2) to ensure public accountability.^{21,22} Investigators inherently have multiple, legitimate interests—interests to conduct high quality research, to complete the research expeditiously, to protect research participants, to obtain funding and advance their careers, and so forth.^{18,19} Even for well-intentioned investigators, these diverse interests can generate conflicts that may unwittingly distort or undermine their judgments regarding the design, conduct, and analysis of research, as well as adherence to ethical requirements.^{19,68–70} Wanting to complete a study quickly may lead to the use of questionable scientific methods or to the use of readily available participants rather than fairer participant selection criteria; enthusiasm for and commitment to the research project may lead to overemphasis of potential benefits and underemphasis of potential harms to participants. Independent review by individuals unaffiliated with the clinical research study helps to minimize the potential impact of such conflicts of interest.^{21,22,34,71} In this way, independent reviewers can assure potential research participants that the study they are considering is ethical—that is, it will generate socially valuable information, and the risk-benefit ratio is favorable.

Independent review of clinical research is also important for a second, less emphasized, reason: social accountability.²¹ Clinical research imposes risks on participants for the benefit of society. An independent review of a study's compliance with ethical requirements assures members of society that people who enroll in trials will be treated ethically. Based on this review, members of society can have confidence that they will not benefit from the exploitation of other humans.

Four benchmarks help in fulfilling this principle. First, procedures established by law and regulation should be followed. Research has not revealed the best mechanism to conduct independent review.⁷² Consequently, the actual review mechanisms are usually determined by laws and regulations that vary both internationally and locally. For instance, some countries and institutions separate scientific and ethical review, whereas others integrate scientific and ethical assessments into a single review. Similarly, some countries have ethics review committees composed only of laypersons, whereas others have committees dominated by medical scientists and physicians. Nevertheless, prevailing laws and regulations establish the standards that should be followed for independent review. They should be amended as better processes are identified.

Second, whatever the process, the review must be independent and competent. Members of the review committees must be free of any conflicts with the researchers or the research study. The reviewers should not be collaborators on the research or with the researchers, and should not have any financial interests in the outcomes of the study. Similarly, reviewers should be excluded from the review if they have other conflicting interests, such as responsibility for the financial interests of the institution in which the research is conducted, that might preclude them from evaluating the protocols according to ethical principles and without bias. Similarly, the reviewers should have sufficient expertise—or be able to access advice—in the scientific, clinical, and statistical areas necessary to assess the research protocol. Training in research ethics for the reviewers may be necessary.

Third, the review should be transparent. This is especially important in multinational research in which differences in culture, practices, and understandings may yield different judgments. One fundamental aspect of transparency is that the reasons for decisions of the independent review committee are explained. This allows observers to assess whether the reasons are appropriate and relevant considerations have been addressed.

Finally, given the increasing complexity of research, multiple independent reviews frequently occur.^{73–75} Multiple independent reviews may seem to be required by law or regulation for multisite studies or studies conducted by investigators from multiple institutions. Importantly, however, the ethical principle of independent review does not require multiple reviews.⁷⁶ The only requirement is that the reviewers competently and independently assess relevant scientific and ethical considerations. Indeed, multiple reviews may have no added value or may even be counterproductive, by taking time and requiring adjudication without added protections.⁷² Such situations are unethical—resources are expended that produce no value or even waste value.⁴⁰

If there is disagreement among such reviews, it is important to clarify its nature. Disagreement may reflect different ways of balancing various principles and benchmarks, or the appropriateness of different ways of fulfilling them. That is, disagreement might reflect *how* the ethical principles are met, rather than *whether* they are met.⁷⁷ Conflicts may also arise because of different guidelines or regulatory requirements, which themselves may not have good ethical justification or may be insensitive to particular cultural or social circumstances.⁷⁸ Only rarely are there fundamental disagreements about whether ethical principles and benchmarks are fulfilled. Unfortunately, there is no widely accepted procedure for adjudicating such conflicts. In practice, the requirements specified by the sponsor's review board are often determinative. This contravenes the principle of collaborative partnership and the notion that the community that assumes the risks of the research should make the assessment about the research protocol.⁷⁹

Informed Consent

No requirement has received as much explication as informed consent. The purpose of informed consent is to show respect for the autonomy of individuals.^{4,6,15,25,34,80–85} To enroll individuals in clinical research without their authorization is to treat them merely as a means to purposes and ends they may not endorse or even know about, denying them the opportunity to choose what projects they will pursue and subjecting them to Kantian-type exploitation.^{23–25} By allowing individuals to decide if—and how—they contribute to research, informed consent respects persons and their autonomy.^{4,25}

Valid informed consent requires that the consenting person has the capacity to understand and make decisions, receives relevant information about the research study, understands that information, and consents voluntarily and without coercion.^{4,15,25,34,80–84} Each of these elements is necessary to ensure that individuals make rational and free determinations of whether the research trial is consonant with their interests.⁸⁶

Seven benchmarks are necessary to fulfill the principle of informed consent. First, recruitment procedures and incentives for participants should be consistent with *cultural, political and social practices of the potential participants*. In some communities, compensation for participation in research may be expected, whereas

in others, it may be considered offensive. The appropriate form and level of compensation depends upon the local economic and social context.⁸⁷ Although concerns about undue inducement are frequently raised,^{4,5,84} high potential social value and a favorable risk-benefit ratio—implying minimal net risks to the participants—dispel these concerns.^{88–91} Indeed, worry about undue inducement could reduce compensation and some other benefits for participants and host communities. Paradoxically, balancing fair compensation and undue inducement may result in less compensation for members of impoverished communities and raise the specter of exploitation.^{26,88}

Second, both written and verbal disclosure of information should be sensitive to participants' culture and context. Disclosures should use the language, culturally appropriate idioms, and analogies of the prospective participants at a level they can understand. This entails a need for collaborative partnership. After disclosure, investigators should feel confident that participants understand the information and are consenting without any pressure or major misconceptions. In some cases, a formal assessment of understanding, monitoring of the consent process, or independent assessment of participants' capacity to consent may be warranted.⁹²

Third, the disclosure of information relevant to the research study must be complete and accurate, but not overwhelming. Providing less than complete and accurate information raises concerns about potential deception of participants. However, complete information does not imply lengthy or exhaustive disclosure forms detailing every aspect of the research study, which may be overwhelming to the participants. Indeed, shorter, more focused forms, without repetition and boilerplate disclosures, may be more effective.⁹³ Disclosure forms must balance completeness with not being overwhelming.

Fourth, some research entails enrollment of individuals unable to consent because of their age, permanent mental incapacity, an acute loss of mental functions, or other reasons. In these cases, researchers must have a strategy for obtaining permission from legally authorized representatives of the potential participants.^{15,83,84,94–99}

In some cases, "spheres of consent" ranging from spouses to heads of households to school principals to village elders or community leaders may be required before researchers can invite individual participation.^{30,100,101} With a few exceptions, such as emergency research, it is unacceptable to supplant individual consent of competent adults by family or community consent.¹⁰² The family or community gives permission only to approach individuals. When family or community permission to approach individuals is reasonable, special care should be given to assure that the individual can still refuse participation—that is, that there is no coercion.

Sixth, researchers should utilize consent procedures that are acceptable within the local context, while ensuring that an independent observer could verify voluntary participation by the individuals. For instance, U.S. regulations require a written signature.⁵ In many cases, this is an acceptable and efficient way to document consent authorization. However, in some cases, because of limited literacy or cultural differences, such requirements may be inappropriate and unethical.⁷⁷ Alternative methods to express consent, such as handshakes, embracing, or sharing a meal, are known.⁷⁷ Appropriate alternative procedures for documenting informed consent might include tape recordings or witnessed written documentation of these methods of consent.

Finally, special attention must be given to ensure that individuals are aware of their right to, and are actually free to, refuse to participate or to withdraw from research. A key element of informed consent is the ability to refuse or withdraw participation without penalty.¹⁰³ Prorating offered compensation and other research-related benefits may help to obviate possible familial or community coercion or retribution.

Respect for Participants

The ethical conduct of clinical research does not end when informed consent is obtained.^{21,22,104} Researchers have ongoing obligations to treat individuals with respect from the time they are approached—even if they refuse enrollment—throughout their participation and even after their participation ends. Respecting potential and enrolled participants entails multiple activities. First, and arguably most important, this principle requires monitoring the health and well-being of participants, and intervening to prevent or treat harms that might result from the adverse reactions, untoward events, or changes in clinical status associated with the research.¹⁰⁴ In some cases, research studies need to include procedures to adjust drug doses and even withdraw study participants because of adverse events. Furthermore, specific stopping rules may be necessary if excessive adverse events or benefits are identified.

Second, pledges of confidentiality should be honored and procedures to protect confidentiality implemented. Such procedures include securing databases, locking file cabinets containing data, coding specimens and data forms, as well as interviewing participants in private spaces where they cannot be overheard. In addition, it is important to alert participants that despite researchers' best efforts, absolute confidentiality cannot be guaranteed.

Third, respect includes permitting participants to change their minds, to decide that the research does not comport with their interests or preferences, and to withdraw without penalty. Fourth, as new information about the impact of the intervention or about the participant's clinical condition is gained during the course of the research, respect requires providing this new information to the participants. Researchers should also develop explicit strategies to inform participants and host communities of the results of the research. Having participated in research and assumed risks, the participants and host communities have a right to know what was found and its implications for public health and health-care policies.

Finally, plans should be made regarding the care of participants when the trial is over. In some cases, this may simply involve referral to a primary care provider. In other cases, this may require researchers to find creative strategies for providing access to treatments benefiting the participants, even when these interventions are unlicensed.

Characteristics of the Principles

The eight general principles and the benchmarks delineate a systematic and comprehensive way of assessing the ethics of particular clinical research.^{21,22} They provide a coherent and organized way for researchers, ethics reviewers, participants, and others to

evaluate a research protocol and to determine whether it fulfills ethical standards. They should not be seen as adding ethical requirements, but rather distilling and coherently articulating the ethical norms underlying much of the prevailing guidance. These principles and benchmarks offer a more organized and systematic delineation of what many researchers, ethics reviewers, and others already do.

Importantly, these principles are not independent of all other ethical principles. They operate within and presume compliance with more general moral norms, such as honesty and promise keeping.²² Similarly, these principles focus on what is required to evaluate research studies, not on the enforcement or proper conduct of the research itself. Having ethical researchers is important for implementation of the framework but not a requirement for evaluating the research protocol. Determining *what* is ethical and what needs to be enforced must be done prior to and should not be confused with *how* to implement an ethical protocol or to enforce the requirements.^{21,22}

These eight principles are necessary. The presumption is that they must all be fulfilled for a research protocol to be ethical. There is no picking and choosing. However, in specific cases, such as emergency research, informed consent may be legitimately waived. These principles are justified by ethical values that are widely recognized and accepted, that reasonable people would want to be treated in accordance with—avoidance of exploitation, the just distribution of benefits and burdens, beneficence, respect for persons, and so forth.^{105,106} These requirements are precisely the types of considerations that would be invoked to justify clinical research if it were challenged. The benchmarks provide more practical considerations for discerning satisfaction of the general principles.

The principles are sufficient. Fulfilling these eight principles means the research is ethical. Failing on any one principle—except for waiving informed consent in specific cases, in which waiving consent must be justified—makes the research unethical. The proposed benchmarks, however, may not be sufficient, and may need revision with experience and time. They certainly provide a useful first estimation of the kind of specific elements that need to be fulfilled.

These eight principles are universal; they apply in all countries and contexts, regardless of sponsorship. The principles are general statements of value; they must be elaborated by traditions of interpretation and require practical interpretation and specification. The benchmarks offer a first level of specification, indicating how to fulfill these principles. However, the details of this specification will inherently be context and culture dependent. This does not make them relativistic or less universal. It simply recognizes that applying ethical principles in the world requires taking facts into account, and these facts depend upon the context.

Moral arguments take place in context, and they therefore depend at least implicitly on matters of fact, estimates of risk, suppositions about feasibility, and beliefs about human nature and social processes. . . . Even those who rely on what they regard as universal moral principles do not presume that their practical conclusions are independent of reliable facts and plausible assumptions about particular societies. The arguments begin from where we are, and appeal to those with whom we now live. This is why moral relativism is seldom as important an issue in practical as it is in theoretical ethics.¹⁰⁷

Importantly, that there are eight principles suggests that the ethics of research is complex. Adherence to a single ethical principle rarely provides a complete solution; most situations implicate multiple principles.^{48,62,64,105,107–110} Consequently, the various principles and benchmarks will sometimes conflict. What is fair participant selection could at times increase risk; what is required for informed consent may sometimes compromise scientific validity. Unfortunately, there is no simple algorithm for determining how to balance or weigh these principles when they conflict. Different researchers and communities will balance the principles in different ways, some emphasizing informed consent, others the importance of minimizing risks or enhancing social value. Ignoring or rejecting basic principles in designing or conducting a research study could render it unethical. Conversely, accepting the principles and benchmarks, yet disagreeing about how to balance them in a particular case, highlights the intricacies of ethical judgments entailing multiple considerations. Disagreement on the balancing of the various benchmarks does not necessarily make one assessment ethical and the other unethical. Rather, it reflects different, but perhaps legitimate, ways of resolving competing ethical claims.¹⁰⁷ In fact, this framework can help narrow disagreements and elucidate the different underlying views. When conflicts between principles and benchmarks occur, or when different groups weigh the principles differently, the important point is to be clear about the reasons for the evaluation and the differences. Ultimately, a thoughtful process of balancing ethical considerations can be as important as any particular judgment in the effort to ensure that research is conducted ethically.

The Nuremberg Code

History

The Nuremberg Code is a primary foundational document informing all ethical codes on research with humans. Many consider it the most authoritative legal and human rights code on the subject of human experimentation. Its significance cannot be appreciated without a basic knowledge of its historical origins: It is a legal and ethical code promulgated by U.S. judges at the trial of the Nazi doctors at Nuremberg after World War II.

Immediately after World War II, the Allies prosecuted the major surviving Nazi war criminals at the International Military Tribunal (IMT) before judges from the United States, the United Kingdom, France, and the former Soviet Union. The IMT made new international law and can properly be seen, together with the promulgation of the 1948 Universal Declaration of Human Rights, as the birth of the international human rights movement. The IMT produced the Nuremberg Principles, which recognize that there are crimes against peace, war crimes, and crimes against humanity, and that individuals can be punished for committing these crimes even if their actions were consistent with the laws of their own country, and even if they were “obeying orders.”

The subsequent Doctors Trial (1946–47) opened on December 9, 1946. During this trial, U.S. physicians, especially Leo Alexander and Andrew Ivy,^{1,2} worked together with U.S. prosecuting attorneys, especially Telford Taylor and James McHaney, to present evidence of murder and torture under the guise of medical experimentation to a panel of U.S. judges.

Chief prosecutor Taylor, who held the Army rank of Brigadier General, set the tone for the trial in his opening statement:

The defendants in the dock are charged with murder, but this is no mere murder trial. We cannot rest content when we have shown that crimes were committed and that certain persons committed them. To kill, to maim, and to torture is criminal under all modern systems of law. These defendants did not kill in hot blood, nor for personal enrichment. Some of them may be sadists who killed and tortured for sport, but they are not all perverts. They are not ignorant men.³

Taylor also warned that “[t]he perverse thoughts and distorted concepts which brought about these savageries are not dead. They cannot be killed by force of arms. They must not become a spreading cancer in the breast of humanity.” And he echoed the declaration of U.S. Supreme Court Justice Robert Jackson, chief prosecutor at the IMT, that “[t]he wrongs which we seek to condemn and punish have been so calculated, so malignant, and so devastating, that civilization cannot tolerate their being ignored because it cannot survive their being repeated.”³

The 23 defendants, including 20 physicians, faced varying charges including conspiracy, war crimes, crimes against humanity, and membership in a criminal organization, the SS. Sixteen were found guilty. Seven were hanged.

The Evidence

The Doctors Trial documented that Nazi medicine was formed and nurtured by a symbiosis of National Socialist ideology and social Darwinism, mixed with a theory of racial hygiene and

eugenics that viewed some racial and ethnic groups as subhuman and gave physicians an ideological excuse to use their medical skills to harm people in the name of the state (see Chapter 2). This transformed murder and mayhem into legally endorsed medical euthanasia and sterilization. Physicians rose in power and prestige to the extent that they agreed to treat the racial “sickness” that threatened the health of the German *Volk*. In this sense, physicians and the German state used each other: The Nazis used physicians to perform horrific tasks to implement Nazi racial hygiene theories—which would have been much harder to accomplish without the use of physicians—and physicians were granted privileges and power in the Nazi regime. These physicians were able to accept the pseudoscientific Nazi ideology that labeled certain humans, like Jews, gypsies, Slavs, homosexuals, and the disabled, as subhuman (*Untermenschen*) and thus not entitled to basic human rights. In its verdict, the Nuremberg court recognized that Nazis are not the only human beings who are vulnerable to seduction by social, political, or economic organizations that seek to corrupt medicine for their own agendas. No one is immune.

A number of themes recur in Nazi medicine: the devaluation and dehumanization of defined segments of the community; the medicalization of social and political problems; the training of physicians to identify with the political goals of the government; fear of the consequences of refusing to cooperate with civil authority; the bureaucratization of the medical role; and a lack of concern for medical ethics and human rights. Nazi physicians failed to see themselves as physicians first, with a calling and an ethic dedicated to healing and caring for the welfare of human beings. Instead they were seduced by power and ideology to view the state as their “patient” and to see the extermination of an entire people as “treatment” for the state’s health.

Nazi Medical Experiments

The Doctors Trial centered on what Taylor described as “crimes committed in the guise of scientific research.”³ One of the most notorious was the so-called high-altitude or low-pressure experiments at Dachau concentration camp, in which prisoners were placed in a pressure chamber to simulate conditions that German pilots might encounter when bailing out of their planes without oxygen and without pressure suits. One Nazi document gave this description of the experiments:

Some of the experimental subjects died during a continued high altitude experiment; for instance, after one-half hour at a height of 12 kilometers. After the skull had been opened under water, an ample amount of air embolism was found in the brain vessels and, in part, free air in the brain ventricles. . . . [In another experiment,] in order to find out whether the severe psychic and physical effects, as mentioned [elsewhere] are due to the formation of embolism, the following was done: After relative recuperation from such a parachute descending test had taken place, however before regaining consciousness, some experimental subjects were kept under water until they died. When the skull and cavities of the breast and of the abdomen were opened under water, an enormous volume of air embolism was found in the vessels of the brain, the coronary vessels, and the vessels of the liver and the intestines.³

“The victims who did not die in the course of such experiments surely wished that they had,” Taylor told the court. He introduced the report of another experiment in which the subject was given an oxygen mask, raised to a simulated altitude of 47,000 feet, and then deprived of oxygen and subjected to a simulated parachute jump. As described by the report, the victim’s reaction was “spasmodic convulsions,” “agonal convulsive breathing,” “clonic convulsions, groaning,” “yells aloud,” “convulses arms and legs,” “grimaces, bites his tongue,” “does not respond to speech,” “gives the impression of someone completely out of his mind.”³

Other “experiments” with death as their planned endpoint included immersing victims in freezing water or subjecting them to open-air freezing to test various rewarming techniques, with the objective of developing treatments for German aviators who were forced to parachute into the icy North Sea. The Nazi doctors also subjected prisoners to experiments involving malaria, mustard gas, bone transplant, sea-water drinking, epidemic jaundice, typhus, poison, and sterilization.

“The Nazis were searching for methods of extermination, both by murder and sterilization, of large population groups by the most scientific and least conspicuous means,” Taylor told the court. “They were developing a new branch of medical science which would give them the scientific tools for the planning and practice of genocide. The primary purpose was to discover an inexpensive, unobtrusive, and rapid method of sterilization which could be used to wipe out Russians, Poles, Jews, and other people.”³

The Trial

During the trial, which spanned 139 trial days from December 9, 1946, to August 20, 1947, 32 witnesses gave oral testimony for the prosecution, and 53 witnesses, including the 23 defendants themselves, gave oral evidence for the defense. In addition, 570 affidavits, reports, and documents were introduced into evidence by the prosecution and 901 by the defense, for a total of 1,471. All English-language documents were translated into German, and each defendant was represented at trial by a lawyer of his own choosing.

The Doctors Trial was the first of 12 separate and so-called “subsequent” trials conducted at Nuremberg by the U.S. Army. It was based on international law, but because of the military jurisdiction of the occupying power and the U.S. composition of the court, the trial could produce definitive law directly applicable only to Germany and the United States. The trial judges, who were appointed by President Harry S. Truman, were Walter B. Beals, a justice of the Supreme Court of Washington, as presiding judge; Harold L. Sebring, a justice of the Supreme Court of Florida; Johnson Tal Crawford, an Oklahoma District Court judge and Victor C. Swearingen, alternate judge, a former assistant attorney general of Michigan. Hundreds of other Nazis, including some physicians, were tried before military tribunals made up exclusively of military officers, including trials at Dachau, Mauthausen, and Buchenwald.^{4–6}

The charges in the Doctors Trial primarily involved war crimes and crimes against humanity committed in concentration camp experiments. The judges based their conclusion on universal human rights principles and, as the prosecution requested, they saw themselves as speaking as the “voice of humanity.”

The Nuremberg Code

The final judgment, which was delivered in August 1947, also set forth the Nuremberg Code, a 10-point statement of rules designed to protect the rights and welfare of research subjects⁷ (see Box 12.1). The court prefaced its enunciation of the Code as follows:

The great weight of the evidence before us is to the effect that certain types of medical experiments on human beings, when kept within reasonably well-defined bounds, conform to the ethics of the medical profession generally. The protagonists of the practice of human experimentation justify their views on the basis that such experiments yield results for the good of society that are unprocurable by other methods or means of study. All agree, however, that certain basic principles must be observed in order to satisfy moral, ethical and legal concepts.⁷

The Code's Strengths

The most significant strength of the Nuremberg Code is that it is a legal code based on principles of natural law and human rights that have universal application. Another central strength is its

articulation of the principle of informed consent, insisting that the voluntary, competent, informed, and understanding consent of the research subject is a necessary (but not sufficient) prerequisite for lawful human experimentation, and requiring that a person retain the right to withdraw his or her consent at any time during the experiment.

Although discussions and debates continue about the use as research subjects of individuals who are incapable of providing informed consent on their own behalf, there is worldwide agreement that the voluntary and informed consent of those capable of giving it is a prerequisite to lawful and ethical experimentation with humans. This proposition has become a central principle of medical ethics, in both the research and therapeutic settings, and has been enshrined in international human rights law, including the International Covenant on Civil and Political Rights, which states in Article 7: “[N]o one shall be subjected without his free consent to medical or scientific experimentation.”⁸ The Nuremberg Code’s eight other provisions relate to the welfare of research subjects and the obligation of researchers to protect subjects’ welfare when conducting research.

The Code has been invoked and endorsed by a variety of U.S. courts.⁹ A U.S. district court in Ohio has ruled that it applies to

BOX 12.1
The Nuremberg Code

1. The voluntary consent of the human subject is absolutely essential. This means that the person involved should have legal capacity to give consent; should be so situated as to be able to exercise free power of choice, without the intervention of any element of force, fraud, deceit, duress, over-reaching, or other ulterior form of constraint or coercion; and should have sufficient knowledge and comprehension of the elements of the subject matter involved as to enable him to make an understanding and enlightened decision. This latter element requires that before the acceptance of an affirmative decision by the experimental subject there should be made known to him the nature, duration, and purpose of the experiment; the method and means by which it is to be conducted; all inconveniences and hazards reasonably to be expected; and the effects upon his health or person which may possibly come from his participation in the experiment.
 The duty and responsibility for ascertaining the quality of the consent rests upon each individual who initiates, directs or engages in the experiment. It is a personal duty and responsibility which may not be delegated to another with impunity.
 2. The experiment should be such as to yield fruitful results for the good of society, unprocurable by other methods or means of study, and not random and unnecessary in nature.
 3. The experiment should be so designed and based on the results of animal experimentation and a knowledge of the natural history of the disease or other problem under study that the anticipated results will justify the performance of the experiment.
 4. The experiment should be so conducted as to avoid all unnecessary physical and mental suffering and injury.
 5. No experiment should be conducted, where there is an *a priori* reason to believe that death or disabling injury will occur; except, perhaps, in those experiments where the experimental physicians also serve as subjects.
 6. The degree of risk to be taken should never exceed that determined by the humanitarian importance of the problem to be solved by the experiment.
 7. Proper preparations should be made and adequate facilities provided to protect the experimental subject against even remote possibilities of injury, disability, or death.
 8. The experiment should be conducted only by scientifically qualified persons. The highest degree of skill and care should be required through all stages of the experiment of those who conduct or engage in the experiment.
 9. During the course of the experiment, the human subject should be at liberty to bring the experiment to an end if he has reached the physical or mental state where continuation of the experiment seems to him to be impossible.
 10. During the course of the experiment the scientist in charge must be prepared to terminate the experiment at any stage, if he has probable cause to believe, in the exercise of the good faith, superior skill and careful judgment required of him that a continuation of the experiment is likely to result in injury, disability, or death to the experimental subject.
-

both civil and criminal cases in federal courts.¹⁰ The Maryland Court of Appeals, the state's highest court, has adopted it as a common law standard; the Maryland court noted in 2001 that the Code "at least in significant part, was the result of legal thought

and legal principles, as opposed to medical or scientific principles, and thus should be the preferred standard for assessing the legality of scientific research on human subjects."¹¹ The U.S. Supreme Court's view is complex. It has recognized the Nuremberg Code as part of U.S. law, and yet by a 5 to 4 vote in 1987 it refused to permit members of the U.S. military to use the Code as a basis to sue the U.S. government for money damages for violating its provisions.¹²

The Nuremberg Code has also informed every other major code of conduct regarding human experimentation developed since its promulgation in 1947.

The Code's Limitations

The Code's deficiencies are directly related to its strengths and its origin. Perhaps its major problem has been its origin as an American response to Nazi medicine. The Code originated in a U.S. Army tribunal. It was formally adopted by the U.S. Defense Department as doctrine in 1953. Incredibly, it was classified "top secret" and not declassified until 1975. For decades, physicians around the world, but U.S. physicians especially, treated Nazi medicine as such an aberration that the Nuremberg Code was marginalized and seen as having nothing to teach non-Nazi physicians. Some even argued that the Nuremberg Code itself is a good code for barbarians, but not for civilized physicians.

Furthermore, the emphasis on consent did not really fit the Nazi crimes. Yale law professor Robert Burt correctly observes that the "basic problem" of the murders and tortures by the Nazis in the name of medical research was not that "the subjects did not agree to participate." Thus the emphasis on consent in this setting, he writes, seems "peculiar."¹³ Unlike many others, however, Burt recognizes that the judges at Nuremberg were forward-looking in their judgment and that they sought to craft a document to provide some assurance against a repetition, not only in Germany but around the world, including the United States. Because the judges could not rely on physicians to police themselves, Burt writes, "The Nuremberg judges established, as their first line of defense against recurrence of these barbarities, the individual subject-patient armed with the principle of self-determination."¹³

A related problem has been what has sometimes been seen as the Code's "rigid" insistence on informed consent as the most important aspect of ethical research. Jay Katz of Yale Law School, the world's leading authority on informed consent, argued in 1963, and again in the *Final Report of the Advisory Committee on Human Radiation Experiments*,¹⁴ that:

[O]nly when the Nuremberg Code's first principle on voluntary consent is firmly put into practice can one address the claims of . . . society to benefit from science. Only then can one avoid the dangers that accompany a balancing of one principle against the other that assigns equal weight to both; for only if one gives primacy to consent can one exercise the requisite caution in situations where one may wish to make an exception to this principle for *clear and sufficient* reasons.¹⁴

Katz acknowledges that exceptions could be made to the Code's consent principle, but he argues that such exceptions must be democratically arrived at by society at large, not determined by

researcher-dominated institutional review boards (IRBs) or by researchers themselves. The judges at Nuremberg, although upholding research on humans as a legitimate activity, nonetheless considered that using individuals for the benefit of others by testing a hypothesis on them and putting them at risk of harm is inherently a suspect activity. In the absence of the informed consent of the research subject, research on human beings is (and should be) extremely difficult to justify.

As influential as the Code is, it is incomplete as guidance for research ethics. The Nuremberg judges made no attempt to deal with clinical research on children, patients, or mentally impaired people. More importantly, the Code fails to address many issues related to international research trials, including the questions of care for research subjects after the trial's end and benefit to the host community.^{15,16}

Enduring Legacy

The year 2007 marks the 60th anniversary of the Nuremberg Code. On the 50th anniversary of the Code, many people offered commentaries.¹⁷ We wrote: "Human rights law is similar to medical ethics in that both are universal and aspirational, and since the Nuremberg Trials, both have been unenforceable. A critical challenge is to make both meaningful, and this may be the most important legacy of the Nuremberg trials."¹⁸ We proposed that physicians and lawyers work together to make the promise of the Code as a human rights document a reality, just as physicians and lawyers worked together at Nuremberg to bring the Nazi physicians to justice.

Ten years later, what have we learned? Informed consent continues to be recognized as the core ethical and legal requirement for legitimate medical research, but the globalization of research has made the realization of this principle even more difficult in practice. Nonetheless, the continued distancing of time from the Nazi horrors has permitted the Nuremberg Code to gain new adherents, and its universal aspiration is gaining in reality.

In 2005, on the 60th anniversary of the signing of the World War II surrender of Germany, Berlin finally was able to build a memorial to the Holocaust.^{19,20} Consisting primarily of 2,700 concrete slabs constructed in the former no man's land where the Berlin Wall once stood, it is meant to symbolize the bureaucratic processes that allow human beings to accept evil as a normal part of the world. The question that the memorial failed to ask, according to Paul Spiegel of Germany's Center Council of Jews, is, "Why were members of a civilized people in the heart of Europe capable of planning and carrying out mass murder?"²¹ This question echoes one that Elie Wiesel has asked over and over again about the Nazi doctors: "How is it possible?"²¹ How is it possible that physicians could turn into mass murderers?

Of course, memorials can't do everything and can't speak to everyone. In a real sense the Nuremberg Code can be seen as a living memorial to the suffering and deaths of the concentration camp victims of the Nazi doctors. And the more we are distanced temporally from the crimes of the Nazi doctors, the more we may be able to see our relationship not just with the victims, but with the U.S. judges and physicians at Nuremberg who were able to confront this evil and attempt to imagine a way to prevent its repetition.²² In this regard, we may come to see the legacy of

Nuremberg as a U.S. legacy, not a Nazi legacy; and as a profound human rights code, not a Nazi relic.

The Declaration of Helsinki

The Declaration of Helsinki is arguably the most widely known and influential guideline in medical research worldwide. Titled the “World Medical Association Declaration of Helsinki: Ethical Principles for Medical Research Involving Human Subjects,” it is an official policy of the World Medical Association (WMA). Initially promulgated in 1964, it has been revised five times, most recently in 2000. The 2000 revision was greatly controversial before, during, and after its publication, and subsequently two “clarificatory” notes have been added, in 2002 and 2004. This chapter reviews the history of the Declaration, describes its current contents, discusses its strengths and deficiencies, and gives a prognosis for its future importance and influence.

History of the Declaration

The Declaration of Helsinki was adopted by the WMA at its annual General Assembly in Helsinki in 1964. The WMA had been founded in Paris in 1947 as an association for national medical associations.¹ Its mission, as currently stated, is “to serve humanity by endeavoring to achieve the highest international standards in Medical Education, Medical Science, Medical Art and Medical Ethics, and Health Care for all people in the world.”²

When it was established, its member institutions were particularly concerned with the violations of human rights and medical ethics that had taken place in Germany and elsewhere during the Nazi period. The establishment of the WMA was roughly contemporaneous with the Nuremberg doctors’ trial, the establishment of the United Nations, and the adoption of the Universal Declaration of Human Rights. The Association adopted a declaration on fun-

damental medical ethics, the Declaration of Geneva, in 1948 and an International Code of Medical Ethics in 1949. However, medical research was not formally discussed by the WMA until 1953, when a position paper on human experimentation was discussed by the WMA’s Ethics Committee. This became a “Resolution on Human Experimentation: Principles for Those in Research and Experimentation,” adopted by the WMA’s Eighth General Assembly in Rome in 1954.³ The then president of the WMA, Lambert Anthonie Hulst, a Dutch specialist in internal medicine who had attended the Nuremberg Doctors’ Trial, was a member of the drafting committee for the 1954 resolution.⁴ Discussion of these issues continued within the WMA, leading to a draft Declaration in 1961 and, finally, the adoption of the original Declaration in 1964.⁵

It is not clear why the Resolution was proposed in 1953, or why once the Resolution had been adopted in 1954, a further draft Declaration was proposed in 1961. Nor is it clear why it took a further three years for the Declaration finally to be adopted. Historians generally have been able only to speculate: None seems to have had full access to public or private papers, or to interviews with participants in the process. The WMA itself implies that the whole process was a natural development of the founding documents of the Association, and that the process involved “discussion and research.”^{5,6} Scholars, such as David Rothman and Jay Katz, have focused on the role of Henry Beecher’s exposés of unethical medical research in 1966 to explain the reception of the Declaration, but this obviously does not explain its production. Beecher’s revelations brought about a great explosion of concern with the ethics of medical research and the realization that unethical research was not merely a pathology of totalitarian regimes, but could also be found in liberal democracies.^{7,8}

More recent scholarship suggests that discussion of the ethics of medical research was widespread in funding agencies, government research institutes, and elsewhere even before 1964, but that this discussion was not part of mainstream medical debate.⁹ Paul McNeill suggests that the long delays between 1954 and 1961, and between 1961 and 1964, are evidence of internal dissent and debate.¹⁰ He cites George Annas and Leonard Glantz to the effect that one of the main drivers for the adoption of the Declaration was the U.S. Food and Drug Administration's need to tighten drug registration regulations after the thalidomide disaster.¹¹ Annas elsewhere suggests that the Declaration was an attempt on the part of doctors to refashion the Nuremberg Code in terms that were more physician-friendly and more facilitative of research.¹² Recent works by Gerald Kutcher and Wolfgang Weyers lend further weight to this interpretation.^{3,13} These issues are complex, and further detailed historical scholarship will be necessary to untangle them.

The 1954 Resolution

Comparison of the 1954 Resolution with the Nuremberg Code and the 1964 Declaration is instructive. The Nuremberg Code commenced with an insistence on voluntary consent of the individual research subject, and went on to consider the utility of the research for human health, the necessity for research to be based on sound medical knowledge and research in animals, minimization and control of risk of harm, and the need for medical oversight at all times (see Chapter 12). It set out 10 strict norms. The 1954 Resolution, however, stated only 5 principles (see Box 13.1). It started with the need for scientific and moral justification for the research, then considered the need for "prudence and discretion" in the publication of results.³ The third and fourth principles referred to the differing requirements of research on healthy volunteers and sick patients, and the final principle stated the need for written informed consent, either from the subject him- or herself, or—if the subject is "irresponsible" (lacks the capacity to decide)—from his or her legal representative.

The Resolution is clearly focused on the conduct of the physician-investigator, rather than the rights of patients. Interestingly, the Resolution addressed experimentation in sick subjects in terms of heroic medical or surgical interventions rather than in terms of clinical trials under uncertainty. In many respects the Resolution was a poorly drafted document, particularly in comparison with the Nuremberg Code. However, in introducing a distinction between the healthy volunteer and the patient-subject, and in considering that experimentation may be a form of medical care, the Resolution did contain the seeds of the later Declaration, and represented an important revision of the approach contained in the Nuremberg Code.

The 1964 Declaration

The Declaration of Helsinki in its 1964 version was a much more formal document than the earlier Resolution. It had a formal preamble, relating it to the WMA's Declaration of Geneva and International Code of Medical Ethics, and stating the rationale behind its promulgation:

BOX 13.1

Code of the World Medical Association, 1954: Principles for Those in Research and Experimentation³

I. Scientific and Moral Aspects of Experimentation

The word experimentation applies not only to experimentation itself but also to the experimenter. An individual cannot and should not attempt any kind of experimentation. Scientific qualities are indisputable and must always be respected. Likewise, there must be strict adherence to the general rules of respect for the individual.

II. Prudence and Discretion in the Publication of the First Results of Experimentation

This principle applies primarily to the medical press and we are proud to note that in the majority of cases, this rule has been adhered to by the editors of our journals. Then there is the general press, which does not in every instance have the same rules of prudence and discretion as the medical press. The World Medical Association draws attention to the detrimental effects of premature or unjustified statements. In the interest of the public, each national association should consider methods of avoiding this danger.

III. Experimentation on Healthy Subjects

Every step must be taken in order to make sure that those who submit themselves to experimentation be fully informed. The paramount factor in experimentation on human beings is the responsibility of the research worker and not the willingness of the person submitting to the experiment.

IV. Experimentation on Sick Subjects

Here it may be that, in the presence of individual and desperate cases, one may attempt an operation or a treatment of a rather daring nature. Such exceptions will be rare and require the approval either of the person or his next of kin. In such a situation it is the doctor's conscience which will make the decision.

V. Necessity of Informing the Person Who Submits to Experimentation of the Nature of the Experimentation, the Reasons for the Experiment, and the Risks Involved

It should be required that each person who submits to experimentation be informed of the nature of, the reason for, and the risk of the proposed experiment. If the patient is irresponsible, consent should be obtained from the individual who is legally responsible for the individual. In both instances, consent should be obtained in writing.

Because it is essential that the results of laboratory experiments be applied to human beings to further scientific knowledge and to help suffering humanity, the World Medical Association has prepared the following recommendations as a guide to each doctor in clinical research. It must be stressed that the standards as drafted are only a guide to physicians all over the world. Doctors are not relieved from criminal, civil and ethical responsibilities under the laws of their own countries.¹⁴

This statement expressed the essential feature of all subsequent versions of the Declaration—balancing the need to generate useful medical and therapeutic knowledge with the need to protect the health and interests of research participants, especially the

health and interests of ill patients participating in research. In this regard, the Declaration differed fundamentally from the Nuremberg Code, which was essentially a statement of the need to protect the rights and welfare of individuals, with an implicit assumption that scientific research is “experimentation in man” which is contrary to human dignity. The shift in language from the language of “experimentation”—still present in the 1954 Resolution—to the language of “clinical research” in the 1964 Declaration marked this shift in emphasis.

The language of the 1964 Declaration was more carefully crafted than the language of the 1954 Resolution. Some features merit particular attention. First, there was a strong shift back toward the categorical language of the Nuremberg Code. Although the 1964 Declaration presented itself as merely offering guidance, each of its 14 numbered paragraphs stated some requirement which “must” or “should” be met. Second, although these requirements were categorical, the 1964 Declaration frequently reverted to a language of “proportion” and “comparison,” particularly in relating the risks of research to the benefits the subject, the patient, or society will gain from the research. Yet, as Charles Weijer has argued, the 1964 Declaration contained no principled account of risk, or of “proportionality.”¹⁵ Thus, principle I.3 reads: “Clinical research cannot legitimately be carried out unless the importance of the objective is in proportion to the inherent risk to the subject”¹⁴

Although this is where the concept of benefit in proportion to risk is introduced, no guidance is given on how to assess this proportionality, and no qualitative or quantitative concept of risk is defined. Addressed as it is to the physician-investigator, it appears that what is “in proportion” must be judged by the physician in accordance with his or her professional judgment and sense of good conduct, rather than being subject to external technical evaluation.

Third, the 1964 Declaration, like the 1954 Resolution, concerned the responsibilities of doctors toward their patients or their research subjects, rather than the rights or wishes of patients. In particular, the 1964 Declaration continued to distinguish between therapeutic and nontherapeutic research and to give a higher priority to the assessment of risk than to the obtaining of consent. Unlike the 1954 Resolution, the 1964 Declaration did stress that consent is a requirement in research with both healthy volunteers and patients, but it qualified this requirement in the case of patients. The second paragraph of principle II.1. reads:

If at all possible, consistent with patient psychology, the doctor should obtain the patient’s freely given consent after the patient has been given a full explanation. In case of legal incapacity, consent should also be procured from the legal guardian; in case of physical incapacity, the permission of the legal guardian replaces that of the patient.¹⁴

This is a complex paragraph, with particular difficulties attending what was meant by “physical” and “legal” incapacity, the role of legal guardians, and what was meant by “also” obtaining consent from the legal guardian in the case of legal incapacity. The qualification “consistent with patient psychology” is particularly significant. It is clear that in 1964, it was possible to override the obligation to obtain consent from some patients who had the legal capacity to decide, if obtaining consent was “inconsistent” with the patients’ psychology. Obviously this was a serious departure from the Nuremberg Code’s insistence that consent is “absolutely

essential,” even if it may not have been a serious departure from widely understood clinical practice according to concepts of “therapeutic privilege.” In context, this paragraph related to “clinical research combined with professional care,” and would have been consistent with the then applicable ethos relating to informed consent in routine clinical care. This, in a nutshell, is the still vexed debate over whether standards of consent in clinical research should be lowered to be consistent with the standards of consent in routine clinical medicine, or whether the standards of consent in clinical medicine should be raised to the level of the standards applicable in clinical research.¹⁶

The difficulty of interpreting this paragraph from today’s standpoint is great. Given 40 years of bioethics and health law scholarship on notions of mental capacity, patient autonomy, and research ethics, it is difficult now to step back and read the paragraph as it may have been intended in 1964. Further, issues such as the limits of informed consent remain controversial now, so that some ambiguity or vagueness in 1964 should not unduly surprise the reader in the 21st century. A critical ambiguity in interpretation here is that it is possible to read the 1964 Declaration as a weakening of the Nuremberg Code (with the Declaration’s references to proportionality and to making allowances for patient psychology, as I have discussed) or instead as a humanization of a legalistic code (with the Declaration’s emphasis on research as part of patient care and the norms of ordinary clinical medicine).

The 1964 Declaration also contained some inconsistencies and ambiguities. For example, the provisions in part III of the 1964 Declaration for “non-therapeutic clinical research” included the following paragraphs:

3a. Clinical research on a human being cannot be undertaken without his free consent, after he has been fully informed; if he is legally incompetent, the consent of the legal guardian should be procured.

3b. The subject of clinical research should be in such a mental, physical, and legal state as to be able to exercise fully his power of choice.

3c. Consent should as a rule be obtained in writing. However, the responsibility for clinical research always remains with the research worker; it never falls on the subject, even after consent is obtained.¹⁴

Paragraph 3b is clearly inconsistent with 3a, because 3b seems to require full mental and legal capacity, whereas 3a implies that if potential research subjects are legally or mentally incapacitated, a legal guardian can give consent. This is particularly striking because for many commentators, the rationale behind the 1964 Declaration was to develop standards consistent with the spirit of Nuremberg for research involving the mentally or legally incapable, such as young children, the seriously mentally ill, or the unconscious. Moreover, these commentators contended that placing responsibility for risks and benefits on the researchers created a test that could substitute for the consent of the patient when the patient was legally, mentally, or physically incapable of consenting.^{10,17} Whether 1964 Declaration did, in fact, create such a loophole was unclear, however. The inconsistency between paragraphs 3a and 3b suggests that this substitute test would not be applicable, and that the strict bar on nontherapeutic research with incompetent subjects remained in force.

In addition, it can be argued that a prisoner or a member of the armed forces is not in a “legal state” to exercise her or her

choice, and therefore could be considered incapable of giving informed consent. Depending on the interpretation of the conflict between 3a and 3b, the 1964 Declaration either banned research on prisoners and military personnel, or permitted it on the authorization of their “legal guardian”—the prison authorities or superior officers. Of course, theoretically such permission would only be sought if the research met the risk/benefit tests of the Declaration. But this dilemma, or inconsistency, would prove to be of great significance over the following decades, as controversies involving research with vulnerable subjects took place fairly regularly, notably the controversial research at Willowbrook, Tuskegee, and Holmesburg Prison^{18,19} (see Chapters 7, 8, and 43).

The 1975 Declaration

Eleven years after the adoption of the original version, the Declaration was revised again.²⁰ Povl Riis, a Danish researcher, physician, and ethicist who was a coauthor of the 1975 version, argues that the motivation behind this second version of the Declaration was to strengthen the protections for research subjects in response to revelations of a range of shocking disclosures about research on the dying, the mentally disabled, and other socially or medically vulnerable groups in the United States and elsewhere.²¹ A revised Declaration was adopted at the 1975 WMA General Assembly in Tokyo, shortly after the establishment of the U.S. National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (see Chapter 14). The history of the 1975 revision has received considerably less discussion than the 1964 Declaration, but for most commentators, the 1975 version is in fact the classical text of the Declaration.²² The revision was led by the Danish, Norwegian, and Swedish medical associations. Riis believes that their role was primary because of the mutual interests of the democratic political institutions in the Nordic countries, and the response to the democratizing movements in the United States (the civil rights movement) and in Europe (the “events” of May 1968, the month-long French riots and strikes that threatened the government of President Charles de Gaulle).²¹

The 1975 revisions to the text were substantial, although much of the language of the 1964 text was retained. The preamble was extended, with new paragraphs setting out the rationale for biomedical research (the word *biomedical* entered the Declaration for the first time here). The 1975 Declaration emphasized that the risks of research should be weighed in the light of the risks of treatment and that medical progress depends on medical research—that is, that current treatments depend for their success on earlier research. This seemed to imply that we should not be overly cautious about research risks and also, perhaps, that we have a duty to participate in research, if we are willing to benefit from its results. But, as the Declaration was addressed to researchers, it is not clear what the implications of making these statements are, or why they are there. Persuading patients of the merits of medical research can hardly have been a function of the Declaration. In addition, as McNeill argues, the Declaration’s rationale justifying research was specifically tied to the need to develop knowledge of pathology, physiology, and therapeutics for diagnosis and treatment, rather than the vaguer purpose of advancing science generally.¹⁰

Interestingly, the 1975 Declaration also contained a single-sentence paragraph in the preamble urging that “Special caution

must be exercised in the conduct of research which may affect the environment, and the welfare of animals used for research must be respected.”²⁰

This nod to bioethics beyond human bioethics may reflect contemporary concerns about the environmental impact of the use of technologies to protect human health, such as DDT. It also reflects a wider appreciation of the types of experiment used in drug development, as later picked up in Basic Principle 1: “Biomedical research involving human subjects must conform to generally accepted scientific principles and should be based on adequately performed laboratory and animal experimentation and on a thorough knowledge of the scientific literature.”²⁰

The final paragraph of the preamble stressed, as in 1964, that the guidelines were only recommendations, but added that the Declaration should be “kept under review in future.”

The 1975 Declaration also introduced the statement that “concern for the interests of the subject must always prevail over the interests of science and society.” Although this was part of the statement of Basic Principles, it is buried about halfway down the document, rather than making its appearance in the Introduction (as in the 2000 revision). The 1975 Declaration made much more detailed statements than had the 1964 Declaration and 1954 Resolution about the interests of research participants in privacy, informed consent, management of the hazards of research, and protection from the abuse of dependency on one’s doctor. Although the 1975 document was not a statement of research subjects’ rights, it placed more emphasis on the interests of human subjects than on the duties of doctors. This is a delicate nuance, yet it marked an important change. The most important indicator of this change was the Declaration’s requirement, for the first time, of a clearly stated research protocol and review of that protocol by an independent committee.

The remainder of the 1975 Declaration continued to observe the 1964 distinction between therapeutic and nontherapeutic research, and its statement on therapeutic research was no longer concerned solely with heroic “experimental” interventions, but implicitly focused on clinical trials. The famous requirement that “every patient—including those of a control group, if any—must be assured of the best proven diagnostic and therapeutic method” made its appearance in section II.3. There was now a presumption in favor of informed consent, strengthening the position of the 1964 document, and requiring, in section II.5, that “if the doctor considers it essential not to obtain informed consent, the specific reasons for this proposal should be stated in the experimental protocol for transmission to the independent committee.” Thus, doctors were no longer free to judge for themselves whether informed consent could be waived if a patient’s “psychology” did not permit it. Similarly, in section III.2, on nontherapeutic research, the confused language of 1964 was replaced with the much clearer statement that “the subjects should be volunteers—either healthy persons or patients for whom the experimental design is not related to the patient’s illness.” This clearer statement apparently ruled out nontherapeutic research in the legally, mentally, or physically incompetent.

Other Revisions Before 2000

The Declaration continued to evolve, being revised again at the Venice assembly of 1983, the Hong Kong assembly of 1989, and

the Somerset West, Republic of South Africa, assembly of 1996. Most of the revisions were minor, and continued in the spirit of the 1975 revisions. The Declaration commanded wide support across the worlds of medical research in academia and industry, and was taken up as the normative statement of research ethics standards in the rapidly developing system of research ethics committees and institutional review boards in the developed world. It had wide influence in policy, for example, in the development of bioethics standards such as those elaborated in the U.S. Belmont Report. One key example of the influence of the Declaration is that, as Riis argues, the 1975 Declaration's requirement for ethical review introduced greater transparency and openness on the part of both the pharmaceutical industry and academic researchers.²¹ In combination with the development of drug regulations over the same period, this led to the adoption of the Good Clinical Practice guidelines in 1996.²³ The emphasis of the Declaration became more and more clearly directed toward the ethical governance of clinical trials of drugs. By 1996, reference to the responsibilities of sponsors, duties regarding publication (not seen since the 1954 Resolution), and "the use of inert placebo in studies where no proven diagnostic or therapeutic method exists" had appeared. The other main development was more detailed consideration of risk assessment, including an emphasis on the predictability of hazards. Interestingly, the exclusion from nontherapeutic research of subjects who are unable to volunteer for such research remained.

Current Content of the Declaration

By the late 1990s, the Declaration had become widely criticized among regulators and within the research community and industry. Many academic and patient groups felt that the Declaration was too weak. They contended that it should bar the use of placebo in trials in which a proven effective treatment exists, require the publication of research results (in order to improve the reliability of the evidence base), ensure that patients who benefit from trial treatments could continue to receive treatment after the trial, and demand that trials conducted in the developing world (or in resource-poor settings) are held to the same standards as trials in the developed world, in terms of treatment of controls and availability of treatment after the trial. Academic and industry groups argued that placebo controls could be justified even in many situations in which active treatment had been proven effective, and that the "standard of care" in resource-poor settings should be the "best available" treatment, not the "best proven" (see Chapters 64–67). In addition to this controversy, some critics had argued for many years that the Declaration's distinction between therapeutic and nontherapeutic research was incorrect. Instead, these critics contended that the Declaration should distinguish between therapeutic and nontherapeutic procedures done in the context of treatment for research purposes.¹⁷ This controversy led to a very significant redrafting of the Declaration in 2000, together with the addition of "Notes of Clarification" in 2002 and 2004.²⁴

The revision process for the eventual 2000 Declaration proved controversial. A revision process began in 1997, only one year after the adoption of the 1996 revision. A draft revision got as far as the 1999 meeting of the WMA before being rejected, and a new working party was established in 1999 under the chairpersonship of Nancy Dickey of the American Medical Association, which then

initiated a consultation in February 2000.²⁵ As the debate developed, it progressed on two fronts—the debate about the ethical norms of the Declaration itself, and the debate on the authority of the WMA and of its Declarations to regulate clinical research worldwide. An important feature of the latter debate concerned the authority of doctors who were (or were not) active clinical researchers to shape the Declaration, and the authority of those who were (or were not) citizens or residents of the developing world to prescribe norms for the conduct of research in developing world settings.²⁶ As with the overlapping debate about the revision of the Council for International Organizations of Medical Sciences (CIOMS) guidelines, a lot of discussion turned on how far such norms were universal or situation-relative, and on how transparent and accountable the revision process was. That the debate coincided with the dramatic explosion of the Internet made this a far more open debate than on previous occasions, but also may have heightened the impression that the consultation mechanisms used were neither democratic nor transparent. Given the international importance of the Declaration, many commentators felt that the process of revision and its accountability were of crucial importance for its legitimacy. Yet the WMA as a membership association is not accountable to anyone save its membership, and the Declaration is not law. It is not clear that the WMA was obliged to be accountable in the way its critics suggested.

The current structure of the Declaration is as follows. The 1964–1996 distinction between therapeutic and nontherapeutic research has been dropped, and the Declaration is now in three parts: Introduction; Basic Principles for All Medical Research; and Additional Principles for Medical Research Combined With Clinical Care.

The introductory section begins (paragraphs 1–3) by setting out the scope of the document and relating it to other WMA policy (the Declaration of Geneva and the International Code of Medical Ethics). The scope of the document, for the first time, includes not only experimental procedures on the body and mind of subjects but also the use of human tissue or data that can be identified with a particular individual. This reflects the role of epidemiology, pathology, and genetic research in modern biomedicine. The next four paragraphs (paragraphs 4–7) set out the rationale for medical research, as in the 1975–1996 versions, placing the statement about the priority of the interests of the individual over those of science and society at paragraph 5. Paragraph 8 is a detailed statement of the need to protect the "health and rights" of human beings, and describes different types of vulnerability, both of individuals and of populations. This is a significant change both in its reference to populations and in its suggestion that vulnerability may take the form of "economic vulnerability" or "economic and medical disadvantage." Paragraph 9 states the relationship between the Declaration and national laws, reversing the relationship established in 1964 by holding that "no national ethical, legal or regulatory requirements should be allowed reduce or eliminate any of the protections for human subjects set forth in this Declaration." Whereas in 1964 the Declaration was seen as guidance that helped researchers in areas in which the law was silent, now it is seen as a human rights document that takes moral and jurisprudential priority over national laws that are seen as compromised.²⁷

The next section sets out the basic principles for all medical research. It starts by stating the duty of the physician to protect the "life, health, privacy and dignity of the human subject" (paragraph

10). It requires research to be founded on accepted scientific principles and prior research, including both animal research and literature review (paragraphs 11–12). It then requires the research protocol to be reviewed by an independent ethics committee, for the research to be open to external monitoring, and for the researcher to state compliance with the Declaration as part of the protocol (paragraphs 13–14). The next paragraphs (15–19) relate the responsibilities of the physician to supervise the research, to control and monitor risks, and to ensure that the research risks are reasonable in the light of the importance of the research objective.

There are two controversial elements here. First, the necessity for biomedical research to be supervised by a “clinically competent medical person” has been queried by nurse researchers as well as by basic scientists, who do not see why a doctor must be in charge, as opposed to merely assisting. Second, the Declaration states that, among other considerations, research risks are justified only “if there is a reasonable likelihood that the populations in which the research is carried out stand to benefit from the results of the research.” Here it could be argued that this excludes some people from participation simply on the ground that others (in the same population) will not be able to benefit. Further, it could be argued that this paragraph places the responsibility for providing treatment on the researcher, rather than on government, sponsor, patient, or other purchasers. This issue arises again at paragraph 30.

Paragraphs 20–26 set out the requirements of informed consent. Here, controversial issues include the relationship between paragraph 20, which requires subjects to be volunteers, and paragraphs 24, 25, and 26, which discuss alternatives to consent when the subject is legally incompetent. Paragraph 22 requires disclosure of the source of funding for the research. Paragraph 23 requires research participants to have access to a physician who is not involved in the research, in order to protect them from duress due to dual relationships (researcher-subject and physician-patient). Paragraphs 24–26 allow research on incompetent subjects, including minor children, provided that “the research is necessary to promote the health of the population represented and this research cannot instead be performed in legally competent persons,” which is accepted in some jurisdictions but not in others (as was demonstrated in the debates over the Council of Europe’s Convention on Human Rights and Biomedicine).

All of these paragraphs are controversial to some extent. Some of the Declaration’s requirements are criticized as impractical in resource-poor settings, in which an independent physician may be hard to find. Some of the guidelines are viewed as inconsistent, and industry officials consider them unduly restrictive or motivated by “industry bashing.” This criticism has also been leveled at paragraph 27, which requires the publication of research data, positive and negative, and states that research in breach of the Declaration should not be published.

The final section delineates principles for research combined with medical care. Paragraph 28 justifies such research provided the procedure has potential diagnostic, prophylactic, or therapeutic value. Paragraphs 29 and 30 are the most controversial elements of the whole Declaration. Paragraph 29, as amended by a “Note of Clarification” in 2002, requires that new methods of treatment, prophylaxis, or diagnosis should be tested against “the best current . . . methods.” Placebo control is not ruled out if there is no proven method in existence. This is qualified by the Note of Clarification, which states that placebo controls may be used even when a proven method does exist, provided that placebo

controls are necessary “for compelling and scientifically sound methodological reasons,” or when the disease is “a minor condition and the patients who receive placebo will not be subject to any additional risk of serious or irreversible harm.”

The controversial points here are whether placebo controls can be justified even if this means that patients are denied effective treatment, whether placebo can be justified if patients normally would not receive the best standard treatment for economic reasons, and whether a moral obligation to provide the best possible care (if there is such an obligation) can be trumped by a scientific or methodological requirement.²⁸

Paragraph 30 states that every participant, at the end of the study, should receive the best proven prophylactic, diagnostic, and therapeutic methods identified by the study (if they need them). This again is controversial: For how long should they continue to be provided with care? By whom? Paid for by whom? In a vaccine trial, does this mean providing long-term treatment for a disease they might have caught anyway? Most supporters of the Declaration in its current form accept that there are problems with the way this guideline is formulated, but would argue that the underlying principle of nonabandonment of patients in whom a relationship of dependency has been created is sound.²⁹ The Note of Clarification added at the Tokyo meeting of the WMA in 2004 reads:

The WMA hereby reaffirms its position that it is necessary during the study planning process to identify post-trial access by study participants to prophylactic, diagnostic and therapeutic procedures identified as beneficial in the study or access to other appropriate care. Post-trial access arrangements or other care must be described in the study protocol so the ethical review committee may consider such arrangements during its review.²⁴

This allows, but does not require, ethics committees to require researchers to consider and describe their position on posttrial access, and give reasons for it, even if it stops short of obliging researchers to provide such access themselves.

Paragraph 32 describes the principles relating to attempts to use unproven or experimental interventions on patients in the interests of “saving life, re-establishing health or relieving suffering” if everything else has failed. This is a return to some of the concerns of the 1964 Declaration. However, it requires that such experiments be made the object of research, and thus subject to the provisions of the Declaration.

Strengths, Weaknesses, and Prospects for the Declaration

Strengths

The undoubted strength of the Declaration is its standing as the most well known and widely available guideline on medical research ethics. Its historical status as the preeminent guideline for doctors conducting medical research, and its international status placing it over and above national legal and policy questions, vest it with considerable authority. The basic structure of the Declaration—attempting to define the moral status of clinical research, the importance of balancing risk and benefit to subjects and to society, the role of informed consent, and the importance of considerations of justice for patients, subjects, and populations—

is undoubtedly sound. Although every version of the Declaration has contained contradictions, vague formulations, and some controversial elements, in general terms it is a clear and helpful document that can be cited by researchers wishing to avoid unethical practice and by ethical committees wishing to enforce ethical standards. Some of the provisions of the recent Declaration reflect a welcome concern with the scope of biomedical research today, both in terms of the resources it requires (data, population participation, tissue, as well as patient participation in clinical research) and in terms of the way modern research is sponsored and conducted (commercial and multinational multisite research are a large component). Particularly welcome is the Declaration's recognition of the need to ensure that research is conducted in a way that produces genuine medical advance, rather than repetitious or imitative work (through the requirement of prior literature review and publication of both positive and negative results). This shift is due largely to the growing importance of meta-analysis and systematic review in medicine and health policy. The current Declaration sees research as only one part in a more complex process of medical progress and health-care quality improvement.

Weaknesses

The greatest weakness of the Declaration now is the way it has become highly contested—some would say, “politicized.” Some critics of the original WMA Resolution and Declaration argued that these were a medical attempt to soften the Nuremberg Code, by weakening the centrality of informed consent in order to permit a wider range of medical research to take place. They see the Declaration as always a political document framed with doctors' interests at its heart. Although this is an extreme view, it cannot be doubted that the 2000 Declaration and the attempts to “clarify” it were highly contested, especially in the context of the overlapping debates about intellectual property rights and access to treatment. However, the precise nature of the contest is hard to specify simply. Although some critics felt that this was a struggle between U.S. interests and developing world interests, many developing world participants in the debate shared “U.S.” views, and many U.S. and European commentators argued from a “developing world” perspective.^{21,30} In this respect, the debate over the revision of the Declaration overlapped both chronologically and intellectually with the debate over access to essential medicines that took place during the debate about compulsory licensing and parallel generic production of patented pharmaceuticals in the context of the World Trade Organization's Trade Related Intellectual Property rights framework at the beginning of the 2000s.

There were in both cases debates about principle and about practice. A developing world physician might insist that placebo-controlled trials were in his population's interest, whereas a developed world human rights activist might insist that this created an indefensible relativism about moral standards. This could be seen as a debate about moral universals, but was equally a debate about how best in practice to promote international justice in the health and development contexts. Hence it is perhaps better to see this as a debate about political interests and strategy than as purely a debate about moral philosophy and practice.

Internally, the main weaknesses of the Declaration remain persistent internal contradictions and vagueness of statement, as illustrated by the debates over paragraphs 29 and 30 and their

interpretation. Perhaps the main difficulty is the problem of producing a comprehensive ethical guideline that covers everything from *in silico* genetic research to clinical trials of surgical procedures, and applies everywhere from Washington to rural Africa. The Declaration has no explanatory notes and no discussion points, so its interpretation is always somewhat controversial. The text of the Declaration states that it is for guidance, rather than a set of strict rules, yet in its 2000 version it places itself above national legal norms, suggesting that where legal norms conflict with it, the Declaration should take priority. This claims for the Declaration of Helsinki a moral standing equivalent such documents as the Universal Declaration of Human Rights, or similar conventions. Yet it was produced by the World Medical Association and ratified by the WMA's General Assembly, which has only a small membership (fewer than half of the world's nations have a member association). Moreover, very few individual members of national medical associations have any influence over what happens at the WMA, because it is constituted as an association of associations. The drafting of the Declaration and its revisions has normally been done by a small group of doctors (usually three or four).

Given the structure and working methods of the WMA it is perhaps unsurprising that the Declaration has become complex in statement and controversial in content and in authority. In many countries, however, the Declaration has been enacted as law, and adherence to its principles (if not its exact letter) is a requirement of many national and international guidelines, such as the International Conference on Harmonisation's Good Clinical Practice guidelines. Many groups clearly have a powerful interest in influencing the formulations adopted by the Declaration.

Prospects

The Declaration of Helsinki probably will continue to be the central international guidance document on research ethics, and it probably will continue to be revised, and each revision undoubtedly will remain controversial. In a sense these three predictions are all of a piece: Each explains the other. Nonetheless, it is arguable that since 2000 the authority of the Declaration has weakened, and it is an open question whether this is because the latest revision could not command consensus, or because its vagueness and internal contradictions became less tenable, or because it set ethical standards that are too high for most to be able to follow—and therefore are useless—or whether its standards are high but appropriate, and vested interests are trying to discredit it. Be that as it may, it is hard to see how any other international organization could produce guidelines with a similar authority and importance to replace the Declaration. Certainly much could be done to improve the quality of the drafting of the Declaration, but the underlying ethical principles will continue to guide and inspire, however controversial they may be.

The Belmont Report

The Belmont Report is a short document on moral principles that was published in 1978 by the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (National Commission). Since that time it has provided a basic framework for analyzing ethical issues that arise during medical research in the United States and in many other countries.

History

The National Commission was established in 1974 by the U.S. Congress with a charge to identify ethical principles and develop guidelines to govern the conduct of research involving humans. It was hoped the guidelines would ensure that the basic ethical principles would become embedded in the U.S. research oversight system, so that meaningful protection was afforded to research participants. Another mandated goal was to distinguish the boundaries between the accepted and routine practice of medicine, on the one hand, and biomedical and behavioral research, on the other.

The Commission held its first meeting on December 3–4, 1974, and its 43rd and final meeting on September 8, 1978.¹ It completed a draft of the Belmont Report in late 1977, and issued it in final form on September 30, 1978. The report was published in the *Federal Register* on April 18, 1979—the date now commonly cited as the original date of publication.

The National Commission also published 16 other reports and appendix volumes, most focused on ethical issues in research involving vulnerable populations. Its more than 100 recommendations for reform went directly to the Secretary of the Department

of Health, Education and Welfare (DHEW)—now the Department of Health and Human Services (DHHS)—and many of these were eventually codified as federal regulations.² The Belmont Report itself was not written in the style of federal regulations and was never so codified. It was the National Commission's statement of a general, principled moral framework. The foundation of this "analytical framework," as it is called in the report, was a collection of moral principles appropriate for research that first emerged during discussions at a retreat the National Commission held on February 13–16, 1976, at the Smithsonian Institution's Belmont Conference Center in Elkridge, Md. There had been no draft or planning for this framework prior to the retreat. This conference center's name was then appropriated, and the report was published under the full title of *The Belmont Report: Ethical Principles and Guidelines for the Protection of Human Subjects of Research*.

The National Commission came into existence in the aftermath of public outrage and congressional uncertainty over the Tuskegee syphilis experiments and other questionable uses of humans in research (see Chapter 8). The socioeconomic deprivation of the African American men who were enrolled in the Tuskegee experiments made them vulnerable to overt and unjustifiable forms of manipulation at the hands of health professionals, as had been widely reported in news media and widely circulated in the report of an advisory panel to DHEW in 1973.³ Other reports of the abuse of fetuses, prisoners, children, and "the institutionalized mentally infirm" appeared in the news media.

The law that created the National Commission specified that no more than 5 of the Commission's 11 members could be research investigators (see Table 14.1). This stipulation testified to congressional determination at the time that research activities of

Figure 14.1. Members of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, 1977. Source: Tom L. Beauchamp. Reproduced with permission.

the biomedical and behavioral sciences be brought under the critical eye, and possibly the control, of persons outside of the sciences. At that time, the research system generally placed responsibility for the protection of humans in research on the shoulders of individual investigators. That is, federal policies relied on the discretion and good judgment of investigators to determine the conditions under which research should be conducted. Federal involvement and review committees were then in the formative stages. They were destined to undergo rapid change toward protectionism under the guidance of the National Commission.

Carol Levine offers the following sobering, but accurate, statement of the context in which the National Commission deliberated:

The Belmont Report . . . reflected the history of the 30 years immediately preceding it. This emphasis is understandable, given the signal event in the modern history of clinical-research ethics [Nazi experimentation]. American public opinion was shaped by the revelations of unethical experiments such as the Willowbrook hepatitis B studies . . . ; the Jewish Chronic Disease Hospital studies . . . ; and, especially, the Tuskegee Syphilis Study. . . . Our basic approach to the ethical conduct of research and approval of investigational drugs was born in scandal and reared in protec-

tionism. Perceived as vulnerable, either because of their membership in groups lacking social power or because of personal characteristics suggesting a lack of autonomy, individuals were the primary focus of this concern.⁴ [see Chapters 6 and 7]

Content and Core Strengths

The Belmont Report is especially well known for its framework of basic moral principles, which are still today referred to as the “Belmont principles.” The National Commission identified three general principles as underlying the conduct of research: respect for persons, beneficence, and justice. The key organizing conception underlying the Commission’s presentation of these principles and their use was the following: Respect for persons applies to informed consent; beneficence applies to risk-benefit assessment; and justice applies to the selection of research participants. The following abstract schema represents this conception: In this way, each moral principle makes moral demands in a specific domain of responsibility for research—a general conception of the relationship between abstract moral principles and research ethics. This conception of the connection between abstract moral

principles and applied bioethics has been enduring. Many engaged in research ethics carry this general conception with them today.

Principle of	Respect for persons	Applies to	Informed consent
	Beneficence		Risk/benefit assessment
	Justice		Selection of research participants

The principle of respect for persons demands that the choices of autonomous persons not be overridden or otherwise disrespected and that persons who are not adequately autonomous be protected by the consent of an authorized third party likely to appreciate their circumstances and who will look after their best interests. This principle in effect requires valid permission before investigators can proceed with research. To achieve this goal, the principle insists on the individual's informed consent, analyzed in terms of the conditions of information disclosure, comprehension, and voluntariness. The National Commission proposed "the reasonable volunteer" as an appropriate standard for judging the adequacy and clarity of information disclosure. Investigators are held responsible for ascertaining that research participants have comprehended the information they have been given about the proposed research. The purpose of consent provisions is not protection from risk, as earlier federal policies seemed to imply, but protection of autonomy and personal dignity, including the personal dignity of incompetent persons incapable of acting autonomously. The report went on to suggest that third parties be encouraged to follow the research as it proceeds, retaining the right to withdraw an incompetent person from his or her research participation.

The principle of beneficence is an abstract norm that includes rules such as "Do no harm," "Balance benefits against risks," and "Maximize possible benefits and minimize possible harms." This principle is satisfied in the research context by refraining from intentionally causing injury and by assuring that risks are reasonable in relation to probable benefits. The National Commission required that there be an array of data pertaining to benefits and risks and of alternative ways of obtaining the benefits (if any) sought from involvement in research. It demanded that, if possible, systematic and nonarbitrary presentations of risks and benefits be made to research participants as part of the informed consent process and that the assessment of risks and safeguards be considered by an institutional review board (IRB) in weighing the justifiability of research protocols. The National Commission stated that participants ought not to be asked or allowed to consent to more risk than is warranted by anticipated benefits and that forms of risk incommensurate with participants' previous experience should not be imposed in the case of groups such as children, who might be overburdened and possibly disturbed or terrified. However, the report recognized that risks must be permitted during the course of many forms of research in order for investigators to be positioned to distinguish harmful from beneficial outcomes.

The principle of justice requires fairness in the distribution of both the burdens and the benefits of research. The National Commission insisted that this principle requires special levels of protection for vulnerable and disadvantaged parties. This principle demands that researchers first seek out and select persons best prepared to bear the burdens of research (e.g., healthy adults) and that they not offer research only to groups who have been repeatedly targeted (e.g., mentally retarded children). The National Commission noted that, historically, the burdens of research were placed heavily on the economically disadvantaged, the very sick, and the vulnerable, owing to their ready availability. This conclusion was not based on a systematic review, but was based more on impressions from published data, reports in the media, public testimony to the Commission, and some onsite visits to places such as prisons. Yet the advantages of research benefit all in society. The overutilization of readily available, often compromised, segments of the U.S. population was a matter of deep moral concern to the National Commission. The theme of justice and proper selection of research participants was the Belmont Report's way of saying that because medical research is a social enterprise for the public good, it must be accomplished in a broadly inclusive and participatory way. If participation in research is unwelcome and falls on a narrow spectrum of citizens because of their ready availability, then it is unwarranted. Likewise, the National Commission recommended that persons who are already burdened by some form of disability or institutionalization should not be asked to accept the burdens of research—unless, as occurs in some cases, other participants cannot be located or are otherwise inappropriate.

The Belmont Report includes not only these three abstract principles and their analysis, but also a moral view that moves modestly in the direction of an applied research ethics. Just as there is a distinction between theoretical or general ethics and applied or practical ethics, so the National Commission thought of the Belmont Report as its theoretical framework. However, because of its objectives, the explanation of the principles had a noticeably applied character. Nonetheless, the National Commission

had no ambition to make the report itself specific and practical for institutions that conduct research. This objective was to be accomplished by the other 16 volumes on problems of research ethics that the National Commission issued. The Belmont Report itself was intended to provide only a general framework of basic principles for research ethics.

National Commission members and staff were keenly aware that this framework was too indeterminate by itself to decide practice or policy or to resolve moral conflicts. The process of molding the general principles in the Belmont Report so that they become sufficiently concrete is a process of reducing the indeterminateness and abstractness of the principles to give them increased action-guiding capacity. The report looks to educational institutions, professional associations, government agencies and IRBs to provide the more specific rules and judgments required for research ethics.

The works of philosophers such as W. D. Ross and William Frankena were often consulted in the drafting of the Belmont Report, but the moral principles featured in the report should not be read as deriving from the writings of philosophers. The Belmont Report made reference to values “generally accepted in our cultural tradition” as the basis of its principles. These principles derived from National Commission members’ understanding of social morality. What the commissioners meant by our “tradition” is unclear, but the import of the Belmont principles is not to be tied to the unique views of a particular tradition or nation. The National Commission apparently conceived of its principles as universally valid norms. That is, the principles were taken to be applicable to all contexts of human research, not merely to some local region, such as an institution or a nation. The presumption is that no responsible research investigator could conduct research without reference to these principles; these principles form the core of any policy worthy of the name “research ethics.”

Weaknesses, Deficiencies, and Unclarity

Despite the Belmont Report’s wide acceptance, several issues have been or can be raised about the adequacy of the Belmont principles. Here are six possible problems.

1. The way the principles are delineated is arguably confused, especially the principle of respect for persons. This appears to confusingly blend two principles: a principle of respect for autonomy and a principle of protecting and avoiding harm to incompetent (nonautonomous) persons. The National Commission said that it was attempting to protect both autonomous persons and those with “diminished autonomy,” those who are incapable of self-determination. Both are persons, it said, and both are entitled to protection.

The question is whether protections for persons who are incapable of self-determination can be justified in any way other than by the principle of beneficence. If not, so the criticism goes, then the National Commission adopted an incoherent position in thinking that respect for persons and beneficence are independent principles. Robert Veatch seems to both criticize and defend the National Commission for this apparent confusion:

The Belmont Report offers a three-principle theory that uses the Kantian term: “respect for persons.” It subsumes autonomy under this broader notion, but in a strange way it also

subsumes the welfare of the incompetent under respect for persons. This is hard to defend. Autonomy may be an element of a more fundamental notion of respect for persons, but it seems that the duty to serve the welfare of the incompetent is straightforwardly a part of the duty of beneficence. Nevertheless, if respect for persons includes autonomy, it could include other elements as well. . . . [I myself include] principles other than autonomy as part of respect for persons. If respect for persons includes only respect for autonomy, then nonautonomous persons are left stranded. . . . Respecting persons must involve . . . Veracity . . . Fidelity to promises . . . [and] Avoidance of killing.⁵

Veatch is suggesting that although the National Commission erred in its explication of respect for persons, its general viewpoint could perhaps be reconstructed and rendered viable.

2. The National Commission was very concerned that using utilitarian justifications of research had become too easy in the biomedical world. The Nazi experiments, Tuskegee, and the Jewish Chronic Disease Hospital cases all seemed to have been driven by a very utilitarian view of (social) beneficence that justified using humans on grounds of benefit to the broader public. However, the National Commission itself has been accused of having inadequate internal controls in its moral framework to protect research participants against abuse when there is the promise of major benefit for society. Two Commission members, Robert Cooke and Robert Turtle, sternly criticized the Commission’s report on children as endorsing an unjustifiable utilitarian justification of research that placed children at undue risk.^{6,7}

Whatever the merits of this criticism, the Belmont Report was written, in part, to ensure that we appropriately balance appeals to social utility in the justification of research. That is, a major purpose of the report was to properly balance the interests of research participants with those of science and society. Considerations of autonomy, justice, and risk control were set out to limit utilitarian overbalancing and investigator discretion. However, it is doubtful that the question of how best to control utilitarian balancing was ever resolved by the Commission.

3. Paradoxically, the Belmont Report and the National Commission more generally can be criticized for being overly protective of research participants—and consequently insufficiently utilitarian to meet the needs of certain classes of persons. The National Commission’s emphasis was on the protection of humans from research injury. Research participation was conceived as a burden that individuals accepted in order to advance the public good and that should be distributed equitably. It is unclear why this assumption was so deep in the Commission’s work, but it can likely be explained by the atmosphere of scandal that had emerged at the time. The nature and acceptability of the public’s interest in research and the goals of research were little-explored matters in the Belmont Report. The notion that research is not always viewed by participants as burdensome was underexamined.

The AIDS epidemic altered this mind-set, perhaps forever. Whereas the Belmont Report sought to protect research participants, AIDS activists sought not protection from but inclusion in the research process. They wanted justice and respect for their autonomy, but not along the lines staked out in the Belmont Report. They wanted to be able to choose unapproved drugs; considerations of justice, they thought, should be used to allow them access to clinical trials. To them, the Belmont principles could be

interpreted as protectionist to the point of excluding those who might benefit from research and from access to potentially beneficial drugs. In the end, this push for inclusion in research and broader access to the potential benefits of research altered the course of research ethics. Whether this development constitutes an expansion in the scope and use of the Belmont principles or a confrontation with these principles is debatable, but it certainly reconfigured research ethics^{4,8} (see Chapters 9 and 23).

4. The Belmont Report has also been criticized for its abstractness and inability to resolve or otherwise treat practical moral problems. The report anticipated this criticism and cautioned that its principles “cannot always be applied so as to resolve beyond dispute particular ethical problems. The objective is [only] to provide an analytical framework that will guide the resolution of ethical problems arising from research involving human subjects.” The National Commission thus warned readers that they should not expect to use Belmont principles as a checklist of federal regulations or as guidelines like recipes in cooking. Nonetheless, several critics have asked whether these principles are in any meaningful respect practical, or even useful. The concern is that norms as general as the Belmont principles underdetermine almost all moral judgments because there is too little content in abstract principles to determine concrete judgments.

Danner Clouser and Bernard Gert have objected to the Belmont principles, and all related analytical frameworks, contending that “principles” function more like chapter headings in a book than as directive rules and theories. Therefore, receiving no directive guidance from the principle, anyone who is working on a problem in bioethics is left free to deal with that principle in his or her own way and may give it whatever meaning and significance he or she wishes. Consider justice. The Belmont principle of justice (in the selection of research participants) instructs a moral agent to be alert to various matters of justice; but does such a general principle actually guide conduct? Other moral considerations besides the principle(s) of justice, such as moral intuitions and ethical theories, may be needed to do the real work of ethical reflection.^{9–11}

This criticism merits careful attention, but can any system of principles, rules, or general guidelines escape this problem? Clouser and Gert maintain that some general moral rules can provide deep and directive substance, but these authors have had difficulty in clarifying and justifying this claim. Their point is no doubt correct for unspecified principles, but all abstract principles and rules will need some sort of specification-in-context to become directive. The National Commission anticipated this problem. It did not advance the Belmont principles as sufficient for resolving problems, but only as a starting point. The Commission noted that “other principles may be relevant” and that its principles should be able to “serve as a basic justification” for more “particular prescriptions and evaluations.”

5. The Belmont Report has also been faulted for another, closely related reason: It gave no indication of how to prioritize or weigh its principles. Several commentators assert that the National Commission should have argued that one or more of its principles has priority—for example, that considerations of respect for persons and justice take priority over considerations of social benefit.^{5,7,12} These critics support a model of basic moral principles and protections that cannot be violated under any circumstances, even if there is a clear and substantial benefit for society. Such restrictions—often said to be deontological in contrast to

utilitarian—are analogous to constitutional rights that constrain conduct and prohibit balancing of interests in various political and social matters. Some who propose such an ordinal or priority ranking of principles argue that it is the morally correct view; others are more concerned to show that the National Commission has not found a way out of situations in which its own principles come into conflict. Some critics also point out that a priority ranking of the sort they propose (to mitigate conflict between beneficence and either autonomy or social justice) would allow the National Commission to escape the accusation that its schema too readily invites utilitarian justifications of research protocols.

Other commentators have argued that the National Commission was correct in its assumption that the principles are more or less weighty depending upon the particular circumstances in which they are to be applied. These accounts are often referred to as balancing theories. They do not allow any principle in the basic analytical framework to have an ordered (or a priori) priority over any other principle. Thus, when principles conflict, the balance of right over wrong must be determined by assessing the weight of competing considerations as they emerge in the circumstance. What agents ought to do is determined by what they ought to do, all things considered. This appears to be the view presumed in the Belmont Report, and it seems also to be the view currently accepted in federal regulations for protocol review, waivers of consent, and the like.^{13–15}

6. One former National Commission member, Albert Jonsen, and one staff member, Stephen Toulmin, have jointly questioned whether the National Commission actually used its framework of Belmont principles to support or defend its own bioethical conclusions.^{16,17} They have argued that the Commission members believed and published as principlists, but actually worked as casuists. This thesis is not a criticism of the National Commission’s substantive work, but rather a methodological comment on the use and limits of its principles. These authors hold that the National Commission’s actual moral deliberations proceeded by the consideration of influential cases rather than by appeal to universal principles; and they think, more generally, that this paradigm of reasoning is the best method in bioethics. Jonsen and Toulmin present this understanding of the National Commission’s work as follows:

The one thing [*individual* Commissioners] could not agree on was *why* they agreed. . . . Instead of securely established universal principles . . . giving them intellectual grounding for particular judgments about specific kinds of cases, it was the other way around. . . . The *locus of certitude* in the Commissioners’ discussions . . . lay in a shared perception of what was specifically at stake in particular kinds of human situations. . . . That could never have been derived from the supposed theoretical certainty of the principles to which individual Commissioners appealed in their personal accounts.¹⁶

The point is that National Commission members reasoned by appeal to particular cases and families of cases, and reached consensus through agreement on cases and generalization from cases. Principles were therefore of lesser importance than readers might suppose when they read the Belmont Report. Although the Belmont principles are important guiding ideals, they are overrated if revered for their practicality. Although Jonsen has supported the moral principles delineated in the Belmont Report, he has also

maintained that in practical ethics, these principles must be interpreted and specified by the force of examples and counterexamples that emerge from experience with cases.¹⁸ From this perspective, the National Commission should be thought of as using principles primarily as very general guiding ideals.

Enduring Legacy and Influence

The Belmont Report is one of the few documents that has influenced almost every sphere of activity in bioethics: moral theory and general standards of research ethics, government regulatory activity, bioethics consultation, and even medical practice. Its influence has arguably been as extensive in practice as in theory.

Many interested in the role of moral theory and principles in bioethics have honored Belmont for its framework of principles, even if those principles have not been widely analyzed in this literature. As Dan Brock has observed, “The Belmont Report . . . had great impact on bioethics because it addressed the *moral principles* that underlay the various reports on particular aspects of research.”¹⁹ Brock is noting the influence of the idea that a body of principles can be used to frame and discuss a wide range of practical moral problems.

In federal regulatory oversight and law, the Belmont Report has at times assumed a near canonical role. The Advisory Committee on Human Radiation Experiments noted in 1995 that

Many conditions coalesced [historically] into the framework for the regulation of the use of human subjects in federally funded research that is the basis for today’s system. . . . [T]his framework is undergirded by the three Belmont principles. The federal regulations and the conceptual framework built on the Belmont principles became so widely adopted and cited that it might be argued that their establishment marked the end of serious shortcomings in federal research ethics policies.²⁰

Similarly, an Institute of Medicine report, issued by its Committee on Assessing the System for Protecting Human Research Participants, stated in 2002 that “The ethical foundations of research protections in the United States can be found in the three tenets identified in the Belmont Report.”²¹ Moreover, the Belmont principles found their way into every document the National Commission published, and these became the backbone of federal law. From this perspective, as Christine Grady has observed, “probably the single most influential body in the United States involved with the protection of human research subjects was the National Commission.”²²

The legacy of Belmont may be most enduring in areas of practice. Federal regulations require that all institutions receiving federal funds for research espouse a statement of principles for the protection of human research participants. Virtually all such institutions have subscribed to the Belmont principles as the basis of their efforts to assess research protocols from an ethical point of view. Professional associations, too, have widely recognized the authority and historical significance of the Belmont principles.²³ Eric Cassell has also argued that the Belmont principles have “permeated clinical medicine” as extensively as they have medical research.²⁴ His claim is that the Belmont principles were a sig-

nificant force in a broad cultural shift in medicine toward a reworking of the relationship between doctor and patient.

Whatever the influence and enduring legacy of Belmont, it is not clear that scientists who today are involved in research with humans are any more familiar with the Belmont principles than their predecessors of several decades ago were familiar with documents such as the Nuremberg Code. When the National Commission deliberated, it seemed to some observers that the general system of protecting human research participants in the United States was in need of serious repair, that research investigators were not educated about research ethics, and that participants were not adequately protected. To some observers, the system seems today caught in a notably similar state of disrepair. From 1997 to 2002 a large number of hearings, bills, and reports by official, prestigious government bodies and government-mandated bodies in the United States concluded that the system of IRB review and the practice of informed consent—the core of research ethics established by the National Commission—are seriously defective.^{8,21}

The National Commission and its Belmont Report may have succeeded both in “resolving” some major problems of research ethics and in bringing “oversight” to the research context, as historian David Rothman has claimed,²⁵ but this may have been a temporary, time-bound fix. Today the Belmont principles may be more revered than they are understood and practiced.

Regulations for the Protection of Humans in Research in the United States

The Common Rule

Ethics and regulation of research with humans have coexisted in a somewhat uneasy relationship in the United States for the past 60 years. Wartime atrocities committed by Nazi doctors and scientists under the guise of “medical experimentation” set the stage for increasing awareness in the United States of ethical issues raised by experimentation on humans, even though few U.S. scientists at the time viewed their own work as “unethical.” During the 1950s and 1960s, concerns about ethics and human research continued to spread within the U.S. scientific community and among the public as reports of abuses of human subjects in research, including children, became increasingly frequent. The monumental work by Jay Katz¹ provides a scholarly account and analysis of several troubling cases of human experimentation in the United States prior to revelation of the so-called Tuskegee Syphilis Study conducted by the U.S. Public Health Service from 1932 to 1972 (see Chapter 8). Similarly, the 1996 final report of the Advisory Committee on Human Radiation Experiments provides a detailed and sometimes chilling account of studies conducted by U.S. physicians and scientists with the support of the U.S. government during the years of the Cold War.²

Policies requiring informed consent and peer review of proposed research, intended to protect the interests of subjects and promote ethical conduct, were not enthusiastically embraced by much of the research community, even after adoption of federal regulations. Today, the research community readily, even if sometimes begrudgingly, acknowledges the need for an appropriate mechanism for ethical review of research and for protection of human research subjects, who now are often called research participants. In recent years, the view that protection of human subjects should be a primary goal of all responsible members of the

research community has become much more widely accepted and enthusiastically endorsed by scientists, the government, and the public than ever before. Still, imposition of federal regulations to achieve these goals is not considered necessary or appropriate by some in the research community, who argue that self-regulation ought to be sufficient. The enthusiasm for these processes is dampened by the logistical, administrative, and regulatory burdens they necessarily entail, rather than by lack of concern for ethical conduct or well-being of research subjects.

The notion that ethical conduct can be “enforced” by law is not well supported, and many scientists still resent mandatory review and modification of their proposals by review committees that, from the scientists’ viewpoint, may not have sufficient expertise to properly carry out these tasks. Conversely, institutional review boards (IRBs), the bodies charged with review, approval, and oversight of human research in the United States, often believe that scientists are not well trained in research ethics. Not surprisingly, tensions remain among scientists, ethicists, patient advocates, and regulators, as well as among institutions and federal agencies that fund and conduct research with humans.

Passage of the National Research Act and the establishment of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (National Commission) in 1974 laid the foundation for formal adoption of federal regulations for protection of human subjects by the Department of Health, Education, and Welfare (DHEW), now the Department of Health and Human Services (DHHS). Prior to adoption of the regulations in 1981, similar practices had been implemented through policies instituted in the mid-1970s by the agencies of the Public Health Service for funding of its grants and contracts. The

regulations were intended to implement an effective process for review, approval, and continuing oversight of research with humans within the framework of ethical principles identified in the National Commission's Belmont Report—namely, respect for persons, beneficence, and justice³ (see Chapter 14).

The regulations themselves are process-oriented. They define what human subjects research is and what types of research are subject to regulation and review. They define the minimum requirements for composition of IRBs and the required elements of informed consent; more precisely, they spell out the elements and statements that must be included in a written consent form. They define an assurance process through which an institution wishing to receive federal funds for research makes a legally binding commitment to establish and maintain a program for the protection of human research participants, including providing resources and space for a duly constituted IRB. In doing so, they also create a mechanism for enforcement of the regulations through review and approval of an institution's assurance by the Office for Human Research Protections (OHRP) within the DHHS, formerly the Office for Protection from Research Risks (OPRR) within the National Institutes of Health (NIH).

The processes established in these regulations are intended to apply, in an operational sense, the ethical principles and practices set forth by the National Commission. The National Commission understood that regulations could not be expected to delineate on a case-by-case basis whether or not a given proposal was safe, ethical, or scientifically sound. Rather, the National Commission explained how these principles could be conscientiously applied during a review process that draws upon the collective knowledge and expertise of a committed panel of IRB members responsibly exercising good judgment in the interests of human research participants. The procedures cannot, in and of themselves, protect humans enrolled in research. A signature on a consent form does not mean that appropriately informed consent has been obtained, nor does approval by a quorum of an IRB ensure that a proposed study is ethical, safe, or will provide meaningful scientific data. These goals can be achieved only when all responsible parties do more than merely go through the process in compliance with minimal regulatory requirements.

This chapter discusses that portion of the federal regulations known as the Common Rule. The story of the Common Rule is one of trying to overcome government bureaucracy and statutory impediments to simplify the processes intended to promote responsible conduct, ethical study design, and safety of research subjects. Why did the creation of the Common Rule for federal departments and agencies, a project with noble intentions that ought to benefit everyone, take more than a decade to achieve? Even more perplexing is that having achieved the goal through great effort, many still view the Common Rule as ineffective and even as an impediment to progress and much needed reform. We will examine the historical context of the Common Rule, discuss its provisions and applications, and offer some thoughts about revisions that are still needed and associated reforms to the system for protection of humans in research.

Background and History of the Common Rule

The United States was among the first of a small but growing number of countries to adopt a formal, statute-based regulatory

framework for protection of humans in research. The legislation passed by Congress in response to abuses of humans by government and private researchers was intended to prevent future abuses of the rights and welfare of research participants by establishing a system for review, approval, and oversight of all human research supported, conducted, or otherwise regulated by the U.S. government. This includes private research that is conducted to meet Food and Drug Administration (FDA) requirements but excludes some types of privately funded research for which there is no other mechanism to invoke federal jurisdiction.

The regulations promulgated by DHEW in 1974 under the statutory authority of the National Research Act (Pub. L. 93-348) replaced or augmented policies previously adopted by the agencies of the Public Health Service. Several years later, when the Department of Education was created and DHEW became DHHS, the regulations were transferred to DHHS, where they are incorporated in the Code of Federal Regulations (CFR), Title 45, Part 46, also referred to as 45 CFR 46.⁴

These regulations represented the government's efforts to respond to the National Commission's Belmont Report. The Belmont Report established an ethical framework for responsible conduct of research with humans and in so doing, laid a foundation of principles upon which a workable set of rules could be established to ensure that all human studies would be conducted ethically. As originally promulgated, the regulations broadly addressed research in the biomedical and behavioral sciences and set forth requirements for review and approval of proposed research by IRBs and a process of informed consent. Compliance with the regulatory requirements was to be enforced through an assurance process linked to the receipt of federal research support. Institutions receiving support from DHEW were required to give written assurance of compliance that the provisions of the regulations would be fulfilled. Failure to provide such an assurance would result in denial of DHEW support to institutions for research involving humans. To the core of those regulations, commonly referred to as Subpart A, were later added subparts pertaining to special groups of potential research participants deemed to warrant additional specific protections, among them pregnant women and fetuses (Subpart B), prisoners (Subpart C), and children (Subpart D). Originally, these additional provisions were deemed necessary to protect these "vulnerable" populations. Today, the view that women are vulnerable simply because they are pregnant is considered overtly paternalistic, so that terminology is less commonly used in this context. At the same time, the view that all research participants are vulnerable to exploitation has gained greater acceptance in view of widespread concern over the effectiveness of the existing system for protection of humans in research.

In this chapter, we will focus on 45 CFR 46, Subpart A, which is the DHHS's codification of the Common Rule. By now, other federal departments and agencies have codified the same rule at other sections of the code specific to each. When the regulations were first issued by DHEW, however they were not binding on other federal agencies, even though the need for comparable regulations for other agencies engaged in or supporting human research was evident. Nor were they acceptable to the FDA, which maintained its own process for regulation of clinical studies and approval of test articles under the Food, Drug, and Cosmetic Act. As an agency of DHHS, FDA does use the Common Rule when it conducts intramural research, however, and has its own internal IRB.

Table 15.1
Timeline of the Evolution of the Common Rule

<i>Date</i>	<i>Event</i>
May 1974	Basic Regulations Governing the Protection of Human Subjects Involved in Research issued by Office of the Secretary, Department of Health, Education and Welfare (30 FR 18914).
Nov. 1978	The President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research is established by Pub. L. 95-622.
Jan. 1981	Public Health Service issues Final Regulation Amending Basic Department of Health and Human Services (DHHS) policy for the protection of human research subjects 45CFR46, Vol. 46, No. 16 (46 FR 8366).
Dec. 1981	The President's Commission issues its First Biennial Report on the Adequacy and Uniformity of Federal Rules and Policies, and their Implementation for the Protection of Human Subjects in Biomedical and Behavioral Research, "Protecting Human Subjects."
May 1982	Federal Coordinating Committee on Science, Engineering, and Technology (FCCSET) appoints an Ad Hoc Committee for the Protection of Human Subjects in Research, chaired by the Assistant Secretary for Health of DHHS.
Mar. 1983	Office of the Secretary, DHHS, issues Children Involved as Subjects in Research, Additional Protections, Final Rule, Vol. 48, No. 46 (48 FR 9814).
Oct. 1983	Interagency Human Subjects Coordinating Committee is chartered under FCCSET, chaired by Director, Office for Protection from Research Risks.
June 1986	Office of Science and Technology Policy (OSTP) issues Proposed Model Federal Policy for Protection of Human Subjects, Response to the First Biennial Report of the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research, Office of Science and Technology Policy, Vol. 51, No. 106 (51 FR 106).
Nov. 1988	OSTP issues a refined version of proposed Federal Policy for the Protection of Human Subjects; Notice and Proposed Rules, Vol. 53, No. 218 (53 FR 45661), launching three more years of debate and negotiation over the details of a Common Rule.
June 1991	OSTP publishes the Common Rule as Federal Policy for the Protection of Human Subjects; Notice and Rules, Vol. 56, No. 117 (56 FR 28003). Upon promulgation of the Common Rule, the Interagency Committee becomes a temporary subcommittee of FCCSET.
1994	Human Subjects Research Subcommittee placed under the auspices of the Committee on Health, Safety, and Food of the National Science and Technology Council (NSTC).
Oct. 1995	President Bill Clinton issues Executive Order 1295, Protection of Human Subjects and Creation of the National Bioethics Advisory Commission. Executive Order requires each department and agency that conducts, supports, or regulates research involving human subjects to review the protections of the rights and welfare of human subjects that are afforded by the department's or agency's existing policies and procedures and report to the Commission.
1997	NSTC is reorganized; Human Subjects Research Subcommittee becomes a subcommittee of the NSTC Committee on Science.

Not surprisingly, not all of the federal agencies shared a common view of which research projects ought to be subject to IRB review and approval, or, for that matter, what activities properly constituted research involving human subjects. At times, the policies and practices of some agencies actually conflicted with requirements of the regulations adopted by DHEW, a situation that caused great confusion at institutions engaged in research activities under the auspices of more than one funding agency, as well as some confusion and contentiousness among the agencies themselves. Therein lay the rationale and inspiration for a uniform regulatory framework afforded by a common rule.

Content of the Common Rule

The Common Rule is focused primarily on the processes of review, approval, and oversight of research with humans generally, rather than on being a substantive document specific to any one kind of research. These processes are based on three fundamental ethical principles found in the Belmont Report: (1) respect for persons, (2) beneficence, and (3) justice. Respect for persons requires that individuals be treated as autonomous agents and that persons with diminished autonomy are afforded additional protection. Informed consent is a requirement that derives from this principle, as is the consideration of special protections for vulnerable subjects who may not be able to consent fully to participation in research. Beneficence translates to (1) do no harm, and (2) maximize possible benefits and minimize possible harms. These concepts are reflected in the deliberations an IRB must make in its systematic assessment of risks and benefits. The third principle, justice, addresses who ought to receive the benefits of research and bear its burdens. The principle of justice requires that there be fair procedures and outcomes in the selection of research subjects. Each of these principles is embodied in the regulatory requirements.

The Common Rule applies to all research involving humans conducted, supported, or otherwise subject to regulation by any federal department or agency that takes appropriate administrative action to make the policy applicable to such research. Not all federal agencies and departments have adopted the Common Rule through regulation. In some cases, the departments and agencies may not see their activities as being research as defined by the regulations, or more specifically, may not consider that they are doing research with human subjects. Under the Common Rule, department and agency heads may determine how the rule will be applied, or not, to activities conducted or supported by their agencies. This flexibility was probably an important factor in acceptance of the rule by several federal agencies with widely varying interests and scope of research activities. The applicability section also describes six categories of exemptions from the Common Rule. It states, however, that research that takes place in foreign countries must follow the Common Rule or follow at least equivalent procedures determined and published by the department or agency head.

The Common Rule defines several terms that are used precisely in its application, particularly when compliance with its provisions is assessed. These include "research," "human subject," "minimal risk," "IRB approval," and many others. Many of these terms are further clarified in formal guidance issued by the departments and agencies, and their application may not always be entirely consistent from one agency to another. Even today, controversy exists

over whether certain activities are rightfully considered “research,” “human subjects research,” or “research subject to regulation,” and there are similar disputes over the definitions of “equivalent in protections to that in other countries” and “minimal risk.” These controversies have been a source of continuing discussion, and sometimes confusion, among members of the research community as well as those who regulate it.

The written “assurance” that is required from institutions must describe how compliance with the rule will be achieved, including specification of principles that govern the conduct of the research, a description of the IRB(s) to be involved, written procedures that must be in place, and institutional responsibilities, including provision of adequate resources, space, and personnel to support the process.

Many of the Common Rule provisions deal with the IRB, including its membership, functions, operations, responsibilities, and authority. Among the basic responsibilities of IRBs, they must determine the following:

- Risks to research participants are minimized.
- Risks to participants are reasonable in relation to anticipated benefits, if any, to participants, and in relation to the importance of the knowledge that may reasonably be expected to result.
- Selection of participants is equitable, and special problems arising in research involving vulnerable populations, such as children, prisoners, pregnant women, and mentally, economically, or educationally disadvantaged people, have been considered.
- Informed consent is properly sought and documented.
- Appropriate monitoring is in place.
- Adequate provisions will be made to protect the privacy of research participants and to maintain the confidentiality of data.

The Common Rule also describes an expedited review procedure for certain kinds of research involving no more than minimal risk and for minor changes in approved research. In addition, DHHS publishes and regularly updates in the *Federal Register* a list of review categories that IRBs can use to expedite review of minimal risk research. The IRB chairperson or one or more experienced reviewers designated by the chairperson from among members of the IRB may carry out the expedited review. The list of expedited categories was last modified in November 1998 to clarify and expand the types of research for which IRB review could be expedited if the research were minimal risk.⁵

Importantly, the Common Rule details the criteria for IRB approval of research, suspension or termination of IRB approval, and arrangements by which cooperative research might be reviewed. It also covers IRB record-keeping requirements, required and additional elements of the consent form, criteria for waiving informed consent or documentation of informed consent, and other conditions that must be met when applications and proposals for IRB review lack specific plans for involvement of humans in research. Additional sections cover other conditions for administrative requirements and timing of reviews before research may begin.

In summary, the Common Rule lays out the process and specific requirements for review, approval, and oversight of research involving humans, but grants institutions and IRBs broad powers and flexibility with respect to the details of their implementation. This is considered by many to be the greatest

strength of the rule, and by others to be its greatest weakness. Some complain that the procedural requirements of the Common Rule impose unnecessarily rigid administrative impediments to the initiation of research, whereas others call for even more detailed and directive guidance for following its provisions, as will be discussed later in this chapter.

Development of the Common Rule

The creation and adoption by multiple agencies of a single rule for protection of humans in research was itself a major exercise in compromise, interagency diplomacy, and leadership. The President’s Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research (President’s Commission) was established on November 9, 1978, by Pub. L. 95–622. One of the charges to the President’s Commission was to report biennially to the president, Congress, and appropriate federal departments and agencies on the protection of humans involved in biomedical and behavioral research. The President’s Commission was directed to conduct a review of the adequacy and uniformity of (1) the rules, policies, guidelines, and regulations of all federal departments and agencies regarding the protection of humans in biomedical or behavioral research that such departments and agencies conduct or support, and (2) the implementation of such rules, policies, guidelines, and regulations by such agencies, including appropriate recommendations for legislation and administrative action.

In December 1981, the President’s Commission issued its first biennial report, entitled, *First Biennial Report on the Adequacy and Uniformity of Federal Rules and Policies, and Their Implementation, for the Protection of Human Subjects*.⁶ Morris B. Abram, chairman of the President’s Commission, noted in his transmittal to the president:

The Commission does not propose any major changes in the substance of the rules on human research, although a number of adjustments are recommended to recognize the flexibility needed by research institutions, particularly in responding to allegations of wrongdoing or other problems. We also propose a simple improvement in the reports filed by researchers, to provide information on the number of subjects and on any that are adversely affected by participation in a research project.

The Commission does recommend one major organization change, namely that a uniform core of regulations be adopted, based upon the present rules of the Department of Health and Human Services, and that HHS become the lead agency in this field. This consolidation would eliminate needless duplication in the rules of the 23 other Federal entities that support or regulate research, thereby simplifying both local compliance with the rules and Federal oversight of the system. Copies of this report are being sent to all affected Federal agencies, with a request for action, pursuant to the Commission’s enabling legislation.⁶

The Commission’s report specified which departments and agencies it thought were involved. Barbara Mishkin of the President’s Commission staff worked with Charles McCarthy, director of OPRR, to identify federal departments and agencies that conduct or support research involving human subjects, and it was here that

this idea for a core policy was really begun. Ultimately, some of the agencies declared that they did not do human subjects research, reducing the field to 16 or 17 agencies. In fact those agencies that indicated they were not doing any research may have been doing so, given that the definition of research is so broad.

The law that created the President's Commission required that each federal department or agency that received recommendations from the Commission with respect to its rules, policies, guidelines, or regulations, should publish the recommendations in the *Federal Register* and provide an opportunity for interested persons to submit written data, views, and arguments with respect to adoption of the recommendations. A decade of work to carry out the President's Commission's recommendations thus began.

From the outset it was clear that a coordinating mechanism would be necessary. For each federal department and agency to respond individually to the recommendations would be laborious and time consuming, if not unwieldy and impractical. Recent efforts to coordinate gathering and sharing of intelligence information among federal agencies, and even the need to create a new cabinet-level Department of Homeland Security to deal with a matter as essential and critical as defense against terrorism, dramatically underscore the complexity encountered when undertaking an interagency initiative of any kind, even when the rationale is sound and the need great. An interdepartmental or interagency initiative to achieve this type of coordination would prove challenging, especially because there were few clear-cut precedents for jointly publishing policies or regulations in common on issues of this scope.

OPRR Director McCarthy took the initiative with officials from the Office of Science and Technology Policy (OSTP), the Office of Management and Budget (OMB), and DHHS leadership to discuss how coordination could be accomplished with OPRR as the lead agency. On March 29, 1982, DHHS Secretary Richard S. Schweiker published the President's Commission's first biennial report on behalf of all the departments and agencies affected by the recommendations.⁷

In May 1982 the chairman of the Federal Coordinating Council for Science, Engineering and Technology (FCCSET) appointed an Ad Hoc Committee for the Protection of Human Research Subjects under the auspices of the FCCSET. This committee, chaired by Edward N. Brandt Jr., DHHS assistant secretary for health, was composed of representatives of affected departments and agencies. In consultation with OSTP and OMB, the Ad Hoc Committee was charged with developing responses to the recommendations of the President's Commission. An Interagency Human Subjects Coordinating Committee was chartered in October 1983 under the auspices of the FCCSET to provide continued interagency cooperation in the protection of humans in research after the Ad Hoc Committee had completed its assignment. It was chaired by the director of OPRR and had basically the same membership as the Ad Hoc Committee.

The Ad Hoc, and later standing, Committee met over many months to respond to the first recommendation in the President's Commission's First Biennial Report:

The President should, through appropriate action, require that all federal departments and agencies adopt as a common core the regulations governing research with human subjects issued by the Department of Health and Human Services (codified at 45 CFR 46), as periodically amended

or revised, while permitting additions needed by any department or agency that are not inconsistent with these core provisions.⁶

The Committee produced a Model Policy to apply to research involving humans that is conducted, supported, or regulated by federal departments and agencies. The Model Policy encompassed only what was equivalent in scope to Subpart A of 45 CFR 46. Clearly OMB wished to have as much uniformity as possible and required several modifications and compromises in the Committee's draft that would minimize the "departures" from the core policy that had been added by various departments and agencies. After considerable discussion and negotiation, the department or agency heads, or their designees, concurred in the Model Policy in March 1985. It was not until June 3, 1986, however, that the Proposed Model Federal Policy was published in the *Federal Register* on behalf of 16 federal departments and agencies.⁸

During the intervening 14 months, OMB and OSTP acted to diminish the number of "departures" from the core policy through which many of the participating federal departments and agencies sought to accommodate their own organizational structures, procedures, and philosophies, and possibly to protect their own interests when deemed necessary. The position of the OMB was that there should be no departures unless there were statutory requirements for them in department and agency legislation, as was the case for the FDA. This position was not met with enthusiastic acceptance by the agencies, some of which may not have had specific legislative exceptions to substantiate their desired departures.

Despite the considerable efforts expended to promote uniformity among the agency positions, when the Model Policy was finally published there were still several departures indicated. Twelve agencies had no departures; the Department of Education had one; DHHS had two; FDA had two; and the Veterans Administration, now the Department of Veterans Affairs (VA), had many. To meet the concerns of the President's Commission that unnecessary and confusing regulations would impose burdens on institutions conducting research, the policy was drafted to have the following: uniform procedures for assurance and certification; consistency in IRB roles, responsibilities, and composition; provisions to assure compliance; procedures for expedited review; and provisions for obtaining and documenting informed consent. The specific intention was that departments and agencies could have their own implementing directives and procedures to supplement the Model Policy. The Model Policy was drafted in the form of a policy statement rather than in the form of a regulation so that departments and agencies could reference it within a reasonable time and in a manner that each department or agency was accustomed to using.

The President's Commission also recommended that the president authorize and direct the secretary of DHHS to designate an office with government-wide jurisdiction to coordinate, monitor, and evaluate the implementation of all federal regulations governing research with humans. The Ad Hoc Committee recommended that OPRR, then housed within the NIH, serve in the coordinating role. The OPRR director became the head of a standing committee of the FCCSET, the Interagency Human Subjects Coordinating Committee, which was chartered in 1983, and the Ad Hoc Committee was integrated into the new one. The new committee, composed of representatives of federal departments and agencies that conduct, support, or regulate research involving

humans, was to evaluate the implementation of the Model Policy and recommend changes as necessary.

An Addition to the 1981 DHHS Regulations

On March 4, 1982, DHHS issued a “Notice of Waiver” in the *Federal Register*.⁹ DHHS had been faced with a lawsuit raising the issue whether demonstration projects in the Social Security Administration constituted research under 45 CFR 46. The waiver was issued under 45 CFR 46(e). It pertained to demonstration projects approved under section 1115 of the Social Security Act, which test the use of cost-sharing, such as deductibles, copayment and coinsurance, in the Medicaid program. The rationale for the waiver was that it would facilitate the timely and efficient operation of demonstration projects that are likely to assist in promoting the objectives of the Medicaid program. Demonstration projects are pilot programs designed to determine if a particular practice or policy is effective in the setting(s) in which it is ultimately intended to be used. These projects are intended to provide evidence or proof that the practice or policy is valid or sound. The waiver was effected immediately with the publication of the Notice in the *Federal Register*. The Notice of Waiver was followed on March 22, 1982, with a “Notice of Proposed Rulemaking,”¹⁰ whereby DHHS proposed to include among the types of research specifically exempt from the application of the regulatory requirement of 45 CFR 46, research and demonstration projects conducted under the Social Security Act and other federal statutory authority and designed to study certain public benefit or service programs, the procedures for obtaining benefits or services under those programs, and possible changes or alternative to those programs or procedures, including changes in methods or levels of payment. The argument was that these demonstration and service projects were already subject to procedures that provide for extensive review by high-level officials in the department and that IRB review would be duplicative and burdensome to state and local agencies and to other entities participating in demonstration projects. The proposed exemption would have added item (6) to the list in 46.101(b) as follows:

Unless specifically required by statute, research and demonstration projects which are conducted by or subject to the approval of the Department of Health and Human Services, and which are designed to study, evaluate, or otherwise examine: (i) Programs under the Social Security Act, or other public benefit or service programs; (ii) procedures for obtaining benefits or services under those programs; (iii) possible changes in or alternatives to those programs or procedures; or (iv) possible changes in methods or levels of payment for benefits or services under those programs.¹⁰

Among the commentators on this provision was the President’s Commission itself. The Commission proposed alternative language that would not have exempted research that reduced benefits to some recipients, whereas others in similar circumstances continued to receive a higher level of benefits. The Commission proposed that research projects in any way limiting or reducing the benefits to which recipients would otherwise be entitled would continue to be subject to IRB review. DHHS did not adopt the Commission’s alternative, however.

The Final Rule was published on March 4, 1983, with language modified in response to public comment.¹¹ To ensure the continued protection of human research participants, DHHS added a specific requirement for written informed consent even if the research was exempt. In the Final Rule, DHHS modified the proposed exemption in 45 CFR 46 to indicate in part (i) of section 101 the following:

If, following review of proposed research activities that are exempt from these regulations under paragraph (b)(6), the Secretary determines that a research or demonstration project presents a danger to the physical, mental, or emotional well-being of a participant or subject of the research or demonstration project, then federal funds may not be expended for such a project without the written, informed consent of each participant or subject.¹¹

Section 116 was further modified by the addition of part (c), which provided that the IRB could approve a consent procedure that does not include or that alters some or all of the elements of informed consent; or it could waive consent altogether if the research or demonstration project is to be conducted by, or subject to, the approval of state or local government officials and is designed to study, evaluate, or otherwise assess the areas listed in 101(b)(6), and the research could not practicably be carried out without the waiver or alteration.

The drafting committee for the Model Policy now had an addition to DHHS regulations to consider for incorporation into the Model Federal Policy. The proposed Model Federal Policy published in 1986 changed the “public benefits exemption” only slightly in Section 101(b)(5) to drop the reference to programs under the Social Security Act and to change DHHS as the approving authority and to substitute in its place the department or agency head. Section 116(c) was similarly modified. The exemption remains as perhaps one of the most misunderstood and misused of the Common Rule exemptions.

Highlights of the Proposed Model Policy

The Model Policy was based on the 1981 version of 45 CFR 46, but there were some modifications. The Model Policy contained a definition of regulated research and identified which sections of the policy were applicable to regulated research. Some drafting had to be done to exclude FDA from the provision requiring assurances in advance of the conduct of research; this was considered to be inconsistent with the operating provisions of FDA’s new drug approval (NDA) process.

Under then existing DHHS regulations, which had been adopted in 1981, certain classes of research were exempt from IRB review and approval. Changes in these exemptions were arguably the most significant modifications under the newly proposed Model Policy. The Model Policy revised certain exemptions to make them clearer. For example, in the 1981 version of Subpart A of the DHHS regulations, the exemption at 46.101(b)(2) read: “Research involving the use of educational tests (cognitive, diagnostic, aptitude, achievement), if information taken from these sources is recorded in such a manner that subjects cannot be identified, directly or through identifiers linked to the subjects.”¹²

The exemption at 46.101(b)(3) read as follows:

Research involving survey or interview procedures, except where *all* of the following conditions exist: (i) Responses are recorded in a manner that the human subjects can be identified, directly or through identifiers linked to the subjects, (ii) the subject's responses, if they became known outside the research, could reasonably place the subject at risk of criminal or civil liability or be damaging to the subject's financial standing or employability, *and* (iii) the research deals with sensitive aspects of the subject's own behavior, such as illegal conduct, drug use, sexual behavior, or use of alcohol. All research involving survey or interview procedures is exempt, without exception, when the respondents are elected or appointed public officials or candidates for public office [emphasis added].¹²

And the exemption at 46.101(b)(4) read as follows:

Research involving the observation (including observation by participants) of public behavior, except where *all* of the following conditions exist: (i) Observations are recorded in such a manner that the human subjects can be identified, directly or through identifiers linked to the subjects, (ii) the observations recorded about the individual, if they became known outside the research, could reasonably place the subject at risk of criminal or civil liability or be damaging to the subject's financial standing or employability, *and* (iii) the research deals with sensitive aspects of the subject's own behavior such as illegal conduct, drug use, sexual behavior, or use of alcohol [emphasis added].¹²

The Model Policy, however, combined these three exemptions into two at sections 101(b)(2) and (3). These were as follows:

- (2) Research involving the use of educational tests (cognitive, diagnostic, aptitude, achievement) survey procedures, interview procedures or observation of public behavior, *unless*:
- (i) information obtained is recorded in such a manner that human subjects can be identified, directly or through identifiers linked to the subjects; *and*
 - (ii) any disclosure of the human subjects' responses outside the research could reasonably place the subjects at risk of criminal or civil liability or be damaging to the subjects' financial standing or employability [emphasis added].⁸

And,

- (3) Research involving the use of educational tests (cognitive, diagnostic, aptitude, achievement), survey procedures, interview procedures or observation of public behavior that is exempt under paragraph (2), if:
- (i) the human subjects are elected or appointed public officials or candidates for public office; or
 - (ii) federal statute(s) require(s) without exception that the confidentiality of the personally identifiable information will be maintained through the research and thereafter.⁸

In 1981, three requirements had to be in place if the research could not be exempted. In the Model Policy, only two criteria had to be met before the research could not be exempted.

To accommodate the Department of Justice and the Department of Education, a clause was added to the exemption at section 101(b)(3)(ii) that would permit research involving the use of

educational tests, survey procedures, interview procedures, or observation of public behavior to be exempt even if identifiers were recorded and a disclosure of the research participants' responses outside the research could place them at risk of criminal or civil liability or be damaging to their financial standing or employability. Under this provision, the research also could still be exempt if "federal statutes(s) require(s) without exception that the confidentiality of the personally identifiable information will be maintained throughout the research and thereafter."⁸

In this process, a new exemption was created that had to be negotiated with the FDA, the Environmental Protection Agency, and the Department of Agriculture to harmonize the terms with existing regulations and policies; this is known as the "taste and food quality evaluation study exemption." Each organization had its own terms in legislation or regulation that had to be carefully woven into the exemption to accomplish what all wanted to do to permit an exemption for taste and food quality evaluation studies where other safeguards were in place.

The Model Policy incorporated a new section, 101(g), to state what was only implicit in the DHHS regulation, namely, that the Model Policy does not affect any foreign laws or regulations that may otherwise be applicable and that provide additional protections for humans in research.⁸ Furthermore, in section 101(h), it allows department and agency heads discretion in accepting equivalent procedures for research carried out in foreign countries, although it offers no definition or guidance as to what policies and procedures might be considered to provide "equivalent protections."⁸ Departments and agencies are still struggling with how exactly to determine equivalency. For example, is another country's requirement to have an IRB-like body sufficient, or must that body have exactly the same kinds of functions and membership composition requirements as those under the Common Rule? To date, few departments or agencies have issued announcements of what would be equivalent protections in the method prescribed by section 101(h), although in 2002 the OHRP imppaneled a DHHS working group to develop guidelines for making such a determination of equivalent protections. The report of that working group was published in July 2003 for public comments without further action at the time of this writing.¹³

A long period of negotiation was required with OMB and the Department of Justice regarding the language concerned with IRB membership. Section 107 of the Model Policy replaced the requirement in the DHHS regulations that if an IRB regularly reviews research that involves a special or "vulnerable" category of participants, the IRB must include one or more individuals who are primarily concerned with the welfare of those individuals. In the Model Policy, the inclusion of such an individual is left to the institution establishing the IRB. This was done in the spirit of deregulation. Although the 1981 DHHS regulations also indicated that no IRB may consist entirely of men or entirely of women, or entirely of members of one profession, OMB representatives in consultation with Department of Justice wanted the language to indicate the following:

Every nondiscriminatory effort will be made to ensure that no IRB consists entirely of men or entirely of women, including the institution's consideration of qualified persons of both sexes, so long as no selection is made to the IRB on the basis of gender. No IRB may consist entirely of members of one profession.⁸ [finally incorporated as Section 107(b)]

This modification was requested in the spirit of moving away from any appearance of quotas.

By far the largest concern from public commentators concerned section 103(a) of the Model Policy and the “grace period.” The 1981 regulations required certification of IRB review and approval by the institution receiving funds when the research is supported by a federal department or agency and not exempt. Along with the submission of an application or proposal for approval or support, an institution with an approved assurance covering the research was to certify that the application or proposal had been reviewed and approved by the IRB within 60 days of submission of the application or proposal. These were the institutions holding so-called Multiple Project Assurances, generally institutions with a large volume of research activity and well-established infrastructures for human research administration and oversight. Institutions without an approved assurance covering the research had to certify within 30 days after receipt of a request for such a certification from DHHS that the application or proposal had been approved by the IRB.

The Model Policy stated, however, that if the certification is not submitted with the application or proposal (or within 30 days after request for the institutions with no assurances covering the research), the application or proposal may be returned to the institution. The preamble to the Model Policy announced that there would be no grace period incorporated into the policy, whereas the 1981 DHHS regulations had explicitly permitted institutions that held an approved assurance to delay submission of certification of IRB review and approval until 60 days after submission of an application or proposal for financial support.

Most of the groups that represented the colleges and universities responded with concern that they couldn't work under this provision. They were used to turning in the certifications of IRB review long after the applications and proposals had been submitted to DHHS. Although the grace period was not explicitly noted in the Model Policy, this did not mean that there would be no grace period allowed. The idea was that each department and agency would need to decide what grace period it would permit and make that known through an information process other than incorporation explicitly into the Model Policy. When institutions and professional groups understood that the grace period was not being taken away in DHHS procedures simply by removing reference to it explicitly in the regulation, the swell of concern abated. DHHS had in the departure section of the published policy a comment that it would evaluate whether ending the grace period was an appropriate step before the next iteration of the policy could be published.

Two Years Later

The Model Policy next surfaced in the *Federal Register* on November 10, 1988.¹⁴ The OSTP again published the proposed policy on behalf of the participating departments and agencies. Each time a proposed or final document was published in the *Federal Register*, the long bureaucratic process of department and agency clearance to the topmost echelons of the organizations had to occur. When administrations changed, new officials had to be briefed and convinced that the Model Policy or common regulations were important to issue.

The 1988 publication in the *Federal Register* served both as a notice that a final Model Policy was forthcoming and as a formal

Notice of Proposed Rulemaking in compliance with the requirements of the Administrative Procedure Act. Over the course of the 2 years since its previous publication, there continued to be concerns on the part of the Interagency Committee and the OMB that too many departures could be made from the core policy.

As noted, over 200 public comments came in concerning the 1986 proposed Model Policy; most requested continuation of a grace period. The comments came primarily from medical schools and other academic institutions, some from professional associations, industry, IRBs, and research administrators. Almost unanimously, the respondents enthusiastically supported the concept of a Model Federal Policy, provided a grace period was retained. The Interagency Committee did revise the Final Model Policy to indicate that the certification of IRB review and approval must accompany the application or proposal unless the department or agency specified a later date for submission of the certification. DHHS announced in the preamble to the 1988 Model Policy/Proposed Rule that it intended to retain the “grace period” administratively. Other departments and agencies would have to advise institutions of appropriate timing of certification through their information dissemination mechanisms.

Because the departments and agencies were not required to use the Model Policy, the burdens of redundant and confusing policies on institutions carrying out research involving humans could continue if inconsistencies in federal policies and procedures persisted. Further, DHHS, the Department of Energy, and some other departments and agencies had regulations that did not conform to the Model Policy and would have to be formally updated: The Model Policy itself was not binding. Clearly, regulations were in order.

The Interagency Committee, with the help of OMB, made several other changes in response to public comments on the 1986 proposed Model Policy. For example, one of the exemptions was modified so that the effect of disclosure of identifiable information on the “reputation” of an individual was to be taken into consideration. The taste and food quality evaluation exemption was clarified, a definition of IRB was included, and some further clarifications on reporting requirements were added.

One area of discussion in the preamble of the Final Model Policy/Notice of Proposed Rulemaking was that the Veterans Administration (VA), which had proposed many departures from the Common Rule, indicated that it did not intend to have assurances under Section 103 for its Medical Centers that participated in research. That policy changed dramatically in 1988. VA, which became a cabinet-level Department of Veterans Affairs the following year, indicated that it would withdraw all of its departures, but would narrowly construe exemptions and the informed consent provision to be consistent with other statutory requirements on it. VA recognized that it could, by internal policies that applied to its intramural research program, address many concerns about adequate protections for veterans and others in VA research.

The Department of Education now had two proposed departures from the Common Rule language. That department proposed that one of the exemptions relating to research involving the use of educational tests, survey procedures, interview procedures, or observations of public behavior could be used if the research was under a program subject to the General Education Provisions Act. In addition, the Department of Education now proposed another departure concerning membership on IRBs. This departure resulted from the special concern about providing

additional safeguards for mentally disabled persons and handicapped children who are involved in research. Thus, the Department of Education proposed a rewording of language in section 107 of the Common Rule to apply to research under Department of Education auspices providing the following:

When an IRB reviews research that deals with handicapped children or mentally disabled persons, the IRB shall include at least one person primarily concerned with the welfare of the research subjects. If an IRB regularly reviews research that involves other vulnerable categories of subjects, such as non-handicapped children, prisoners, or pregnant women, consideration shall be given to one or more individuals who are knowledgeable about and experienced in working with these subjects.¹⁵

FDA had two departures from the proposed Model Policy. First, FDA indicated that it must diverge from the proposal with regard to research that takes place in foreign countries. For clinical investigations that take place in a foreign country and are conducted under research permits granted by FDA, FDA must follow provisions of the Food, Drug, and Cosmetic Act; in other words, FDA does not have the authority to accept the procedures followed in a foreign country in lieu of the procedure required by FDA's authorizing legislation. The second departure was in the area of informed consent requirements. The Food, Drug, and Cosmetic Act requires that informed consent be obtained from all those enrolled in clinical investigations except in limited circumstances. Therefore, the FDA could not use the waiver provision offered in the proposed Model Policy.

Three More Years

Three years, and another round of public comments were to pass before publication of a final rule in 1991. Of course, during those years, there would be yet another change of administrations, another team of new players, and a new thrust to miniize regulations. The majority of public comments made on the 1988 "Notice of Proposed Rulemaking" were in three categories. First, some commentators were concerned because Sec.103(b)(5) of the Common Rule required institutions holding assurances to report unanticipated problems or scientific misconduct to department and agency heads. "Scientific misconduct" reporting appeared to expand the role of the IRB into areas covered by other regulations and policies and handled through channels other than the IRB in many institutions.

Additional concerns were raised about which kinds of suspensions of research made by the IRB had to be reported to department and agency heads—for example, whether suspensions simply for tardiness in submission of materials had to be treated the same way as suspensions for some substantive reason relating to the research. In response to concerns, the Interagency Human Subjects Coordinating Committee dropped from the Common Rule the requirement to report scientific misconduct. Further, the Preamble to the Common Rule clarified that reports did not have to be made to the heads of departments or agencies, but that they would be made to whomever in those organizations was delegated authority. Agencies had the flexibility to establish channels of reporting to meet their own individual requirements.

Another major concern involved the composition of IRBs. The majority of the comments were directed to the departure from the proposed Common Rule requested by the Department of Education in 1988. As noted, the department proposed that when an IRB reviews research that deals with handicapped children or mentally disabled persons, the IRB should include at least one person primarily concerned with the welfare of the research participants. The majority of the 21 commentators on this matter thought that the proposed departure was unnecessary and that there were many other groups that might need special representation on the IRB.

Negotiations in the OSTP and the OMB took place over many months so that a suitable arrangement could be worked out and all of the participating departments and agencies could move on to promulgate the Common Rule. The Department of Education withdrew its proposed departure regarding the Sec.101(b)(3) exemption and accepted the language we have today. The secretary of the Department of Education decided, however, to address the concerns outlined in the 1988 proposed departure concerning IRB composition by amending other regulations concerning the department's National Institute on Disability and Rehabilitation Research (34 CFR parts 350 and 356). In addition, the word *handicapped* was added to the examples of potentially vulnerable populations found in Sec.107 of the Common Rule.

A further set of comments involved the proposed exemptions. Some expressed concern that some of the exemptions would allow sensitive data to be used in such a way that subjects would be at risk. The regulations at 45 CFR 46 Subpart D, the so-called Children's Regulations promulgated by DHHS in 1983,¹⁷ do not permit research involving survey or interview procedures, or observation of public behavior, except when the investigator(s) do not participate in the activities being observed.

The proposed Final Rule introduced a footnote to indicate that the exemptions could not be used for children. A provision of DHHS regulations was thus added with virtually no public input as an additional protection to children as a class of vulnerable individuals.

The area that had previously caused so much comment, the "grace" period, was again the area most addressed by the public in comments on the Notice of Proposed Rulemaking. Again, commentators wanted 60 days after submission of a research application or proposal to provide certification of IRB review and approval, as had been customary in DHHS policy. The Preamble to the Common Rule indicated that many federal departments and agencies do not have application review schedules that correspond to those of DHHS. A 60-day grace period is without relevance to their review systems. The proposed Final Rule made no reference to such a grace period, but rather indicated that certification must be submitted with the application or proposal or by such later date as may be prescribed by the department of agency to which the application or proposal is submitted. Thus, the timing was left to an administrative level of decision in each department or agency.

Finally, on June 18, 1991, OSTP published the Federal Policy for the Protection of Human Subjects as a Final Rule.¹⁸ Upon promulgation of the final rule, the Interagency Committee became a temporary subcommittee of the FCCSET Committee on Life Science and Health (CLSH) and was redesignated as the CLSH Human Subjects Research Subcommittee. Sixteen federal departments and agencies had signed on, and the Central Intelligence Agency, which was required by Executive Order to follow DHHS rules, was also included. At last, after a decade of incubation and

nurturing, the Common Rule, as it has come to be known, was born.

Now that the Common Rule has been in effect for more than a decade, its strengths and weaknesses have been probed and are better understood. Although the adoption of the Common Rule was itself a major milestone and accomplishment, its promise has never been fully realized, and perhaps never will be. Many have suggested that major and more fundamental reform may be necessary to achieve a more effective and efficient human research process. The DHHS Inspector General, the National Bioethics Advisory Commission (NBAC), the Government Accountability Office, and the Congress have questioned whether such reforms can be accomplished under the regulatory framework of the Common Rule. Understanding the basis for these concerns is critical for continuing progress.

The Following Years

In 1994, the Human Subject Research Subcommittee (HSRS) was rechartered under the auspices of the Committee on Health, Safety and Food of the National Science and Technology Council (NSTC), the successor to FCCSET. A restructuring of NSTC committees resulted in the redesignation of HSRS as a subcommittee of the NSTC Committee on Science (COS) in 1997.

On October 3, 1995, President Clinton issued Executive Order 12975, Protection of Human Subjects and Creation of National Bioethics Advisory Commission, requiring, among other provisions, each department and agency that conducts, supports, or regulates research involving humans to review the protections of the rights and welfare of humans in research that are afforded by the department's or agency's policies and procedures and report to NBAC. Furthermore, the Executive Order required that, to the extent practicable and appropriate, each affected department and agency develop professional and public education programs to enhance activities related to the protection of humans involved in research.

The Human Subject Research Subcommittee still exists as of 2007, and retains a coordinating role in interpreting policies and exchanging information about human research participant protection issues, but it had not attempted major harmonization efforts to streamline the federal regulatory and oversight processes for human research. Shortly after the creation of OHRP in June 2000, the charter for the subcommittee was revised to include other departments and agencies that were not part of the original group that promulgated the Common Rule or participated in its development. Additions included the Smithsonian Institution, the Appalachian Regional Commission, the National Foundation on the Arts and the Humanities, the Nuclear Regulatory Commission, the Social Security Administration, and the Small Business Administration.

Originally chaired by the director of OHRP, the Human Subject Research Subcommittee is now chaired by designees from both OHRP and the National Science Foundation. This structure essentially reflects the shared chairmanship of the parent Committee on Science, without a specific cochair from OSTP. The emphasis on behavioral and social science research relative to biomedical research is perhaps now more prominent given the change in leadership for the subcommittee. Organizationally and administratively, the Human Subject Research Subcommittee is

hierarchically placed so as to report to the NSTC Committee on Science, and it has limited autonomy and no policy-making authority.

Under its new charter and operating procedures, the subcommittee is charged with coordinating interpretation of policies and procedures for protections of humans involved in research across federal agencies, but it has made only modest progress in this area relative to the magnitude of the task at hand. The subcommittee also attempts to integrate interdepartmental approaches for the protection of human subjects, thereby supporting the department and agency heads who promulgated the Common Rule and other departments and agencies to which Executive Order 12975 applies. In so doing, the subcommittee provides a source of advice and a mechanism for development of a consistent approach to implementation of the final Common Rule, as well as a clear and uniform interpretation of the Common Rule and related federal policies.

The major strength of the subcommittee at this point in time is that it serves as a consistent and responsible forum for networking and exchange of information comparing and contrasting implementation practices. It also serves as a body from which federal liaisons and experts can be drawn to support work of such groups as the DHHS Secretary's Advisory Committee on Human Research Protections. Members of the subcommittee represent the interests and views of their own departments and agencies, and major regulatory or policy change requires agreement of all departments and agencies at the highest level before change can occur. Leadership of OMB and OSTP, or some other authority above the departments and agencies, is required now as it was in the past when the Common Rule was created. This makes changing the Common Rule difficult, even when change is consistent with the subcommittee's charge.

An example is the initiative to secure adoption of a unified assurance mechanism for use by all Common Rule agencies. Prior to December 2000, there had been a proliferation of several types of assurance mechanisms, both within DHHS and among the federal agencies. The assurance process had become an arcane paper-laden exercise in bureaucracy that utilized much of the resources and personnel of OPRR, focusing more on the assurance document itself than on substantive efforts to protect human subjects. The formal adoption in 2005 of a dramatically streamlined, uniform, federalwide assurance mechanism for the protection of humans in research—an effort spearheaded by OHRP, and endorsed by the Human Subject Research Subcommittee (or at least, not opposed by it)—was a significant accomplishment. That it took 5 years of discussions at the interagency level after approval by the Human Subject Research Subcommittee to secure final approval by OMB suggests that even when the agency representatives to HSRS may be in agreement, there is no assurance that others at the agency level will support a given change. Furthermore, changes are often subject to other procedural requirements, such as the Paperwork Reduction Act and the Administrative Procedure Act, compliance with which are necessary for OMB approval.

This example underscores the enormity of the achievement that we now call the Common Rule. It also demonstrates that without a central committee or office with appropriate authority to effect such changes, future efforts to simplify and harmonize policies and procedures across the federal departments and agencies for protection of human research participants established

within the framework of the Common Rule will not be easy or timely, even if greatly desired. In fact, in its 1998 report on the status of the national human subjects protection process,¹⁹ the DHHS Office of Inspector General concluded that the Common Rule might actually be an impediment to reform of the system because of the need to secure clearance and approval of any substantive changes from all of the signatory agencies.

The NBAC echoed this view and proposed the creation of an independent National Office for Human Research Oversight (NOHRO) to assume overall responsibility for federal human participant protection policies and their enforcement.²⁰ Over the past several years, legislation to strengthen and streamline the system for protection of humans in research has been introduced in both the House of Representatives and the Senate, but to date, none has advanced out of committee for votes on the floor, and few believe that much progress is likely until there is another tragedy resulting in harm to human subjects.

In the interim, several areas for action have been identified. Perhaps foremost among these is the need to harmonize provisions for additional protections beyond Subpart A for special populations of research subjects, including women and fetuses, prisoners, children, persons with impaired decision-making capacity, and those who participate in classified research. Such protections are currently provided for DHHS-supported or DHHS-conducted studies under Subparts B, C, and D, but these subparts have not been adopted by all of the signatories to the Common Rule. Within the past year, the DHHS Secretary's Advisory Committee on Human Research Protections, which replaced the National Human Research Protections Advisory Committee in 2002, continued to focus on the issues related to special protections, with participation by ex-officio members from departments and agencies other than DHHS. All recognize that making changes in the Common Rule through a regulatory change process will likely be a long and arduous path as all of the departments and agencies are tied together. This is unfortunate and somewhat ironic, because most major research institutions receiving federal support, under the terms of their institutional assurances, already apply the provisions of Subparts B, C, and D to all research conducted under those assurances regardless of the source of funding.

One of the greatest strengths of the Common Rule, ironically, is also one of its greatest weaknesses in practice. Because the Common Rule was intentionally stated in general terms, essentially providing guidelines and some requirements to implement the recommendations of the National Commission, its application permits a great deal of flexibility, but also requires a large measure of interpretation and good judgment. In an era when many institutions are still primarily concerned about the potential consequences of compliance failures, there is great hesitation to stray far from the well-beaten path.

Guidance on many of the provisions of the Common Rule has been offered by the federal agencies, but these are not always entirely consistent, leaving research institutions and their review boards in a difficult position. In some cases, the activity in question may be viewed by some agencies as research that is subject to regulation, whereas another agency may classify the very same activity as an educational exercise or a program evaluation that is not subject to regulation. Health services research, quality improvement activities, oral histories, and evaluation of education programs or public health programs are not discussed in detail in either the Belmont Report or the regulations, and agency guidance

has sometimes been insufficient or nonspecific. Additional guidance, in and of itself, may be useful on the one hand, but it can create even greater confusion when unusual cases arise that do not fit neatly within the analytical or practical framework used to formulate the guidance.

Many IRBs find it confusing, impractical, illogical, or even unethical to apply different regulations and standards for protection of humans in research simply on the basis of the source of support, particularly when the rules are supposedly based upon fundamental ethical principles for responsible conduct of research with humans, principles that ought to command widespread support. Indeed, the original intent behind promulgation of a true common rule, as envisioned by the President's Commission nearly a quarter century ago, was to avoid such confusion and its attendant inconsistencies and inefficiencies. Reconciliation of the outstanding differences in interpretation and application of the provisions of the Common Rule, and adoption of harmonized provisions for protection of those in need of protections in addition to those currently afforded under the Common Rule, ought to be a high priority for the federal government, not only for protecting the interests, rights, and well-being of research participants, but for promoting and facilitating the responsible conduct of high quality biomedical, social, and behavioral research in the interest of all. Many dedicated people are still striving to make it happen.

International Ethical Guidance From the Council for International Organizations of Medical Sciences

The Council for International Organizations of Medical Sciences (CIOMS) was formally constituted by the World Health Organization (WHO) and the United Nations Educational, Scientific, and Cultural Organization (UNESCO) in 1949, and it still remains under the aegis of these two specialized UN agencies. Today, CIOMS has more than 70 international and national members, representing a significant proportion of the world's biomedical scientific community. Much of its work in the field of bioethics has been undertaken in close cooperation with WHO. In particular, its 1982 Proposed International Guidelines for Biomedical Research Involving Human Subjects—its first effort to generate guidance in this field—was the outcome of a joint project between CIOMS and WHO. The purpose of these proposed guidelines was to indicate how the ethical principles that were set forth in the 1975 version of the World Medical Association's Declaration of Helsinki¹ could be effectively applied, particularly in developing countries, given their socioeconomic circumstances, laws and regulations, and executive and administrative arrangements.

Just over a decade elapsed before the 1982 proposed guidelines were revised and, following very extensive consultation, the 1993 International Ethical Guidelines for Biomedical Research Involving Human Subjects were formulated and promulgated. Numerous innovative developments in biomedicine and new public health, ethical, and social challenges regarding research with humans in the 1990s required CIOMS to initiate, at the end of 1998, a process to update and revise its 1993 guidelines to respond to these new and often difficult questions. The revised version of the CIOMS Guidelines appeared in 2002.²

New Ethical Challenges for Biomedical Research

Research on the effectiveness and safety of disease treatment, diagnosis, and prevention has increased in developing countries, where the application of ethical principles formulated in industrialized countries requires careful consideration and adaptation. However, HIV/AIDS, malaria, tuberculosis, diarrhea, respiratory infections, and many neglected diseases are most prevalent in developing countries, and their control requires local research. Yet traditions of scientific research and the infrastructure for it are limited in many of these poorer locales.

Several new issues and questions have recently arisen in the context of multinational research. For example, low-income developing countries and countries in transition with many untreated patients have become attractive partners for multinational clinical trials. In these circumstances, the use of comparators other than the "best current therapeutic method" by the external sponsor have prompted lively discussion in the scholarly literature.^{3–13} The rationale behind the departure from the "best current therapeutic method" standard is that there is a need to test low-cost and technologically appropriate public health solutions that poorer countries can afford, even if this means that comparators in such trials are not the best current interventions. Among the questions raised are the following: Is it not exploitative to conduct a clinical trial of a new product in a population that could not afford to buy it, making the benefits available only to the rich who live elsewhere? How has the study in question affected the research participants, their communities, or health care in their own country? Was there any prior agreement to make the

new treatments available in the country concerned after termination of the study? If so, for how long will the new treatment be available? Is the new treatment affordable and sustainable there? (See Chapters 64–67.)

The revised 2002 CIOMS guidelines attempt to respond to questions of this kind, although consensus proved difficult to achieve during the revision process. The guidelines were designed to be of use, particularly in developing countries, in the following areas:

- Defining national policies on the ethics of biomedical research
- Applying ethical standards in local circumstances
- Establishing mechanisms for ethical review of clinical research, taking into account the 2000 revision of the Declaration of Helsinki¹⁴ (see Chapter 13)

The Revision Process

The revision process elicited strong support from both WHO and the Joint United Nations Programme on HIV/AIDS (UNAIDS), involved expertise from both developed and developing countries, and consisted of a series of steps over a period of nearly four years. The revision process is summarized in Table 16.1.

Structure and Content of the 2002 Guidelines

The 21 guidelines are preceded by a detailed description of the background, an introductory discussion, a brief account of other

Table 16.1

CIOMS Guidelines Revision Timeline

Date	Event
Dec. 1998	First draft prepared by a consultant
May 1999	Steering Committee reviews draft, recommends papers to be commissioned
Mar. 2000	International consultation (report published in November 2000) ³
Jan.–Mar. 2001	Five-day meeting of multinational drafting group; draft placed on the CIOMS website
July–Oct. 2001	Comments solicited from a wide range of institutions and individual experts
Oct. 2001	Multinational editorial group established
Jan. 2002	New draft placed on the CIOMS website
Feb. 2002	Draft text considered and endorsed by CIOMS Conference
Aug. 2002	Final text endorsed by CIOMS Executive Committee
Sept. 2002	Final text placed on the CIOMS website
Oct. 2002	Printed version of International Ethical Guidelines for Biomedical Research Involving Human Subjects published by CIOMS
Oct. 2002–2003	Procedures initiated to produce translations in as many languages as possible, notably WHO's official languages

international research ethics instruments and guidelines, an outline of the general ethical principles governing research ethics (based on the Belmont Report,¹⁵ described in Chapter 14), and a preamble that discusses the nature and significance of research involving humans.

General Guidance for Clinical Research

Any clinical study involving humans, including placebo-controlled trials, must be scientifically sound and justified, and ethically acceptable. These prerequisites are outlined in the following terms in Guideline 1:

The ethical justification of biomedical research involving human subjects is the prospect of discovering new ways of benefiting people's health. Such research can be ethically justifiable only if it is carried out in ways that respect and protect, and are fair to, the subjects of that research and are morally acceptable within the communities in which the research is carried out. Moreover, because scientifically invalid research is unethical in that it exposes research subjects to risks without possible benefit, investigators and sponsors must ensure that proposed studies involving human subjects conform to generally accepted scientific principles and are based on adequate knowledge of the pertinent scientific literature.²

The commentary on this guideline indicates that the methods used should be appropriate to the objectives of the research and that these considerations should be adequately reflected in the research protocol submitted for review to independent scientific and ethical review committees. These principles were widely accepted during the revision process; they have also been affirmed in a number of other recent documents providing guidance on ethical aspects of clinical research.^{16–19}

Ethical Review Committees and Sanctions

Guideline 2 outlines the responsibilities of ethical review committees, stresses the need for sufficient resources, and suggests that review of protocols could be supported by payments. Ethical review committees should be independent of the research team, and any direct financial or other material benefit they may derive from the research should not be contingent on the outcome of their review. The CIOMS Guidelines are in agreement with paragraph 13 of the Declaration of Helsinki, which states that the ethical review committee should conduct further reviews as necessary in the course of the research, including monitoring of the progress of the latter.¹⁴

Guideline 2 goes beyond the Declaration of Helsinki, however, by recommending that ethical review committees may withdraw their approval if this is deemed necessary, and must report to the health authorities any serious noncompliance with ethical standards. Governmental, institutional, professional, or other authorities may then impose sanctions as a last resort.

There is general agreement that the ethical review committee is to verify that the safety, integrity, and human rights of the research participants are protected, thereby providing public reassurance about the soundness of research. However, mechanisms and

procedures for local ethical review in some nonindustrialized countries are not well developed.^{7–10,19,20}

Externally Sponsored Research

This topic has inspired lively discussion in recent years.^{7–11,19,20} In Guideline 3, “externally sponsored research” means research undertaken in a host country but sponsored, financed, and sometimes wholly or partly carried out by an external international or national organization or pharmaceutical company with the collaboration or agreement of the appropriate authorities, institutions, and personnel of the host country.

The guideline states that the investigator should submit the research protocol for ethical and scientific review not only in the country of the sponsor but also to the health authorities of the host country, as well as a national or local ethical review committee. The investigator should also ensure that the proposed research is responsive to the health needs and priorities of the host country and meets this country’s requisite ethical standards. Moreover, review of the protocol by the local ethical review committee is necessary to ensure that the means of obtaining informed consent are appropriate to local customs and traditions, as well as to assess the competence of the research team and the suitability of the proposed research site in the host country.

Research in Communities With Limited Resources

Guideline 10 states that research in populations or communities with limited resources should be responsive to the health needs and the priorities of the population or community and that any intervention or product developed, or knowledge generated, should be made reasonably available for the benefit of that population or community.

Prior to the trial, the sponsor and investigator should undertake negotiations with the representatives of stakeholders in the host country (such as the national government, the health ministry, local health authorities, and concerned scientific and ethical groups, as well as representatives of the communities and relevant nongovernmental organizations) to determine the practical implications of “responsiveness” to local health needs. In particular, they should discuss the reasonable availability of any potential intervention or product that the trial might develop.

The negotiations should cover the health-care infrastructure required for safe and rational use of the intervention or product, the likelihood of authorization for distribution, and decisions regarding payments, royalties, subsidies, technology and intellectual property, as well as distribution costs. Ideally, there should be an agreement in advance spelling out for whom, for how long, by whom, and at what cost a potential intervention or product resulting from a trial should be provided to the population with limited resources. These principles have also been adopted as a condition of externally sponsored research in certain other guidance documents.^{16,19,20}

For research studies such as Phase I or early Phase II studies with pharmaceuticals or candidate vaccines, and when the outcome is scientific knowledge rather than a commercial product, such complex planning or negotiation is rarely, if ever, needed.

Informed Consent

Guidelines 4–6 provide comprehensive guidance on informed consent. The consent process, the use of comprehensible language and information, documentation of consent, requirements for waiver of consent, renewal of consent, cultural considerations, and consent to use biological materials, biological specimens, and medical records for research purposes are all covered. A total of 26 categories of information that must be communicated to prospective research subjects are listed in Guideline 5.

“Informed consent” is interpreted to mean a decision to participate in research, taken by a competent individual who has received the necessary information; who has adequately understood the information; and who, after considering the information, has arrived at a decision without having been subjected to coercion, undue influence or inducement, or intimidation.

The design and methods of placebo-controlled studies are often rather complicated. To explain research designs such as randomization and double-blinding using simple language, and to assure full comprehension by the prospective research participant, requires time and effort on the part of the investigator; but there must also be an opportunity for the individual to seek clarifications and ask questions. These principles are necessary in order to assure full comprehension of the study design and to make it clear that a prospective participant could be randomized to a placebo arm of the study.

As a rule, the prospective participants of placebo-controlled studies should be volunteers. If an individual is not capable of giving informed consent, a placebo-controlled study can rarely be considered appropriate and must in all cases be approved by an independent ethical review committee.

Vulnerable Persons, Children, and Pregnant Women

The term “vulnerable persons” is interpreted in Guideline 13 to mean those who are relatively (or absolutely) incapable of protecting their own interests because they may have insufficient power, intelligence, education, resources, strength, or other needed attributes to protect these interests. In all instances, research with persons thought to be vulnerable requires “special justification” and the means of protecting their rights and welfare must be “strictly applied.”

Research with children is addressed in Guideline 14. The participation of children is indispensable for research into diseases of childhood as well as for clinical trials of drugs or vaccines that are intended for children. A sponsor of any new therapeutic, diagnostic, or preventive product that is likely to be indicated for use in children is obliged to evaluate its safety and efficacy for children before it is released for general distribution. Guideline 15 deals with research involving individuals who by reason of mental or behavioral disorders are not capable of giving adequately informed consent.

Guidelines 14 and 15 have a parallel structure and very similar content. In order to undertake research with children or those unable to consent by reason of mental or behavioral disorder, the following conditions must be satisfied: (1) the research question cannot be answered by research carried out with a less vulnerable population (e.g., competent adults); (2) the research must address an issue that is relevant to the particular study population (child-

dren and those unable to consent, respectively); (3) agreement to participate has been obtained to the extent of the individual's capabilities; (4) permission to enroll the individual in research has been granted by the appropriate authority (parent, family member or legally authorized representative); and (5) refusal to participate in the research should (almost always) be respected.

Guideline 16 provides guidance on the research participation of women. It states that investigators, sponsors, or ethical review committees should not exclude women of reproductive age from biomedical research, because the potential to become pregnant is not a sufficient ground for such exclusion. The guideline stresses the need for a thorough discussion of risks to the pregnant woman and to her fetus as a prerequisite for the woman's ability to make a rational decision to enroll in a clinical study. It further discusses the need for pregnancy tests and access to effective contraceptive methods.

According to Guideline 17, research with pregnant women should be performed only if it is relevant to the particular health needs of a pregnant woman or her fetus, or to the health needs of pregnant women in general. Reliable evidence from animal experiments, particularly regarding the risks of teratogenicity and mutagenicity, provides invaluable support for such studies.

Best Current Method, Active Comparator, and the Use of Placebos

There has been extensive discussion on the ethics of using placebo in comparative trials when a known therapy for the condition exists.^{3-6,8,19,20} Much of this discussion was prompted by the 2000 version of the Declaration of Helsinki, in particular, its paragraph 29. Paragraph 29 states that the benefits, risks, burdens, and effectiveness of a new method should be tested against those of "the best current methods" but that this does not exclude the use of placebo, or no treatment, in studies in which no proven method exists.¹⁴ When drafts of the revised CIOMS Guidelines were considered, interpretation of this paragraph became especially contentious as commentators raised the question of the standard of care to be provided to a control group.

When a method of treatment existed, those in favor of placebo use suggested that if the condition being studied was mild—such as baldness, smoking cessation, overweight, headache, allergic reactions, cough, or mild elevation of cholesterol or blood pressure—the use of placebo in comparative studies would be appropriate and ethical. However, they noted that proper surveillance of research participants should be assured, the duration of placebo use should be minimized, escape or reserve treatment should be available, and there should be valid informed consent from participants.

Furthermore, those favoring the use of placebos argued that the use of active comparators instead of placebos in controlled trials might produce unreliable results. The assay sensitivity in many conditions remains weak, the clinical symptoms and treatment response in some conditions may vary, or the spontaneous improvement rate may be high. Treatment response for certain conditions can also be modest and almost the same as with placebo. In these circumstances, a comparative study without a placebo arm may yield no reliable scientific results.

In fact, such clinical studies conducted without a placebo arm might be considered unethical because they may expose partici-

pants to unnecessary burdens and risks and also cause a waste of resources. In their discussion of a hypothetical comparative trial, Ezekiel Emanuel and Franklin Miller contend that the use of placebos instead of an active comparator may dramatically reduce the number of participants required to demonstrate a certain therapeutic response rate.⁶ Failure to use placebos in such comparative trials could be considered unethical. Similarly, Robert Temple and Susan Ellenberg argue that the acceptability of placebo-controlled trials is determined by whether research participants will be harmed by deferral of therapy.⁴ If they are not harmed, such trials can ethically be carried out.

The main argument against placebo use in comparative clinical trials includes the fact that, for a patient and a practicing physician, the comparison of a new therapy with existing therapies is the objective, rather than the comparison with placebo. An additional argument voiced against placebo use is that placebos may be harmful even in mild conditions, because as symptoms continue, the disease may worsen and may result in irreversible changes or even in death.

Many drug regulatory authorities, including the European Agency for the Evaluation of Medicinal Products²¹ and the U.S. Food and Drug Administration (at 21 CFR 314.126),²² however, have pointed out that they require placebo-controlled trials to demonstrate the efficacy and safety of new therapies, even in cases in which there is an existing therapy.

"Established Effective Intervention"

The CIOMS Guidelines depart in one respect from the terminology of the Declaration of Helsinki. "Best current method," the term used in the Declaration, is most commonly used to describe the active comparator that is ethically preferred in controlled clinical trials. For many conditions, however, there is more than one established "current" intervention, and expert clinicians do not necessarily agree on which is superior. In some cases in which there are several established "current" interventions, some expert clinicians recognize one as superior to the rest; some commonly prescribe another because the superior intervention may be locally unavailable, or prohibitively expensive, or unsuited to the capability of a particular patient to adhere to a complex and rigorous regimen.

In contrast to the Declaration of Helsinki's "best current method" terminology, the CIOMS Guidelines use the term "established effective intervention," which refers to all such interventions, including the best and various alternatives to the best. One could also hypothesize that this term may not exclude even placebo or no treatment as an intervention in some conditions. It is well known that placebo can be effective and is commonly used in some mild conditions and that application of no treatment is the best "therapeutic" intervention in some situations.

The CIOMS Guidelines suggest that in some cases, an ethical review committee may determine that it is ethically acceptable to use an established effective intervention as a comparator, even in cases in which such an intervention is not considered the best current intervention.

Appendices

There are a series of Appendices to the Guidelines. Appendix 1 consists of a list of 48 items to be included (when relevant to the

study) in a protocol (or associated documents) for biomedical research involving human subjects. Appendix 2 reproduces the 2000 version of the Declaration of Helsinki—including the Note of Clarification on paragraph 29, adopted in 2002, which approved the use of placebo even when a current therapy is available, if necessary “for compelling and scientifically sound methodological reasons” and if it does not pose serious risk. The phases of clinical trials of vaccines and drugs are elucidated in Appendix 3. The remaining three Appendices deal with nonsubstantive matters.

Conclusions

The 2002 CIOMS Guidelines described in this chapter provide guidance for the ethical conduct of clinical research, taking into account discussions prompted by the 2000 version of the Declaration of Helsinki and considerations related to externally sponsored research in resource-poor countries. Standard of care, availability after a trial of an intervention or product developed as a result of the trial, and the use of placebos as comparators aroused lengthy debate during the revision process. CIOMS considers that the individual guidelines and the commentaries thereon offer useful and practical solutions. They emphasize the need to involve experts and ethical review committees from resource-poor countries in negotiations prior to the conduct of clinical trials in these countries.

Epilogue

In 1991, CIOMS, in cooperation with WHO, formulated International Guidelines for Ethical Review of Epidemiological Studies. Again in cooperation with WHO, these guidelines are currently being revised, with input from a number of distinguished experts in the fields of ethics and epidemiology, as well as relevant scientific institutions, associations, and other entities. It is hoped that the revision process will be completed by the end of 2007. It is anticipated that the final Guidelines will closely resemble, in terms of structure and format, the 2002 International Ethical Guidelines for Biomedical Research Involving Human Subjects.

The Council of Europe

The Council of Europe and Its Involvement in Bioethics

Founded in 1949, the Council of Europe is an intergovernmental organization with a pan-European mandate to foster political, legal, and cultural cooperation between its 46 member countries. Its Convention and the protocols that have been negotiated under its aegis form a set of legally binding treaties addressing a wide variety of topics at the international level. The Council is distinct from the 25-nation European Union (EU), although all EU member countries are also members of the Council of Europe. Its aims, as specified by its Statute, are to protect human rights and strengthen pluralist democracy, to enhance European cultural identity, and to seek solutions to the major problems of our time such as the bioethical problems addressed by the Convention on Human Rights and Biomedicine.

The most tangible results of intergovernmental cooperation in the Council are European conventions, drawn up as contracts between signatory nations. Each nation accepts a number of obligations in return for acceptance of the same obligations by other nations. These treaties are not legal instruments of the Council of Europe as such, but owe their existence to the member nations that sign and ratify them. Even though the treaties have a life of their own, they are in many cases followed by expert committees set up within the Council of Europe.¹ The Council of Europe has drawn up more than 200 multilateral conventions.²

Bioethics Instruments of the Council of Europe Relevant to Clinical Research Ethics

The Convention on Human Rights and Biomedicine

The Convention on Human Rights and Biomedicine is the first international agreement on the new biomedical technologies. Its full title is the Convention for the Protection of Human Rights and Dignity of the Human Being with regard to the Application of Biology and Medicine. It was opened for signature on April 4, 1997, in Oviedo, Spain, and by 2006, 34 countries had signed and 19 had ratified it, putting it into effect in those countries (see Tables 17.1 and 17.2). In addition to member countries, the following countries that took part in the preparation of the Convention may sign: Australia, Canada, the Holy See, Japan, and the United States. Mexico has requested permission to sign, and this has been granted by the Committee of Ministers.

The Convention on Human Rights and Medicine was prepared in order to establish a common, minimum level of protections for patients and human participants in research throughout Europe. Finding a consensus on such a minimum level was not a simple task. The traditions and approaches of some countries favored stringent prohibitions in some spheres. Others believed that some prohibitions could be seen as paternalistic and could deprive individuals of the choice, as well as the opportunity, to receive

Table 17.1

Hungary	Romania	of Macedonia

some of the benefits from biomedicine. A balance also needed to be found between the freedom of research and the regulation of research to protect research participants.

Now or in the future, some countries may wish to offer a yet higher standard of protection; the Convention was drafted with such a possibility in mind. Article 27 (Wider Protection) states that none of the provisions shall be interpreted as limiting or otherwise affecting the ability of a party to grant a wider measure of protection with regard to the application of biology and medicine than is stipulated in the Convention.

The Convention first came into force on December 1, 1999. It is up to the countries that have signed and ratified it to implement its provisions in their national legislation. This process is followed by the Secretariat, specifically by the Bioethics Department and the Steering Committee on Bioethics (CDBI, Comité Directeur pour la Bioéthique) at the Council of Europe. These bodies also provide assistance, if needed, to signatories to adapt their institutions and legislation to the requirements of the Convention.

The Convention gives precedence to the human being over the sole interest of science or society. Its aim is to protect human rights and dignity, and all of its articles must be interpreted in this light. The term “human rights” as used in the title and text of the Convention refers to the principles enunciated in the European Convention for the Protection of Human Rights and Fundamental Freedoms of November 4, 1950, which guarantees the protection of such rights. The Convention on Human Rights and Biomedicine shares the same underlying approach as the 1950 pact as well as many ethical principles and legal concepts, and also elaborates on some of the principles found in that Convention.

Provisions of the Convention

Two types of provisions are contained in the Convention. Its first part is a codification of the principles of modern medical law in regard to informed consent and the protection of those unable to consent. Its second part addresses biomedical research and the new biomedical technologies, and provides that newly arising issues can be addressed in additional protocols. Thus, the Con-

Table 17.2

vention and its protocols are a system that can respond to new (and sometimes threatening) developments in biomedicine. An example of such a response was the rapid preparation of a protocol prohibiting human cloning after the disclosure of the birth of Dolly, the first cloned mammal, in late 1997. Another example is the provision of the draft Protocol on Biomedical Research addressing research in nonparty States (Article 29), which was developed in response to allegations of exploitation by Western researchers of research subjects from developing countries and central and eastern Europe.

Five additional protocols were originally proposed to supplement the Convention on Human Rights and Biomedicine. In order to address the ethical and legal issues raised by present or future scientific advances, protocols on the prohibition of cloning human beings and on transplantation of organs and tissues of human origin already have been opened for signature. In 2005, a draft protocol on human genetics was being written by a working party of high-level experts nominated by Council member states with the assistance of the Secretariat.

The so-called Additional Protocol on Biomedical Research was approved by the CDBI in June 2003. The Committee of Ministers of the Council of Europe, following its usual procedure, decided to send the draft Protocol to the Council of Europe’s Parliamentary Assembly for an opinion in September 2003. It was opened for signature in January 2005, and by late that year had been signed by a dozen countries.

The Convention’s purpose and object are set out in its Article 1: protecting the dignity and identity of all human beings and guaranteeing, without discrimination, respect for the integrity, other rights, and fundamental freedoms of every person. The Convention clearly states that an intervention in the health field may be carried out only after the patient has given free and informed consent (Article 5). It also provides safeguards for people who are unable to consent (Article 6); these include a requirement that the intervention be only be for that person’s direct benefit, that when a minor is involved, the person or body responsible for that minor by law must authorize any intervention, and that the opinion of a minor must be taken into consideration as an increasingly determining factor in proportion to his or her age and degree of maturity.

Requirements for research to be undertaken on persons in the fields of biology and medicine are set out in the Convention in the chapter on scientific research as well as in other chapters, in particular, in the 2005 Additional Protocol Concerning Biomedical Research. The general rule for scientific research is set out in Article 15. It states that scientific research in biomedicine shall be

carried out freely, subject to the provisions of the Convention and the other legal provisions ensuring the protection of the human being. The freedom of scientific research is a constitutionally protected right in some of the member states. For example, Article 20 (“Freedom of Science”) of Switzerland’s Constitution states: “The freedom of scientific research and teaching is guaranteed.”³

The protection of persons who are unable to consent to research and of embryos *in vitro* are both specifically addressed in the Convention itself. Article 17 states that research on a person not able to consent to research may be undertaken only if the Convention’s protective conditions are met, and it sets stringent conditions for permitting research that does not have the potential to produce results of direct benefit to the health of a person who is unable to consent. Such research may be approved if it has the aim of ultimately benefiting persons in the same age category, or afflicted with the same disease or disorder, or having the same condition, through significant improvement in scientific understanding of the condition, disease, or disorder. In addition, the research must entail only minimal risk and minimal burden for the individual concerned.

Article 18 of the Convention prohibits the creation of human embryos for research purposes and states that where the law allows research on embryos *in vitro*, that research must ensure adequate protection of the embryo. However, it does not prohibit research on excess embryos created for purposes of *in vitro* fertilization.

The Additional Protocol on Biomedical Research

The Additional Protocol on Biomedical Research will be the first legally binding international instrument to address the whole field of biomedical research, and it is not confined to pharmaceuticals.^{4,5} The provisions of Articles 1 to 32 of this Protocol will be regarded as additional articles to the Convention on Human Rights and Biomedicine for the parties, and all the provisions of the Convention will apply accordingly.

The scope of the Protocol is set out in Article 2. The full range of research activities in the health field involving interventions on human beings are covered. This includes all phases of a research project, including selection and recruitment of participants. Paragraph 3 of this article states that, for the purposes of the Protocol, the term “intervention” covers physical interventions. It includes other interventions insofar as they involve a risk to the psychological health of the participant. The term “intervention” must be understood here in a broad sense; in the context of this Protocol it covers all medical acts and interactions relating to the health or well being of persons in the framework of health-care systems or any other setting for scientific research purposes. Questionnaires, interviews, and observational research taking place in the context of biomedicine constitute interventions if they involve a risk to the psychological health of the person concerned. One ramification of defining such research as coming within the scope of this Protocol is that review by an ethics committee would be required. The ethics committee could point out any potential problems in the research project to those submitting it for review. The Protocol does not address established medical interventions independent of a research project, even if they result in biological materials or personal data that might later be used in biomedical research. However, research interventions designed to procure biological materials or data are within the scope of the Protocol.

Research on archived biological materials and data is not covered by the Protocol. This is a point on which it differs from the 2000 version of the World Medical Association’s Declaration of Helsinki, which includes “research on identifiable human material or identifiable data.”^{6,7} As noted above, an “instrument” on research on archived biological materials has been prepared by a working party of the CDBI. The instrument contains a chapter addressing biobanks, such as those recently developed in Estonia, Latvia, and the United Kingdom.⁸ The CDBI has decided that this instrument should be a recommendation and not an additional protocol to the Convention. The Additional Protocol on Biomedical Research does not apply to research on embryos *in vitro*, but does apply to research on embryos *in vivo*.

The Protocol further states that research may only be undertaken if there is no alternative of comparable effectiveness. Comparable effectiveness refers to the foreseen results of the research, not to individual benefits for a participant. Invasive methods will not be authorized if other less invasive or non-invasive methods can be used with comparable effect. This does not imply that the Protocol authorizes or encourages using alternatives that are unethical. The Protocol does not evaluate the ethical acceptability of research on animals, using computer models, or other alternatives. These matters are addressed by other legal instruments, such as the Council of Europe Convention for the Protection of Vertebrate Animals used for Experimental and Other Scientific Purposes (1986) and relevant professional standards.

The Protocol specifies that research shall not involve risks to the human being disproportionate to its potential benefits. When medical research may be of direct benefit to the health of the person undergoing research, a higher degree of risk may be acceptable provided that it is in proportion to the possible benefit. For example, a higher degree of risk may be acceptable on a new treatment for advanced cancer, whereas the same risk would be quite unacceptable when the research is aimed at improving the treatment of a mild infection. A direct benefit to a person’s health signifies not only treatment to cure the patient but also treatment that may alleviate suffering, thus improving quality of life.

Article 7 requires that research be undertaken only if the research project has been approved by the competent body after independent examination of its scientific merit and multidisciplinary review of its ethical acceptability. It is acknowledged that in some countries, the ethics committee could also act as the competent body, whereas in other cases or in other countries, the competent body might be a ministry or a regulatory agency (for pharmaceuticals, for instance), which would take the opinion of the ethics committee into account in formulating its decision. This provision is not intended to curtail the freedom of research. In fact, Article 4 of this Protocol states that biomedical research shall be carried out freely. However, this freedom is not absolute. It is qualified by the legal provisions ensuring the protection of the human being. Independent examination of the ethical acceptability of the research project by an ethics committee is one such protective provision. Allowing unethical research to utilize human beings would contravene their fundamental rights. It is the responsibility of parties to designate within the framework of their legal system the ethics committee or a different competent body that would act as the decision making organ in order to protect those taking part in the research.

Chapter III of the Protocol addresses ethics committees. Its Article 9 requires that research projects be submitted to inde-

pendent examination in each country in which any research activity is to take place. This includes countries from which research subjects are to be recruited for research physically carried out in another country.

The article refers to “ethics committees.” The drafters considered that this term covers ethics committees or other bodies authorized to review biomedical research involving interventions on human beings. In many countries this would refer to a multidisciplinary ethics committee, but review by a scientific committee might also be required. The article does not require a positive assessment by the ethics committee because the role of such bodies or committees may be solely advisory in some countries.

The purpose of the multidisciplinary examination, after the precondition of scientific quality has been met, is to protect the dignity, rights, safety, and well-being of research participants. Further, the article states that assessment of the ethical acceptability shall draw on an appropriate range of expertise and experience adequately reflecting professional and lay views. The existence of an independent ethics committee ensures that the interests and concerns of the community are represented, and the participation of laypersons is important in ensuring that the public can have confidence in the system for oversight of biomedical research. Such laypersons must not be health-care professionals and cannot have experience in carrying out biomedical research. However, expertise in an unrelated field, such as engineering or accountancy, does not preclude a person from being able to express lay views within the meaning of this article. Thus this article further details what is meant by the term “multidisciplinary.” One may also conclude that it follows from this article that thought should be given to gender and cultural balance in the bodies carrying out the assessment. In creating an ethics committee, the nature of the projects that are likely to be presented for review should also be taken into account, and the committee may need to invite experts to assist it in evaluating a project in a specialized sphere of biomedicine. The ethics committee must produce an opinion containing reasons for its positive or negative conclusion. Whether the reasoning and conclusions are the final say on the project or are further considered by the competent body in granting or denying approval, the basis for the conclusion should be clearly comprehensible both to specialists in the field and to laypersons.

The independence of the ethics committee itself and of the individual members of the committee is addressed in Article 10. It states that parties to the protocol shall take measures to assure the independence of the ethics committees and that those committees shall not be subject to undue external influences. Members of the ethics committees must declare all circumstances that might lead to a conflict of interest. If such conflicts arise, those involved shall not participate in the review in question.

The fulfillment of the Convention’s and the Protocol’s requirement that multidisciplinary ethics committees review the acceptability of biomedical research projects has been particularly emphasized by the Council of Europe. Since 1997, the Council has been cooperating with its member countries on a program of multilateral and bilateral meetings, study visits, and informative materials on best practices in the ethical review of biomedical research—called the *Demo droit* Ethical review of Biomedical Research Activity (DEBRA). The independence of ethical review committees is paramount. As Senator Claude Huriet, who served as a *rapporteur* for a DEBRA meeting in Vilnius, wrote in the French Senate report on the protection of persons undergoing

biomedical research, the independence of the committees is the foundation of their credibility and legitimacy.⁹

Article 11 of the Protocol on Biomedical Research requires the researcher to submit all information necessary for the ethical assessment of the research project, in written form, to the ethics committee, and the Protocol’s appendix lists items that are to be provided if they are relevant to the research project. These include details of all payments and rewards to be made in the context of the research project and of any potential further uses, including commercial uses, of the research results, data, or biological materials. Payments to research participants or to the researchers themselves are not prohibited, but the Protocol requires that the ethics committee be informed about the types and amounts, and the committee would have to consider their appropriateness.

Having received this information, the ethics committee might conclude, for example, that a payment to a research subject is excessive in relation to the inconvenience caused and is, in fact, an inducement to accept a higher level of risk. On the other hand, lucrative financial incentives for a doctor to enroll a large number of patients in a research project might call into question the physician’s objectivity in explaining the positive and negative aspects of participation to his patients. Article 12 of the Protocol states that the ethics committee must be satisfied that “no undue influence, including that of a financial nature” has been exerted to persuade people to participate in research. If the ethics committee is not satisfied that no undue influence has been exerted, then the project should not receive a positive assessment unless changes are made to address the problem.

Neither the Convention nor the Protocol on Research takes a stand on patenting or on commercial use of research results, data, or biological materials. Rather, the fact that the motivation for participation in biomedical research for many persons may be out of solidarity is acknowledged. Information on foreseen commercial uses of their contribution to the research may be important to potential participants in making a decision on their participation. Again, in the interests of transparency, the ethics committee reviewing the research project and the potential research participant must be informed of such foreseen uses of the results, data, or biological materials.

Chapter IV of the Protocol addresses consent and information. Article 13 requires that people being asked to participate in a research project be given adequate information in a documented and comprehensible form, and it lists the items of information that they must receive. The same items of information must be furnished to those asked to provide authorization for the participation of a person in research (Article 16).

Consent to biomedical research is addressed by Article 14. Consent can be freely withdrawn at any phase of the research. Refusal to give consent or the withdrawal of consent shall not lead to any form of discrimination against the person concerned, in particular regarding the right to medical care. If the capacity of the person to give informed consent is in doubt, arrangements must be in place to verify whether or not the person has such capacity. Such persons may be those who have not been declared incapable of giving consent by a legal body, but whose capacity to give consent may be questionable due to an accident or due to a persistent or worsening condition, for instance. The aim of this requirement is not to set out any particular arrangement for verification but simply to require that such procedures exist. The arrangements would not necessarily be in the framework of

the court system; they could be developed and implemented through professional standards in the medical sphere. The researcher is ultimately responsible for verifying that the participants from whom he obtains consent have the capacity to give the consent.

If the person in question is not able to give consent, then Chapter V (“Protection of Persons Not Able to Consent to Research”) applies. Article 15 of this chapter is based on Article 17 of the Convention, which provides protection for those not able to consent to research. Both the Convention and the Protocol foresee the possibility of authorizing research in which there is no potential direct benefit to the research subject if additional conditions are fulfilled. One of these is that the research entails no more than minimal risk and minimal burden.

One of the critical comments made about the Convention was that it did not define “minimal risk” and “minimal burden.” The draft Protocol now offers such a definition. It specifies that the research bears a minimal risk if, “having regard to the nature and scale of the intervention, it is to be expected that it will result, at the most, in a very slight and temporary negative impact on the health of the person concerned.” It is deemed that research bears a minimal burden if it is to be expected that the discomfort will be, at the most, temporary and very slight for the person concerned. The Protocol adds that in assessing the burden for an individual, a person enjoying the special confidence of the person concerned shall assess the burden when appropriate. It might be said that this article is more explanatory than normative, but its political value in the very sensitive area of research on those not able to consent is unquestionable.

Chapter VI addresses specific situations, in particular those of persons in emergency clinical situations, pregnant or breastfeeding women, and persons deprived of their liberty. Research during pregnancy or breastfeeding is addressed by Article 18. The provision seeks to balance respect for the autonomy of the pregnant or breastfeeding woman with the need for special protection of the embryo, fetus, or child in the framework of any such research.

Safety and supervision are addressed by Chapter VII. Articles are included on minimization of risk and burden, assessment of health status, noninterference of research with necessary clinical interventions, and reexamination of ongoing research projects if relevant developments or events arise during the research. Article 23 (“Non-interference with Necessary Clinical Interventions”) of this chapter states that the use of placebo is permissible when there are no methods of proven effectiveness or when withdrawal or withholding of such methods does not present unacceptable risk or burden.

Research in countries not party to this Protocol is addressed by Article 29. It specifies that sponsors and researchers within the jurisdiction of a party to the Protocol who plan to undertake or direct a research project in a country not party to the Protocol shall ensure that, without prejudice to the provisions applicable in that country, the research project complies with the principles on which the provisions of the Protocol are based. For example, if the nonparty country does not require independent ethical examination of research projects, then the project in question should be reviewed in the country that is a party to the Protocol. This does not imply that the country which is party to the Protocol can override the laws of the nonparty country state or authorize research that the nonparty country does not approve. Instead, it means that the researchers may be required to observe additional

conditions, over and above those of the nonparty country, if they choose to conduct research there.

Article 35 of the Protocol provides for its re-examination within the Committee referred to in Article 32 of the Convention on Human Rights and Biomedicine no later than five years from its entry into force, and thereafter at such intervals as the Committee may determine. Article 32 of the Convention identifies this Committee as the Steering Committee on Bioethics (CDBI), or any other Committee so designated by the Committee of Ministers.

Article 34 of the Protocol deals with wider protections. The text lays down common standards with which countries must comply, but it allows them to provide additional protections to human participants in biomedical research. A conflict may arise between the various rights established by the Protocol—for example, between a scientist’s right of freedom of research and the rights of a research participant. However, the expression “wider protection” must be interpreted in the light of the purpose of the Protocol, as defined in Article 1, namely the protection of the human being with regard to any research in the field of biomedicine. In the example cited above, any additional statutory protection can only mean greater protection for a research participant.

Research on Biological Materials

The aforementioned work in the CDBI on research on biological materials was approved by its Steering Committee in October 2005 and submitted for adoption to the Committee of Ministers of the Council of Europe. The draft recommendation places a strong emphasis on consent to research on biological materials. When collecting samples, the initial consent for future use should be as specific as possible; materials collected for other purposes may only be used for research with appropriate consent or authorization. Exceptions are allowed if three conditions are fulfilled: (1) the research addresses an important scientific interest; (2) the aims could not be reached if one needs to obtain consent; and (3) there is no evidence that those who donated the tissue samples would object to such research use (Article 22). Those who have consented to tissue storage can withdraw their consent later or alter the scope of the consent. Tissue may not be removed after death without appropriate consent or authorization.

The recommendation also deals with transport of samples and discourages transfer to other countries that do not have an adequate level of protection (Article 16). Whenever samples are collected, clear conditions governing access and use of samples need to be established (Article 14).

Chapter V deals with biobanks, defined as collections of biological materials with a population basis that contain associated personal data, that will be used for multiple research projects, and that receive materials on a regular basis. The recommendation stipulates that such biobanks need to be subject to independent oversight and regular audits (Article 19), and that there should be a policy for access to the materials contained in them (Articles 19 and 20).

Conclusions

International cooperation is needed to extend the individual protections embodied in the Convention on Human Rights and Bio-

medicine beyond the member states of the Council of Europe. A number of observers have noted the tendency toward a certain homogenization of the law—in a positive sense—in the field of bioethics. Differences do remain between the approaches followed in the United Kingdom and on the Continent, and sometimes even more so between Europe and some other countries. However, the experience of the Convention, which is the first legally binding international instrument addressing the new biomedical technologies and has had tangible influence on national legislation, could be useful as the basis for a future, expanded discussion. The Standing Conference of European National Ethics Committees (COMETH) provides an opportunity for national ethics committees to come together biannually to discuss practical and ethical aspects of their work. Conferences such as the 1999 International Conference of the Council of Europe on ethical issues arising from the application of biotechnology will continue to be organized.

The European Community Directives on Data Protection and Clinical Trials

The two legislative instruments of the European Community (EC) with the greatest impact on medical research are Directive 95/46/EC, the “Data Protection Directive,”¹ and Directive 2001/20/EC on good clinical practice in clinical trials, the “Clinical Trials Directive.”² Although Directive 95/46/EC had to be implemented by October 1998, there has as yet been no case law at the EC level on its requirements in relation to medical research. The deadline for implementation of Directive 2001/20/EC was May 2004, and, again, no case law about it has yet emerged. This renders it difficult to make definitive legal statements about many aspects of these directives. Consequently, our analysis is to a degree speculative and tentative, and some of the statements we make might be controversial.

Outline

After a brief explanation of the legal force of European Community directives, we outline the basic requirements of the Data Protection Directive and the Clinical Trials Directive, with emphasis on the rights of research participants. In the context of Directive 95/46/EC, which is older and in some ways more complex, we indicate the rights of data subjects and the duties of the data controller and assess the scope of the exemption for medical research. We also discuss specific points such as the requirement for consent, the further processing of data for purposes not initially envisaged, and some issues surrounding the anonymization of data. We conclude this section with a comment on the likely impact of the directive.

We discuss Directive 2001/20/EC in the second part of the chapter. We examine the role given to independent research ethics

committees (RECs) to protect the rights of research participants, the duties of research sponsors in relation to RECs, and the time limits for an REC to give an opinion. We also discuss some problematic aspects of the directive and evaluate its likely impact on medical research, in particular, highlighting the connection between the two directives regarding the role of RECs in ensuring data protection. We make brief reference to the Directive on Good Clinical Practice (2005/28/EC), which was to have been implemented nationally by January 29, 2006.³

The Legal Force of EC Directives

EC directives are legally binding on states of the European Economic Area (EEA), which comprises Iceland, Liechtenstein, and Norway in addition to the member states of the European Union. EC directives are directed in the first instance at member states, not individuals. Clinical researchers need to attend to their national law implementing an EC directive. However, as explained below, an EC directive informs the interpretation of national law and its provisions are applicable across countries. For these reasons, individuals will be assisted by some understanding of EC directives as well as of their national law.

EC directives have two parts: a preamble made up of recitals, and an operative part consisting of articles. Articles prescribe what must or may be achieved by implementation in national laws. Recitals, in addition to describing the legislative basis and context of the directive, provide reasons on which the directive is based and thus guidance on interpreting the articles. They are important because national authorities are required to interpret national law in the light of the purpose of the directive.⁴ If a member state has failed

to implement a directive, or if its implementing provisions are incompatible or not sufficiently precise, then any national provision must give way to EC law.⁵ This holds *except* when the national law gives effect to an international obligation entered into before the member state became bound by the relevant Community treaty.⁶

Directive 95/46/EC—the Data Protection Directive

Aims of the Data Protection Directive

The aim of this directive is to enable the free flow of personal data while ensuring that fundamental rights and freedoms—in particular, but not limited to, privacy—are safeguarded (Article 1, Recitals 3 and 10). In so doing, the directive (see Recital 11) gives substance to the Council of Europe Convention for the Protection of Individuals with Regard to Automatic Processing of Personal Data of 1981.⁷ It is therefore more accurate to view adequate safeguarding of fundamental rights and freedoms as a condition of the free flow of personal data, rather than as something merely to be weighed in the balance against having such a flow.

The directive has direct relevance for data collected and stored for research purposes. For example, there are specific rules for how long data can be stored, specific requirements for informed consent, and rules for future research use of stored data. Researchers and RECs need therefore be aware of the specific requirements of the Data Protection Directive, which may at times be more stringent than those required by research ethics regulations and guidelines.

Provisions and Definitions

At the risk of oversimplification, the directive lays down five principles of data protection (Article 6), specifies that data subjects have certain rights (Table 18.1), imposes certain duties on data controllers (Table 18.2), prohibits data controllers from processing sensitive personal data unless certain conditions are met (Table 18.3), and charts the official responsibilities of member states (Table 18.4).

There are some operative definitions: *Data controllers* are defined as any persons or institutions (private or public) that individually or jointly determine the purposes and means of processing (Article 2(d)). *Personal data*⁸ is any information relating to an identified or identifiable natural person (*data subject*). Recital 26 specifies that data is personal if indirect identification is reasonably likely by the data controller or any other person. Although it may seem obvious that this means that data is personal if anyone is reasonably likely to be able to identify the data subject

Table 18.1

The Rights of Data Subjects

Data subjects have the right to the following:

- Access their personal data (Article 12)
- Object to processing of personal data on pressing legitimate grounds (Article 14(a))
- Object to the use of personal data for purposes of direct marketing (Article 14(b))
- Not be subjected to decisions that produce legal or other significant effects that are based solely on automated processing (Article 15)

Table 18.2

Duties of Data Controllers

Data controllers must do the following:

- Obtain data fairly by ensuring the individual is informed about the identity of the data controller, the persons or type of persons to whom the information will be disclosed, and the exact purpose the data is required for, including all secondary or future uses (Articles 10 and 11).
- Notify processing to the supervisory authority (Articles 19 and 28).
- Keep data only for the initially specified purpose and retain it no longer than necessary (Article 6.1(e)).
- Process data only in ways compatible with the initially specified purpose (Article 7.1(b)).
- Keep data safe and secure (Article 17).
- Keep data accurate, complete, and up-to-date, as well as adequate, relevant, and not excessive (Article 6.1© and (d)).
- Provide individuals with access to their personal data on request (Article 12).

Table 18.3

Conditions for Processing Data*

Personal data (Article 7)

Processing is legitimate only if there is unambiguous consent of the data subject; or if the processing meets one of the following criteria:

- Is necessary to perform or enter a contract to which the data subject is party
- Is necessary to comply with a legal obligation
- Is necessary to protect the vital interests of the data subject
- Is necessary in the public interest
- Is necessary in the exercise of official authority
- Is in the legitimate interests of the controller or recipients of the data and the protection of the fundamental rights and freedoms of the data subject is not overriding.

Sensitive personal data (Article 8, Recitals 33–36)

There is a blanket prohibition on processing sensitive personal data (Article 8(1)), which may be lifted under one of the following conditions:

- There is explicit consent of the data subject.
- Processing is necessary to protect the vital interests of the data subject (which, according to Recital 31 means “essential for the data subject’s life”) or of another person in cases in which the data subject physically or legally cannot give consent.
- The data has been manifestly made public by the data subject.
- Processing is necessary to establish, exercise, or defend a legal claim.
- Processing is in the substantial public interest (to be notified to the Commission, Recital 34, identifying scientific research and government statistics as an important reason of public interest that might justify processing).
- Processing is necessary for the purposes of preventive medicine, medical diagnosis, the provision of care or treatment, or the management of health-care services, and processing is by a health professional under the obligation of professional secrecy or by another person subject to an equivalent obligation of secrecy.

*It is important to note that these conditions are necessary but not in themselves sufficient. Just because a condition is met, it does not mean that all legal requirements are fulfilled.

Table 18.4
Official Responsibilities of Member States

Member states must, among other actions, do the following:

- Establish a public data protection authority (Article 28, Recitals 63 and 64).
- Require prior checking, by the authority or an independent data protection officer appointed by the data controller, of operations likely to pose specific risks to fundamental rights and freedoms (Article 20).
- Take measures to publicize all processing operations (Article 21).
- Provide judicial remedies for breaches of the specific rights (Article 22) and for the award of damages for violations (Article 23).
- Prohibit the transfer of personal data to countries outside the EEA unless certain conditions are satisfied (Article 26(1) and Recital 58), or the Commission has found that a country provides adequate protection. (This is of special relevance in the case of medical research, because this research is often sponsored by international companies. By 2007, only Argentina, Switzerland, and Canada had been recognized as providing “adequate protection.”)

indirectly, the United Kingdom has apparently interpreted this differently. The U.K. Data Protection Act defines personal data, in effect, as data from which the data subject can be identified directly by anyone or indirectly by the data controller.⁸ In the case of sensitive personal data, processing is prohibited unless certain conditions are satisfied. Data concerning health is in this category (Article 8(1), Recital 33).

The directive does not apply to anonymized personal data, but whether or not data can be considered anonymous is not always a straightforward decision. Anonymous data is sometimes confused and conflated with *reversibly anonymized* or *coded* data, in which personal data is encrypted so as to conceal a person's identity, but a key is being lodged with an overseer or custodian. However, it is evident from the directive's definition of personal data that coded data remains personal if the identity of the subject can be ascertained by anyone. Furthermore, if apparently anonymous health data can be combined with associated data, such as age of the person, and various locations and dates, it may be possible to deduce the identity of a patient reasonably easily, especially in the case of rare diseases.

Processing covers anything that can be done with personal data automatically or manually (Articles 2(b) and 3.1, Recital 27). However, the directive covers manual processing only if the data is part of, or intended to be part of, a *filing system* (Article 3, Recital 15), which is defined as a “structured set of personal data which are accessible according to specific criteria” (Article 2(c), Recitals 15 and 27). The directive does not cover processing of personal data for purposes that fall outside of the scope of EC law or processing for purely personal or household purposes (Article 3.2; Recitals 12, 13, 16).

Most of the directive's provisions are subject to exemptions under specified conditions. Space precludes a detailed presentation, but the scope for exemption for medical research will be considered in more detail.

The Scope for Exemption of Medical Research

Directive 95/46/EC does not explicitly provide an exemption for medical research. The scope for exemption must be in-

ferred and collated from exemptions provided for research or statistics generally and for processing involving personal data on health.

For example, the prohibition against further processing (Article 6(1)(b)) provides that data must be collected for an explicit purpose, which according to Recital 28 must be determined at the time of collection, and must not be further processed in a way incompatible with that purpose. Regrettably, no guidance is provided about what would constitute compatible processing. This creates problems for interpreting the provision that further processing for historical, statistical, and scientific purposes is not to be considered incompatible, provided that states provide appropriate safeguards that “must, in particular, rule out the use of the data in support of measures or decisions regarding any particular individual” (Recital 29). Under the same conditions and for the same purposes, the prohibition against keeping personal data in a person-identifying form for longer than necessary may also be lifted (Article 6(1)(e)).

The prohibition on processing sensitive personal data (Article 8(1)), which includes data relating to a person's health, may be lifted when there are suitable specific safeguards (Recital 34), if specified by national law or the decision of the supervisory authority to be in the substantial public interest (see Article 8(4)). The prohibition may also be lifted for medical purposes, provided that data are processed by a health professional or another person under an obligation of professional secrecy (Article 8(3), see also Recital 33). Medical research is not expressly listed as a medical purpose in the directive. Nonetheless, some states—like the United Kingdom in schedule 3, paragraph 8 of the 1998 U.K. Data Protection Act⁸—treat it as such for the purpose of lifting the prohibition of Article 8(1).

The duty to provide information (Article 11(1)) when personal data was not obtained from the data subject does not apply for statistics or historical or scientific research, if the provision of information would be impossible or would involve disproportionate effort, or if recording or disclosure of data is expressly provided for by law (see also Recital 40). This exemption is not applicable when data was obtained from the data subject (except, possibly, when the processing for statistics or historical or scientific research was not anticipated at the time that the data was obtained; see Recitals 39 and 40 and further below).

The rights of access to personal data granted by Article 12 may be limited “when data are processed solely for the purposes of scientific research or are kept in personal form for a period that does not exceed the period necessary for the sole purpose of creating statistics,” provided that the following criteria are met: the derogation is by a legislative measure; there is clearly no risk of breaching the privacy of the data subject; and adequate legal safeguards are provided—in particular, provided the data are not used to take measures or decisions regarding any particular individual (see Article 13(2)).

In principle, Article 13(1) provides the widest scope for exemption. Member states may restrict the scope of the obligations and rights for specific purposes such as national security, inspection, and others. It is difficult to see the applicability of much of this for medical research. If Article 13 is invoked, Article 28(4) requires each national supervisory authority to hear “claims for checks on the lawfulness of data processing lodged by any person.” At the very least, this suggests that member states may only appeal to Article 13 if they do so explicitly. Exemptions based on

protecting “the rights and freedoms of others” (Article 13(g)) would need to be assessed on a case-by-case basis.

Finally, member states may permanently exempt data that has been held in manual filing systems since before Oct. 24, 1998 from Articles 6, 7, and 8, when the data is kept for the sole purpose of historical research.

Explicit Consent

There is some debate over the need to obtain explicit consent—which some member states have interpreted to be written consent, even though there is no compelling reason to do so—each time a patient’s data is used in a new research project. The directive is not clear about whether the conditions for legitimate processing that are stated in Articles 7 and 8(2) are indiscriminate alternatives or whether consent must be sought wherever practicable and possible. If the jurisprudence of the European Court of Human Rights, which has persuasive force for EC law, is followed, then to process personal health data without explicit consent is to violate the right to private and personal life (Article 8(1) of the European Convention on Human Rights) and requires special justification to be permissible. This suggests that conditions other than explicit consent may be appealed to only if seeking explicit consent would be impracticable or disproportionate or would violate overriding values.⁹

Processing Data for Purposes Not Initially Declared

Article 10 applies to cases in which data was obtained from the data subject and requires the data subject to be informed about the purposes of the intended processing; Article 11(1) applies to cases in which data was not obtained from the data subject. However, the operative part of the directive does not cover the case in which data was obtained from the data subject, but the data controller now wishes to process the data for purposes not originally envisaged. It is arguable that, when data was obtained from the data subject for purposes not intended or envisaged at the time, such processing may proceed only if the data subject is contacted and informed. However, Recital 39, read with Recital 40, suggests that in relation to “unanticipated” disclosures to third parties, the data subject need be informed only if this would not be impossible or involve disproportionate effort.

In other words, where data was obtained from the data subject, the duty to inform the subject of unanticipated disclosures to third parties may be exempted (parallel to an Article 11(2) exemption to the duty under Article 11(1)). Thus, a purposive construction may permit extension to processing for purposes not “anticipated” at the time the data was obtained from the subject.¹⁰

Obtaining Data That Will Be Anonymized

It is not entirely clear whether the principles of protection apply to processing that will occur after personal data are rendered anonymous. For example, if researcher A collects data from data subject B, intending to render the data anonymous and process it for purpose P (or intends to pass nonpersonal data abstracted from the personal data to researcher C, and envisages that C will wish to process it for P), must A inform B of the envisaged processing and

its purpose? Because it is clear that anonymization is itself a process performed on personal data, and Article 10 requires the data subject to be informed of the purposes of processing, it is arguable that B must be informed at least of the intention to anonymize and the purposes of so doing. Whether this is indeed the case still requires authoritative clarification.¹¹

Likely Impact of the Data Protection Directive

The pharmaceutical industry and medical researchers, epidemiological researchers in particular, have been antagonistic toward the directive, and some have called for medical research to be exempted altogether.¹² However, such calls are probably premature and even misplaced. They are premature because the impact of the directive is difficult to assess without authoritative guidance on uncertainties about what is personal data, when data is rendered anonymous, and so on. They appear misplaced in that they do not discriminate among different kinds of medical research (not all of which is an unqualified good) and they ignore the principle that a fundamental right or freedom cannot be set aside unless there is an unavoidable direct conflict with another more important fundamental right or freedom.

As it is, the directive creates a good deal of scope for research to continue. It does, however, require the value of medical research to be weighed against fundamental rights and freedoms—in particular, privacy—in the way that Article 8(2) of the European Convention on Human Rights permits derogation from the right to private life, and it does not create a presumption that the needs, let alone the mere convenience, of medical researchers in pursuing their research objectives take precedence.

Much will depend on the attitude of the supervisory authorities and their willingness to take action. However, if the directive is to be effective, RECs must play a central role in judging whether the directive is being complied with. If this role is marginalized, or if there is insufficient attention to the need for RECs to be independent (bearing in mind that RECs traditionally are dominated by medical researchers, and the researchers’ involvement is essential for the value of medical research to be assessed expertly) or at least to be truly representative of opinion relevant to the public interest, then the directive will fail to achieve the objective stated in Article 1(1) in relation to medical research. Perhaps above all, the attitudes of medical researchers will be crucial. If they resist the directive’s aims, then there is a good chance that the directive will not be effective, no matter what else is done.

Directive 2001/20/EC—“Clinical Trials Directive”

The Clinical Trials Directive must be viewed in the context of Directive 65/65/EEC,¹³ the “Medicines Directive,” which requires medicinal products for human use to have been subjected to clinical trials before they can be licensed and placed on the market (see Recital 1). Article 1(1) of the Clinical Trials Directive requires member states to impose requirements of good clinical practice on clinical trials conducted on human subjects when these investigate medicinal products for human use as defined in Article 1 of the Medicines Directive. The Commission has issued some further technical guidance¹⁴ and recently, the Clinical Trials Directive has been supplemented by Directive 2005/28/EC on good clinical practice.

The initial impetus for the Clinical Trials Directive came from the pharmaceutical industry, which desires a harmonized process and set of standards for the granting of REC approval for clinical trials. Large parts of Directive 2001/20/EC are thus devoted to the role of RECs, and in this section we will focus on this aspect of good clinical practice management.

The Role of Ethics Committees

Article 2(k) of the directive defines an “ethics committee” as follows:

an independent body in a Member State, consisting of healthcare professionals and non-medical members, whose responsibility it is to protect the rights, safety and wellbeing of human subjects [see also Recital 2] involved in a trial and to provide public assurance of that protection, by, among other things, expressing an opinion on the trial protocol, the suitability of the investigators and the adequacy of facilities, and on the methods and documents to be used to inform trial subjects and obtain their informed consent.

A clinical trial may begin only if the REC and/or the competent authority consider that the anticipated therapeutic and public health benefits justify the risks. Compliance with this requirement must be permanently monitored (Article 3(2)(a)). Clinical trials on minors and on adults incapable of giving their consent may not proceed without the endorsement of a specialist REC or one that has obtained specialist advice (Articles 4(h) and 5(g)).

Article 6, among other things, does the following:

- Provides a list of matters that RECs must, in particular, consider when formulating their opinions.
- Permits member states to devolve consideration of some of these things to the competent authority that each state must set up under Article 9.
- Permits the REC to make one request only for supplementary information when examining an application.

There must be only one REC opinion in each member state (Article 7). The favorable opinion of an REC must be communicated to all member states via a European database to which access is restricted (Article 11(1)(d)), and which is to be treated as confidential (Article 11(3)).

The competent authority must inform the REC when it suspends or prohibits a clinical trial (Articles 12(1) and (2)). Member states may provide for inspection reports for the purposes of verifying compliance with good clinical practice to be made available to the REC (Article 15(2)). RECs must be given the power to obtain from the investigator additional information on any reported deaths of subjects (Article 16(3)).

Although the directive requires that the risk/benefit balance in a clinical trial be constantly monitored (Article 3(2)(g)), this is the only aspect that expressly needs monitoring, and there is no prescription that this aspect be monitored by RECs. Penalties for breach of the national laws implementing the directive are at the discretion of member states; the directive itself does not prescribe any penalties for failure to submit to an REC or to adhere to its decision. However, trials conducted in breach of the directive will not be able to obtain regulatory approval in the EU for the tested products. The responsibilities of research sponsors are presented in Table 18.5.

Table 18.5

Sponsors' Duties in Connection With RECs

Sponsors must do the following:

- Not begin trials without the favorable opinion of an REC (Article 9(1)); authorization may be implicit as well as explicit (Recital 11).
- Submit any substantial amendments to protocols to the REC (Article 10(a)).
- Inform the REC of any urgent safety measures in emergency situations (Article 10(b)).
- Report to the REC all relevant information about suspected serious unexpected adverse reactions as well as relevant follow-up information (Article 17(a),(b)).
- Inform the REC when a clinical trial has ended (see Article 10(c)).

REC Time Limits

Generally, the REC has 60 days from the date of receipt of a valid application to give its reasoned opinion to the applicant and the competent authority. The time limit is suspended during an ongoing request for supplementary information. In the case of trials involving gene therapy, somatic cell therapy, or medicinal products containing genetically modified organisms, an extension is permitted of a maximum of 30 days, and a further 90 days in the event of consultation with a committee. There is no time limit in the case of xenogenic cell therapy.

Data Protection and RECs

Article 3(2)(c) specifies that a clinical trial may be undertaken only if, among other conditions, the data protection rights of research subjects are safeguarded in accordance with Directive 95/46/EC (see also Recitals 2 and 17). Regarding this, Article 6(3) states that when RECs prepare their opinions they must consider, among other factors, the following:

- (g) the adequacy and completeness of the written information to be given and the procedure to be followed for the purpose of obtaining informed consent and the justification for the research on persons incapable of giving informed consent as regards the specific restrictions laid down in Article 3.

The question has arisen whether the competence to consider data protection can be taken away from an REC and delegated to another agency. Reading Article 3(2)(c) with Articles 6(3)(g) and 6(4) seems to imply that RECs have a responsibility to safeguard subjects' data protection rights under Directive 95/46/EC that may not be devolved elsewhere.¹⁵ This is reinforced by Article 6(1) of Directive 2005/28/EC,³ according to which RECs must have procedures to handle the requirements of, in particular, Articles 6 and 7 of Directive 2001/20/EC.

Presumably to assist RECs to assess data protection matters, Article 8 of Directive 2001/20/EC requires the Commission to provide detailed guidance on “the application format and documentation to be submitted in an application for an ethics committee opinion, in particular regarding the information that is given to subjects, and on the appropriate safeguards for the protection of personal data.”¹⁶ The role that this gives to RECs in relation to data protection matters is surely appropriate. Research subjects are in a

very weak position in relation to defending themselves from breaches of their data protection rights. They are usually not in a good position to find out that these rights have been violated. Even if they find out, they might be reluctant to complain, because they are in a vulnerable position in relation to their clinicians. In addition, they usually are not well placed to take legal action, through lack of knowledge and financial resources. Even if they do manage to take legal action, they might find the courts reluctant to award any meaningful redress unless there is some extrinsic harm. It is, therefore, altogether better for breaches to be prevented than for action to be taken only after a breach has occurred. RECs are in an excellent position to know of proposed breaches, and if they do not have responsibility to withhold approval from protocols that involve breaches of research subjects' data protection rights, a major means of protecting these rights will be absent.

Likely Impact of the Clinical Trials Directive

The Clinical Trials Directive is likely to have a positive impact in improving research subjects' rights in the area it covers, if only because it makes REC review a legal requirement for research to go ahead.

The interests of the pharmaceutical industry are clearly catered to in the time limits set for REC review and in the requirement for only one national opinion on the ethics of a clinical trial. Although implementation of these requirements will expedite ethical review, and that is a legitimate aim, the limits are arguably too tight and restrictive to be suitable in all cases if the safety and rights of research subjects are paramount.

The directive is restricted to clinical trials involving medicinal products for human use. From an ethical point of view, it is arguable that an opportunity has been missed to regulate clinical research generally. It must be noted that the directive's definition of good clinical practice has been complemented by the provisions of Directive 2005/28/EC. In Recital 8 of Directive 2005/28/EC, reference is made to the requirements of good clinical practice set by the International Conference on Harmonisation (ICH GCP),¹⁷ and the 1996 version of the Declaration of Helsinki¹⁸ is officially incorporated into Article 3 of Directive 2005/28/EC. This is significant because the Commission specifically chose to rely on the version in which the right of individual patients over the interest of science and society are framed in an especially strong manner. Nothing in either directive precludes member states from extending the requirements of good clinical practice in other areas, and many will choose to do so in order to simplify the structures of ethical review.

At the same time, cynics might suspect that the directive will serve to expedite research without necessarily giving greater protection to research subjects, because it will undoubtedly increase the appearance that such protection is improved. This has not stopped the pharmaceutical industry complaining that Directive 2001/20/EC will damage R&D (primarily on the grounds that a 60-day time limit for the REC to make a decision and a further 30 days for the competent authority to give approval is unacceptably long).¹⁹ Whether this will be the case will depend very much (as with Directive 95/46/EC) on the independence, transparency, and accountability of REC review structures, and on the extent to which RECs are able to play a part in data protection. It will also depend on national laws in relation to who might be a legal representative for a minor or an incapacitated adult. On many of these

matters, it will be possible to pass judgment only once member states have fully implemented the directive as well as its offspring, Directive 2005/28/EC.

National Bioethics Commissions and Research Ethics

I. Introduction

One of the more visible features of the current bioethics and public policy landscape is the existence of national and transnational commissions of experts in science, law, bioethics, medicine, religion, and related disciplines. Unlike individual bioethicists, the credentials, expertise, and functions of whom have been the subject of considerable study and commentary,¹⁻⁴ these commissions are less well understood. They exist in many countries, tend to be established in response to particular events, cases, or problems, and are increasingly being referred to by governments, courts, professional organizations, and the media.⁵⁻¹⁰

Given the tremendous growth in biomedical research across the globe, it is not surprising that ethical, legal, and policy issues in research involving humans would be among the topics addressed by many of these bodies. Many countries are now facing similar issues: How should informed consent be obtained in clinical trials? What is the proper structure and function of ethics review bodies? How should the most vulnerable be protected in studies? Are there obligations to provide any ongoing treatment to patients at the conclusion of a clinical trial, and if so, on whose shoulders should these obligations fall? These topics, and others such as the conduct of human embryonic stem cell research, xenotransplantation, and genetic studies using human tissue samples, have been the focus of reports, studies, and recommendations by commissions appointed by governments and other nationally recognized organizations.

The aim of this chapter is to provide an overview of national commissions with particular attention to their activities related to research involving humans. The chapter is divided into three sections. In Section I, we set the stage by providing a brief history of

the long-standing interactions between science, research, and government. In particular, we situate the existence and use of these commissions within a larger and richer context of the way advice can be provided on important social issues.

In Section II, we provide some working definitions of bioethics commissions gleaned both from the literature and from descriptive data obtained from a number of such commissions around the world. In providing a stipulative definition, we are able to examine these commissions and their work products, and we illustrate some of the ways that national commissions function in the area of research ethics.

In Section III, we discuss some of the implications for research ethics resulting from the existence of national commissions. In particular, we comment on the challenges that arise from trying to assess the potential impact that such commissions may have, both for their own countries and, given the growing number of these bodies, for research ethics issues that arise internationally.

II. A Brief History of the Interaction Between Science, Research, and Government

The gathering of scholars and experts to inquire into matters of social and political importance is a phenomenon that has been occurring for over 2,000 years. For example, the Great Library at Alexandria proved both politically and socially useful in its promotion of intellectual debate, scientific inquiry, and discovery through scholarly societies.¹¹ Scholars in various disciplines had met throughout early modern history in groups like the *Compagnie du Gai Sçavoir* (established in 1323);¹² the *Academia Platonica*

(1462–1522) founded by Cosimo de Medici to study Plato;¹³ and the Barber Surgeons of Edinburgh, later called the Royal College of Surgeons of Edinburgh.¹⁴ However, it was not until the 17th century that academies of science and medicine gained prominence throughout Western Europe. In the late 17th century, scholarly societies like the British Royal Society and the French Academy of Sciences began to conduct inquiries as a service for their governments. Later, as the relationship between science and government grew stronger, government-commissioned advisory bodies began to supplement (if not replace) the advice provided by independent scholarly societies. These temporary, specialized bodies became more common throughout the 18th and 19th centuries and were appointed for the sole purpose of reporting on topics of importance to the monarchy.

The use of royal commissions by governments established the precedent for using what in the United States are sometimes called “blue ribbon commissions”—groups of nationally and internationally renowned experts assembled to conduct inquiries and issue advice. One such blue ribbon commission, the Commission Charged by the King with the Examination of Animal Magnetism, led by Benjamin Franklin, investigated physician/scientist Anton Mesmer’s claims about the healing power of animal magnetism. Franklin’s commission rejected animal magnetism on both scientific and moral grounds,¹⁵ but more importantly, the commission was one of the first to concern itself with issues in research ethics: the use and selection of human participants in research, the ethics of using unscientific medical treatments, and the “influence of the imagination” (the placebo effect) upon patients.¹⁶ In the United States, the scientific establishment initially resisted the intermingling of science with politics. Scientists wanted to maintain a certain level of independence from government control and resisted the development of any state-sponsored institutions for research.¹⁷ Despite this early independence, the U.S. government eventually gave great weight to the utility of science for government and society.

By the middle of the 20th century, commissions ceased to consist solely of politicians and political advisors, and began to include civilians from a variety of academic disciplines and backgrounds. This democratization of science and research, particularly in the post–World War II era marked a significant change for science policy making, particularly in the United States. This change in the interaction between government, science, and society would have repercussions not only in the basic sciences but would extend to medical, social, and behavioral research. Just as medical research entered a golden era of unprecedented expansion at this time, the increasing use of humans in medical experimentation raised profound questions about the ethical issues arising from the involvement of humans in medical studies. Henry Beecher’s 1966 exposé of unethical conduct of research with humans published in well-respected research journals¹⁸ and the extensive discussions by Pappworth¹⁹ and Katz²⁰ contributed to a literature on medical research ethics that influenced both the public’s perception of the value of science and the trust that government had in the ability of science to regulate itself.

In 1974, the U.S. Congress established the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (the National Commission) “to identify the ethical principles of human subjects research and to recommend federal policy for research.”²¹ This was the first national bioethics commission in the United States, and it addressed important issues in research with humans, profoundly influencing both po-

litical and public opinion on medical practice and research in the process. In 1979, after preparing nine reports on topics such as research on the fetus, psychosurgery, and individuals who were institutionalized as mentally infirm, the National Commission published its most influential work, the *Belmont Report*, defining the ethical principles that ought to inform research involving humans,²² a document that still has an impact on medical research three decades later²³ (see Chapter 14). Since that time, six time-limited national bioethics commissions of one form or another have been established in the United States.²⁴

By the end of the 1980s, national bioethics commissions had been established in many other countries including Australia, Canada, Denmark, France, Hungary, Luxembourg, Malta, the Philippines, Sweden, the United Kingdom, and Zimbabwe. In 2005, national bioethics commissions existed in at least 85 countries, on every continent of the globe except Antarctica.²⁵

III. National Bioethics Commissions: Definitions and Characteristics

Although definitional matters seem less important than normative ones, it is helpful to set out what national commissions are before examining what they do. No definition of a national bioethics commission has been formally adopted, but a consensus is gradually emerging, one that largely is based on the literature describing the history of public advisory commissions generally;^{26–30} the history of bioethics commissions in particular;^{5–10,31} the experiences of commission members and staff about the role, function, and effectiveness of commissions;^{24,32–36} and the impact of these commissions.³⁷ Supplementing this scholarly work are the reports produced by the commissions themselves. To understand how commissions define themselves, we obtained reports from many who attended the Fourth Global Summit for National Bioethics Advisory Bodies in Brasilia (2003) and supplemented this material with information about commissions from the UNESCO³⁸ and the World Health Organization web sites.²⁵

Definitions

We reviewed reports of more than 50 commissions and found that they tended to have the following characteristics:

- They were national-level advisory bodies. By “national-level,” we mean that the commission aims to address bioethical issues deemed to be of importance to the country as a whole.
- They addressed issues in public bioethics. This characteristic is closely related to the one above, because issues of national importance can also be described as involving a notion of *public bioethics*—a term proposed more than a decade ago by John Fletcher who defined it as “[a] process . . . by which ‘society’ supports ethical inquiry prior to developing directions for public policy.”³⁹ This definition is supported by the analytic literature on governmental, particularly executive, advisory bodies in the United States and some other countries. This characterization is also complementary to an emerging consensus in the political science literature about the role and function of executive advisory bodies.^{26,29,40,41}
- They were established and funded either by a national government or other recognized national-level body. Although

most of the commissions that have contributed significantly to public discourse about research ethics were established by national governments or their agencies, a small minority were established by nongovernmental organizations (e.g., medical associations, foundations). Therefore, as in the first criterion, “national-level” also refers to a commission’s location within the political system. Local or regional bioethics review boards or committees within a given country were omitted.

- Their members represented different disciplines, competencies, and perspectives. This means that a commission would typically include various academic, private, political, and public points of view. Among the more intriguing and persistent issues facing commissions is the way in which public representation or public engagement occurs. Some commissions, like those in the United States, are required by law to include opportunities for public input—whether by including members of the public or by convening open meetings accessible to members of the public. Other commissions have no such requirement.

Commission Characteristics

In addition, there are a number of characteristics that help to understand these bodies. These characteristics are important to understanding how these commissions function in diverse ways around the globe.

(i) Creation

Some commissions were created to address a particular topic; others were put in place to anticipate and address certain types of topics. A number of theories exist about why governments and or heads of state use commissions for various public policy problems. One theory suggests that governments use commissions as responses to crises, for policy analysis, as long-range educational projects, as issue avoidance or misdirection, or as “window dressing.”⁴⁰ Bioethics commissions may emerge for several of these complementary reasons, but essentially they serve as a public response to particular controversial scientific or political events that present a public policy problem. As a general observation, bioethics commissions are often established in response to three primary cues: a scientific controversy, lack of knowledge, and lack of policy alternatives. In addition, when these three elements are satisfied, commissions can also be used as a means of resolving disagreement about which policy alternative is optimal.

In the area of ethical conduct of research with humans, commissions can be created as a means of generating research ethics guidance or providing oversight of human-participant research in a number of countries around the world. The U.S. National Commission arose from the establishment of a federal law, the *National Research Act*, which was itself the product of a series of prominent congressional hearings that highlighted concerns about research involving humans.⁴² In contrast, the U.S. Advisory Committee on Human Radiation Experiments was established in 1995 in response to specific allegations about the conduct of radiation research on both military personnel and civilians.⁴³ The two most recent commissions—the National Bioethics Advisory Commission (NBAC) and the President’s Council on Bioethics (PCB)—were established by a presidential Executive Order. However,

committees in other countries have had similar experiences in which public discourse and political attention to emerging issues in health care, science, technology, and research generated increased attention to the associated ethical, legal, and social issues and the need for policy analysis and education in these areas.^{10,44,45–47}

(ii) Scope

Governmental bioethics commissions can address either a wide or a very narrow set of public bioethical issues. Although the majority of commissions are given a broad mandate to deal with research ethics topics in general or as needed, a few single-issue bodies also exist, usually influenced by governmental officials and government priorities. In our sample, these commissions dealt primarily with issues in assisted reproduction or biotechnology research. The Spanish National Commission on Assisted Human Reproduction is asked to “inform or advise in respect to assisted reproductive technologies and . . . the investigation or experimentation upon human fertility, gametes, and preembryos.”⁴⁸ Alternatively, the Bioethics Advisory Commission of Singapore has included in its mandate “to protect the rights and welfare of individuals while allowing the biomedical sciences to develop and realize their full potential in Singapore, and for the benefit of humankind.”⁴⁹ This kind of broad mandate allows commissions to address a variety of issues related to research with humans, either at the discretion of the commission members or based upon input from political leaders. This kind of “broad scope” advisory commission appears to be more common than the “narrow scope” commissions.

(iii) Accountability

Substantial variation exists in regard to accountability among bioethics commissions. We found that commissions tend to exist in a number of locations within governmental systems. Although the majority of governmental bioethics commissions are accountable to ministries or departments (e.g., health, education, science, culture), these bodies are also located under the auspices of research councils, heads of state and their cabinets, and funding agencies. Because no patterns are apparent in regard to particular types of commissions and their government location, it is likely that the development of bioethics commissions in various countries is largely dependent upon contingent factors including leadership interest in research with humans, funding availability, and other political factors.

(iv) Governance and Oversight

Commissions also differ with respect to specific governance issues such as the frequency of meetings, rules of procedure (e.g., voting, consensus), budgets, and staffing. These characteristics are often determined by a commission’s terms of reference. These terms are usually written by the political authority to which the commission is accountable and vary according to the commission’s function. For example, some protocol review commissions meet only on an “as-needed” basis, when protocols require review; other commissions meet monthly while they are generating policy recommendations for a report. The terms of reference can also govern other aspects of a commission including membership, topics to be addressed, and the powers given to the commission.

(v) Locus of Authority

Although the majority of national commissions described in this chapter trace their origins to the executive or legislative branches of their national governments, other “national” bioethics commissions trace their origins to nongovernmental sources. As with government bodies, these commissions are created to address issues considered to be of national importance by a particular group of leaders interested in bioethics and consist of members who represent a diversity of expertise, typically including various professional interests. One of the most influential and effective of these independent commissions is the United Kingdom’s Nuffield Council on Bioethics. The Nuffield Council was established and is funded by a private foundation—the Nuffield Foundation—which is responsible for appointing the council’s chair, whereas members are selected by the chairperson and currently sitting members. The Nuffield Council has been one of the most active and productive advisory commissions in the world, having produced more than a dozen major reports on bioethics topics, eight of which relate directly to research ethics.⁵⁰

Other Bioethics Advisory Bodies

There are several countries whose primary public bioethics activity is not conducted through a national bioethics commission. These nongovernmental bioethics advisory bodies are of two different kinds: professional organization bodies and independent bioethics commissions. Often, economically developing countries conduct bioethics and public policy work in whatever institutions can support them and wherever interest in bioethics thrives. In some cases, these bodies can simply serve as nongovernmental sources of information and analysis. In other cases, these bodies may have an advantage over governmental commissions in that they are freer from political influence and limitations. On the other hand, the scope of authority and the influence of these bioethics advisory bodies may be much more limited than that of national bioethics commissions sponsored by governments.

A much smaller group of bioethics advisory bodies provide advice, recommendations, and information to professional associations and groups. Similar to national bioethics commissions, these professional bodies can serve a number of functions including policy recommendation, guidance generation, professional education, and protocol review. For example, the Cyprus Medical Association Bioethics Committee performed multiple functions including protocol review and policy recommendations on research ethics. It is one of three research ethics review bodies that have existed in Cyprus.⁵³ The most common location for these professional bioethics advisory bodies is in national-level medical societies or associations. Medical societies in the United States and the United Kingdom also serve similar policy, guidance, and educational functions.

IV. Commissions and Research Ethics

One hundred twelve national commissions have existed whose work has focused in whole or in part on issues arising from research involving humans. These commissions have addressed topics ranging from aging research to xenotransplan-

tation. Table 19.1 lists a range of topics addressed by these commissions.

Among national bioethics commissions, there is great variety in their functions with respect to research ethics. Below we describe a typology of various functions. These functions are not mutually exclusive, because a substantial number of commissions have served in more than one capacity. Moreover, a number of countries have or have had more than one national bioethics commission functioning at any one time. For example, Norway and Finland have a number of separate national-level research ethics commissions in areas such as medicine, the social sciences, and biotechnology. The presence of multiple bioethics commissions in a country often means that each commission serves a different role within the government.

Advice and Guidance

Advice is probably the most frequent service sought from national bioethics commissions. Commissions can be asked to provide advice on a wide range of bioethical issues or can be given a narrow mandate in just one area of public bioethics. Often these commissions are asked to conduct policy analysis and generate policy statements, as well as to provide general counsel to government officials or departments that require advice in regard to bioethical issues. Commissions can be given additional functions besides the provision of policy advice. Sometimes they can serve as protocol review bodies (usually serving as an appellate or specialized review body) or are given guidance or administrative powers. The first combination of duties has occurred in a number of countries including the Philippines, Slovenia, the United Kingdom, and China. Commissions combining policy advice and administrative duties are found in Mexico, Canada, Australia, and India. The United States has used national bioethics advisory commissions for three decades, with four commissions (the National Commission, the President’s Commission, NBAC, and the current PCB) producing more than 20 advisory reports.

Some bodies, like the Central Ethics Committee on Human Research in India, are given the authority to produce guidance for research ethics in their country. This commission produced Ethical Guidelines for Biomedical Research on Human Subjects in 2000. Guidance commissions are also created with other functions included in their mandate. Commissions in Australia, Canada, Japan, India, and Mexico provide policy advice in addition to preparing guidance. Two other countries, Denmark and

Informed consent	Vulnerable participants
International health research	Xenotransplantation
International clinical trials	

Thailand, combined guidance authority with the capacity for protocol review in their national bioethics commission.

Inquiry

Sometimes commissions are created to investigate an emerging policy issue about which there is insufficient information, policy alternatives, or consensus about which policy alternative is most justifiable. Commissions of this sort tend to have certain defined legal powers, such as subpoena power, that they exercise carefully. Internationally, a number of advisory bodies have been created to deal with such issues as human cloning and embryonic stem cell research, including commissions that rapidly emerged in response to public policy problems in countries such as Australia, Chile, France, the United States, and the United Kingdom.

Education and Training

A number of bioethics commissions have received the task of providing public and/or professional education on bioethical issues in their country. In particular, the Swedish National Council on Medical Ethics was charged to “stimulate exchange of information and ideas and promote discussion on new medical research and applications.”⁵¹ Similarly, commissions in Australia, Canada, the Dominican Republic, Estonia, and Greece each specifically mention an educational goal in their terms of reference.

Administration

Other governmental bioethics commissions function as administrators in dealing with regulatory issues in research ethics. In particular, Canada’s National Council on Ethics in Human Research (NCEHR) has a mandate to assist research ethics boards (REBs) in “interpreting and implementing guidelines,” assisting in resolving contentious issues in REBs, and “providing assistance to REBs” in quality control in review and oversight of research.⁵² Another such commission is Brazil’s National Commission for Ethics in Research, which similarly aims to foster and monitor review boards in its country.

Protocol Review

Governmental bioethics commissions frequently engage in research protocol review, often combining this role with another function such as policy advice or policy construction. Commissions can serve in a number of different capacities—for example, as national-level appeal bodies for resolving local ethics review committee disputes or confusion over research regulations. Other commissions conduct only specialized reviews: They review certain types of research protocols, such as gene transfer research (e.g., the U.S. Recombinant DNA Advisory Committee) or assisted reproduction and embryo research (e.g., the U.K. Human Fertilisation and Embryology Authority, and New Zealand’s National Ethics Committee on Assisted Human Reproduction). Particularly in countries with less extensive research infrastructures, commissions can also serve either as a national ethics review committee required to review all research in a given country or as an ethics review committee that reviews only research conducted in a national-level or government-sponsored organization. Examples of the latter occur in China, Cyprus, Gambia, Latvia, Slovenia, and

Zimbabwe. National-level institutional research ethics review bodies existed in three countries: Estonia, Kenya, and Venezuela. Some countries use their national ethics commission in a capacity that is complementary to local or regional research review. Australia is an example in which such a system is used.⁴⁴

Table 19.2 provides a list of the commissions and, where possible, their major functions.

V. Commission Impact and Influence

Assessing Impact

National bioethics commissions that address research ethics issues exist in many countries and carry out different functions. To date, little consideration has been given to assessing the impact of such advisory bodies on research ethics. This is due in part to the inherent difficulties in measuring the impact of a national bioethics commission. Elisa Eiseman recently assessed the impact of the U.S. National Bioethics Advisory Commission (NBAC) on public policy³⁷ using the following methods:

- Tracking and analyzing responses from government agencies and departments to commission reports and recommendations
- Tracking and analyzing responses from professional societies, organizations, and foundations to commission reports and recommendations
- Tracking legislation that was introduced or enacted abroad that was a result (direct or indirect) of reports and recommendations
- Tracking policies, statements, and other documents from national scientific, medical, and bioethics bodies and international organizations that refer to or are based on any of the commission’s reports or recommendations
- Tracking the peer-reviewed literature to assess the scholarly responses to reports and recommendations
- Tracking the media (print, visual, web) to determine the coverage given to particular topics or discussions

Eiseman’s assessment concluded with the following observation:

NBAC has increased the awareness of the U.S. and foreign governments, international groups, the research community, and the public about complex bioethical issues, providing a forum for their public debate, and making recommendations that have been incorporated into the system of oversight for the protection of human research participants.³⁷

By each of these methods, any commission could be judged to have a greater or lesser impact, so it is important to acknowledge (as Eiseman did) the inherent difficulties in any such assessment. The difficulties included the following:

- The impact of any report will have both a short-term and a long-term effect, and only the former can be addressed at any point in time.
- Reports developed earlier in a commission’s tenure have a greater likelihood of being considered in policy discussions than those released later in a commission’s tenure because interested parties have had more time to respond to the earlier reports.

Table 19.2
Commissions by Country and Type

<i>Country</i>	<i>Title</i>	<i>Type(s)</i>
Albania	Albanian Committee on Bioethics	Advisory
Algeria	National Council of Ethics in Science and Health	Advisory
Argentina	National Commission of Biomedical Ethics of Argentina	Advisory
Australia	National Bioethics Consultative Committee	Advisory
Australia	Australian Health Ethics Committee	Advisory
Austria	Austrian Commission on Bioethics	Advisory
Belgium	Belgian Advisory Committee on Bioethics	Advisory, Education
Bolivia	National Ethics and Bioethics Steering Committee of the Bolivian Academy of Medicine	Advisory, Guidance
Bolivia	National Bioethics Committee of Bolivia	Advisory
Brazil	National Commission for Ethics in Research	Guidance, Protocol Review
Burkina Faso	National Ethics Committee for Health Research	Guidance, Protocol Review
Cameroon	National Ethics Committee for the Protection of Medical Research Participants	Protocol Review
Canada	Royal Commission on New Reproductive Technologies	Inquiry, Advisory
Canada	National Council on Ethics in Human Research	Administrative
Canada	Interagency Advisory Panel on Research Ethics	Advisory
Canada	CIHR Standing Committee on Ethics	Advisory
Canada	Tri-Council Working Group (Joint effort of Medical Research Council of Canada, Natural Sciences and Engineering Research Council of Canada, and the Social Sciences and Humanities Research Council of Canada)	Advisory
China	Ministry of Health Ethics Committee	Advisory, Protocol Review
Congo	National Bioethics Committee	Protocol Review
Côte d'Ivoire	Côte d'Ivoire National Bioethics Advisory Commission	Advisory
Cuba	Cuban National Bioethics Commission	Advisory
Cyprus	Cyprus National Bioethics Committee	Protocol Review, Advisory
Czech Republic	Central Ethics Committee of the Ministry of Health of the Czech Republic	Advisory
Czech Republic	Bioethical Commission Associated to the Research and Development Council of the Government of the Czech Republic	Advisory
Denmark	Central Scientific Ethical Committee	Guidance, Protocol Review
Denmark	Danish Council of Ethics	Advisory
Dominican Republic	National Bioethics Commission	Advisory
Ecuador	Ecuador National Commission for Bioethics	Unknown
Egypt	Egyptian National Committee for Bioethics	Advisory
Estonia	Estonian Council on Bioethics	Advisory, Protocol Review, Guidance
Estonia	Human Research Ethics Committee	Protocol Review
Estonia	Ethics Committee of the Estonian Human Genome Project	Advisory
Ethiopia	National Health Research Ethics Review Committee	Guidance, Protocol Review
Finland	National Advisory Board for Biotechnology	Advisory
Finland	National Advisory Board for Health Care Ethics/Subcommittee on Medical Research Ethics	Advisory, Protocol Review
Finland	National Advisory Board on Research Ethics	Advisory, Education
France	French National Ethics Committee for the Ethics of Experimentation on Human Subjects	Advisory
France	National Consultative Ethics Committee on Health and Life Science	Advisory
Gambia	Gambia/Medical Research Council Joint Ethical Committee	Protocol Review
Georgia	National Bioethics Council of Georgia	Advisory, Protocol Review, Guidance
Germany	National Ethics Council	Advisory
Greece	Hellenic National Bioethics Commission	Advisory

Table 19.2 (Continued)

Country	Title	Type(s)
Hungary	Scientific and Research Ethics Committee of the Medical Research Council	Advisory
Iceland	National Bioethics Committee of Iceland	Advisory, Protocol Review, Guidance
India	Central Ethics Committee on Human Research	Guidance
Iran	Committee of Bioethics, National Committee for Ethics in Science and Technology	Unknown
Ireland	Irish Council for Bioethics	Advisory, Education
Israel	Bioethics Advisory Committee	Advisory
Italy	Italian National Bioethics Committee	Inquiry, Advisory
Italy	National Research Council Bioethics Commission	Guidance
Japan	Bioethics Committee of the Council for Science and Technology of Japan	Guidance
Kenya	National Ethical Review Committee	Protocol Review
Latvia	Central Medical Ethics Committee	Protocol Review
Lebanon	Bioethics Committee of the National Scientific Research Council	Unknown
Lithuania	Lithuanian Bioethics Committee	Administrative, Advisory
Luxembourg	National Ethics Advisory Commission on the Life Sciences and Health	Advisory
Malta	Bioethics Consultative Committee	Advisory
Mauritius	National Bioethics Committee of Mauritius	Unknown
Mexico	National Commission of Bioethics	Guidance, Advisory
Nepal	Nepal Health Research Council	Guidance, Protocol Review
Netherlands	Health Council of the Netherlands	Advisory
Netherlands	Central Committee for Research Involving Human Subjects	Protocol Review, Administrative
Netherlands	The Rathenau Institute	Education, Advisory
New Zealand	National Ethics Committee on Assisted Reproductive Technology	Advisory
New Zealand	Health Research Council Ethics Committee	Administrative
New Zealand	National Ethics Advisory Committee—the National Advisory Committee on Health and Disability Support Services Ethics	Advisory
New Zealand	National Ethics Advisory Committee	Advisory
Nigeria	National Ethics Committee of Nigeria	Unknown
Norway	National Committee for Research Ethics in the Social Sciences and Humanities	Advisory
Norway	National Committee for Medical Research Ethics	Advisory
Peru	Peruvian Bioethics Commission	Advisory
Philippines	National Health Research Ethics Committee	Administrative
Philippines	National Ethics Committee	Advisory
Poland	Commission for Research Ethics	Advisory
Portugal	National Council of Ethics for the Life Sciences	Advisory
Russia	Russian National Committee on Bioethics	Advisory
Saudi Arabia	National Committee for Medical and Bioethics	Guidance, Protocol Review
Senegal	National Health Research Council, Ethics Committee	Protocol Review
Senegal	National Ethics Committee	Unknown
Singapore	Bioethics Advisory Committee	Advisory
Slovakia	Central Ethics Committee for the Ministry of Health	Advisory
Slovenia	National Medical Ethics Committee	Advisory, Protocol Review
South Africa	National Health Research Ethics Council	Advisory, Protocol Review
Spain	Committee on Ethics for Science and New Technologies	Advisory
Spain	National Commission on Assisted Human Reproduction	Advisory, Education
Spain	Catalonian Bioethics Committee	Advisory, Administrative

(continued)

Spain	Advisory Committee on the Ethics of Scientific and Technical Research	Advisory
Sri Lanka	National Science and Technology Commission	Education, Advisory
Sweden	Swedish National Council on Medical Ethics	Advisory
Sweden	The Swedish Council on Technology Assessment in Health Care	Advisory
Switzerland	Swiss National Advisory Commission on Biomedical Ethics	Advisory
Syria	Syrian National Bioethics Committee	Advisory
Tanzania	National Ethics Review Committee	Guidance, Protocol Review
Thailand	Ethical Review Committee for Research in Human Subjects	Guidance, Protocol Review
Tunisia	National Medical Ethics Committee	Advisory
Uganda	National Bioethics Committee of Uganda	Unknown
Ukraine	National Bioethics Commission	Advisory
United Kingdom	Nuffield Council on Bioethics	Advisory
United Kingdom	Medical Ethics Committee of the British Medical Association	Advisory
United Kingdom	Ethics and Governance Interim Advisory Group, U.K. Biobank	Advisory
United Kingdom	Human Fertilisation and Embryology Authority	Administrative, Guidance
United Kingdom	Human Genetics Commission	Advisory
United Kingdom	Central Office for Research Ethics Committees	Administrative
United States	Bioethics Advisory Commission	Advisory
United States	The President's Council on Bioethics	Education, Advisory
United States	Recombinant DNA Advisory Committee	Protocol Review, Advisory
United States	President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research	Advisory
United States	Advisory Committee on Human Radiation Experiments	Inquiry
United States	National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research	Advisory
United States	National Bioethics Advisory Commission	Advisory
Venezuela	Bioethics Commission of the Venezuelan Institute of Scientific Research	Protocol Review
Zimbabwe	Medical Research Council of Zimbabwe Ethics Committee	Protocol Review, Administrative

- Issues differed in their immediate importance to policy makers. For example, NBAC's reports on cloning and stem cell research were of immediate concern to policy makers and received a lot of attention, whereas the report on clinical trials research in developing countries received far less attention.
- When a government agency, professional society, or international organization develops policy or adopts guidelines that make use of or refer to a commission's work, it does not necessarily mean that the commission should be credited with having had a direct influence on the decision to develop or adopt guidelines.
- Much of a commission's contribution to the policy-making process has been to inform public discussion and debate over some highly contentious and value-laden issues, a contribution that is not easily measured.

One immediately recognizes that these methods (alone or in combination) are but proxies for assessing the full impact of a commission. Many indicators of impact are much less easily measurable but may be more substantial, such as changes in public attitudes on bioethics issues, increased interest in the field

of bioethics, or heightened awareness of issues on the part of policy makers. We recognize that further work must be done in this area if policy makers, legislators, health-care providers, and others are to understand and appreciate the value of such commissions.

Implications of National Bioethics Commissions for Research With Humans

For many countries, their national commissions are often the first source of consultation for their respective governments on emerging issues in science and technology.⁵⁴ Assigning a commission to address an issue provides government with the opportunity to step back and reflect rather than to precipitously act/react. This was an effective method used by President Bill Clinton in 1997 and 1998 when he directed NBAC to examine the issues arising from the cloning of the sheep "Dolly"⁵⁵ and from researchers' isolation of human embryonic stem cells, respectively.⁵⁶ In a similar vein, national and international discussion of the ethical issues arising from the conduct of clinical trials in

developing countries was stimulated, in part, by the attention given to it by NBAC⁵⁷ and the Nuffield Council.⁵⁸ The ethical acceptability of placebos, harmonization of guidelines, and the obligation to provide posttrial benefits at the completion of trials were actively discussed by these two commissions before achieving wider discussion in the international community.⁵⁹

For some commissions, the impact of their work may be direct and obvious. For example, the Central Ethics Committee on Human Research in India created research ethics guidelines that in 2007 were pending regulatory approval.^{60, 61} Similarly, for more than two decades, the comprehensive work of France's National Consultative Ethics Committee on Health and Life Science has had a direct impact on French health law, including the recent revisions to the Laws on the Protection of Persons in Biomedical Research, commonly known as the French Bioethics Laws.^{62,63}

However, individual commission productivity is only one frame of reference. In recent years, commissions around the world have begun to work together, benefiting from each other's expertise. Since 1995, five "global summits" of national bioethics commissions have convened—in San Francisco, Tokyo, London, Brasilia, and Canberra. These summits were facilitated by the efforts of national bioethics bodies in the United States, France, the United Kingdom, and Australia, and by the World Health Organization and the International Association of Bioethics. They have been productive in certain ways. For example, the Tokyo Summit produced a communiqué, the content of which suggests a willingness to use the combined knowledge and expertise of national commissions to address important issues in research ethics.⁶⁴ The work of these commissions, in concert with transnational organizations, has the potential to have a significant impact on issues of global bioethics.

VI. Conclusion

We think the future is promising for national bioethics commissions. In particular, we are optimistic about the untapped potential that these groups can draw on to influence both domestic and international research ethics policy. If the history of national commissions is a guide, we expect more countries to develop committees, and countries with existing committees to expand their use. As with all capacity building, time will tell whether efforts like these will be instrumentally as well as symbolically important. Because the existence of a commission often means greater access to the bioethics literature, the sharing of bioethics scholarship and work, and greater openness by public, private, and nongovernmental organizations, it is likely that many of the more pressing topics in research ethics—such as access to clinical trials, informed consent, and assessment of risk and potential benefit—will enjoy the fruits of national as well as transnational deliberation. As efforts to harmonize international research ethics policies and protocols take on great force, national bioethics commissions may offer resources previously unavailable to their governments.

As both repositories and conveyors of information, national bioethics commissions carry on an important tradition of bridging medicine, science, and ethics, with the aim of improving public discourse and policy. Beginning with the Great Library at Alexandria, through the Royal Societies and Royal Commissions of the early 18th and 19th centuries, to the present day, countries have made use of organized committees to advise societies and political

leaders. Given the expansion of research involving humans, we expect that these advisory bodies will continue to be an important political tool throughout the 21st century.

Acknowledgments

The authors gratefully acknowledge the assistance of all bioethics commissions and their staff that provided information, reports, and related materials. These commissions and staff members are not responsible for any unintended errors in our reporting of their work. We also thank Elizabeth Garman, who helped collect reports from national commissions and assisted with the initial analysis; Amy Hatfield, who continues to collect bioethics commission reports for our database; and both Reidar Lie and Robert A. Crouch for helpful comments on an earlier draft.

Financial Disclosure

The Indiana University Center for Bioethics is supported by the Indiana Genomics Initiative (INGEN), which is supported by the Lilly Endowment, Inc.

Context, Purpose, and Value of Clinical Research

This page intentionally left blank

Exploitation in Clinical Research

Some writers on research ethics have argued that the principle “minimize exploitation” is a rationale—even *the* rationale—for many of the oft-mentioned principles of ethical research. The four canonical principles of bioethics (nonmaleficence, beneficence, respect for persons, and justice) do not invoke the language of exploitation, nor do some of the standard principles of research ethics, such as social value, scientific validity, fair participant selection, favorable risk-benefit ratio, and respect for human research participants. Still, it can be argued that many or all of these principles are based on a more general principle: minimize exploitation. For example, it can be argued that research that has no social value or is not scientifically valid is exploiting research participants because they are being “used” for no good end. Similar things can be said about research that involves unfair participant selection or that does not have a favorable risk-benefit ratio.

Yet despite the arguable breadth and power of the principle “minimize exploitation,” the language of exploitation came to the fore only in the context of criticisms of research on vulnerable populations and, in particular, research in underdeveloped societies. This concern may have reached its apogee in response to the use of placebo-controlled trials that were designed to test the efficacy of a short course treatment of AZT in reducing maternal-fetal transmission of HIV when it was already known that a long-course treatment was effective. The trials were conducted in developing countries in which few could afford the long-course treatment and would probably not be able to afford the short-course treatment if it proved to be reasonably effective. Although the rationale for those trials was to find a less costly regimen that could be used in developing countries, the studies prompted an

outbreak of ethical outrage, much of it couched in terms of exploitation. Here are some representative examples:

- “Unless the interventions being tested will actually be made available to the impoverished populations that are being used as research subjects, developed countries are simply exploiting them in order to quickly use the knowledge gained from the clinical trials for the developed countries’ own benefit.”¹
- “. . . the placebo-controlled trials are exploitative of poor people, who are being manipulated into serving the interests of those who live in wealthy nations.”²
- “. . . there is always the nagging possibility that the assurances of such benefits may offer inordinate inducements to poor and impoverished populations and thus represent another form of exploitation.”³
- “If the knowledge gained from the research in such a country is used primarily for the benefit of populations that can afford the tested product, the research may rightly be characterized as exploitative and, therefore, unethical.”⁴
- “If the results of a clinical trial are not made reasonably available in a timely manner to study participants and other inhabitants of a host country, the researchers might be justly accused of exploiting poor, undereducated subjects for the benefit of more affluent populations of the sponsoring countries.”⁵
- “Residents of impoverished, postcolonial countries, the majority of whom are people of color, must be protected from potential exploitation in research. Otherwise, the abominable

state of health care in these countries can be used to justify studies that could never pass ethical muster in the sponsoring country.”⁶

- “. . . it is a fundamental ethical principle that those involved in research in developing countries . . . should not take advantage of the vulnerabilities created by poverty or a lack of infrastructure and resources.”⁷

Yet despite the frequency with which commentators appeal to the language of exploitation, the term has been woefully under-analyzed in the bioethics literature. Indeed, the concept of exploitation has received relatively little attention from political and moral philosophers, who have been more concerned with liberty, equality, justice, and the like. There is little agreement on (or attention to) the defining characteristics of exploitative relations or transactions, and even less agreement as to why and whether exploitation is wrong.

In this chapter, I try to do the following. First, I illustrate the range of contexts in which the concept of exploitation is invoked. Second, I offer an account of the concept of exploitation and discuss several features and implications of this account. Third, I apply my account of exploitation to the sorts of charges that were raised in response to the maternal-fetal HIV trials. Although it will take some doing before we return to issues of exploitation in clinical research, rigorous analysis of these issues requires that we first step back from the immediate context and think in wider terms about the characteristics of exploitative transactions.

Examples of Alleged Exploitation

Consider the following examples, in which it often is or could be said that a practice is exploitative.

The Concept of Exploitation

The first task of any account of exploitation is to say when and why charges of exploitation are true. After all, people disagree as to whether the volunteer army is exploitative, whether universities do exploit student athletes, whether commercial surrogacy really does exploit surrogate mothers, and so on. We sometimes use the verb *exploit* in a morally neutral sense, in which we simply mean “to make use of.” So we might say that the surgeon exploits his natural manual dexterity or that a baseball pitcher exploits the batter’s inability to hit an inside curve ball. Those concerned with research ethics are interested in the morally charged sense of exploitation—the sort of exploitation in which it is thought that A wrongfully exploits B when A takes “unfair advantage” of B.

When is a practice or transaction exploitative? Although the concept of exploitation has not been central in the history of ethical theory, there are two traditions in which it has figured prominently. Karl Marx argued that capitalists exploit their workers when they do not pay workers the full value of their labor. Marx’s view is consistent with the notion that exploitation involves taking unfair advantage of others, but is limited to the context of labor and relies on an almost universally rejected labor theory of value. Philosophers who have been inspired by Immanuel Kant have argued that one exploits another when one treats that person as a mere means to one’s own ends, when one “uses” another person,

Table 20.1
Alleged Exploitation

Scenario	Description
Student athletes	It is often said that universities exploit their student athletes when they gain income, entertainment, and loyalty from alumni, whereas the athletes get little education and relatively few receive their degrees or go on to play professional sports.
Lumber	If there is a hurricane in Florida and lumber retailers were to raise their prices, we might say that they were exploiting their customers.
Strip club	It is often said that strip clubs exploit the women they employ or women as a group.
Volunteer army	It is sometimes claimed that the volunteer army exploits those citizens who lack decent civilian career opportunities: “A society as unjust as ours must draft its military to avoid unfair exploitation . . .” ⁸
Rescue	Suppose that B’s car slipped into a snowbank on a rural road late at night. A can pull B out by attaching a rope to his four-wheel drive pickup truck. A offers to help B for \$200.
Nazis	Nazi doctors who performed hypothermia experiments on Jews were exploiting their victims.
Surrogacy	Commercial surrogacy involves the exploitation of the surrogate mothers.
Kidneys	The sale of bodily organs, such as kidneys, involves the exploitation of impoverished persons.
Interns	Hospitals exploit interns by requiring them to work long hours for relatively low pay.
Inducements	Medical researchers exploit people when they offer inducements to participate in research.
Embryonic stem cells	Embryonic stem cell research treats “nascent human life as raw material to be exploited as a mere natural resource.” ⁹
Unfair surgery	B needs life-saving surgery. A is the only surgeon available. A proposes to perform the surgery for \$20,000 when the normal fee is \$5,000. B agrees.

or when one “fails to respect the inherent value in that being.”¹⁰ The concepts of failing to respect or using are murky, and it is not clear when one treats another merely as a means.

Exploitation is best captured by the broader and simpler notion that one exploits another when one takes unfair advantage of that person.¹¹ As it stands, this definition is correct but not all that helpful. We must go a bit deeper. In what follows, I try to refine and amplify this definition.

1. *Exploitation requires the exploiter to benefit.* This distinguishes it from neglect or discrimination or paternalism. A cannot take unfair advantage of B unless A gets some *advantage* from B, unless A benefits from his use of B. A discriminates against B when A wrongfully deprives B of some opportunity or benefit because of some characteristic of B that is not relevant to A’s action. If clinical researchers discriminate against African Americans by excluding them from their study in violation of the principle of “fair participant selection,”

they would be doing something seriously unethical, but it would not be exploitation. A neglects B when A has an obligation to provide for B and fails to do so. For example, if a drug company chooses not to engage in research on drugs for malaria because it did not expect to make a profit on such drugs, it might be accused of neglecting the victims of malaria, but it could hardly be accused of exploiting them. A is wrongfully paternalistic to B if A acts so as to promote B's interests by interfering with B's liberty or autonomy. If a physician chooses not to disclose to his patient that she had cancer because he thought it would be in her interest not to know of her condition, the physician may have acted wrongly, but he did not exploit her, in part because he gains nothing from the failure to disclose and might even be putting himself at risk.

2. *Exploitation can involve benefit to those being exploited.* Some exploitative transactions or practices are clearly harmful to the exploitee and decidedly nonconsensual (see Table 20.1, "Nazis"). Importantly, in many cases exploitation can occur when the person seems to gain from the transaction and consents. Indeed, exploitation is of much less theoretical interest on a "no harm, no exploitation" rule. It is trivially true that it is wrong for A to gain from an action that unjustifiably harms or coerces B. By contrast, it is more difficult to explain when and why it might be wrong for A to gain from an action that also benefits B and to which B voluntarily consents.

For these reasons, it will be useful to make two sets of distinctions. First, we can distinguish between harmful exploitation and mutually advantageous exploitation. Mutually advantageous exploitation refers to those cases in which the exploitee and the exploiter gain from the transaction. In other words, it is the advantageousness of the transaction that is mutual. For instance, in Table 20.1 we might regard "unfair surgery" as exploitative even though B benefits greatly from the surgical procedure. In other words, "unfair surgery" is an example of mutually advantageous exploitation.

3. *Because exploitation can involve consent of the exploited, it is useful to distinguish between nonconsensual exploitation and consensual exploitation.* In cases of nonconsensual exploitation, the exploitee does not give consent at all or fails to give appropriately valid or voluntary consent, as when the consent is compromised by coercion, deception, or incompetence. By contrast, in cases of consensual exploitation, the exploitee makes a voluntary, informed, competent, and rational decision to agree to the transaction under the conditions in which she finds herself, even though she might not agree to it under better conditions or would prefer a more favorable transaction (see Table 20.1, "student athletes").

The two sets of distinctions (harmful/mutually advantageous and nonconsensual/consensual) are not equivalent. B could consent to being harmed by A, as when B agrees to sell a kidney for an unfair price. Nonetheless, the distinctions do overlap. Most cases of harmful exploitation are nonconsensual, and most cases of consensual exploitation are mutually advantageous. So for present purposes we can simplify things by distinguishing between harmful nonconsensual exploitation and mutually advantageous consensual exploitation.

4. *Exploitation mainly concerns unfair results rather than defective or unethical procedures.* Taking unfair advantage can be understood in two ways. First, it may refer to some dimension of the outcome of the exploitative act or transaction; that is, the transaction is substantively unfair. The benefit to A may be unfair because it is wrong for A to benefit at all by harming B or because A gains too

much whereas B gains too little. Second, to say that A takes unfair advantage of B may imply that there is some sort of defect in the process by which the unfair outcome has come about, for example, that A has coerced B or deceived B or withheld information from B. Because A can exploit B, even when B consents voluntarily, exploitation does not necessarily involve a defect in process. It is, rather, mainly about unfair outcomes.

5. *To determine whether exploitation is harmful or mutually advantageous, use an "all things considered" analysis, rather than an analysis of each element of a transaction.* A engages in harmful exploitation of B when A gains by harming B. A engages in mutually advantageous exploitation when A gains wrongly or unfairly from a transaction with B that also benefits B. But how is it possible to distinguish between harmful and beneficial transactions? This is actually complicated. In asking how A's action affects B's interests, we must be careful to adopt an "all things considered" point of view. There are, after all, negative elements in virtually all uncontroversially beneficial transactions. Paying money for a good that is clearly worth the price is still a negative element in the transaction. It would be better to get it for free. Similarly, we do not say that a worker is harmed by employment merely because the worker prefers leisure to work. If the financial benefits to B from employment are greater than the cost of sacrificing leisure, then employment is beneficial to B, all things considered. So in deciding whether a case of alleged exploitation should be classified as harmful exploitation or mutually advantageous exploitation, we must look at its net effect on B. Even if the sale of a kidney has significant negative elements, it is possible that the value of the gains to the seller exceed the value of the costs, in which case it is a transaction that is beneficial to B.

6. *To determine whether exploitation is harmful or mutually advantageous, use an ex ante (before) rather than ex post (after) perspective in assessing the effects of a transaction on B.* Suppose that A enters into a type of business transaction with B, in which B expects, ex ante, to gain 80% of the time and lose 20% of the time. For example, A might sell B land on which B realistically hopes to find oil. We don't think that A has harmed B in those cases when the land produces no oil unless A knew that this would happen beforehand. To consider another example, if the sale of a kidney is advantageous to B ex ante, then even if B is harmed, ex post, by the sale of a kidney, it is a mutually advantageous transaction. Similarly, if B agreed to receive standard therapy for her medical condition, then this transaction is advantageous ex ante even if B doesn't benefit, or benefits less than her physician predicted, from the therapy. The general point is that one's assessment of the advantageousness of a transaction should not turn on the outcomes of that transaction; it should turn, instead, on an up-front and informed assessment of the possible outcomes and the probability that these outcomes will materialize.

7. *Vulnerability is not necessary or sufficient for exploitation.* It may be thought that a transaction is exploitative whenever A takes advantage of B's vulnerabilities or desperate situation to strike a deal. That is false. For if A makes a reasonable proposal that B has no alternative but to accept given B's desperate situation, it would be silly to say that A exploits B. If a doctor proposes to perform life-saving surgery for a reasonable fee, the patient is hardly exploited, even though the patient would not have agreed but for the fact that his or her life was in danger.

8. *Unequal benefits are also not necessary or sufficient for exploitation.* The most common view is that a transaction is unfair

when A gains much more than B. This view is also false. For if we measure the parties' gains by reference to the utility they receive, then the alleged exploitee may well gain more than the exploiter. If a doctor overcharges for life-saving surgery that only he can perform, the patient still gains much more than the doctor. The doctor gets some money; the patient gets his or her life. On closer inspection, the exploiter's power over the exploitee stems precisely from the fact that the exploiter does not stand to gain too much. The exploiter can easily walk away from the transaction, whereas the exploitee cannot. Unequal benefit is therefore a problematic criterion of exploitative transactions, for on that view, many paradigmatically exploitative transactions would turn out not to be exploitative at all.

9. *It is important to determine whether the exploitee's consent to a transaction is valid.* Let us assume that a transaction is mutually advantageous although unfair and hence exploitative. It is still important to distinguish between consensual and nonconsensual exploitation because there may be reason to prohibit nonconsensual exploitation, but to permit consensual exploitation. So when is a transaction consensual? There are many ways that consent can be invalidated, but I will discuss only two: coercion and seductive offers. Limited choice does not necessarily lead to coercion. Many people claim that B's consent is coerced when B has no reasonable alternative but to consent. This is wrong. Suppose that B will die unless his or her leg is amputated, and B therefore agrees to the amputation. B's consent is valid, even though B has no reasonable alternative but to agree. A coerces B to do X only when A proposes to violate B's rights if B refuses to do X.¹² And A certainly doesn't propose to violate B's rights if he or she doesn't agree to the amputation. People can and do give appropriately voluntary consent even when they make choices that they would not have made under more favorable circumstances or more just background conditions.

Coercion is often confused with a different defect in consent. Seductive offers, or what is often referred to as undue inducement, can also compromise the validity of consent. A makes a seductive offer when A's offer distorts B's ability to make a reasonable judgment about his or her long-term interests. This can occur when A's proposal contains such great short-term benefits that it causes B to excessively discount the long-term costs and to make a decision that does not serve his or her long-term interests. "Kidneys" is not a case of coercion, because A does not propose to make B worse off if B refuses to consent. But B's consent may not be valid if A's offer gets B to make an unreasonable judgment. If kidney donors systematically overestimate the economic benefits of donation and underestimate the long-term costs, then we would have reason to question the validity of their consent.

The main point is that there are numerous cases of alleged and actual exploitation in which B would not have agreed under better or perhaps more just background conditions, but in which B is fully informed as to the consequences of various choices and fully capable of making such choices. Such conditions may obtain in "kidneys," "surrogacy," "rescue," and "lumber." Precisely because B's objective situation is what it is, it may be reasonable for B to agree to proposals to which those who are better situated would not agree. Although it would not be rational for an affluent American to sell a kidney for \$25,000, it does not follow that it is irrational for an impoverished Egyptian to do so.

10. *Unfairness is based on a normative standard.* If a transaction or interaction between A and B is mutually advantageous, B gains

as well as A. A transaction is exploitative only if the outcome is unfair to B, even if B gains or benefits. When is a transaction unfair? This is the most difficult issue for an account of exploitation.

If we cannot evaluate the fairness of a transaction by comparing how much utility the parties receive, then we must measure the fairness of their gains against a normative standard as to how much the parties ought to gain. Unfortunately, that standard is notoriously difficult to specify. A promising but not unproblematic candidate is to measure the parties' gains against what they would have gained in a "hypothetical competitive market," in which there was relatively complete information.¹¹ On this view, there is no independent standard of a "just price" for goods or services such as lumber, kidneys, or labor. Furthermore, the just price is not whatever the actual market yields, because the market has many known imperfections. Rather, we evaluate the parties' gains by what they would have received under relatively perfect market conditions, just as we may try to determine the "fair market value" of a home by what the home would sell for under relatively perfect market conditions in that locale.

Acknowledging all of the difficulties, and granting that reasonable people may disagree about the appropriate standard, mutually advantageous transactions can be unfair by reference to an appropriate normative standard, and A exploits B when A gains more than A should or B gains less than B should from the transaction.

11. *Exploitation is distinct from background injustice.* Exploitation is transaction-specific. It does not follow that the transaction itself is unfair or exploitative just because a transaction may leave B worse off than background justice requires. Consider "surrogacy" in Table 20.1. If society should provide people with an adequate standard of living, then a woman might consider serving as a surrogate only because society has not fulfilled its obligations and her background conditions are therefore unjust. Still, it does not follow that A's transaction with B is exploitative or unjust if A bears no responsibility for causing B's unjust background condition, nor does A have an obligation to repair those conditions. To put the point slightly differently, we must distinguish between two claims: (1) A takes advantage of unfairness to B; and (2) A takes unfair advantage of B.

It is important to see that (1) does not entail (2). Other commentators disagree. They argue, "If we gain advantage from an interaction with another, and that advantage is due in part to an injustice he has suffered, we have failed to give him appropriate respect;"¹⁰ in other words, we have taken unfair advantage of him. To see why this is mistaken, consider this case:

Unemployed Lawyer: B has been unjustly fired from his position with a law firm, where he earned \$150,000 per year. A local community college offers him a position teaching law courses for \$35,000 per year.

Even if the community college is taking advantage of an injustice that has been done to B, it does not follow that it is exploiting B. If B has a complaint, it is with those who fired him, not with those who propose to hire him for a much lower salary.

This distinction between a transaction that is exploitative and background conditions that are unjust is important for clinical researchers. If clinical researchers take advantage of the unjust background conditions in which people in developing societies find themselves, it does not follow that they are taking unfair advantage of the people. They may or may not be doing so. To say

that they are taking unfair advantage of the people, it must be shown that researchers have a specific—not general humanitarian—obligation to provide more to their research participants than they are actually providing.

Put somewhat differently, it is absolutely crucial to distinguish between moral defects in B's background situation and moral defects in the transactions that occur within that situation. Justice relates to background situations, whereas exploitation relates to transactions. People often focus on the wrong target. Although we often have moral reason to object to the background situation in which people find themselves, the relative invisibility of background situations compared with transactions, and our relative helplessness with respect to people's unfortunate or unjust background situations, may lead us to wrongly object to transactions that are themselves completely ethical.

Arguments for Intervention

It is always wrong to take unfair advantage of or to exploit another person. Interestingly, however, the force of that wrongness is much less clear. Many people believe we should prohibit or otherwise remedy all types of exploitation, be it harmful and non-consensual exploitation or mutually advantageous and consensual exploitation. They justify their view with the following logic: (1) If a transaction is exploitative, it should not be permitted. (2) Transaction X is exploitative. (3) Therefore, X should not be permitted. This is not well argued. For even if it is true that some transactions are exploitative, it does not automatically follow that X should be prohibited. Although it is always wrong to exploit another person, it is sometimes ethically permissible, all things considered, to allow an unethical transaction to occur.

Now some people question whether a mutually advantageous and consensual transaction could be exploitative. It might be thought that there can be nothing seriously wrong about an agreement from which both parties benefit and in which A has no obligation to enter into any transaction with B. This is false. There can be transactions in which B consents and gains advantage, but which are wrong because A is treating B unfairly. Recall a paradigmatic example of exploitation, such as "rescue," in which B's car slips into a snowbank on a rural road late at night. A can pull B out by attaching a rope to his four-wheel drive pickup truck. A offers to help B for \$200. Suppose that Table 20.2 represents the gains in utility from three hypothetical transactions in which scenario 2 is "rescue."

As noted above, a fair transaction does not necessarily yield equal utility gains. Because being rescued is important to B, she gets as much utility in the unfair transaction (scenario 2) as does A. And if B were rescued for only \$20 (scenario 3), she would get

much more overall utility than A. Still, even if A is under absolutely no obligation to transact with B, we might still think A has moral reasons to be fair to B, especially because A benefits from the interaction with B. Charging \$200 for a few minutes of work is arguably unfair, however much B benefits from that work.

Yet even if A's behavior is seriously wrong, it does not follow that we should prevent A and B from transacting on those terms. It is always important to distinguish between two claims: (1) A's action X is wrong; and (2) we should prevent A from doing X. I believe it would be seriously wrong for someone to give a speech in which he denies that the Holocaust happened. I believe that it might be wrong for a woman to abort her male fetus because she wanted a girl. It certainly does not follow, however, that it would be right to prevent the person from delivering that speech or to prevent the woman from having an abortion. Similarly, it does not follow that just because A is engaged in wrongful exploitation of B that we would be justified in preventing A from exploiting B. We might be so justified, but that must be determined independently, that is, on grounds other than that the transaction is exploitative.

What would justify interfering with a case of mutually advantageous consensual exploitation, a case in which B both gains and consents to the exploitation? We sometimes interfere with transactions on paternalistic grounds, in order to protect B from making a decision that does not advance her own interests. But a paternalistic argument for interference cannot apply to mutually advantageous exploitation. Paternalism is justifiable only when B's important interests are at serious risk of being harmed. Even if we think it legitimate to interfere with someone for her own good (as when we require people to wear seat belts), we cannot justify intervention on paternalistic grounds if the exploitative transaction is advantageous to the exploitee and if interference is not likely to result in a transaction that is more beneficial to B.

Obviously, we could justifiably interfere with mutually advantageous and consensual transactions if they give rise to harm to others. For example, even if allowing kidney sales were beneficial to the participants directly involved, such a policy might have diffuse negative effects on the way in which we think about persons and their bodies. Although averting harm to others may be an important reason to limit certain transactions, it is an empirical question—and often an extraordinarily complex empirical question—as to whether interfering with a practice would actually avert harm to others. Unfortunately, these sorts of claims are often made without any evidence or appreciation of the need for evidence. Moreover, this line of argument for intervention actually has nothing to do with exploitation per se. The point is not to protect the exploitee, but to protect others.

The strongest argument for intervention in mutually beneficial and consensual exploitative transactions is that a policy of disallowing unfair transactions makes it more likely that a fairer transaction will occur than that no transaction will occur. Reconsider the matrix of the benefits in "rescue." Suppose A proposes that he gets \$200. B counters that they should agree on \$20. A rejects B's proposal and replies that it is either \$200 or no transaction. Given these options, B is prepared to pay \$200. At first glance it seems that society is not justified in preventing B from paying the unfair \$200, for given the choice between being exploited and not rescued, B would rather be exploited. Nonetheless, if we prohibit A from entering into an unfair transaction with B, it is possible that A will propose a fair transaction rather than refusing to transact with B. After all, A benefits from a fair

Table 20.2
"Rescue" and Its Alternatives

Scenario	Description	A's Benefit	B's Benefit
1	No transaction	0	0
2	Unfair transaction (\$200)	5	5
3	Fair transaction (\$20)	2	8

transaction with B and so has no reason to refuse to transact with B if the unfair transaction is prohibited. It is important to recognize that this is a strategic argument for prohibiting exploitation rather than one about inherent evils of exploitation.

However, there are problems with prohibiting exploitation if the strategic argument does not apply. Suppose that A is under no obligation to transact with B on any terms. Then A proposes terms that are unfair to B. If we prevented A from transacting with B on unfair terms, then A would choose not to transact with B at all. In this case, prohibiting A from exploiting B is actually worse for B than allowing A to exploit B. In the context of research, this may raise the following question: Can the state or the writers of a code of ethics or an institutional review board justifiably prevent a transaction that is good for the parties involved, is worse for no one else, and to which the parties give perfectly rational consent under the nonideal conditions in which they find themselves?

Some would argue, "No." By claiming that some exploitation may be "permissible," I do not mean that it is ethically permissible for A to exploit B. A acts wrongly in exploiting B. Permissible exploitation means that society should permit A to exploit B and that it would be wrong for society to prevent A from exploiting B. There is a very strong presumption in favor of accepting this principle. Although I do not think it incoherent to claim that there might be deontological reasons to reject such a principle, such a view is difficult to justify. Moreover, because permitting this kind of exploitation precludes intervention only when the parties consent to the transaction, one cannot easily reject the principle on the Kantian ground that it allows A to use B as a mere means to his own ends. For it is at least plausible to maintain that A does not treat B as a mere means if B's valid consent is a necessary condition of any transaction between A and B.

Although I lack a knockdown argument for contending that we should permit exploitative transactions when doing so is better for all concerned, I suspect that this is a plausible principle of nonideal ethical theory as contrasted with ideal ethical theory. Whereas ideal moral theory aims to provide the principles for a just society and a just world, nonideal moral theory aims to provide the principles by which individuals, the state, and organizations should act under unjust or nonideal moral conditions. Although ethics must ask how things should be, ethics must also ask what we should do given that things are not as they should be.

The ethics of clinical research in developing countries is a problem of nonideal moral theory. In a more just world, these nations would not be so underdeveloped. But just because a transaction would not occur under ideal or just conditions, it does not follow that it is wrong for it to occur under nonideal conditions. Given the nonideal background conditions under which people find themselves, there should be a very strong presumption in favor of principles that would allow people to improve their situations if they give appropriately robust consent, and if doing so has no negative effects on others, even if the transaction is unfair, unjust, or exploitative.

Exploitation in Clinical Research

How does this analysis of exploitation in general apply to exploitation in clinical research? There are many famous examples of research that involved harmful or nonconsensual exploitation: the Nazi doctors, the Jewish Chronic Disease Hospital, and Tuskegee

are a few examples (see Chapters 2, 6, and 8). These cases are important examples of exploitation. However, we are obviously justified in seeking to prevent harmful or nonconsensual exploitation. Mutually advantageous consensual exploitation may be less serious, but it poses more complex ethical challenges. Consider the following case:

Pharma, a large American pharmaceutical company, wants to test a new antibiotic, Q, for meningitis. There is a standard treatment, T, for meningitis, but Pharma believes Q may be more effective or have fewer side effects than T. Pharma could run an active-controlled trial in the United States, in which it tests Q against T, but it prefers to run a placebo-controlled trial in Ecuador, because a placebo-controlled trial requires a smaller sample size, produces cleaner statistical results, and will save Pharma money. Because virtually no one in Ecuador can afford T, people are willing to enroll in a trial for which they have a 50% chance of receiving Q. If Q proves successful, it will not be generally affordable by the citizens in Ecuador even if it obtains regulatory approval.

Many will charge that such a study is a paradigmatic case of exploitation. They would argue something like the following.

1. If a practice is exploitative, it should not be permitted.
2. Randomized placebo-controlled trials such as Pharma's proposed trial of Q in Ecuador are exploitative.
3. Therefore, we should prohibit a randomized placebo-controlled trial of Q in Ecuador.

As it stands, this argument moves much too quickly. First, it is not clear just who is regarded as the victim of exploitation. Some statements suggest that the participants in this study would be exploited, that researchers would be taking advantage of the participants' vulnerabilities to get them to participate in studies from which half can expect not to benefit at all because a known treatment is withheld from them. Other statements imply that it is the nation or its citizens who are exploited. In this view, it is not so much that the participants are treated unfairly. After all, they stand to gain and they do consent to participate in the research. Rather, it is the nation of Ecuador that is exploited because its citizens are used to test drugs that won't be available there even if the research is successful.

Second, despite the confidence with which these charges of exploitation are often advanced, to say that the proposed trial is exploitative requires an account of an unfair transaction. We cannot just assume that the terms of these transactions are unfair. All the critics seem to implicitly or explicitly accept that Pharma would not be acting unfairly toward the citizens of Ecuador or potential research participants if it chose to do its research in the United States, in which case it would do nothing for people in Ecuador. How much does the company owe research participants or the nation of Ecuador if it chooses to do research there?

Many discussions of exploitation in clinical research implicitly accept something like the following argument.

1. A researcher does not act wrongly by choosing not to do research with B.
2. If the researcher profits from a mutually advantageous and consensual transaction with B, the researcher acquires special obligations toward B, including obligations of fairness.

3. It is worse for researchers to treat B unfairly than to fail to interact with B, even though B benefits from the research and consents to it.

Assume that the benefits in utility for Pharma and its research participants would be something like those in Table 20.3. Many seem to believe, in effect, that Pharma acts more wrongly in (B) than in (A) with respect to Ecuadorians, even though Ecuadorian research participants are better off in (B) than in (A). According to this analysis, once Pharma conducts research in Ecuador, it acquires obligations toward research participants or other Ecuadorians that it would not have if it neglected them—that is, if it had chosen to do its research in the United States. Perhaps the company must make Q available to all those who participated in the trial or provide other benefits to Ecuador. On this view, the wrongness of Pharma's behavior does not correspond to its effect on the well-being of Ecuadorians. Before we decide that *Pharma* would be exploitative, we have to think long and hard as to how much the Pharmas of this world owe research participants (or their nations) when they interact with them.

Third, let us assume for the sake of argument that Pharma does exploit Ecuadorian research participants, that it would be treating them unfairly. It is still not clear whether we should accept the premise that if research is exploitative, then it should not be permitted. If we believe that we should permit some cases of mutually advantageous consensual exploitation, then it is arguable that we should permit Pharma to conduct its trial. Let us assume that all participants receive care that is at least as good as, and probably better than, if the trial had not been conducted at all. After all, even those who receive the placebo may be receiving better (and certainly no worse) than normal care in Ecuador. Moreover, all the research participants stand to gain *ex ante* (they have a 50% chance of receiving beneficial treatment) even though they do not all gain *ex post*. Second, if Pharma is not permitted to conduct a placebo-controlled trial in Ecuador, it is possible that the company will either abandon the study or go elsewhere. I do not mean that Pharma would merely threaten to abandon the investigation as a bargaining tactic to secure what it regards as a better arrangement. Rather, I mean that Pharma might in fact abandon the investigation or go elsewhere if it is not allowed to conduct a placebo-controlled trial in Ecuador. It would, for example, prefer (A) to (C). With these assumptions in mind, let us now consider the various claims and prescriptions that are frequently linked to the claim that this sort of research is exploitative.

Table 20.3
Expected Utilities of Three Research Scenarios

Scenario	Description	Pharma's Utility	Ecuadorian Research Participant's Utility
A	Active-controlled trial in U.S.	900	0
B	Placebo-controlled trial in Ecuador	1,000	1
C	Active-controlled trial in Ecuador	800	2

The Declaration of Helsinki states, “The benefits, risks, burdens and effectiveness of a new method should be tested against those of the best current prophylactic, diagnostic, and therapeutic methods”¹³ (see Chapter 13). The Pharma trial seems to be incompatible with this principle, unless one fudges with the notion of the “best current . . . methods” by arguing that we should adopt a “local” standard, under which the best current method is no treatment at all. But the real question is not whether Pharma's trial is compatible with the principles of the Declaration of Helsinki or other similar documents, but whether we should accept the principles articulated in the Declaration of Helsinki or other comparable documents. If Pharma proposed to run an active-controlled trial in the United States, thereby providing no care to anyone in Ecuador, it would not violate the principles of the Declaration of Helsinki. So if Pharma Pharmaceuticals is not required to provide any care at all to Ecuadorians, why should we insist that it provide the best current method of care to all participants in the study?

We can consider the Declaration of Helsinki's “best current . . . methods” principle in terms of the strategic argument for intervention. In the developed world, if we insist that active-controlled trials be used whenever a standard therapy exists and whenever there are no very strong scientific reasons for preferring a placebo-controlled trial, there is little risk that the research will simply go away. Although the drug companies might prefer placebo-controlled trials because they are cheaper, quicker, and provide better data, the potential participants in the developed world are helped by rules that force researchers to treat patients better than they otherwise might. After all, if patients are assured of the best current methods of care, there is no reason why they should consent to participate in a placebo-controlled trial.

By contrast, the strategic argument may or may not work so easily in the developing world. On the one hand, a developing nation may fear that the researchers will go elsewhere if too many constraints are placed on research. Precisely for that reason, it is possible that such constraints will prevent a “race to the bottom” among developing nations that are competing for the inadequate benefits of being used for such research. On the other hand, it is also possible that—given such constraints—the researchers will decide that they might as well use active-controlled trials in their own nations. There may be little reason for Pharma to run an active-controlled trial in Ecuador when it could run such a trial in the United States, especially if it needs to invest in upgrading the Ecuadorian health-care system to ensure adequate diagnostic tests and therapeutic interventions to conduct the trial. If that is right, prohibiting Pharma from conducting a placebo-controlled trial in Ecuador cannot be justified as the best strategy for improving the lot of potential research participants in Ecuador or other developing nations. In any case, it is an empirical question as to whether disallowing such trials will work to the advantage of potential participants or increase the welfare of persons in developing nations. This will not be solved by calling some study exploitative or by ethical discussion.

We must also ask how much moral weight we should place on the benefits that accrue to the researchers or to the citizens of the developed society as contrasted with the effects of the trials on the participants. First, there is the issue of commercial profit. Although seeking profit is not itself unethical, it might be thought that Pharma cannot justify running placebo-controlled trials if its primary motivation is simply to save money and fatten its coffers.

Interestingly, however, the standard arguments cited previously do not appeal to worries about commercial profits. After all, such studies could easily be conducted by nonprofit organizations such as the National Institutes of Health. Rather, the main claim is that it is wrong for citizens in developed societies to gain large benefits from trials conducted on citizens of developing societies who may not benefit at all. Recall the statement from the Council for International Organizations of Medical Sciences (CIOMS): "If the knowledge gained from the research in such a country is used primarily for the benefit of populations that can afford the tested product, the research may rightly be characterized as exploitative and therefore, unethical."⁴

Should we accept this argument? I'm not sure. First, this argument does not claim that the research participants are exploited. Rather, it implies that the society or nation is exploited. Second, the country may or may not be exploited, but even if it is, we have to ask whether that is sufficient reason to block such research if three conditions are all fulfilled: (1) the research participants give informed consent; (2) the individual research participants stand to benefit from such research; and (3) their participation in such research does not render their fellow citizens worse off. In addition, it should be noted that the benefit that accrues to citizens of the affluent nations is not something trivial, like cheaper running shoes made in sweatshops in Thailand. Rather they may be getting life-saving medications. The CIOMS statement raises difficult moral questions, and I do not propose to try to resolve them here. I suggest only that the moral truth of the matter is much more complex than the statement suggests.

Some argue that there is something particularly morally obnoxious about a practice in which the affluent entice the poor to provide a service that will primarily benefit the rich. Why should the burden of clinical research be borne by the poor? The answer might be, It is not a burden for anyone, and not a burden for the poor. This is not like asking the poor to take the radioactive and other toxic waste produced by the rich. Moreover it is very unclear that medical research is qualitatively different from a wide variety of practices in which the affluent directly or indirectly hire the less affluent to provide goods or services, as when they work as nannies, gardeners, and domestics. Nor is it acceptable to argue that these occupations are not life-threatening; the affluent also effectively hire others to engage in dangerous jobs such as coal mining, construction work, or volunteer (professional) soldiering. Some bioethicists often assume without argument that there is something morally special about hiring others to serve as participants for medical trials that distinguishes such "hirings" from other sorts of hirings. It is not clear just why that is so.

Of course, this assumes that the participants in studies such as Pharma actually give valid informed consent. There are two questions that we might ask here: (1) Do the participants give valid consent? (2) If not, is it possible that this sort of research could be conducted with valid informed consent? Clearly, the answer to both questions will turn on our criteria for valid consent. Although we cannot resolve that here, it is possible that the answer to (1) is often "no." It is possible that many people do not understand that they are consenting to participate in a placebo-controlled clinical trial as opposed to consenting to medical treatment. They may suffer from the "therapeutic misconception." But the current available data do not substantiate this claim, at least when compared with participants in developed countries.

We should distinguish between these sorts of cognitive deficiencies in a participant's consent and worries that are often advanced about the voluntariness of the consent. It is often argued that a research participant's consent is not voluntary when he or she has "no acceptable alternative." And it is argued that impoverished potential participants who would ordinarily have no medical care available have no choice but to participate in a study in which they have a chance of obtaining medical care and that their consent is consequently invalid on grounds of coercion. But this line of argument is incorrect. A's proposal is coercive only if A proposes to violate B's rights if B rejects the proposal. The central fact is that Pharma did not propose to violate a potential participant's rights should a potential participant decide not to participate.

It might be noted in this connection that many bioethicists have expressed worries about providing inducements to research participants. CIOMS worries that the offer of monetary payments may "induce prospective subjects to consent to participate in the research against their better judgment."⁴ And there may be similar worries about the inducement of therapeutic treatment. We must be careful to properly interpret the phrase "against their better judgment." It is important to distinguish between two claims:

1. The inducements constitute a seductive offer that motivates people to consent to participate when doing so does not advance their interests.
2. Given the people's objective circumstances, the inducements make it rational for them to participate.

Note that in (2), the inducements are large enough to render participation compatible with the participants' better judgment given the objective conditions in which they find themselves, although participation might have been against their better judgment in the absence of those inducements or under different conditions. The real tragedy of poverty is not that (1) is often true, but that (2) is often true. David Rothman writes that "abject poverty is harsh enough without people having to bear the additional burdens of serving as research subjects."¹⁴ But the point could easily go the other way. We might say, after all, that abject poverty is harsh enough without denying people the opportunity to make their lives somewhat less miserable by participating in biomedical research and receiving benefits that they would not otherwise receive. The British Marxist economist Joan Robinson once remarked that for people in many poor countries, "the misery of being exploited by capitalists is nothing compared to the misery of not being exploited at all."¹⁵ Whether a similar view might be correct with regard to clinical research is one of the questions that must be raised and answered.

Worries about exploitation in clinical research often focus not just on the treatment of the experimental participants but on the benefits to the community when the study is over. Recall these two statements: "Unless the interventions being tested will actually be made available to the impoverished populations that are being used as research subjects, developed countries are simply exploiting them in order to quickly use the knowledge gained from the clinical trials for the developed countries' own benefit;"¹ and "If the results of a clinical trial are not made reasonably available in a timely manner to study participants and other inhabitants of a host country, the researchers might be justly accused of exploiting poor, undereducated subjects for the benefit of more affluent populations of the sponsoring countries."⁵

Although the commentators have not been precise about this, they may be arguing that the research would not be exploitative if the products that result from such studies were to be made available to present or future citizens of the host country (so-called reasonable availability). Why should the benefit to future citizens render it permissible to exploit present research participants? They might be arguing that the exploitation of the research participants inherent in the research would be counterbalanced and outweighed by the benefit to other citizens. But this view would seem to violate some of the standard principles for ethical clinical research. We don't say that the exploitation of research participants is justified by gains to other persons.

Consider the following statement: "If the intervention being tested is not likely to be affordable in the host country or if the health care infrastructure cannot support its proper distribution and use, it is unethical to ask persons in that country to participate in the research, since *they* will not enjoy any of its potential benefits [emphasis added]." ¹⁶ But who is the "they" to whom Shapiro and Meslin refer? After all, it is often true that the persons who participate in research will not, themselves, enjoy any of its potential benefits. If it is wrong to ask B to participate in research from which B will not benefit, then it is not clear why it becomes permissible just because B's fellow citizens may benefit. And if it is not wrong to ask B to participate in such research, then I do not see why it should be necessary that B's fellow citizens will also benefit.

Moreover, if it is morally crucial that benefits of doing research with impoverished persons be made available to other impoverished persons, it is not clear to me why the nation is the relevant moral unit here. Suppose that the Pharma trial was a success and that Pharma had to choose between making the results of research available to citizens of Ecuador or Uganda and that it would do more good to do so in Uganda. Do the citizens of Ecuador have a claim on those treatments just because other Ecuadorians participated in the research? Perhaps, but why?

To the extent that the principle of reasonable availability—the principle that a successful result of a clinical trial should be made available in the host country—is motivated by principles of distributive justice, we must be careful not to conflate valid concerns about the distribution of medical resources in the world with concerns about the relationship among the participants or the nations involved in particular studies. It is possible that insisting upon reasonable availability, when feasible, will generate a shift of resources from the more affluent persons of the world (through their governments) to the less affluent. But if reasonable availability is not feasible, then insisting on reasonable availability as a precondition for a trial will result in no study at all, and will result in less redistribution, not more.

In this connection, it is also important to distinguish between the claim that the distribution of resources in the world is unjust and the claim that a sponsoring nation (or the home country of the sponsors) is causally responsible for the injustice. Crouch and Arras argue that the misery of people in underdeveloped societies "must be due in no small measure to the flagrantly unjust behavior of the former colonial powers, which plundered their natural resources and subjugated their peoples."⁵ Certainly, this is sometimes right, but equally often this is false. The poorest societies of the world are those that have had the least economic contact with the highly industrialized nations. They have suffered not because imperialism has made them worse off, but because the affluent

nations have found too little there to be exploited. Of course, even if the industrialized nations have not caused the poverty of the underdeveloped society, they may still have an obligation to ameliorate that poverty. The question is whether insisting on reasonable availability is the best way to do that and why the burden of ameliorating background injustice should be placed on clinical researchers.

Many commentators have argued, in effect, that to allow a placebo-controlled trial in a developing nation that would not be permitted in a developed society is to countenance moral relativism or a double ethical standard. If the Pharma trial would not be permitted in the United States, then it should not be permitted in Ecuador: "Residents of impoverished, postcolonial countries, the majority of whom are people of color, must be protected from potential exploitation in research. Otherwise, the abominable state of health care in these countries can be used to justify studies that could never pass ethical muster in the sponsoring country."⁶

Or, as Marcia Angell puts it, "Acceptance of this ethical relativism could result in widespread exploitation of vulnerable Third World populations for research programs that could not be carried out in the sponsoring countries."¹⁷

This is much too quick. Those who would defend trials such as Pharma in Ecuador but who would oppose such trials in the United States are not necessarily guilty of ethical relativism or applying double standards. Rather, an argument for allowing clinical trials to which the parties give voluntary informed consent maintains that this principle of informed consent should be universally applied. More importantly, all things are not equal between the United States and Ecuador. If, for example, it would be irrational for Americans to consent to participate in a placebo-controlled trial because they can assure themselves of a standard treatment, but it would not be irrational for Ecuadorians to do so because no treatment is available to them, then insisting that rational consent can be taken as valid will have different implications in the two societies, but there is no relativism or double standard here.

The most important point is this: We will not resolve questions as to the justifiability of studies such as the Pharma trial simply by invoking the derisive language of exploitation. This is just demagoguery. We will resolve them by the rigorous examination of ethical arguments and by the painstaking empirical study of the relevant data as to the effects of various policies on people's lives.

Empirical study is crucial. The principles of research ethics are not just high-minded ideals. They are regulations that affect what happens. Without endorsing any particular method of doing cost/benefit analysis, it would be highly unethical to ignore the consequences of imposing regulations in the world as we find it, however well intentioned. It's not just that regulations can be costly. Some regulations are actually self-defeating in their own terms. The FAA once considered a proposal that would have required young children to be placed in a child restraint on an airplane rather than allowing them to be held by an adult. The goal was to reduce infant deaths, and it was demonstrable that there would be (a few) fewer deaths on airplanes if infants were so restrained. Good idea? Probably not. The regulation would have saved relatively few lives at great cost because virtually everyone dies in most airplane accidents. More importantly, there is good reason to think that this regulation would actually have led to more infant deaths because the extra cost of buying a ticket for

one's child would motivate some parents to drive rather than fly, and being a passenger in a car is less safe than being held by an adult in a plane.

Similarly, it is possible that however well intentioned the principles designed to minimize exploitation in clinical research, the consequences of adopting those principles might well be worse for the people that they are designed to help. I do not claim that this is so. I suggest only that we must study the effects of such regulations on the people that they are designed to help and we should not assume that good intentions will be matched by good results. Interested parties should withdraw some of their heavy rhetorical artillery and begin the hard work of deliberating about the best ethical principles for the decidedly nonideal conditions that we encounter.

The Nature, Scope, and Justification of Clinical Research

What Is Research? Who Is a Subject?

This chapter begins with an examination of the nature and scope of medical practice. As we shall see, there are several alternative visions of the nature and scope of medical practice. *Clinical research* is a subset of a larger category called *biomedical research*, which has as its purpose the enhancement or improvement of medical practice. We cannot begin to consider the nature, scope, and justification of clinical research until we have a clear understanding of the enterprise it is intended to serve. This chapter also includes a review of the definitions of *research* and *human subject* that have been developed in the context of developing policy to safeguard the rights and welfare of human research subjects.

Definitions

The term *clinical* is derived from the Greek *klinikos* meaning “of or pertaining to a bed.”¹ Its original usage in the context of medical practice referred to a physician who attends bedridden patients, a clinician. It has since developed multiple meanings. A *clinic* commonly means a place where ambulatory (not bedridden) patients go to receive advice and treatment from health-care professionals. (It is also worth noticing, perhaps with some alarm, that we now have legal clinics and tennis clinics.)

In this chapter, the term *clinical research* means research involving human subjects that is designed to advance the goals of medicine (and other health-care professions). Some clinical research contributes directly to enhancing the professional capabilities of physicians and other health-care professionals through the development of new therapeutic (including diagnostic and preventive) interventions or procedures. Some other clinical research is de-

signed to contribute to the fund of knowledge in those sciences that are traditionally considered “basic” in the medical setting, such as biochemistry, physiology, pathology, pharmacology, epidemiology, molecular biology, and the cognate behavioral sciences; some, but not all, such research contributes indirectly to enhancing the professional capabilities of health-care professionals by adding to or refining the fund of knowledge that provides the basis for future research aimed at the development of new therapeutic modalities.

Biomedical research, which has the same purpose as clinical research, includes research that does not involve humans as subjects. The terms *clinical research* and *biomedical research* are, in common parlance, often used interchangeably. Much of the research carried out in medical school departments of medicine or surgery is biomedical research, which does not involve humans as subjects; those who do this research are commonly called clinical investigators, and the reports of their research findings are published in such vehicles such as the *Journal of Clinical Investigation*. *Investigation*, in this sense, means “research.”

The Domain of Medicine

In the introduction to his monumental work on the history of medicine, Henry Sigerist states:

The scope of medicine is so broad that it includes, under any circumstances, infinitely more than the physician’s actions. The task of medicine may be outlined under the following four headings: 1. Promotion of health; 2. Prevention of illness; 3. Restoration of health; and 4. Rehabilitation.²

In the traditional medical model, the focus is on the last two functions and their extensions. A person who feels ill initiates contact with a physician with the hope—and increasingly since the mid-20th century, the expectation—that he or she will be treated and consequently rendered healthy. The physician first makes a diagnosis, naming the disease that is causing the patient to feel ill. Based upon the diagnosis the physician can perform the other functions expected of him or her.³ The physician can provide (1) a prognosis, predicting what will become of the patient, and (2) therapy designed to cure the disease, to delay the progress of or compensate for its disabling manifestations, or to relieve symptoms. Finally, the physician is expected to care for the patient, with all that the word *care* implies.⁴

The principal focus of the medical profession and of biomedical research is on disease. In the modern concept of a disease, it is a distinct entity, the presence of which is verifiable objectively; it has a cause, and if we can identify the cause the physician can either cure or prevent it, or the means for its cure or prevention inevitably will be developed by the biomedical researcher. This view of disease presupposes that it is something distinct from the person who contracts it and that if rid of it, the person will be normal (healthy).

The doctrine that each disease is a distinct entity, the presence of which is verifiable objectively, was established firmly in the closing years of the 18th century by a group of Parisian physicians whose intellectual leader was Xavier Bichat.⁵ Their philosophical perspective was largely that of the French *ideologues* who accepted the philosophical empiricism of Locke; their concentration was on the careful observation of phenomena and their correlations and an avoidance of speculation and theory. Under their influence, two major traditions of medical science—each of which had yielded a classification of disease—were fused: (1) careful and systematic observation of the living sick person (clinical observation), and (2) systematic dissection of the dead person (necropsy), which yielded a body of knowledge known as morbid anatomy (forerunner of pathology, the study of diseases).

Morbid anatomy became the dominant science of clinical medicine because at the time, it was the only science of the human body that could provide objective evidence of concrete abnormalities. Most diseases were named after the abnormality found at necropsy. Thus, if a disease produced inflammation of the liver, it was named hepatitis (*hepar* = liver; *itis* = inflammation). During the late 18th and most of the 19th centuries, most maneuvers now recognized as the modern physical examination were developed. The ultimate test of a diagnostic maneuver was that it could predict what would be found at necropsy, and the ultimate test of a physician was that he or she could predict what would be found at necropsy.³ Through the remainder of the 19th and into the 20th century, other natural sciences were applied with increasing success to the description of normal and abnormal structure and function, to the identification of the causes of diseases, and to the mechanisms through which they produce malfunction and disability. With time, names began to be assigned to diseases according to their causative agents, for example, streptococcal sore throat (named for the bacteria that cause it); or by the physiological (e.g., high blood pressure) or biochemical (e.g., phenylketonuria) aberrations through which they might be identified.

Although the scientific disciplines used to identify and explain disease have evolved, the necessity of objective verification remained constant. Lack of objective verification may cast doubt on

the legitimacy of a discipline, on a proposed disease entity, or on the credibility of a patient. Thus, the specialty of dynamic psychiatry was admitted very slowly and grudgingly into the traditional medical profession. Early acceptance of organic psychiatry into departments of neurology was based on the fact that anatomical abnormalities, if any, were found in the brain and that some mental illnesses were caused by infection (e.g., syphilis), vitamin deficiency (e.g., pellagra), or hormonal imbalances (e.g., hypothyroidism).⁵ Full acceptance of dynamic psychiatry was delayed until the mid-20th century, when it was demonstrated that some severe behavioral disorders responded favorably to either surgery (e.g., frontal lobotomy), electroconvulsive therapy, or drugs (e.g., tranquilizers).

The modern examination of a patient by a physician evolved in the same philosophical tradition. A patient must receive an “adequate” examination consisting first of a complete “history” including a systematic quest for complaints that the patient may have neglected to mention and for diseases that may either be familial or related to environment or habits. After the initial examination the physician formulates an “impression” (equivalent to a hypothesis) as to what might be wrong. Evidence of the possible presence of various diseases is pursued with further diagnostic testing. When all the necessary data are available, the physician makes a diagnosis (equivalent to a theory). At this point, the other functions of the physician begin. If there is objective evidence of disease, a diagnosis is made; if not, a problem is presented to both physician and patient.

Until recently, a dichotomy was made between organic and functional illness. The former classification was assigned to patients having validated diseases, whereas the latter was a suspect set. Patients with functional illness were informed that there was nothing wrong and that they should stop complaining, or else the physician delicately suggested that they might see a psychiatrist—a suggestion that until recently patients usually resisted and frequently rejected.⁶ Talcott Parsons vividly described the sick role as one in which an individual might be excused from his or her usual obligations only on the conditions that (1) the sick role was legitimized by a physician and (2) the sick person was obligated to cooperate with the physician’s healing efforts.⁷ The paradigmatic experience is when a doctor’s note is required to permit return to school or work after an alleged illness. Consider the plight of the person with a functional illness.

Since the Second World War, several things have happened to change the composition of medicine. Three have had a profound impact on the orientation of biomedical research. First, the concept of disease began to expand. Disease, always recognized as a type of abnormality, gradually came to be equated with any deviance from accepted norms.⁸ But now the deviations increasingly derived their objective verification through the devices of the social and behavioral as well as the natural sciences. The identification of some sorts of children with learning disabilities as diseased or sick led to the development of therapies that often enhance their abilities; however, it reversed the model presented earlier. In some cases such children are “diagnosed” by school authorities and sent home with a note *to* the doctor. Illegitimate classification of a group may be associated with the social stigmatization of being sick without any possibility of therapy. As we label as diseases such things as alcohol abuse and drug abuse, inappropriate aggression and deviant sexual behavior, we begin to blur the distinctions between sin, crime, and disease. One who deviates from accepted

norms may now be offered the choice between the criminal role and the sick role. The physician, accustomed to playing legitimizer, may now be called upon to function as illegitimizing.⁷

As a consequence of the success of the struggle against infectious diseases—until the early 20th century the perennial greatest killers of people—a new constellation of diseases has emerged to dominate the lists of causes of death. These include the familiar triad of heart disease, cancer, and stroke. Treatment of these diseases is most effective if begun before they become manifest as illness. For example, high blood pressure, by producing relentless destruction of arteries over a period of many years, eventually produces heart attacks, strokes, and kidney failure, which, in turn, cause disability and death. Treatments of high blood pressure, begun before the patient feels ill, will greatly reduce the incidence of disabling and lethal complications. The physician, who is accustomed to dealing with patients who feel ill, is increasingly called upon to work with people who, although they may have diseases, feel well.⁵

As a consequence of these and other factors, strong forces have developed within and without the medical profession to change its primary orientation toward the maintenance of health rather than the treatment of disease. There has been an increasing emphasis on the approaches of public health and preventive medicine, and both of these disciplines have influenced the practice of medicine. The World Health Organization provides the following definition in its constitution: “Health is a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity.”⁹ Unlike disease, the presence of health is not objectively verifiable. Thus, the researcher has difficulty focusing on health as a definitive objective.

Public health, which is concerned with maintaining the health of populations, had its origins in the development of sanitation techniques for purposes of preventing contagious diseases. A story of one of its early successes (probably apocryphal, but often rehearsed) demonstrates the characteristic nature of its approaches and emphasizes that it is not always necessary to know the exact cause of a disease in order to prevent it.¹⁰ During an epidemic of cholera in London in 1854, John Snow observed that most fatally infected people seemed to have used the water pump at Broad Street. He persuaded the city authorities to remove the handle from the pump; almost immediately thereafter the epidemic disappeared.

In the 20th century the domain of public health has been extended to manipulations of the environment generally so as to maintain physical, mental, and social health. Among its concerns are improvement of working conditions (to prevent occupational diseases), urban planning (to reduce mental illness, drug abuse), clean air and water, highway safety, and so on.

Preventive medicine, which is concerned with doing something to or for an individual person in order to prevent future disease, also had its origins in the combat against infectious diseases.¹⁰ One of its notable early triumphs was the finding in the 18th century that persons could be protected from severe cases of smallpox (variola) by deliberately infecting them with material from persons with mild cases (variola); subsequently, it was found that even more satisfactory protection could be afforded by deliberate infection with a closely related and much milder disease, cowpox (vaccination). The latter finding was based on Edward Jenner's observation that milkmaids who contracted cowpox (vaccinia) retained a permanent immunity to smallpox.

In the late 19th and early 20th centuries, vaccines were developed that produced lasting protection against many of the major infectious diseases. Further, it was discovered that many severe diseases were due to nutritional deficiencies that could be prevented by appropriate diets, and the probability of acquiring some other diseases, for example, emphysema and venereal diseases, could be minimized through modification of personal habits. The approaches of preventive medicine have been extended into preventive therapy with a current emphasis on early detection of such diseases as high blood pressure and glaucoma so that they might be treated before disabling or lethal complications ensue.

For the purpose of discussing clinical research, I shall assume that the domain of medicine includes preventive medicine and public health. For the reason I mentioned earlier, I shall further assume that it does not embrace the additional component covered in the WHO definition of health. Biomedical research is concerned with physical and mental but not necessarily with social well-being.

Biomedical Research in Relation to Medicine

A revolution in medical education was launched in 1910 by Abraham Flexner, who proposed in his report to the Carnegie Foundation that U.S. medical schools should be reconstructed to emulate the highly successful European (particularly German) university-based model. He suggested that all medical schools should have full-time faculties, that the teachers of medicine should be actively engaged in research, and that medical students should be educated in what he called the laboratory sciences.¹¹ By the late 1930s, all U.S. medical schools conformed to the Flexnerian model.

The disciplines that came to be known as the biomedical sciences are those that Flexner identified as the laboratory sciences. In general, they have comprised most of the first two years of the medical school curriculum; they are commonly referred to as the basic sciences to distinguish them from the primary focus of the second two years, the clinical studies. There is a general tendency to refer to research in these disciplines as biomedical research, whether or not it conforms to the definition used here.¹²

These basic sciences include anatomy (the study of bodily structure), physiology (the study of bodily function), biochemistry, pathology, pharmacology (the study of drugs), and microbiology (the study of microorganisms, many of which can cause disease). With the addition of statistics, behavioral sciences, molecular biology, immunology, and genetics, this model remains generally intact. In the 20th century, biochemistry, defined by Joseph S. Fruton as “efforts to explain biological phenomena in terms of the specific properties of chemical substances present in living organisms,” emerged as the natural science having the greatest power to provide an explanatory theory for the nature of health and disease as well as the development of remedies.¹² The approaches of biochemistry and molecular biology now dominate most research and explanatory theory in the aforementioned sciences.

If we accept the definition of medicine developed in the preceding section, it becomes apparent that biomedical research includes parts of almost all the natural, behavioral, and social sciences as well as many aspects of engineering. For example, although it is absurd to say that sociology is a biomedical science, it is clear that its research approaches are being applied to the

development of explanatory theories for health and diseases and, further, that social science research may suggest approaches to the improvement of public health and to the development of improved medical facilities. Although the researcher is more attracted to the study of disease than of health, this does not mean that he or she eschews the study of normal processes. The concept of a normal process presents no problem to the researcher; rather, it is the totality of the concept of health that defies scientific validation. The researcher knows that an understanding of disease—deviation from normal—is contingent upon a thorough understanding of the normal. As stated earlier, a disease is conceived as a distinct entity that has a cause; if we can identify the cause, the physician can either cure or prevent it, or the means for its cure or prevention inevitably will be developed by the biomedical researcher. The last part of this statement may be recognized as an article of faith that forms the basis for the mainstream of modern biomedical research.¹³

The foundations for this article of faith were established by the proof of the germ theory of disease and the consequent successes of immunization and chemotherapy.⁵ In 1876, Robert Koch first demonstrated beyond doubt that a specific disease (anthrax) was caused by specific bacteria. He developed a set of tests (Koch's postulates), which must be satisfied if an organism is to be accepted as the cause of a disease. Within a short period of time, bacteria that caused many diseases were identified. Aside from firmly fixing the concept of "one disease, one cause" in the tradition of biomedical research, this event had three other important practical consequences.

First, it was possible to isolate these bacteria and grow large numbers of them in pure culture. These cultured bacteria could be treated in various ways so as to render them less virulent. The less virulent bacteria could be administered to normal persons causing little or no illness but conferring a lasting immunity to the disease (immunization). Subsequently, very similar techniques have been applied to the isolation of other microbes and the development of immunizations (vaccines) against them.

Second, it was found that some dyes selectively stained certain cells—either bacteria or the cells of animal tissues—but not others. Presumably, their affinity for specific cells was based upon their chemical properties. It occurred to Paul Ehrlich that some poisonous chemicals might be developed that would have an affinity for bacteria but not other cells. Such chemicals would be "magic bullets" in that they would kill the cause of the disease without killing the other cells of those who were diseased. Among the chemotherapeutic agents (chemical therapies) found by this approach are sulfa drugs (derivatives of the original aniline dyes with which Ehrlich worked) and antibiotics.

Third, it was possible to inject disease-causing bacteria into animals and to produce in the animals the same diseases the bacteria caused in humans (animal models). Thus it became possible to perform increasingly sophisticated studies on the nature of disease. Further, it became possible to test the new vaccines and chemotherapeutic agents to see if they truly effected prevention or cure without seriously damaging the animal.

The expression *biomedical research* ordinarily calls to mind research on human subjects. Yet the vast majority of biomedical research activity is conducted on animals or their tissues, cells, or even parts of cells.¹⁴ Some is done on plants, and some uses nothing derived from living sources, for example, developmental engineering designed to improve devices such as cardiac pace-

makers. Because a need for prior animal experimentation is emphasized in such documents as the Nuremberg Code and the Declaration of Helsinki, it is often thought that its purpose is to try something out on animals to see if it is sufficiently safe to be tried in humans. However, much biomedical research is devoted to the development of animal models of human disease. The purposes of developing animal models are essentially those established in the development of the germ theory. The models provide efficient systems for the studies of mechanisms of disease, providing the basis for the development of more effective therapeutic technologies. Additionally, the availability of animal models greatly facilitates searches for causes, cures, and preventions.

Increasingly, the public tries to ensure the achievement of its research objectives through priority funding of "mission-oriented" or "targeted research."¹⁴ The researcher, perplexed by this, argues that one cannot commission discoveries; these are nearly always accidents. One cannot legislate that a scientist, such as Wilhelm Roentgen, while exploring a fundamental problem in physics, will accidentally discover the X-ray. Rather, through legislation one can create environments in which young prospective scientists will learn how to do research and how to deal with discoveries, their validation and their application to the solution of problems. Comroe and Dripps identified the 10 most important advances in the treatment of cardiovascular and pulmonary diseases—which currently account for more than half the deaths in the United States—and analyzed the sorts of research upon which they were based. Research was defined as "clinically oriented" (analogous to "mission-oriented"), even if performed entirely on animals, tissues, cells, or fragments of cells, if the author mentioned even briefly an interest in a medical problem. By these criteria, 41% of key articles leading to the development of the 10 most important advances were not clinically oriented. Thus, they conclude, if the public chooses to fund only clinically oriented research, it will sacrifice such advances as the development of antibiotics, polio vaccine, and so on.¹⁴

Conflicts Between Medical Practice and Research

There are important conflicts between the traditions and motivations of physicians and researchers. As much as we have attempted to fuse science with medicine, much of the practice of medicine is not scientifically based. Much of what the physician does in practice is dictated by authority.¹⁵ For centuries the authority was Hippocrates (5th century B.C.) as updated by Galen (2nd century A.D.); no physician dared challenge the teachings of Galen until the Renaissance was well established. Subsequently, although some authority (or the statements of some authorities) has been established through the scientific method, the vast majority of physicians' activities—particularly the caring functions—have no scientific validation. Further, the average physician, who has not participated in what scientific validation there is, must accept the statements of the new authorities with faith that the science upon which they are based is sound and accurately reported.

The researcher, by contrast, challenges authority. If there is one overriding ethic in research, it is to learn and to tell the truth. Authority, as established in the Hippocratic Corpus, instructs physicians to use treatment to help the sick according to *their* ability or judgment but never to injure or wrong them. Put another way, to help, or at least to do no harm.¹⁶ Truth is dispensed to the patient as cautiously and judiciously as any powerful remedy, with a clear

weighing of the potential adverse consequences. For thousands of years, the physician has known that a sick person who is convinced that he or she will feel better as a consequence of taking some remedy almost always will.¹⁷ Thus, while administering remedies, some of which were fantastic and nearly all of which were inert, the ancient physician uttered some mystical or magical incantation. The post-Renaissance physician was admonished by authorities to label a prescription with something in Latin that had no meaning to the patient (and often no meaning at all), for example, tincture of Condurango; the modern physician finds that labeling a drug with a long chemical name has similar effects. At times, the modern physician knowingly prescribes an inert substance called a placebo—from the Latin: “I shall please”—usually to produce relief of symptoms.

Similarly, it is in the tradition of the physician not to tell the patient the truth about diagnosis or prognosis unless the physician is reasonably certain that on balance the consequences of doing so will produce more benefit than harm.¹⁸ There are several other important conflicts. Physicians, by virtue of both the immediacy of contact with patients and the expectations of patients, are impelled to do something. Scientists, who can select their problems, are impelled to learn something. Physicians, whose “problems” select them, are constrained by their oath to conduct their practices with utmost confidentiality, and until recently were required by modern medical ethics to shun advertising. Scientists, whatever their primary motivations, can ordinarily achieve their rewards only through publication.

The conflicting motivations of the physician and the researcher produce the most dramatic tensions when both functions are being performed simultaneously by the same individual.¹⁹ Some authors have argued that these conflicts are essentially irreconcilable and—in the interests of protecting the patient who might also be asked to play the role of subject—that the roles of physician and researcher should always be played by different individuals.^{20,21} Others argue that the roles should not be separated because in the final analysis the best assurance that the welfare of research subjects will be protected derives from the motivations, or “conscience,” of the physician.²²

The tensions between the motivations and value systems of the researcher and physician are exemplified well in the widely used research design known as the randomized clinical trial (RCT). The problems associated with the RCT have been discussed extensively.^{21,23} Although the RCT was designed primarily to test new drugs,²⁴ it has since been applied to the evaluation of old drugs, vaccinations, surgical interventions, social policy interventions, and even intercessory prayer.²³

The RCT is a controlled study. That is to say, the therapy that is to be evaluated is administered to part of the subject population while another part—as similar as possible in all important respects—receives either another therapy or no therapy. The purpose of having simultaneous controls is to avoid the fallacy of *post hoc ergo propter hoc* reasoning, the mistaken belief that because B occurs after A, A must be the cause of B.

The significance of the results of the RCT is established through statistical analysis. Frequently, in order to generate sufficiently large numbers for statistical analysis in a reasonably short period of time, it is necessary to involve several medical centers in the study; thus, the design of the protocol and the evaluation of the results may be conducted in a center remote from that in which any particular patient-subject is being studied.

Controlled experimentation and statistical analysis are not recent innovations. The credibility of the former was established firmly in the 18th century when James Lind applied it to demonstrate that scurvy could be treated successfully by feeding citrus fruits to afflicted people. The power of statistical analysis to resolve otherwise irreconcilable conflicts over the relative merits of a particular form of therapy was established in the 19th century. One of its first triumphs was to demonstrate that bloodletting—in the early part of that century, the most popular form of therapy for all fevers—was much more dangerous than no therapy at all.⁵

In the 20th century additional features were introduced to the RCT. First, the suggestibility of patients, known and used to advantage by physicians for centuries, was acknowledged as a cause of some apparent drug-induced results. This is overcome by “blinding” the subjects (not letting them know which therapy they are receiving).²³ When the therapy is designed to produce relief of symptoms, the control group often receives a placebo.²⁵ It was then acknowledged that the biases of investigators might also influence results. Random assignment of patient-subjects to treatment and control groups is done to minimize these and other biases. Similarly, biases in the interpretation of results are eliminated through use of the “double-blind” technique; that is, neither the investigator nor the subject knows until the conclusion of the study who is in which group, treatment or control.²³

One can easily see how—in the negotiations for informed consent for participation in an RCT—nearly all the traditions and motivations of the physician must be suspended. Similarly, the effects on expectations and wishes of many patients may be devastating. There are those who argue that the entire process is so technological and dehumanizing that its use should be sharply curtailed.²¹ On the other hand, there are scientists²⁴ and physicians²⁶ who hold that the power of the RCT to develop sound information on the relative merits of therapies is so great that it would be unethical to introduce a new therapy without this sort of validation.

Ethical Justification of Biomedical Research

Biomedical research as a field of human activity is justified in terms of the good it can and often does produce. It has as its purpose the advancement of goals that are greatly valued by our society—enhancing the capabilities of physicians (and other health-care professionals) to serve the health interests of people. Some biomedical research projects do this directly and others indirectly by adding to or refining the fund of knowledge that provides the basis for future therapeutic innovations and improvements. The value of biomedical research is such that many commentators believe that society has a strong obligation to conduct, support, or otherwise encourage it. I have argued that society does have such an obligation but that this is not society’s strongest obligation.²⁷ As an obligation of society, biomedical research’s priority is not as high as, for example, the obligation to protect its members from harm and to secure the conditions of its preservation. Hans Jonas helps us put the nature of this obligation in perspective:

Unless the present state [conditions of life in our society] is intolerable, the melioristic goal [of biomedical research] is in a sense gratuitous, and this is not only from the vantage point of

the present. Our descendants have a right to be left an un-plundered planet; they do not have a right to new miracle cures. We have sinned against them if by our doing, we have destroyed their inheritance . . . not . . . if by the time they come around arthritis has not yet been conquered (unless by sheer neglect).²⁸

In the ethical justification of any particular research project, the first consideration is also an appraisal of the value and validity of the anticipated consequences.²⁹ The scientific design of the research must be adequate; otherwise one cannot anticipate accurate results (validity). Inaccurate results are of no value to society. Moreover, the anticipated results must be of sufficient value to justify the exposure of human subjects to the risks of harm presented by the project (value).

In addition to these beneficence-related requirements, the ethical justification of particular projects requires responsiveness to rules or norms related to the ethical principles of respect for persons and justice. As stated in Guideline 1 of the International Ethical Guidelines for Biomedical Research Involving Human Subjects, promulgated by the Council for International Organizations of Medical Sciences (CIOMS),

The ethical justification of biomedical research involving human subjects is the prospect of discovering new ways of benefiting people's health. Such research can be ethically justifiable only if it is carried out in ways that respect and protect, and are fair to, the subjects of that research and are morally acceptable within the communities in which the research is carried out. Moreover, because scientifically invalid research is unethical in that it exposes research subjects to risks without possible benefit, investigators and sponsors must ensure that proposed studies involving human subjects conform to generally accepted scientific principles and are based on adequate knowledge of the pertinent scientific literature.³⁰

Regulatory Definition of Research

The definition of research contained in the U.S. federal regulations for the protection of human subjects is, at the time of this writing, a topic of serious controversy. In this section, I shall review the origins of this definition with the aim of providing insight into its intended meaning and then survey briefly the controversy over its meaning. The definition in the U.S. regulations, codified at 45 CFR 46.102(d), is as follows:

Research means a systematic investigation, including research, development, testing and evaluation, designed to develop or contribute to generalizable knowledge. Activities which meet this definition constitute research for purposes of this policy, whether or not they are conducted or supported under a program which is considered research for other purposes. For example, some demonstration and service programs may include research activities.³¹

This definition was derived from that recommended by the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (hereafter, the National Commission) and published in its Belmont Report³² (see Chapter

14). It is worth noting in passing that the entire body of federal regulations that came to be known as the Common Rule is based on the recommendations of the National Commission.

The National Commission's definition is in the following paragraph:

For the most part, the term "practice" [of medicine or behavioral therapy] refers to interventions that are designed solely to enhance the well-being of an individual patient or client and that have a reasonable expectation of success. The purpose of medical or behavioral practice is to provide diagnosis, preventive treatment or therapy to particular individuals. By contrast, the term "research" designates an activity designed to test a hypothesis, permit conclusions to be drawn, and thereby to develop or contribute to generalizable knowledge (expressed, for example, in theories, principles, and statements of relationships). Research is usually described in a formal protocol that sets forth an objective and a set of procedures designed to reach that objective.³²

The National Commission, knowing the danger of stipulated definitions in policy documents,³³ adhered closely to the definition provided in *Webster's Third New International Dictionary*: "Studious inquiry or examination; especially: critical and exhaustive investigation or experimentation having for its aim the discovery of new facts and their correct interpretation, the revision of accepted conclusions, theories, or laws in the light of newly discovered facts, or the practical applications of such new or revised conclusions, theories or laws."³⁴

The first thing we notice about the National Commission's definition is that it was developed in contrast to a vaguely defined activity called *practice*. Why was the definition of practice so equivocal? Because the National Commission wanted to focus its attention on the relationship between the individual practitioner (medical or behavioral) and patient (or client). There are other types of practices including, for example, public health and "practice for the benefit of others" (a class of activities in which interventions or procedures are applied to one individual with the expectation that they will enhance the well-being or convenience of one or many others).³³ Such practices include, for example, organ donation, vaccination, quarantine, and heavy tranquilization of disruptive patients in a mental institution.

The National Research Act (Pub. L. 93-348), which established the National Commission, directed it to "consider . . . the boundaries between biomedical or behavioral research and the accepted and routine practice of medicine."³⁵ It did this because several prominent physicians regarded this as a very important and exceedingly difficult task.³⁶ Jay Katz identified "drawing the line between research and accepted practice . . . [as] the most difficult and complex problem facing the Commission."³⁶ Thomas Chalmers stated, "It is extremely hard to distinguish between clinical research and the practice of good medicine. Because episodes of illness and individual people are so variable, every physician is carrying out a small research project when he diagnoses and treats a patient."³⁶

Chalmers, of course, was only echoing the views of many distinguished physicians who had spoken on this issue earlier. For example, in the classic volume, *Experimentation with Human Subjects*, Herrman Blumgart asserted: "Every time a physician administers a drug to a patient, he is in a sense performing an experiment."¹⁸ Francis Moore added, "every (surgical) operation

of any type contains certain aspects of experimental work.³⁷ In 1975 the National Commission assigned me the task of writing a paper on this topic to inform the Commission's considerations of the boundaries. In that paper I wrote: "It is fortunate that sharp definitions of the boundaries are not required. Even a superficial examination of this problem (contained in this paper) will reveal the impossibility of describing mutually exclusive subsets (one called research and one called practice) of the universe of activities in which health care professionals may be engaged."³⁸ I revised this position later after I identified the barriers to defining research and practice as mutually exclusive sets.^{33,39}

In the 1970s, when the National Commission was doing its work, there were two major types of barriers to distinguishing medical practice from research. One was the fact that much of medical practice entails experimentation. The other was the widespread use of poorly defined terms to describe the use of innovative therapies. I will discuss these below.

Experimentation in Clinical Practice

Blumgart and Moore were right: The practice of medicine is characterized by experimentation. Chalmers illustrates the source of confusion by using the terms *research* and *experimentation* interchangeably. But these words are not synonyms. According to *Webster's Third New International Dictionary*, experiment means: "1a: A test or a trial; b (1) A tentative procedure or policy—especially: One adopted in uncertainty as to whether it will answer the desired purpose or bring about the desired result. . . ." ³⁴ A consideration of the treatment of a patient with antihypertensive drugs will illustrate the experimental nature of clinical practice. The physician usually prescribes a relatively low dose of a drug that is likely to be both safe and effective. At the next office visit, the physician may discover that the patient's blood pressure remains high, in which case he or she will ordinarily increase the dose of the drug. This process is repeated until either the blood pressure decreases to the desired level or the maximum recommended dose is attained. In the latter case, the physician will ordinarily prescribe another drug—one that is known to have effects that are additive to or synergistic with the first drug. Again, the dose is escalated as needed. If there is an unacceptable side effect of the drug, it is discontinued and replaced by another drug. All of this experimentation is intended "solely to enhance the well-being of an individual patient" and not "to develop or contribute to generalizable knowledge." In other words, it is clinical practice and not research.

One of the ethical problems presented by much research, particularly the RCT, is that the patient-subject is deprived of the therapeutic experimentation that characterizes clinical practice. For the duration of most RCTs, the subject receives a fixed dose of either the drug being evaluated or the comparator.

Terminological Inexactitude

An important barrier to the development of a satisfactory definition of research was the use of language that implied that the use of "nonvalidated therapies" was research. The Food and Drug Administration (FDA) referred to drugs that had not been approved for commercial distribution as "investigational." Physicians seeking informed consent to the use of investigational drugs are required by FDA, as codified at 21 CFR 50.25(a)(1), to tell patients

that "the study involves research" even when there is no research, as in the case of "compassionate use."⁴⁰ (*Compassionate use* means the use of an investigational drug for the treatment of patients who do not satisfy the eligibility criteria for drug trials that may be in progress. The FDA permits the use of some investigational drugs in situations in which no alternative drug is available or the treating physician believes that available alternatives would be clearly inferior for the patient. For example, the patient's disease may be refractory to approved alternatives or the patient may have experienced unacceptable side effects to all known approved alternatives. The FDA does not endorse use of the term *compassionate*.)

The FDA has the authority to regulate interstate commerce in drugs (among other things), and its regulations forbid sending across state lines drugs it had not approved for commercial distribution. Sponsors of new drugs who wish to ship drugs across state lines for the purpose of conducting research to evaluate their safety and efficacy are required to file a document called "Notice of Claimed Investigational Exemption for a New Drug." Although the adjective *investigational* is intended to apply to the exemption, with the passage of time, the shorthand expression *investigational new drug* (IND) became commonly used.⁴¹ This confusing usage persists to this day.

Another linguistic infelicity was the use of the term *therapeutic research* to identify research involving the use of interventions or procedures intended to provide direct health benefit for the individual patient-subject. Therapeutic research was distinguished from *nontherapeutic research*, in which there was no possibility of direct health benefit for the individual subject. It is not clear to me when the use of this distinction began to be made in discussions of the ethics and regulation of clinical research. The original Declaration of Helsinki (1964) distinguished nontherapeutic clinical research from clinical research combined with professional care. In the 1975 revision of the Declaration, "medical research combined with professional care" is designated "clinical research," and "nontherapeutic biomedical research" is also called "non-clinical biomedical research." The National Commission recognized that this terminology contributed to the problem in defining *research*. More importantly, it recognized that all policy documents and all discussions that rely on this distinction contain serious errors. Accordingly, it rejected this distinction and replaced it with more suitable terms. A full discussion of this topic is beyond the scope of this discussion; interested readers are referred to the cited publications.^{25,33,42}

Conceptual Clarification

The National Commission also addressed the problem of how to deal with clinical interventions that did not conform to what Congress called "the accepted and routine practice of medicine." In the words of the National Commission,

When a clinician departs in a significant way from standard or accepted practice, the innovation does not, in and of itself, constitute research. The fact that a procedure is "experimental," in the sense of new, untested or different, does not automatically place it in the category of research. Radically new procedures of this description should, however, be made the object of formal research at an early stage in order to determine whether they are safe and effective. Thus, it is the responsibility of medical practice committees, for example, to

insist that a major innovation be incorporated into a formal research project.

Research and practice may be carried on together when research is designed to evaluate the safety and efficacy of a therapy. This need not cause any confusion regarding whether or not the activity requires review; the general rule is that if there is any element of research in an activity, that activity should undergo review for the protection of human subjects.³²

This class of activities is most commonly called *innovative therapy*; I proposed that it should be called *nonvalidated practice* because the defining attribute was not novelty; it was lack of validation (demonstration of safety and efficacy), and the Commission's reasoning about how to deal with such practices applies to diagnostic and preventive measures, not only therapies.³³

As already noted, the National Commission rejected the concepts of therapeutic and nontherapeutic research. Instead of *nontherapeutic research*, the National Commission simply refers to *research* which is, by definition, something other than therapeutic. More cumbersome language is employed by the National Commission to convey the meaning intended most commonly by those who had used the expression *therapeutic research*. For example, in the Commission's report *Research Involving Prisoners*,⁴³ recommendation 2 states in part: "Research on practices, both innovative and accepted, which have the intent and reasonable probability of improving the health or well-being of the individual may be conducted. . . ." The same concept is reflected in recommendation 3 of the report *Research Involving Children*.⁴⁴ It is made clear that the risks and benefits of therapeutic maneuvers are to be analyzed similarly notwithstanding the status of the maneuver as either nonvalidated or standard (accepted). "The relationship of benefits to risks . . . (should be) at least as favorable to the subject as that presented by any" available alternative. The risks of research maneuvers designed to benefit the community at large are justified differently. If the risks are greater than minimal, special substantive and procedural protections are required.

The concept rejected by the National Commission is that entire research projects could (or should) be classified as therapeutic. All research projects include some components that are nontherapeutic. The Commission recommended that the separate components of the research be classified as either "beneficial" or "nonbeneficial" and each justified accordingly. The language recommended by the National Commission in *Research Involving Children* is in the federal regulations at 45 CFR 46.405: "intervention or procedure that holds out the prospect of direct benefit for the individual subject, or by a monitoring procedure that is likely to contribute to the subject's well-being."³¹ The process of sorting out the procedures and interventions according to whether they hold out, or do not hold out, the prospect of direct benefit for the purpose of justification of their risks is called *component analysis*.^{33,45,46}

Controversy Over the Definition of Research

Controversy over the definition of research began even before the promulgation in 1981 of the revision of the federal regulations that contained it. Although some said that the definition was not inclusive enough, most commentators who challenged the definition asserted that it was overly inclusive. In general, the complaints

about the definition were, and continue to be, complaints about the consequences of the definition: Anything that was included within the definition would be covered by the federal regulations for the protection of human subjects. Anxiety was provoked by the National Commission's statement in the Belmont Report of the reason for defining research: "It is important to distinguish between biomedical and behavioral research, on the one hand, and the practice of accepted therapy on the other, in order to know what activities ought to undergo review for the protection of human subjects of research."³²

Some social and behavioral researchers who testified at hearings held by the National Commission claimed that all they did in their research activities was to talk with their subjects. Therefore, they argued, any attempt to regulate this activity would be unconstitutional, an infringement of their first amendment right to freedom of speech. Institutional review board (IRB) review, they argued, would be a "prior restraint" on speech, and this is forbidden by constitutional law.³³ Social and behavioral scientists complained, and continue to complain,⁴⁷ that the definition created a forced fit of their activities into the medical model. Those who protested did not succeed in getting the definition changed; their protests, however, did succeed in getting the regulation writers to create exemptions from coverage by the federal regulations—exemptions that had not been recommended by the National Commission.

The level of complaint appeared to subside during the 1980s and early 1990s only to return forcefully since the mid-1990s. The crescendo in the level of complaint coincided with the increasingly aggressive enforcement of regulatory compliance by the federal Office for Protection from Research Risks and its successor, the Office for Human Research Protections (OHRP). In response to threats of regulatory sanctions, IRBs and other parts of the institutional human subjects protection system have become increasingly attentive to the bureaucratic details of their review and approval activities. Researchers have always considered the IRB review process burdensome,⁴⁸ and many find it intolerable.⁴⁹ Several groups of researchers have proposed that the definition of research should be changed; in general, they are proposing to change the definition so that most or all of their activities would not be considered research. I believe their motivation is to escape from the increasingly burdensome experience of regulatory compliance.

Examples of the fields in which researchers are striving to redefine research are public health,⁵⁰ quality improvement,⁵¹ social and behavioral research,⁴⁷ and health policy research.⁵² Their proposed revisions, each carefully gerrymandered to reduce their own compliance burdens, are not consistent with each other's. I have recommended to each of them that they discontinue their efforts to revise the definition of research. Instead, they should appeal for revisions of the list of exemptions from coverage by the Common Rule. For example, public health officials should appeal for exemptions for their outbreak investigations rather than quibble over whether such investigations are research or public health practice. There is nothing in an outbreak investigation that presents to the subjects risks as great as those presented by research on public benefit or service programs (particularly "possible changes in or alternatives to those programs"), a category that is already exempted at 45 CFR 46.101(b)(5) of the U.S. federal regulations.³¹ Further discussion of this topic is beyond the scope of this chapter.

Definition of “Human Subject”

The U.S. federal regulations define *human subject* and further terms contained within this definition as follows:

45 CFR 46.102 (f) *Human subject* means a living individual about whom an investigator (whether professional or student) conducting research obtains (1) data through intervention or interaction with the individual, or (2) identifiable private information.

Intervention includes both physical procedures by which data are gathered (for example, venipuncture) and manipulations of the subject or the subject’s environment that are performed for research purposes. *Interaction* includes communication or interpersonal contact between investigator and subject. *Private information* includes information about behavior that occurs in a context in which an individual can reasonably expect that no observation or recording is taking place, and information which has been provided for specific purposes by an individual and which the individual can reasonably expect will not be made public (for example, a medical record). Private information must be individually identifiable (i.e., the identity of the subject is or may readily be ascertained by the investigator or associated with the information) in order for obtaining the information to constitute research involving human subjects.³¹

When the foregoing definition made its debut in the revised federal regulations promulgated in 1981 (it had not been recommended by the National Commission), it attracted little or no attention. It became the subject of considerable controversy in 1999 shortly after the occurrence of what came to be known as the Virginia Commonwealth University incident.^{53–55} Researchers sent a copy of a questionnaire by mail to the home of one of their adult research subjects. When it arrived, her father opened the envelope and found that the information solicited in the survey instrument included some aspects of the medical history of the subject and other members of her family. Some of the information was of a highly personal and sensitive nature. He protested to various officials at the university and in the government that he and his family were involved in this study as research subjects without their informed consent. The matter was referred to OHRP, which ruled that he was right; he was a research subject and, because the solicited information was both private and sensitive, consent from the family members should have been obtained.

The ensuing challenges to the definition of *human subject* focused nearly exclusively on whether it was reasonable to require consent from the individuals (variously referred to in the debates as *secondary subjects* or *third parties*) about whom private and sensitive information was solicited. I do not intend to discuss here the merits of the arguments for or against the reasonableness of this requirement; such analysis is beyond the scope of this chapter. These debates have much in common with the efforts of some professionals to alter the definition of research so that they might be spared the burdens of regulatory compliance. The issue is not the definition; the issue is whether or not there should be a requirement for consent of the “secondary subjects.” Those who believe that consent should not be required should focus their attention on revising (or negotiating the interpretation of) the regulatory justifications for “waivers and alterations” of the elements of

informed consent at 45 CFR 46.116(d),³¹ and not on the definition of *human subject*.

Participants or Subjects?

In recent years some commentators have attempted to replace the word *subject* with *participant*. The motivation for this appears to be a concern with egalitarianism. To some, the word *subject* implies subjugation, as in “the King and his subjects;” the parallel would then be “the researcher and his or her subjects.” The word *participant*, by contrast, implies a moral equality between the researcher and the participant; they are each participants in the program known as research. We have seen similar egalitarian gestures in the past. In the 1970s, for example, such distinguished scholars as Jay Katz and Paul Ramsey attempted to replace the word *subject* with *co-adventurer* or *joint venturer*. Clearly these efforts had no lasting effect. The word *subject* in this context was never intended in the sense of *subordinate*. It was introduced into the lexicon of medicine around the beginning of the 19th century in the sense of “the subject matter of an art or science,” or “that which forms or is chosen as a matter of thought, consideration or inquiry, a topic, a theme.”¹ The patients who were presented to senior clinicians or professors for teaching purposes or for clinical consultations were called subjects. In the early 19th century, one definition of *subject* was “a person who presents himself for or who undergoes medical or surgical treatment.”

Undoubtedly, the researcher and the subject should be regarded as moral equals. There is nothing about the word *subject*, properly understood, that is inconsistent with that. They are, however, moral equals who are performing in differing roles. If the day comes that all persons engaged in research are called participants, it will be necessary to invent new language to designate which of the participants is responsible for negotiating informed consent, which will be eligible to share in the Nobel Prize, and which are entitled to compensation in case of research-induced injury.

Summary

Clinical research is defined as that subset of biomedical research in which the subjects of research are human beings. Biomedical research is defined as research having as its ultimate aim the advancement of the goals of medicine. The domain of medicine is defined most narrowly in the traditional medical model, which focuses the attention of the physician on a patient who either feels ill or has a disease, the presence of which is subject to objective verification. The broadest view of the domain of medicine holds that the primary concern of the profession is the maintenance of health, a state of complete physical, mental, and social well-being, not merely the absence of disease. Thus, biomedical research may be seen—according to the traditional medical model—primarily as the application of the natural sciences. In relation to a broader view of the domain of medicine, which includes preventive medicine and public health, biomedical research is extended to include some aspects of virtually all natural, behavioral, and social sciences.

Since early in the 19th century there has been a systematic effort to blend the scientific method into the practice of medicine.

And yet there are important conflicts between the traditions, assumptions, and motivations of physicians and researchers. As a consequence of these conflicts, serious problems may be presented to patients, subjects, physicians, and investigators. These problems are exemplified well in the peculiarly 20th-century device known as the randomized clinical trial.

The definitions of *research* and *human subject* contained in the U.S. federal regulations are each the focus of current controversy. The cause of these controversies is not the definitions themselves. It is the regulatory actions that are contingent on the definitions and their interpretation. The controversies would likely be abated if appropriate additions were made to the list of activities that are exempt from coverage by the regulations and if the regulatory criteria for waiver or alteration of the elements of informed consent were interpreted differently.

Four Paradigms of Clinical Research and Research Oversight

The understanding of appropriate ethical protections for participants of biomedical research has not been static. It has developed over time, with the evolution of biomedical research as well as social values. Since World War II, four major paradigms of research and research oversight have been operative in the United States. These paradigms incorporate different values and provide different approaches to research oversight and the protection of research participants.

For hundreds of years, research to test interventions had been sporadic.^{1,2} Little distinction was made between experimentation and therapy. Evidence of the effectiveness, and even safety, of medical interventions was rare.³ Until the late 19th century, most therapies could properly be considered experimental in the sense that they lacked empirical evidence for their effectiveness. Researchers were usually physicians, motivated to do what they thought best for their patients, and trusted to do the right thing.⁴ There were no specific codes of ethics, laws, or regulations governing the conduct of researchers, but peer judgment and influence served to contain fraud and abuse.⁵ For instance, in 1897 Giuseppe Sanarelli, an Italian researcher working on yellow fever, declared he had produced yellow fever by injecting a bacillus into five people.^{1,6,7} At a 1898 medical meeting, William Osler condemned Sanarelli saying: “To deliberately inject a poison of known high degree of virulency into a human being, unless you obtain that man’s sanction, is not ridiculous, it is criminal.”⁶

Systematic biomedical research began to grow as an enterprise after the development of penicillin and the passage in 1938 of the U.S. Food, Drug, and Cosmetic Act, which required evidence of safety before a product was marketed.⁸ Just before World War II, there was dramatic growth in research as an enterprise. Large

pharmaceutical companies were starting up; both public and private money was devoted to research; and research became increasingly centralized, coordinated, standardized in method, and publicly supported.

Since the beginning of World War II, understanding of the ethics and oversight of human subjects research has proceeded through four distinct periods or paradigms. Each period embodied different perspectives on research and its dangers and different conceptualizations of the goals of oversight. Each period also advanced a different underlying ethical principle guiding the protections of research participants; each empowered different institutions to implement the protections, and each had its own way of balancing protection of research participants against other important values in biomedical research. At least in the United States, the change from one period to another was frequently catalyzed by crises or scandals. To some degree the periods represent “swings of the regulatory pendulum”⁹ but, as will become clear, these swings were not along just one dimension.

Importantly, these periods or paradigms should not be thought of as Kuhnian paradigms with radical, instantaneous paradigm shifts.¹⁰ The transition between paradigms evolved over time, usually due to crises or scandals that forced a reexamination of the existing research oversight paradigm. The ideas that evolved, and were subsequently espoused, had antecedents in the prior paradigm. Furthermore, the dominant ideas and values of a prior paradigm often remained operative and influential in subsequent paradigms. Indeed, distinct paradigms can coexist, and it might be argued that none of the paradigms has been entirely supplanted. Nevertheless, although precise dates cannot be given for each period, there are important changes between periods symbolized

and encapsulated in the values of research oversight that become dominant.

Because the different paradigms overlap, controversies about the oversight system and the ethics of research are frequently disagreements over what values and which paradigms should be dominant. There may also be disagreements over what types of research studies the particular protections apply to. That is, one paradigm and its protections may clearly apply to intervention studies, but there might be controversy over whether they apply to epidemiology, pharmacokinetic, or normal physiology studies. Indeed, some of the more recent paradigms probably apply only to some types of studies. Table 22.1 summarizes the four paradigms and their important features.

Period 1: Researcher Paternalism

World War II had a profound impact on Western society, emphasizing the need for people to contribute to the social good. The importance of individual sacrifice for society's benefit was palpable. Indeed, in Britain it was thought that society's very survival depended upon such sacrifice, and in the United States there was a strong sense that if not survival, then certainly the country's winning of the war depended upon such sacrifice. Obviously this belief was manifest directly in fighting the war, but it also influenced related activities, such as biomedical research. Beginning with the war and extending for nearly three decades, the dominant view was that biomedical research was important for society's benefit and progress against diseases.⁴ Individual sacrifice was necessary for research and was justified by the tremendous good it would produce for all of society.¹¹ The war analogy was vivid, visceral, and, with the victory, validated by experience. Frequently, it was implicitly and explicitly invoked to justify clinical research.

Biomedical research during this period has been described as "unashamedly utilitarian."¹² The federal government and the pharmaceutical industry supported intensive research efforts to develop vaccines and antibiotics to help soldiers at risk from infectious diseases. This research frequently involved available and captive populations in prisons, orphanages, homes for the emotionally or developmentally disturbed and other institutions.¹³ Research was justified as a way for such groups to make their contribution to society. Biomedical research was clearly seen as distinct from therapy; participants who were not necessarily in need of therapy were accepting a personal burden in order to make a contribution to society.

Although utilitarianism is not the only philosophical approach that can justify individual sacrifice for the greater good of society, it is the best developed and accepted rationale. During this period, utilitarianism implicitly or explicitly became the dominant justification for research; and the dominant ethical principle guiding research and research oversight was social value. The ratio of risks to benefits for individual research participants might have been unfavorable—with high risks for the individual. But risks to the individual were thought to be outweighed by the emphasis on social value, the value of the knowledge to be gained for society.

By the late 1960s, clinical research was under attack and researchers found it necessary to articulate the philosophical justification for research, specifying the benefits of biomedical research for society and the need for individual sacrifice to achieve those

benefits. For instance, Hans Jonas attacked the underlying paradigm when he attacked the war image, specifically the idea that research with humans was necessary for society's survival.¹⁴ He also rejected the utilitarian philosophy underlying the research paradigm:

We may observe that averting a disaster always carries greater weight than promoting a good. Extraordinary danger excuses extraordinary means. . . . Much weaker is the case where it is a matter not of saving but of improving society. Much of medical research falls into this category. As stated before, a permanent death rate from heart failure or cancer does not threaten society. . . . The destination of research is essentially melioristic. It does not serve the preservation of the existing good from which I profit myself and to which I am obligated. Unless the present state is intolerable, the melioristic goal is in a sense gratuitous. . . . [Consequently, t]he surrender of one's body to medical experimentation is entirely outside the enforceable "social contract."¹⁴

Probably no one was more explicit in defending clinical research against Jonas's view than Walsh McDermott, one of the leading figures in postwar American medicine. In 1967, when addressing a colloquium on clinical research, McDermott argued:

When the needs of society come in head-on conflict with the rights of an individual, someone has to play God. We can avoid this responsibility so long as the power to decide the particular case-in-point is clearly vested in someone else, for example, a duly elected government official. But in clinical investigation, the power to determine this issue of "the individual versus society" is clearly vested in the physician. . . . [A]s a society we enforce the social good over the individual good across a whole spectrum of non-medical activities every day, and many of these activities ultimately affect the health or the life of an individual. . . . I submit that the core of this ethical issue as it arises in clinical investigation lies in [that] to ensure the rights of society, an arbitrary judgment must be made against an individual. . . . [W]e have seen large social payoffs from certain experiments in humans . . . we could no longer maintain, in strict honesty, that in the study of disease the interests of the individual are invariably paramount. . . . To be sure, by careful attention we can cut down the number of instances in which the problem presents itself to us in its starkest form. But there is no escape from the fact that, if the future good of society is to be served, there will be times when the clinical investigator must make an arbitrary judgment with respect to an individual.¹⁵

Louis Lasagna, chair of Department of Pharmacology and Toxicology at the University of Rochester, agreed that individuals could be sacrificed for the greater social good and noted that the best protection for research participants was the ethical researcher:

Society frequently tramples on the rights of individuals in the "greater interest." . . . [T]he good of the individual and the good of society are often not identical and sometimes mutually exclusive. I submit that the successful development of such an ethical conscience, combined with professional skill, will protect the patient or experimental subject much more effectively than any laws or regulations. . . . I believe it is

Table 22.1
Four Periods and Paradigms of Research Oversight

<i>Period/Paradigm</i>	<i>Dates</i>	<i>Triggering Event</i>	<i>Key Protection</i>	<i>Conception of Clinical Trial Participant</i>	<i>Roles of Research and Health Care</i>	<i>Underlying Philosophy</i>	<i>Highlighted Ethical Principle</i>
Researcher paternalism	1940–early 1970s	World War II	Researchers' judgment	A passive subject of research	Sharp distinction between care and research	Utilitarianism	Social value
Regulatory protectionism	Early 1970s–late 1980s	Jewish Chronic Disease Hospital Scandal; Tuskegee Syphilis Study; Beecher's revelations	IRB review and individual informed consent	A vulnerable patient	Research priorities seen as threat to clinical care	Principlism	Independent review
Participant access	Late 1980s–mid-1990s	AIDS epidemic; breast cancer movement	Individual autonomy	An informed consumer	Clinical trials viewed as best, cutting-edge clinical care	Individual rights–based theory	Informed consent
Community partnership	Mid-1990s	Genetic research among Ashkenazi Jews and aboriginal communities; international HIV/AIDS research	Host community collaboration	An active “participant” in the research enterprise	Research and clinical practice go hand in hand	Communitarianism	Collaborative partnership

inevitable that the many will continue to benefit on occasion from the contributions—sometimes involuntary—of the few. The problem is to know when to say “Halt!”¹⁶

During this period, the main protections for research participants were the integrity of the researcher and the researcher’s judgment. Informed consent was seen as a lesser protection. At the end of the 19th century, Walter Reed had obtained consent for his yellow fever experiments. Over the next 70 years, researchers typically obtained informed consent to research from healthy volunteers. However, consent to research from patients receiving experimental treatments was much more inconsistent. More important than informed consent, it was argued, was the caring, compassionate researcher. Researchers were seen as concerned with the participants’ well-being and wanting to protect them. The judgment of researchers regarding the types of research projects they thought were reasonable, as well as what risks and risk-benefit ratios were reasonable, was deemed an appropriate and acceptable safeguard. Individual researchers’ judgments about what was reasonable were influenced by what the wider research community deemed acceptable, and that remained an important protection. Nonetheless, the main protection was really researcher paternalism.^{4,15,16}

This view was widespread. One of the persons most responsible for ending this paradigm—although he did not intend to end it—was Henry Beecher. Through his 1966 article in the *New England Journal of Medicine* delineating 22 cases of abuse of research participants, he catalyzed a transformation that changed the paradigm of research and research oversight.¹⁷ Yet throughout his career he maintained that the care and integrity of the researcher, rather than informed consent, was the best way to protect research participants. In this sense, he very much supported a kind of researcher paternalism paradigm, although his aim was to emphasize that researchers had to have the right goals in mind:

The ethical approach to experimentation in man has several components; two are more important than the others, the first being informed consent. The difficulty of obtaining this is discussed in detail. . . . Secondly, there is the more reliable safeguard [for the research participant] provided by the presence of an intelligent, informed, conscientious, compassionate, responsible investigator [emphasis added].¹⁷

Importantly, the researcher paternalism paradigm for protecting research participants was not an isolated phenomenon; the social values that informed it influenced other areas of medicine. Paternalism cohered with both the prevailing ethics of clinical care and the legal standards of informed consent for clinical care at that time. During this period, almost everyone agreed that physicians should influence treatment decisions for patients. Although it was accepted that physicians should obtain patients’ consent for medical procedures, the amount of information the physician disclosed was based on what the physician community determined was reasonable to tell the patient, the so-called professional standard. For instance, in the landmark *Natanson v. Kline* case, the Kansas Supreme Court held: “The duty of the physician to disclose . . . is limited to those disclosures which a reasonable medical practitioner would make under the same or similar circumstances.”¹⁸

It also was accepted that physicians might not tell patients about their cancer or other serious, life-threatening illness out of

concern for their best interests.¹⁹ Indeed, the physician was frequently entrusted with deciding what was best for the very sick patient without gaining the patient’s informed consent.²⁰

Period 2: Regulatory Protectionism

The period of researcher paternalism came to an end in the early 1970s after a series of scandals. The Jewish Chronic Disease Hospital case, Henry Beecher’s revelation of many unethical practices in clinical research at leading medical centers, and the Tuskegee Syphilis Study, among others, discredited researchers as concerned protectors of participants’ well-being and interests^{17,21,22} (see Chapters 6, 7, and 8).

What became clear through many of these cases was that researchers were not always judiciously weighing social value over individual risk-benefit assessments when they were in tension. Rather, researcher paternalism was sometimes a cover for blatantly unethical practices with few social benefits. In both the Jewish Chronic Disease Hospital case and the Tuskegee Syphilis Study, pervasive deception was used to enroll and retain relatively powerless participants.^{17,21,22} Although deception might not have had an adverse physical impact in the former case, it certainly prevented many African Americans from getting curative therapy in the Tuskegee case. Furthermore, in some cases, including Tuskegee, the social value of the research was highly questionable.^{21,22} Beecher summarized the problem: “Undoubtedly all sound work has [the good of society] as its ultimate aim, but such high flown expressions are not necessary and have been used within recent memory as cover for outrageous ends.”²³

The cumulative effect of these scandals was to repudiate researchers as effective overseers of the interests of participants and the ethics of research, and to question the underlying utilitarian justification for research ethics. The scandals led to a period of intense debate about the scope and limitations of research involving human subjects. Passage of the National Research Act in 1974 and the creation of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research led to a comprehensive reassessment of the ethics of research and the appropriate oversight system.²⁴ The result was a regulatory system for federally funded research, codified in 1981 as Title 45, Code of Federal Regulations, Part 46, entitled “Protection of Human Subjects,”²⁶ which a decade later became the Common Rule (see Chapter 15).

The underlying view informing this oversight system was that biomedical research, although valuable and in some sense necessary, was inherently dangerous and a threat to the well-being of participants. The goals of therapy and research were distinct. The goal of the oversight system was protectionism—to protect participants from researchers and the inherent risks that they and their research posed. Institutional review board (IRB) review and individual informed consent were thought to be the best mechanisms to protect research participants from the risks and burdens of research. In addition, special protections were built into the regulations for various groups deemed especially vulnerable to the threat and harms posed by research—prisoners, pregnant women, and children.^{27–30}

A critical aspect of the protections put into place during this period was that decision-making authority about research was partially taken away from physician researchers and put it into the

hands of independent review groups, government regulators, and research participants themselves.³¹ IRB review and informed consent did not come out of nowhere. As noted, informed consent for research studies from healthy volunteers had increasingly been standard practice since the turn of the century and was performed consistently with patients at certain institutions. Research review committees had been established at various institutions, such as the Clinical Center of the National Institutes of Health (NIH).³² Nevertheless, before adoption of the federal regulations, there were no uniform rules regarding the content of informed consent or the composition and operation of the independent review committees. Furthermore, under the researcher paternalism paradigm, neither informed consent nor independent review was seen as mandatory, especially in research with patients. As in the case of the Jewish Chronic Disease Hospital, researchers felt that obtaining consent might upset the participants and that therefore it could be suspended. And much research was conducted without any independent review. Thus, a major element of the change in paradigm was to formalize informed consent by requiring written, signed informed consent documents, formalizing the review process and, at least for federally funded research, making both informed consent and independent review mandatory.^{24,27} The underlying ethical philosophy was one of principlism formalized by Tom Beauchamp and James Childress in their book *Principles of Biomedical Ethics*³³ and the National Commission's Belmont Report,³⁴ which Beauchamp took a leading role in writing (see Chapter 14). This approach eschews comprehensive ethical theories in favor of mid-level principles that are shared and can be justified by a variety of ethical theories, particularly utilitarianism and deontology. Three ethical principles—respect for persons, beneficence, and justice—became linked to and justified specific requirements for regulating research: informed consent, determination of a favorable risk-benefit ratio, and fair selection of subjects.³³

Ironically, although these protections emphasized informed consent and were justified in part by appeals to the principle of respect for persons, they remained somewhat paternalistic, although in a manner different from the research paternalism of the previous paradigm. For example, the new federal regulations prohibited most research with prisoners.^{27,29} This restriction clearly limited prisoner autonomy but was believed to be justified because of the coercive circumstances of prison. Similarly, research with pregnant women was limited. The constraint on the autonomy of women was justified by the need to protect their fetuses.²⁸

Once again, the oversight of clinical research was not being reassessed in isolation. At the same time there was a pervasive social reassessment of the ethical norms governing medical practice as well as a reevaluation of informed consent. The claim that professional ethics, codes, and oaths established by physicians should serve as normative standards was being attacked. Physician-generated rules for physicians were viewed as inadequate and suspect.^{20,35} Instead, universal ethical principles that were independent of the profession, such as beneficence and autonomy, became the basis for ethical medical practice. As Robert Veatch argued in his book, *A Theory of Medical Ethics*,

What is being questioned is the authority of a professional group to set its own ethical standards and to adjudicate disputes about the conduct of its members. . . . Our conclusion is that a professional ethics grounded in nothing more than

agreement, custom, or vote by a group's members can have no ethical bite. No one outside the group would have any reason for conforming to the professional ethical judgments.³⁶

Veatch argued for a social contract to replace the profession's ethics. Regardless of his specific alternative, the key point was that general ethical norms should be controlling, not norms specified by the profession for itself. This clearly mirrored the change from research oversight based upon professional judgment to oversight that was imposed from outside and derived from independent ethical principles.

Similarly, in 1972, the *Canterbury v. Spence* ruling by a federal appellate court delineated a different standard for assessing the amount of information that should be disclosed to patients as part of the informed consent process for medical interventions.^{34,37} The court rejected a professional standard and articulated a patient-centered standard in which the goal was to give patients the power to decide what was in their interest rather than entrusting their interests to physicians.^{34,36}

Mortimer Lipsett of the NIH explicitly recognized in 1982 that a utilitarian justification of individual sacrifice for the good of society was no longer tenable. In his defense of Phase I oncology studies, he recognized the centrality of individual autonomy in research:

The larger questions about the ethics of phase I clinical trials of cancer chemotherapies have not been discussed in depth. . . . [I]s this phase I trial an example of the sacrifice of the individual for the good of society? . . . The question is philosophical in nature, and the answers are conditioned by the prevailing morals of society. It is clear that in certain circumstances we mandate individual sacrifice for the good of society. For example, the citizen drafted into the armed services may have to risk his life without prospect of immediate personal gain, although, even here, remote personal gain, such as preservation of home, family, and way of life can be invoked. Although this social contract has been generally accepted . . . considerations change. A foundation stone of our moral and legal framework is autonomy—the right to personal inviolability, control of one's person, and the exercise of free will in taking risks. . . . In medical research, the imperative for sacrifice is not present, nor is it part of the social contract today. One need only recall the horrors of medical experimentation during World War II to appreciate the brutal extension of the utilitarian philosophy of sacrifice of the individual for a societal purpose.³⁸

Period 3: Participant Access

Beginning in the late 1980s, the oversight system built around protecting potential research participants from researchers and the risks of research began to be attacked. Although the change was heralded by heated emotion and protests, the cause was not a scandal in which people were being harmed by research but a new health crisis, the AIDS crisis. The fatal nature of the disease and the paucity of effective treatments induced a demand for more research. People with HIV faced the prospect of dying inevitably and quickly. To them, trying a therapy that was unproven, potentially risky but also potentially beneficial, seemed reasonable. They argued that participation in clinical research was a benefit that in-

dividuals should not be denied, rather than a harm to be protected against. They assailed federal regulations aimed at protecting research participants as obstacles rather than safety measures.¹³ They viewed protectionism as discriminatory in that it prevented them from getting experimental interventions that they wanted. Rather than protecting them from potential exploitation, they considered exclusion or limited access to trials as harmful and unjust. HIV patients rejected regulatory protections from researchers and research interventions and demanded access to experimental interventions. Activists asserted an autonomous right to try risky but potentially beneficial treatments—a right that they claimed should trump regulatory protectionism and paternalism. Martin Delaney of Project Inform said, “People with life-threatening illnesses have rights that supersede those of society to control their behavior.”³⁹

To the AIDS activists, regulations that forced them to die without trying something were more dangerous than researchers with unproven experimental interventions. Just as relying on researcher paternalism often exposed people to excessive risks, HIV activists argued that regulatory protections exposed people to the excessive risk of doing nothing. The justification for regulatory protections in research was challenged as the regulations’ consequences and costs were exposed.⁴⁰ Delaney recounts,

The epidemic will not pause for the traditional modes of science; AIDS has forced the acceleration of the procedures and processes of clinical investigation, as well as the mechanisms of regulations. . . . The basic concept of human experimentation has been radically altered—from protecting individuals from research to attempting to ensure individuals access.³⁹

The regulatory pendulum began to move.

This period marked not only another major reassessment of research but also substantive changes in the way federal research agencies did business. Research was now perceived not as necessarily harmful but as a societal good—and as an opportunity for treatment. Concomitantly, researchers were not to be feared as enemies but to be seen as allies. Moving away from an emphasis on protection against research, laypeople and patient advocates began demanding access to research. Many advocates and patients argued that more efficient and equitable studies could be done, with better patient compliance, if community physicians participated in clinical trials. A number of programs were established to allow clinical providers in the community to participate in conducting research, such as the Community Consortium in San Francisco, the American Foundation for AIDS Research’s (AmFAR) community coalition, and the Community Programs for Clinical Research in AIDS (CPCRA) formed by the National Institute of Allergy and Infectious Diseases (NIAID).¹³ The line between research and treatment was blurred as participation in research was seen as the best, and sometimes only, way to obtain needed treatment, and was being offered by community physicians in community clinics. And, it was argued, the best protection against harm and exploitation was the judgment of individuals about what was in their own best interests, not government regulations or bureaucrats deciding what risks were excessive. Delaney writes,

[R]egulators contend that desperate patients don’t know what’s good for them, that access to experimental treatments must be controlled by those with the proper scientific train-

ing . . . many feel this argument smacks of “big brother.” . . . No one disputes that the multiphase steps of clinical research are a proven way to quantify the effects of a drug. The question is whether those steps should be equally required when seeking to restrain a contagious, world-wide epidemic as when judging a new cold tablet or pain remedy. AIDS is the medical equivalent of war. . . . The question should be, “who gets to decide what risks are acceptable: the bureaucracy in Washington or the patient whose life is on the line?”³⁹

Although this trend began with HIV, it was subsequently re-enforced by activists associated with other serious diseases for which there also were few effective interventions or cures. Thus, advocates for people with breast cancer, diabetes, Alzheimer’s, and other diseases adopted similar pleas for access to clinical trials. Additionally, critics charged that certain groups who were traditionally underrepresented in research were being denied not only the possible benefits of participation but also the benefits of the application of knowledge gained through research. In the early 1990s, the NIH began to require that federally funded researchers enroll more people from traditionally underrepresented groups such as women and ethnic minorities, and later children.^{41,42}

Interestingly, this view also began to be supported by organized medicine. Beginning in 1995, the American Medical Association’s Council on Ethical and Judicial Affairs began considering equitable access to research trials across different groups, including sociodemographic groups. The Council even explored whether researchers had an obligation to secure funding for participation for those too poor to pay for the various medical interventions required by a trial. Ultimately, the Council rendered a much less innovative opinion. It recognized that “ethical considerations in clinical research have traditionally focused on protecting research subjects” and urged that under the rubric of protectionism groups should not be “categorically excluded, or discouraged, from research protocols.”⁴³ However, the Council fell short of demanding access for participants from these groups.

The underlying ethical principle emphasized in this period was the right to autonomy. According to this view, individuals did not need to be protected by regulation; rather, they should be entrusted to know their own good and their own best interests, and they should be free to pursue them. After all, as Mill said, the individual knows best what is in his or her best interest and is in the best position to pursue it. Autonomy was invoked as overriding the protections provided by the federal regulations. Activists demanded changes in the oversight system. They succeeded in getting a faster Food and Drug Administration (FDA) approval process for therapies aimed at life-threatening diseases as well as a change in the clinical outcomes used to determine effectiveness.

Importantly, this new paradigm directed at access to trials had limited applicability. It was most relevant to intervention trials, but not to other types of medical research such as physiology studies or studies recruiting healthy volunteers.

Again, this perspective did not arise in isolation from the wider society. It was during Ronald Reagan’s presidency that individualism and the free market were championed and government regulation was strongly attacked as interfering with individual freedom. The arguments by the AIDS activists can be seen, at least in part, as an adaptation of this libertarian, individual autonomy view to the domain of research ethics. The words of activists could have come from libertarians: “If public and individual good are not

clearly harmed, then government should not stand in the way. That is the American way."³⁹

The pendulum swing to emphasizing the benefits of research and the preeminence of individual choice over societal restraints also occurred against the sociopolitical backdrop of a strong and visible gay rights movement, patients' rights movements, and patient and public skepticism about medical and scientific authority.

Period 4: Collaborative Partnership

Beginning in the mid-1990s, the limitations and potential drawbacks of the participant-access model began to become apparent in three areas: genetic research, research in developing countries, and increased patient demands for participation in planning research.

With dramatic growth in understanding of the human genome and how genes function, families and communities were increasingly being enrolled in research attempting to identify genes that cause disease. Such research implicated not just individuals but extended families and entire communities. Research involving Ashkenazi Jews, for example, especially research to identify genes related to mental disorders, and research that involved aboriginal populations prompted calls for extra protections for communities and for new involvement of communities in the planning, conduct, and dissemination of research.^{44,45} Involvement of communities, it was argued, was the best way to protect them from stigma and other potential harms from genetics research. It was observed that the existing federal research regulations focused on individuals and did not mention communities. This seemed to leave communities vulnerable.

Another development that stimulated reevaluation of benefits and risks was the growth of research in developing countries sponsored by developed countries—which some critics viewed as scandalous. Research on perinatal HIV transmission conducted in developing countries and sponsored by the NIH and the Centers for Disease Control and Prevention (CDC) in the late 1990s was attacked for using placebo controls in the trials and for succumbing to what many saw as an ethical double standard.^{46,47} Much debate and commentary ensued, especially about the possibility of exploitation of people in developing countries by researchers from rich, developed countries^{48–55} (see Chapters 64–67). One frequently recommended response to the possibility of exploitation was to develop partnerships with the community in which the research was being conducted.⁵⁶

At home, activist demands for easier access to clinical trials eventually led to demands for a greater role in research decision making. HIV and breast cancer activists fought for inclusion at the research table, and gradually but increasingly were consulted on the establishment of research priorities, review of protocols, lobbying for funding, and even recruiting clinical trial participants. Ultimately, several groups became less concerned with individual autonomy in deciding about enrollment in a particular study and more focused on community participation in the entire research process, from funding priorities to protocol development to dissemination of results.³⁹

In 2005, the United States was in the midst of this trend toward collaborative partnership in the research enterprise. The idea was far from widely endorsed and solidified. Nevertheless

important attempts were being made to realize this paradigm. For instance, the FDA regulations guiding emergency research promulgated in 1996 require community consultation⁵⁷ (see Chapter 27). Although the purpose and process of community consultation was not well delineated in the regulations, the inclusion of this requirement was a clear recognition of the need for community partnership, even if the mechanism for achieving it remained somewhat undeveloped.

This paradigm may well apply only to a segment of research, such as epidemiology and intervention studies. Nevertheless, collaborative partnership constitutes a new paradigm of research and research oversight. This paradigm is based on the recognition that clinical research does not occur in isolation; clinical research is a collaborative, social enterprise. This is obviously true in that it involves a community of scientists. But, more important, at least for certain types of research, especially disease-specific studies, it also involves a community of participants, medical practitioners, as well as the larger society required to fund the research and also assimilate the results into the health delivery system. The community is a necessary partner for successful research.

In the past, this collaborative partnership was implicit, even hidden. In the current paradigm, it is more explicit, more formalized, and more extensive. Community involvement is an important part of the process of establishing research priorities through public advocacy as well as participation on advisory boards and funding organizations. The community is involved in oversight of research through growing participation on IRBs and on monitoring boards. Community participation may extend to negotiating benefits from the research, assistance with recruitment, and then integrating results into guidelines, reimbursement policies, and other aspects of the delivery system.

The community partnership paradigm rejects professional paternalism as a protection because the responsibilities and privileges of the researcher occur only within a wider social framework. It recognizes that risks and benefits both during and after research are best evaluated by involved communities. In addition, this paradigm lessens the emphasis on individual autonomy and the protections of individual informed consent. Importantly, it does not reject these protections, but places them into a wider context of protections that need to be satisfied prior to seeking the consent of individuals. In this way, community partnership is based more on a communitarian model and less on an individual rights model.

Future

Over the past 70 years or so, the paradigm governing ethical treatment of participants in clinical research has evolved through several stages: from a model based on the social value of research and trust in investigators to one of stringent protections against the dangers posed by researchers and research itself; then to a paradigm that rejected protectionism and demanded wide opportunity to participate in research; and finally to a model that recognizes the importance of the community in ensuring the relevance and integrity of research practices. At least in terms of the involvement of ordinary citizens in the clinical research enterprise, there has been great progress and expansion. The early period of research paternalism minimized the involvement of participants and the public; the currently operative collaborative partnership paradigm

has integrated them as key participants in the entire research enterprise.

Each of these transitions has been catalyzed by scandals, crises, and/or changes in the nature of research practices. Although one paradigm was dominant at any particular historical moment, there has certainly been overlap. Strains of argument and reasoning from prior paradigms persist. The shift between paradigms is evolutionary rather than one of radical breaks, so there is continuity between prior and future paradigms, as well as change in emphases and in dominant values.

How the understanding of clinical research and ethical oversight may evolve in the future is unclear. Greater engagement of research participants throughout the process—from the development of research agendas and protocols to the conduct and dissemination of research and the altering of health policies in response to research results—is certain to shift the paradigm again. Currently, there is an enormous need for greater focus on how that participation can occur most efficiently and effectively in order to promote societal good through valuable research while respecting and attending to the rights and well-being of individuals and communities.

The Role of Patient Advocates and Public Representatives in Research

During the 1980s and 1990s, patient advocates became vocal participants in debates over biomedical research. Patient advocates helped persuade government officials to change rules governing access to clinical trials and unapproved medications. They joined scientific teams designing, conducting, and reviewing research. They lobbied for more government funds for research that could help their constituents, as well.

These developments occurred around the world. For example, the United Kingdom's National Health Service enlisted patient advocates to evaluate research priorities and help in planning health studies.¹ Developed nations sponsoring studies in developing countries worked with community representatives to plan and carry out the research.²

Advocates' insistence on participating in research decision making has changed the politics of biomedical research. Not everyone embraces the changes, however. Scientists worry that advocates focus too much on cures and treatments, without recognizing the importance of basic research. Researchers also fear that good science is threatened by the desire of seriously ill people to "try anything" after conventional therapies have failed. Public officials are unsettled by the apparent competition among patient advocacy organizations seeking government research dollars.

The contemporary patient advocacy movement offers many potential benefits. Advocacy could contribute to a biomedical research enterprise more in tune with the needs of the people the enterprise is designed to assist. It could prevent researchers' personal and professional aims from exerting too much control over research priorities. It could make the potential harms and benefits of research participation less mysterious to people enrolling in studies. It offers fresh opportunities for communication and exchange

between scientists and the society they serve, which could give researchers valuable insights into the human side of the problems they study, and at the same time give members of the public a more realistic picture of how research works and what it can achieve.

Yet these positive outcomes cannot be guaranteed. Genuine communication between scientists and the public is all too rare. Bridging the gap between the two worlds requires mutual willingness to learn and to value the other's knowledge. Shared decision making also costs money. Some will challenge the use of scarce resources to increase public involvement, and others will try to add public involvement cheaply, primarily for public relations purposes.

Advocates and other public participants confront these challenges from a variety of perspectives. Many advocates act as paid or unpaid representatives of specific disease interest groups. Other advocates fill a different role, that of general lay or public representative—sometimes without affiliation with a specific health organization. A third category of advocates comprises those representing communities and ethnic groups with particular interests in health research.

In the United States, the general public and patient advocates entered the biomedical research arena by two different routes. Public participation began with the emergence of the U.S. research oversight system. During the 1960s, as people became aware that research participants had been exposed to serious risks without their awareness or consent, scientists and government officials faced growing demands for safeguards to prevent similar violations in the future. Once officials and their advisers went to work on an oversight system to protect research participants, public representation surfaced as a key component of ethics review.

Designers of the oversight system thought that scientists and physicians too easily lost sight of their duty to put participants' interests above other research aims. They believed that "outsiders" could add an essential moral perspective to judgments about the ethics of proposed studies. Through this process, public oversight became an integral and enduring feature of U.S. research policy. By the early 1980s, federal government policy required ethics review committees to include individuals lacking employment or other personal ties to the institution in which the research would be conducted.

In the ethics review context, it was primarily government officials, professionals, and scholars who argued for a public role in research decision making. The strongest demand for public involvement came not from grass roots activists, but from "experts" designing the oversight system. By contrast, patient advocates became involved in research on their own initiative. Responding to personal and family health threats, advocates undertook a variety of activities in the research arena.

Patient advocates got their start battling restrictive regulations controlling access to promising experimental interventions. Beginning in the 1980s, activists sought to expand patients' opportunities to benefit from biomedical research. Advocates thought research policies focused too much on avoiding risks to research

participants and the public, and too little on promoting research benefits. The rules seemed to impede unnecessarily the development of new treatments to aid people in desperate need.

The U.S. pioneers in this form of advocacy were HIV/AIDS and breast cancer activists. By the 1990s, practically every disease or injury had its advocacy organization; many celebrities and public officials had also become involved in activities to raise awareness about research needs in specific areas.

Contemporary research advocates engage in many different activities. Much of their work focuses on three areas. First, advocates representing many disease constituencies help to plan, conduct, and evaluate research. Second, advocates promote policies allowing more people to participate in disease-related research. Third, advocates engage in extensive fund-raising, in both public and private sectors. This includes lobbying the government for more funds and participating in priority setting at health research agencies.

The remainder of this chapter examines these activities in detail. The first three sections focus on patient advocacy activities, and the fourth section examines public participation in research ethics oversight. The chapter concludes with ideas for enhancing the contributions that advocates and other public representatives make to research practices and policies.

Advocates on the Research Team

Many advocates seek to exert influence over the way biomedical research is conducted. This goal is shared by patient and community activists worldwide. Advocates representing numerous constituencies want to help researchers decide what problems to study, how to study them, and how to apply study results.

U.S. and International Origins

During the 1980s, as gay men in the United States sought to cope with the growing HIV/AIDS epidemic, they looked to medicine for assistance. Activists initially campaigned for more funding and a heightened national commitment to study the condition. Once an intensified research program was under way, however, advocates discovered that they had many disagreements with traditional research methods.

The focus of activist discontent was the randomized clinical trial (RCT). The RCT is commonly regarded as the gold standard for determining whether an experimental drug or other intervention is good enough to enter the realm of accepted therapy. Participants in an RCT are randomly assigned to different groups. Often one group in an RCT is assigned to receive a placebo, an agent believed to have no direct effect on the condition being studied. Adding a placebo group allows scientists to separate the improvements produced by the experimental and other active agents under study from any improvements caused by the placebo effect.³

To the HIV/AIDS activists, many of the RCT conventions seemed shockingly inhumane. In their eyes, it was unethical to give people with a life-threatening disease an inactive agent instead of a promising new experimental drug. They criticized other

aspects of the RCT, as well. For example, people with HIV/AIDS were often told that during trial participation, they would have to refrain from taking other medications, including drugs designed to relieve symptoms unrelated to the study. Some people also were excluded from trials because their past medication use might improperly influence study findings. Activists eventually persuaded researchers that some restrictive RCT demands could be relaxed without reducing the scientific value of the findings.⁴

Quick to learn from their counterparts in the HIV/AIDS community, breast cancer activists began in the early 1990s to demand a greater role in the research process. At first, their influence was most visible in the U.S. Department of Defense (DoD) Program for Breast Cancer Research.⁵ In 1993, advocates persuaded the U.S. Congress to set aside \$210 million of the DoD budget for breast cancer research. Because DoD was not a traditional biomedical research sponsor, the agency lacked established conventions for determining which studies it would fund. Activists saw this as an opportunity for a fresh approach to research decision making.⁶ The system that emerged gave advocates a role in determining the overall goals of the DoD program, as well as in selecting the proposals that received funding.

Breast cancer activists also created a training program to give advocates the scientific knowledge that would enable them to gain the respect of biomedical researchers.⁷ And at the international level, the U.S.-based National Breast Cancer Coalition organized conferences to promote and strengthen advocacy efforts worldwide.⁸

Separately, the participatory research movement—which supports community involvement in planning and conducting health research—has been applied to health research in many Asian, African, and Latin American nations. Participatory research holds that members of the study population possess knowledge that is as essential to a project's success as is the scientific and

medical knowledge researchers contribute. Fully realized, participatory research contemplates “researchers and local people work[ing] together as colleagues with different skills to offer, in a process of mutual learning where local people have control over the process.”⁹

Participatory researchers and the early HIV/AIDS and breast cancer activists shared similar aims. By the mid-1990s, these aims had been accepted in mainstream research settings, as well. For example, a 1995 *British Medical Journal* editorial declared that “patients should help to decide which research is conducted, help to plan the research and interpret the data, and hear the results before anyone else.”¹⁰

Strengths and Weaknesses of Advocate Involvement

Enlisting representatives of the study population as members of the research team highlights the moral and social dimensions of the biomedical research enterprise. The approach recognizes that this form of research is conducted not simply to answer abstract questions, but to provide health benefits to society. Once one accepts this concept of biomedical research, it is not difficult to envision the contributions affected people can make to improved research quality.

First, members of the community can provide information about which health problems, and which aspects of particular health problems, are most important for scientists to study. As one health researcher put it, “[g]reater lay involvement in setting the research agenda would almost certainly lead to greater open mindedness about which questions are worth addressing. . . .”¹¹

Second, representatives of affected groups can provide guidance on study design. For instance, a British researcher reported that when women were told of a proposed study of aspirin to reduce hypertension in pregnant women, they “asked why there were no plans to follow up the babies of women participating in the trial—[given that] for decades women had been warned not to take aspirin during pregnancy because it might harm their babies.”¹¹

Third, community representatives can help decide whether research results should change clinical practice. For example, after a study showed that large doses of antimalarial drugs during pregnancy could increase infants’ birth weights, New Guinea women “living in mud floored huts” pointed out that in their circumstances, bigger babies could make childbirth more risky for both mothers and children.¹¹

Fourth, community representatives can contribute to decisions on research merit. Lay representatives can be as qualified as researchers to evaluate the social value of research. They can also remind scientists and other review panelists “that we don’t want simply jewel-like studies that will stay on library shelves but studies that will actually make a difference.”¹²

Fifth, community representation can promote ethical research. Consulting with members of the study population “ensures both that their interests are central to the project or study, and that they will not be treated simply as objects.”¹² Community members are in a position to know what prospective participants should understand before deciding whether to enroll in a study.¹⁰ As HIV/AIDS activists demonstrated, advocates can also supply a participant-centered perspective on the potential benefits and harms accompanying study participation. Patient and community

advocates can foster justice in the choice of research participants, as well, by evaluating whether research will impose disproportionate burdens on a community or a community’s access to research benefits will be unfairly limited. And involving representatives can protect the community from further contact with researchers who “‘parachuted’ in, took samples, and disappeared with nothing of value resulting in the community.”¹³

Community involvement can be useful at the practical level, too. For example, researchers in Uganda reported that community representatives addressed potential difficulties involving local politics that would have presented “a quagmire for the unwitting outsider.”¹⁴ Recruitment approaches attuned to local concerns can increase study enrollment. Although the process of involving representatives will add to a project’s expense, “in the long run the net result will be an improvement in efficiency as a consequence of increased community support, more rapid recruitment, and enhanced cooperation on the part of subjects.”¹⁵

In sum, more community involvement could improve research in a variety of ways. But the endeavor is far from risk-free. Though many scientists and clinicians are enthusiastic about community participation, others remain unpersuaded.

Among scientists, there is continuing controversy over whether laypersons should participate in merit review of research proposals. Some researchers contend that community representatives on peer review panels are unqualified to judge the caliber of competing proposals. The controversy over merit review reflects divergent perceptions of research merit. Those who perceive a threat to scientific quality see merit in its more narrow technical sense, whereas their opponents see merit as a broader concept that includes social value.

Another threat arises when affected communities seek control over research data and publication of results. Disadvantaged communities most frequently seek this authority, citing past exploitation in research or other social contexts. For the community representatives and researchers supporting them, local control is a reasonable response to prior injustices and to an unfair convention giving researchers nearly absolute control over data and results.¹³

On the other side are scholars and researchers worried about threats to academic freedom and research integrity. An agreement giving a community substantial control over the written products of research “opens up the possibility of serious restrictions on [the researcher’s] academic freedom, and encroachment on the academic authority of his . . . university.”¹⁶ Censorship of results could also impede development of health benefits for the public.

Community involvement creates new issues for advocates, as well. When representatives of the affected community work with investigators to plan, conduct, implement, and evaluate research, they become part of the research enterprise. In the process, they may experience difficulties in maintaining their independence and legitimacy as community representatives. Moreover, some researchers may seek community input primarily for its symbolic or public relations value. In this situation, researchers may pretend to consider community views, but proceed to do what they would have done anyway. If the community opposes what researchers do, or a study has a negative community impact, representatives will be seen as complicit in the objectionable activity.¹⁴

Other challenges are related to community representation. Personal experience cannot in itself confer knowledge of “what it is like” for others in similar situations. Thus, the diversity of individuals within a community adds complexity to the task of

representation. At minimum, direct and ongoing communication with a reasonable number of other community members is essential to legitimate representation.

To succeed in this endeavor, researchers and patient advocates will need additional education, as well as reflection on the best ways to address the new challenges they face. The conclusion of this chapter offers ideas for responses to some of these challenges.

Expanded Access Activities

Patient advocates in the United States are enthusiastic proponents of government policies promoting expanded access to experimental interventions. Advocates contend that investigational agents and procedures offer people fighting serious illness renewed hope when standard therapies have failed. They also contend that involving more people in research is essential to delivering better therapies to the patients of tomorrow.

Contributions to Policy Revisions

During the 1980s, advocates for people with HIV/AIDS mounted a vigorous attack on the rules governing access to unproven interventions. Faced with a lethal epidemic and no effective treatments, activists were intensely committed to the search for new drugs to reduce death and suffering. As they embarked on this mission, they collided with a drug development system that was slow, inflexible, and highly risk-averse.

Displaying banners proclaiming “Red Tape Is Killing Us,”¹⁷ HIV/AIDS activists protested the U.S. Food and Drug Administration (FDA) rules on drug testing. They joined drug manufacturers and conservative policy groups in lobbying for policy changes.⁴ By becoming part of this unusual coalition, activists helped set in motion revisions that made experimental agents more available to seriously ill people.¹⁸

Although the driving force for FDA action was the HIV/AIDS emergency, the new policy measures had a much broader impact. They produced, for example, wider and quicker access to investigational agents targeted at cancer, Alzheimer’s disease, Parkinson’s disease, multiple sclerosis,¹⁸ and heart disease.¹⁹ Because of these revisions, seriously ill individuals unable to benefit from available treatments now enjoy increased liberty to seek help from promising but unproven interventions.

Activists were also key figures in producing a second set of policy changes affecting clinical research. In this development, women’s health organizations joined community health advocates in supporting policies aimed at increasing the participation of women and underrepresented ethnic groups in clinical trials.

This move led to two major policy changes. In 1993, the FDA abandoned its rule against including “women of childbearing potential” as participants in early phases of drug testing. Officials said studying a new agent’s effects in both genders was needed so that any gender-related differences could be identified early and adequately studied in later phases of clinical trials.²⁰

The same year, the U.S. Congress directed officials at the National Institutes of Health (NIH) to ensure that women and members of minority groups were included in government-funded studies. Officials then established guidelines to promote gender and ethnic diversity in study populations. The guidelines

instructed researchers to collect data that would allow valid analyses of possible gender and ethnic differences in response to experimental interventions.²¹

With the encouragement of patient advocates, Congress and agency officials then turned to two remaining barriers to research participation. To make patients more aware of their opportunities to enroll in clinical trials, Congress directed health officials to establish a public database with information about government and privately sponsored trials of “experimental treatments for serious and life-threatening diseases and conditions.”²²

Financial barriers to research participation were the second target of government action. Research grants ordinarily do not include money to cover hospitalization and other costs of routine patient care for people enrolled in studies. Some insurers were unwilling to pay for such care on grounds that trial participants received interventions not established as safe and effective.²³ At the behest of advocacy groups and researchers, officials sought to expand reimbursement for health-care services to trial participants.²⁴ Some states enacted laws requiring coverage²⁵ and in 2000, President Clinton directed the Medicare program to cover routine patient care costs for beneficiaries enrolled in clinical trials.²⁴

Activists were enthusiastic partners in the campaign to expand patients’ access to clinical trials and investigational interventions. These programs were consistent with the advocacy view that clinical trials “are the best means of finding the cause, cure, and prevention” of serious diseases.²⁶ The consequences of expanded access might not be all good, however.

Ethics of Expanded Access

In campaigning for expanded access, advocates could cite three established research ethics principles to support their position.²⁷ The first was respect for individual autonomy in choices about experimental interventions. Advocates argued that restrictive drug testing policies improperly interfered with constituents’ freedom to accept possible harm from exposure to unapproved agents in exchange for a chance to improve or extend their lives.

Advocates for women and ethnic minorities also stressed the value of free choice. Exclusionary policies and practices denied women the freedom to decide for themselves whether to enter trials that could improve health care for others and, possibly, their own care. Advocates supporting the two remaining government efforts to expand access invoked patients’ freedom of choice, too. The government-sponsored clinical trials database would give patients coping with illness a wider array of alternatives. Insurance coverage for trial participants would remove financial constraints on patient choice.

Activists calling for expanded access appealed to the ethical principle of beneficence, as well. Activists representing people with HIV/AIDS and other serious conditions stressed the benefits patients could gain through participating in clinical trials or using investigational agents outside a trial. Trying experimental interventions offered people with terminal illness a chance of benefit and presented insignificant risk, in light of their dire situations.

Advocates for underrepresented groups also invoked the beneficence principle in arguing that the failure to collect adequate data deprived women and ethnic minorities of medical benefits. Advocacy support for government efforts to publicize research

enrollment opportunities and secure insurance coverage for clinical trials rested on the beneficence principle, too. If more of today's patients enrolled in research, future patients would gain more health benefits.

Justice was the third ethical concept advocates cited to support expanded access. Restrictive approaches were a reaction to past cases in which scientists imposed unconscionable burdens on historically disadvantaged groups. But protecting disadvantaged groups from an unfair share of research burdens kept them out of clinical trials that could improve or extend their lives. Members of disadvantaged groups also received possibly inappropriate medical advice and treatment based on narrowly focused research.²⁸

Although expanded access can advance a number of ethical objectives, access alone cannot produce a more ethical research policy. To achieve this broader goal, additional ethical considerations must be taken into account. Moreover, the costs of expanded access must be acknowledged and reduced as much as possible.

A person can make an autonomous decision to enroll in a study or try an unproven agent only when the decision is adequately informed. The need for adequate understanding underlies the informed consent requirement. Yet empirical evidence suggests that many research participants fail to comprehend important information about the studies they join.²⁹ True freedom is not advanced when people choose investigational agents or procedures because they have inflated hopes of therapeutic benefit. If informed decision making fails to accompany expanded access, individual autonomy will be diminished, rather than enhanced.

Another major ethical justification for expanded access is its potential to increase the benefits available through biomedical research. There is no question that expanded access can produce benefits for participants, such as extended life, reduced discomfort, satisfaction from actively fighting one's disease, and solace in contributing to better care for others. At the same time, one should not underestimate the risks presented by investigational agents and procedures. Such interventions can produce physical, psychological, and financial burdens.

Although justice is also cited as an ethical basis for expanded access, financial and social inequalities limit this impact. Expanded access to research and unproven interventions must not be confused with expanded access to health care. Increased opportunities to enroll in clinical trials can do little to meet the needs of those unable to afford adequate health-care coverage. Any personal health benefits people gain through study participation often end with the study. Similarly, the campaign to secure insurance reimbursement for trial participants' patient care costs overlooks people with no insurance at all.

At the same time, expanded access policies require researchers to recruit more members of disadvantaged groups for study participation. Recruitment programs aimed at such groups frequently offer reimbursement for travel, child care, meal, and other expenses associated with study participation.³⁰ However, such incentives can induce people to join studies they would refuse if they were financially better off. The outcome could be that members of disadvantaged groups end up bearing an undue share of research burdens and lacking a fair share of the health benefits produced through such research.³¹

Thus, expanded access can have both good and bad consequences. At its best, expanded access can increase individual

freedom, enhance research benefits, and produce a more just allocation of research benefits and harms. At its worst, expanded access can foster uninformed decisions to try unproven interventions and lead low-income people to join studies in hopes of obtaining a fraction of the health services they need.

Advocates can play an important role in determining how expanded access turns out. Prospective research participants are not well served when advocates downplay the risks of trying unproven interventions or imply that access to research is equivalent to access to proven treatment. When advocates represent constituents in the policy arena, they assume a responsibility to assess access realistically. The final part of this chapter describes ways of meeting this responsibility.

Research Funding Activities

During the 1990s, U.S. officials faced heightened pressure from patient advocates seeking government dollars for health research. Advocates said the intensified congressional lobbying stemmed in part from their dissatisfaction with NIH funding decisions. They claimed that though NIH officials gave lip service to the importance of public participation in research priority setting, scientists actually controlled the agency's funding agenda. Advocates also charged that the agency played favorites, granting certain disease-specific interest groups overly generous amounts for studies on their constituents' health problems.

In response to these developments, NIH officials created more opportunities for advocates to help set funding priorities. But officials and patient advocates confront difficult ethical and policy issues as they seek to achieve the goal of increased public participation.

Advocacy's Potential Contributions

It is not surprising that people affected by disease and injury seek increased government funding for research on their particular conditions. In this sense, advocacy for research funding is simply an instance of the interest group politics shaping U.S. policy in all areas. Supporters say that patient advocates could help produce: (1) a research budget more consistent with public preferences and interests; (2) better-informed government officials and scientists; and (3) valuable health benefits.

Those favoring the changes say that scientific dominance has led to allocation choices that deviate from public preferences and the overall public good. They also suspect that scientists have been overly responsive to certain interest groups, and they contend that creating a more open and inclusive system could yield allocation decisions more consistent with the needs and values of the people whose tax dollars pay for federal research.³²

Besides producing a more democratic research budget, patient advocates supply valuable information to government officials. A graphic account of living with a serious illness or caring for an injured family member conveys personal knowledge missing from the facts and figures officials ordinarily rely on to make allocation decisions. Moreover, although channeling money to particular areas cannot in itself ensure scientific progress, financial resources are a necessary foundation for such progress. Funds enable scientists to conduct exploratory research, obtain training in previ-

ously neglected areas, share ideas, and formulate new avenues for investigation.

Advocacy also raises public awareness of a condition. Increased awareness can lead to higher rates of state and local funding, as well as charitable giving by the general public, wealthy individuals, private foundations, and industry.

Advocacy's Risks

A major concern is that advocacy for research funds could encourage unfair and inequitable allocations of limited public dollars. The problems arise because groups with the most effective presentations and best access to officials can gain disproportionate advantage over others. For example, one explanation offered for the lack of research on improving end-of-life care is that "dying patients do not form an energetic, ongoing constituency to advocate for more research," nor do "their survivors [who] tend to be exhausted and grieving."³³

Partisan research lobbying could also lead to inefficient resource allocation. This would occur if powerful interest groups persuaded officials to award funds for research on particular conditions without proper regard for the quality of proposed studies.³⁴ Poor-quality studies are unlikely to make any contribution to improved health care.

Research advocacy also consumes resources. When organizations spend substantial amounts to lobby for research funding, rather than for improvements in health-care delivery, housing, and other social needs, they arguably compromise their constituents' interests. When organizations focus on increasing funds for research on one condition, they ignore the fact that many of their constituents could be vulnerable to harm from other diseases or injuries.

New Roles for Advocates

With advocates' increased abilities to influence priority setting come changed roles and responsibilities. In many situations, decision makers may expect advocates to represent interests beyond those of their customary constituents. Advocates thus could be asked to express perspectives and values on behalf of the general public, or of a large subset of the population, such as elderly persons, medically underserved communities, or those at risk for genetic diseases. Accompanying this new role are new obligations, obligations that for the most part remain to be defined.

Advocates should recognize that a single-disease focus could be detrimental to their constituents' interests. Many constituents have multiple health needs over the course of their lives; thus, federally funded studies on different health problems could benefit them. Nearly all constituents have loved ones whose health care could be improved by research in a variety of areas. Constituents could also benefit from government support for social programs, such as health care and housing assistance. Advocates exploring these issues with constituents may find that narrowly targeted lobbying for research funding is inconsistent with constituents' actual preferences.

A single-interest approach to research advocacy raises more general moral concerns, as well. When advocates lobby to obtain the maximum possible research support for their specific constituents, they overlook the compelling needs of persons with other health problems.

By putting the spotlight on priority setting, advocates have created an opportunity to develop a more thoughtful approach to allocating biomedical research funds. According to a government report on priority setting, there is "no right amount of money, percentage of the budget, or percentage of projects for any disease."³⁴ But this claim is only partly correct. The "right" amount or percentage is a function of choices regarding which conditions merit more research attention than others, together with scientific and practical judgments on where it is realistic to expect progress. Increased public participation could produce a clearer picture of the relevant values and their relative importance.

There is reason for hope that advocates can contribute to fairness in research funding allocation. Although advocates have different ideas on how funds would be best allocated, most share a common desire to reduce the suffering and death inflicted by illness and injury. Though their constituents' interests affect their preferences on funding, most participants begin with altruistic intentions, too. In the concluding section, I offer principles to guide advocates in funding allocation activities.

Research Oversight Activities

The practice of appointing members of the public to committees reviewing studies involving human participants has long-standing public support. In the United States and worldwide, many policies require committees to include one or more public members. For example, guidelines issued by the Council for International Organizations of Medical Sciences and the World Health Organization advise that committees should include "lay persons qualified to represent the cultural and moral values of the community and to ensure that the rights of the research subjects will be respected."

Government officials, commentators, and review committee members point to five general justifications for including public members. First, public members add a common sense, "ordinary person" worldview that is often missing when professionals discuss research proposals.³⁶ The presence of public members can "transform the committees from closed associations of like-minded professionals who 'understand' one another into a more open forum of community responsibility."

Second, the public member's presence increases the chance that decisions will be consistent with local community attitudes and values. Situating ethics review in the setting in which research is conducted means that ethical judgments will be sensitive to actual conditions in the community.³⁸ Members of the general public are likely to be aware of particular religious, cultural, or economic factors that could affect local reactions to specific research projects.³⁹

Third, the public members help to apply specific ethical and regulatory standards. Public members delineate the real-world meanings of basic ethical concepts. For instance, public members are highly qualified to evaluate whether a proposed consent form and process will give individuals the information they need to decide about study participation.⁴⁰

Fourth, public members make research more transparent to the broader community. If ordinary people know that studies will be scrutinized by someone like them, they will be less worried about the possibility of hidden research improprieties. When they press investigators and researchers on the committee to describe study goals, procedures, and risks in plain language, public

members remind scientists of their responsibilities to communicate with ordinary people.

The public member's fifth contribution is representation. Many assume that unaffiliated institutional review board (IRB) members have a special responsibility to represent research participants. Thus, they are instructed "to see through the eyes of the patient and imagine what he or she is being asked to go through."⁴¹ At the same time, public members receive conflicting messages about their representation responsibilities. Public members are portrayed as representing the general public, poor people and other vulnerable groups, and most expansively, "patient-subjects, future patients, and the research profession all at once."⁴² Public members' activities on the IRB could vary substantially depending on which group they decide to represent.⁴³

Advocates in Ethics Oversight

Critics claim that the public member does little to disrupt "business as usual" in the research enterprise. For example, a 1998 government report declared that few research ethics review committees "seem to seek or be able, on a constant basis, to recruit and maintain lay and/or nonaffiliated members who play an active, effective role in helping the [committees] stay focused on their mission of protecting subjects."⁴⁴ Critics cite three problems with the current situation. First, public participants lack the technical knowledge and independent perspective that would enable them to participate fully in research ethics deliberations. Second, they operate in a system that minimizes their power and impact. Third, they lack a definite constituency to guide their contributions to research ethics deliberations.

Reformers dissatisfied with the current situation propose a number of remedies, such as increasing the proportion of public members on oversight committees⁴⁵ and improving training opportunities for public members.⁴⁶ Another potential remedy is to enlist more patient advocates to participate in ethics review.

To date, patient advocacy groups have devoted relatively little attention to research ethics oversight. Most of their energy has gone into promoting research through activities such as fundraising and lobbying for increased access to clinical trials. Although there are a few notable exceptions,⁴⁷ advocates have generally stayed away from research ethics review committees and debates over whether the rights and interests of research participants are adequately protected.

Yet there are good reasons for advocates to join research ethics oversight. Advocates familiar with clinical research issues would be much better equipped than most public members to evaluate investigators' proposed disclosure procedures, data collection methods, and other matters affecting study participants. Advocates could also bring personal knowledge to research oversight. Because of their close connections to patients, they are more likely than other committee members to appreciate the psychological, familial, and economic conditions affecting research participants. This is a perspective that can rarely be supplied by the attorneys, ethicists, chaplains, and other nonscientists serving on ethics review panels.

Advocates could bring passion, commitment, and energy to ethics deliberations, too. Many advocates are accustomed to negotiating with clinicians and researchers. This experience makes advocates less likely than other laypersons to be intimidated by professionals participating in ethics review. Advocates skilled in

communicating with both expert and lay audiences would also be highly qualified to express participants' concerns in ethics oversight activities.

At the same time, advocates themselves could benefit from such participation. Participating in protocol review would give advocates a deeper understanding of the research process and could be an effective antidote to unrealistic expectations about what research can deliver. The experience could sensitize advocates to the problems of patients outside their ordinary constituencies, which could have a beneficial impact in other advocacy work.

Not all patient advocates would be suited to oversight work. Yet their performance in other areas suggests that many could do an excellent job. Enlisting more advocates for ethics oversight would also be relatively easy to do. This proposal thus has the advantage of being simpler to implement than other suggestions for ethics oversight reform.⁴³ It would require no formal policy revisions; instead, all that would be needed is cooperation among advocacy organizations, review committees, and oversight officials.

Conclusions

By the end of the 20th century, patient advocates were an undeniable presence in biomedical research. Advocates made individual studies more responsive to the patients and communities that the research was intended to benefit. They persuaded U.S. agencies to adopt requirements for gender and ethnic diversity in study populations. They helped make experimental innovations more widely available to seriously ill people. They convinced government agencies to boost funding for biomedical research.

In many respects, the emergence of research advocacy is a welcome development. At the foundation of modern research ethics is the belief that research practice and policy ought not be decided by scientists alone. Rather, the values and preferences of the broader community must guide the conduct of research.

For the most part, however, the broader community has been excluded from the research world. Advocates are capable of changing this situation. The most effective advocates combine an intimate awareness of illness and caregiving with medical knowledge. This mixed expertise equips them to apply abstract ethical principles to specific study situations. Many advocates are vocal and articulate, and have strong ties to people who must live with the consequences of research decisions. At this point in time, advocates are better prepared than anyone else to represent the community in research decision making.

The emergence of patient advocacy also makes it possible to explore research ethics from the bottom up. Not enough has been done to discover what participants value, resent, and would change about the research experience. Advocates have knowledge to fill these gaps. Advocates could help scientists and professional ethicists to see research from the point of view of research participants and patients in the community.

At the same time, advocacy raises a multitude of unrecognized and unresolved ethical issues, and the time is ripe for systematic inquiry into these issues. Advocates are a trusted and powerful force in the research arena. Their choices and actions have a significant impact on constituents and others. To preserve their influence, and use it wisely, advocates must confront the moral dimensions of their work.

Ethical Principles for Research Advocacy

A review of advocacy's influence on research points to three ethical principles for advocates. First, advocates should be truthful when communicating with others about research. In much of their work, advocates convey tidings of hope to constituents and the public. The optimism undoubtedly provides solace to patients and families and is effective in fund-raising. The problem is that optimism can create unfounded expectations about research prospects. Biomedical research over the past 50 years has produced a few sudden and significant advances, many incremental improvements, and numerous advances in knowledge that have not yet produced actual health benefits.⁴⁸ Thus, talk of imminent cures is almost always disingenuous.

Advocates have a responsibility to be realistic when they speak and write about research. Conveying inflated optimism about what research can deliver deprives patients and families of the facts they need to make research, health-care, and other personal decisions. Such optimism can foster public support for research policies and funding allocations that rest on implausible beliefs. It can damage advocates' credibility, as well.

Research advocacy should also be guided by a second ethical principle: appreciation for the diversity of constituents. Like advocates, constituents are a heterogeneous group. Some constituents have the necessary self-assurance, education, and economic wherewithal to be savvy research consumers. Others, however, do not. As a result, a "one-size-fits-all" approach to advocacy risks compromising the interests of certain constituents.

The challenge for advocates is to take into account constituents' different interests and situations. It is fine to promote the liberty of constituents prepared to exercise it, but safeguards are needed for those lacking the ability to protect themselves. Advocacy efforts to date seem most tailored to confident, well-educated patients able to take full advantage of their expanded research opportunities. Advocates should supplement this approach with programs to assist constituents who are not in this situation.

The third ethical principle is to reject parochialism in research advocacy. Advocates applying this principle will support policies and funding allocations to expand constituents' access not only to promising experimental interventions, but also to established health care. These advocates will not concentrate solely on research if significant numbers of constituents lack access to standard treatments of proven benefit. In campaigning to secure insurance coverage for patients in clinical trials, they will endorse measures to make both trials and established treatments more accessible to uninsured patients.

Advocates applying this principle will take into account patients outside their immediate constituencies, too. On first glance, such an approach may appear to conflict with advocates' responsibilities to pursue the most advantageous outcomes for their constituents. Yet often there is no real conflict. Constituents themselves are vulnerable to other health problems, and most have family and friends at risk for or affected by a wide range of diseases. Thus, constituents have interests in maintaining research and other programs designed to assist people with a variety of conditions.

At a broader level, advocates should support measures that promote fair representation for all affected groups in research deliberations. Advocates should also consider collaborating to

devise a comprehensive plan for meeting the nation's health needs. A collaborative approach would reduce unseemly and self-defeating competition among interest groups. Moreover, an alliance of advocacy organizations would be a powerful force in shaping government, industry, and charitable support for research, health care, and other social services.

Preparing for Advocacy's Next Phase

In the next decade, advocates will confront a multitude of questions. At least three broad topics are likely to demand their attention. One is whether HIV/AIDS activism should continue as the model for research advocacy. As the first modern disease activists, HIV/AIDS advocates set the tone for those who followed. The success of HIV/AIDS advocacy prompted other disease interest groups to adopt similar goals and strategies. Now it is time for advocates to examine the virtues and pitfalls of the HIV/AIDS advocacy approach.

Several features of HIV/AIDS advocacy remain worthy of imitation. Most prominent is an emphasis on acquiring scientific and medical knowledge. Traditional patient advocacy organizations were content to leave research decisions to the scientific community. But HIV/AIDS activists proved that patient advocates could be valuable participants in such decision making. The grass roots character of HIV/AIDS advocacy is another feature with persistent appeal. Close involvement with local groups enables advocates to stay in touch with constituents' individual concerns.

Other features of HIV/AIDS activism seem less suited to future research advocacy. Certain deviations from the HIV/AIDS advocacy model might be in order for organizations representing people with cancer, heart disease, chronic obstructive lung disease, dementia, and other common serious conditions. In this context, emphasizing the search for a cure could diminish the attention given to patients' basic needs for health care and appropriate living situations. Cures for degenerative and chronic conditions arising later in life also are less likely to emerge than are cures for infectious diseases like HIV. Another lesson comes from the HIV/AIDS activists who eagerly embraced disease theories and interventions that were later discredited.⁴ These advocates learned the hard way that assertions and anecdotes cannot substitute for rigorous research, and that initially exciting interventions often fail to live up to their promise.

Private sector advocacy is another area demanding attention. To date, advocacy has focused on government research policies. But with industry controlling a growing percentage of biomedical research, advocacy belongs in the private sector, too. Advocates could offer assistance to industry sponsors seeking to meet ethical standards. They could also address research priority setting in the private sector by encouraging firms to develop medications and other innovations that would fill significant gaps in existing therapy.

The increased commercialization of biomedical research confronts advocacy organizations with internal issues, for industry sponsors sometimes seek to enlist advocates as partners in various endeavors. To avoid ethical and legal problems, advocacy organizations should adopt conflict of interest policies. Such policies should define when disclosure of corporate support is sufficient to address ethical concerns, and when support must be rejected as incompatible with the advocacy mission.

In the future, research advocates will also encounter an array of novel biomedical technologies. Advocates already have begun to participate in policy discussions on xenotransplantation,⁴⁹ stem cell,⁵⁰ and gene transfer⁵¹ research. Innovations in biomedical research require advocates to develop new kinds of scientific expertise. Acquiring such knowledge is a necessary step in developing defensible positions on the ethical and policy issues raised by these research innovations. As in the case of human embryo research, novel technologies may also produce contentious debate over the extent to which patients' interests ought to trump other social concerns.

Everyday research advocacy will generate plenty of future challenges, too. Advocates may have difficulty sustaining constituent and public enthusiasm if research fails to deliver dramatic treatment improvements. Researchers and officials in various settings may regard advocates primarily as public relations tools and turn a cold shoulder to patient-centered reforms. Politicians and entrepreneurs may attempt to manipulate research advocacy to advance their own agendas.

Biomedical research both reflects and influences the values of the society in which it occurs. Advocates have fiercely campaigned to put patients' interests at the forefront of research deliberations. Now they face pressure to refine their approach to constituent representation, cultivate alliances with other advocacy groups, and acknowledge the limits of research as a means to advance patients' interests.

Equipoise and Randomization

Most observers believe that randomized controlled trials (RCTs) offer the highest standard of evidence about the safety and efficacy of proposed new treatments.¹ When a new therapy's benefits are dramatic, nonrandomized studies may suffice to show its advantages. However, therapeutic advances more often involve small to moderate incremental benefits. Such benefits may be of substantial public health importance, particularly for common conditions.² Without the ability to conduct RCTs, efforts to evaluate such benefits are fraught with potential for error.

However, RCTs raise ethical challenges. In particular, randomizing patients to receive the experimental therapy, or a conventional therapy, or perhaps placebo, creates a dilemma. Clinicians are ethically required to offer patients the best available therapy. But researchers may propose to offer some participants in the trial an intervention that does not meet this "best available" standard.

Randomization is controversial in part because it draws attention to the uneasy coexistence of experimentation and therapy that exists in most clinical research. Notions of equipoise, which invoke some form of indifference between the interventions offered in a trial, have played a central role in efforts to reconcile the tensions between the roles of clinician and experimenter inherent in RCTs, and have found a place in the U.S. Department of Health and Human Services guidance regarding research design.³

However, equipoise is not universally accepted as the solution to the problems raised by RCTs. Definitions of equipoise vary, many authors doubt that it succeeds in reconciling the obligations of science and care, and more radically, some recent critics deny any need for such reconciliation. The epistemological assumptions underlying the notion of equipoise are also debated.⁴ Finally, even

if the argument for equipoise is correct, it ignores many of the ethical questions that RCTs pose.

In what follows, we outline the rationale for and methodological basis of RCTs, review the history of equipoise, discuss the different conceptions and critiques of equipoise, attempt to situate the challenges associated with RCTs within a systematic framework for ethical research, and suggest scientific and policy implications of these challenges. We also review the relevant empirical data in order to tie normative discussions of equipoise and other ethical concerns to the real-world practice of RCTs.

Before beginning, another word about terminology is in order. Because there are numerous competing notions of equipoise, and the word itself is so unfamiliar in ordinary discourse, in this chapter we will favor a neutral term—*indifference*—unless we are discussing specific conceptions of equipoise advocated by particular authors.

Randomized Trials: Core Conception and Methodological Rationale

All clinical research that aims to inform choices about prophylactic, diagnostic, or therapeutic interventions involves comparing the relative merits of two or more possibilities. Consider a hypothetical single-arm study that appears to show improved outcomes among individuals exposed to a new intervention, compared with outcomes among a historical control group of patients exposed to a standard intervention. There are at least five potential explanations for this apparent benefit. It may result from between-group differences in demographic or other characteristics independently

associated with the outcome under study—that is, from confounding due to selection bias. For example, individuals receiving the new intervention may be younger or healthier than the historical controls. Or, the benefit may result from differences in investigators' interactions with or observations of subjects—that is, from better supportive care, more intensive diagnostic testing, or reduced loss to follow-up. The improvement could be a placebo effect related to expectations about the new therapy. It might simply be due to chance. Finally, it may represent a true difference in treatment efficacy. These alternative explanations for the observed data must be considered whether or not results favor one of the treatments.

RCTs employ three or more devices to minimize the likelihood of false-positive and false-negative errors (see Table 24.1). First, they use concurrent controls, thereby permitting direct comparison between groups⁵ and eliminating confounding by temporal trends. Second, they divide participants into groups using some method of random allocation, thereby increasing the likelihood that the groups will be comparable at baseline.⁶ This is important because, though methods to adjust for known covariates are available, these methods are both imperfect and unable to control for unmeasured or unrecognized confounding variables. Third, RCTs employ statistical tests and sample size calculations to quantify and control the chances of false-positive and false-negative results. In addition, many trials conceal treatment allocation from subjects and/or investigators (a technique known as single- or double-blinding) to reduce the chance that investigators or subjects will tilt the trial by unconsciously favoring one group over the other. Finally, some trials use placebos to facilitate blinding. Such rigorous methodology helps maximize the scientific validity that is among the primary requirements for ethical research.⁷

Of these five error-minimizing devices, use of concurrent controls and statistical tests present no special ethical problems,

Table 24.1
Error-Minimizing Features of Randomized Trials

Feature	Purpose
Concurrent controls	<ul style="list-style-type: none"> • Eliminate between-group differences due to temporal trends • Enable direct comparisons
Randomization	<ul style="list-style-type: none"> • Reduce likelihood that groups will differ at study entry
Statistical tests, sample size calculations	<ul style="list-style-type: none"> • Control chances of false-positive and false-negative results
Blinding*	<ul style="list-style-type: none"> • Reduce likelihood that investigators will interact with or observe study participants in ways that differ systematically between groups • Reduce chance that participants will behave or report symptoms in ways that differ systematically between groups • Distinguish physiologic from placebo effects
Placebo administration**	<ul style="list-style-type: none"> • Facilitate blinding when interventions differ in observable ways between groups

*Not all randomized trials involve blinding or placebo controls.

**In a subset of trials involving placebos, participants in the control arm may be asked to forgo treatment that is available in the context of standard care.

though the choice of statistical approaches may have ethical implications,⁸ as discussed below. Randomization, however, has been debated for at least 40 years. Blinding, though less scrutinized, also raises ethical challenges. Special concerns related to placebos arise when control participants are asked to forgo therapy that is otherwise available^{5,9–12} (see Chapter 25).

There are two general statistical approaches to designing and analyzing RCTs. The most prevalent method, called frequentist, begins with a null hypothesis: that there is no difference in outcome between Treatment A and Treatment B. Before the trial begins, investigators define a probability threshold, called an alpha error, beyond which they will reject the null hypothesis as statistically improbable. The experiment proceeds, and the data are used to calculate the conditional probability, assuming the null hypothesis is true, of “observing a result equal to or more extreme than what was actually observed.”¹³ If this conditional probability (or *P* value) is smaller than the predefined alpha error, the null hypothesis is rejected and the alternative hypothesis—that there is a difference in outcome between Treatment A and Treatment B—is accepted by default. It is critical to note the common misconception that the *P* value describes the probability that the observed difference reflects a false positive. The *P* value represents the probability of the observed data given no true difference, not—as often assumed—the probability of no true difference given the observed data.¹⁴

An alternative analytic approach, called Bayesian, eschews null hypotheses and hypothesis tests. Instead, it starts with an assumption (which may be either subjective or evidence-based) about the true difference in outcome between Treatment A and Treatment B. This assumption takes the form of a prior probability distribution. The experiment is conducted, and the data are used to calculate a measure of the weight of the evidence (known as the Bayes factor or likelihood ratio). This measure is then combined mathematically with the prior distribution to generate a posterior probability distribution. The posterior distribution represents an updated estimate, taking into account information learned from the experiment, of the true difference between A and B.^{15–17}

Historical Perspective

Most discussions of the ethics of RCTs have revolved around the possibility of conflict between research and treatment. The felt need to defend RCTs as consistent with physicians' therapeutic obligations was evident by 1949, when Walker and Barnwell cited the lack of “genuine ignorance or doubt that the drug in question has any therapeutic value” to justify their decision against randomizing in an early U.S. Veterans Administration study of streptomycin for pulmonary tuberculosis.¹⁸ Fisher, who developed the statistical theory underlying randomization, wrote in 1958 that RCTs are acceptable “so long as no body of medical opinion can say with confidence that one [new drug] is better than the other.” (Interestingly, in the same article he criticized the mounting but nonrandomized evidence of an association between cigarette smoking and lung cancer as insufficient to prove causation.)¹⁹ Hill, who helped design the earliest published RCT, the British streptomycin trial, wrote in 1963: “Only if, in his state of ignorance, [the doctor] believes the treatment given to be a matter of indifference can he accept a random distribution of the patients to the different groups.”²⁰ Importantly, Hill did not

invoke indifference in defending the decision to randomize tuberculosis patients to streptomycin versus observation. Rather, because insufficient streptomycin was available to treat all eligible patients, he viewed a random lottery as a fair way to ration the drug while facilitating collection of valuable data²¹ (see Chapter 4).

Charles Fried’s 1974 treatise systematized the theoretical case for the indifference requirement, pointed to the clinician-investigator at the bedside as the primary locus of the moral dilemma, and suggested ways to resolve or lessen the quandary, including emphasis on informed consent and greater openness to nonrandomized designs.²² Fried’s essay opened the modern history of the notion of equipoise.

The Ethics of Randomization

Ethical concerns about randomization, the most striking feature of RCTs, focus on two related but separable aspects of trial conduct. First, some critics object that participants must forgo their right to “personal care.”^{22,23} Put differently, physicians have a duty, grounded in the fiduciary nature of the patient-doctor relationship, to make individualized treatment recommendations in the context of patients’ particular values and circumstances. When physicians also act as investigators, randomization seems to force them to violate this duty. Second, commentators raise the more consequentialist concern that randomization may require assignment of some participants to therapy that is likely to be inferior, even though the preliminary evidence supporting that judgment falls short of conventional standards of methodological rigor. Emerging data during the course of a trial that appear to favor either treatment exacerbate these problems. Reviews of ethical aspects of RCTs are available.^{24,25}

The most common defense of RCTs is to claim a state of indifference between the two treatments—that is, that they are “an equal bet in prospect.”²⁵ Many versions of this requirement have been proposed. Mostly they vary along two dimensions—whether indifference is for physician-investigators or patient-subjects to determine, and whether it should operate at the individual or community level. (Table 24.2 attempts to clarify the nomenclature.) Although these views of indifference vary, they share the intuition that it is ethical to conduct a trial or enroll a patient when there are no strong reasons to favor one treatment over the other. Thus, under indifference, clinician-investigators can fulfill their commitments to personal care while avoiding charges of giving patients predictably inferior therapy.

Table 24.2
Four Conceptions of Equipoise

	Clinician-Investigator	Patient-Subject
Individual*	Individual equipoise**	Patient equipoise
Community	Clinical equipoise [†]	Community equipoise

*The *uncertainty principle* invokes individual preferences among both clinician-investigators and patient-subjects.

**Sometimes called *theoretical equipoise* or *Fried’s equipoise*.

[†]To complicate matters, Gifford has used *community equipoise* to refer to Freedman’s notion of clinical equipoise.³⁰

Fried’s view, which others have termed *individual or theoretical* equipoise, established the benchmark for subsequent authors.²² (Table 24.3 catalogs the key positions in the debate.) Concerned mainly about randomization’s challenge to personal care, Fried held that it is ethically problematic for a physician who favors either treatment to offer enrollment in a trial if his or her preferred treatment is available outside the trial. Furthermore, personal care requires that physicians consider patients as individuals with unique values and circumstances, not as generic exemplars of a given condition. Fried contended that when physicians take such individual factors into account, instances of genuine indifference between treatments for particular patients will be rare. For Fried, physicians’ fiduciary obligations require that they share their beliefs with their patients and recommend their preferred treatment when it is available. Variations of this position continue to appear.^{23,25–33}

The difficulties of conducting RCTs within the constraints of the requirement that individual physicians be indifferent are obvious. Physicians will usually have at least weak treatment preferences, which would impose moral obligations at a minimum to share their preferences with patients and perhaps even to recommend against or decline involvement with the trial. Also, the physicians who conduct a trial are often the same individuals who have led the clinical development of the intervention; they are naturally motivated because they believe the intervention may be superior to standard therapy. Demanding that those who developed the experimental treatment be indifferent about its merits in comparison with standard therapy might seem an unreasonable constraint. Furthermore, even if physicians are indifferent at the start of the trial, they will often develop preferences as it progresses. And they cannot ethically agree to the withholding of interim results to avoid this problem, because doing so violates their obligations of advocacy and fidelity. Though Fried did not wish to create an insurmountable barrier to RCTs, it is difficult to imagine beginning a trial or bringing it to completion in the moral universe he describes. As Hellman and Hellman have argued, “even if randomized clinical trials were much better than any alternative . . . the ethical dilemmas they present may put their use at variance with the primary obligations of the physician. . . . We must develop and use alternative methods for acquiring clinical knowledge.”²³

Before discussing responses to Fried, an aside about the problem of personal care is in order. Because randomization spotlights the fact of experimentation, it sometimes seems like a methodological streetlamp under which we search for our lost ethical keys. In fact, virtually all intervention studies—not just RCTs—challenge obligations of personal care.³⁴ Consider a single-arm trial that has enrolled 18 subjects, none of whom responded to the experimental agent.³⁵ The protocol specifies closing the trial and declaring the drug ineffective if none of the first 19 subjects responds. Is it ethical to enroll the next eligible patient if alternatives are available? Or consider the more pedestrian example of a chemotherapy research protocol that specifies a white blood cell (WBC) count of 1500/uL before beginning each cycle. Adherence to the protocol would require that the subject who arrives in clinic with a WBC of 1450/uL be sent home, even if proceeding with therapy would be clinically reasonable. Thus, if the argument from personal care holds, RCTs are hardly unique in presenting ethical challenges to the conduct of clinical research.

An alternative view holds that standards within the clinical community, rather than individual physicians’ inclinations,

Table 24.3
 Equipoise and Other Responses to the Problem of Treatment Preferences in Randomized Trials

<i>Position</i>	<i>Core Argument</i>	<i>Representative Citations</i>
Arguments From Equipoise		
Individual equipoise	Physicians must view the treatments offered in an RCT as “equal bets in prospect” in order to enroll patients. Some advocates of this position argue that this condition is unlikely ever to be met and would therefore discard RCTs on ethical grounds.	Fried ²² ; Hellman & Hellman ²³ ; Markman ³¹ ; Royall ²⁸ ; Hellman ²⁶ ; Gifford ³⁰ ; Edwards et al. ²⁵
Equipoise among expert clinicians	An RCT is ethical if there is uncertainty or disagreement within the expert clinical community about the relative merits of the two therapies.	Freedman ³⁶ ; Miller & Weijer ⁴⁰ ; Weijer et al. ¹⁸⁸ ; Weijer ³⁷
Standards of evidence	An RCT is ethical if there is no scientifically validated reason to favor either treatment in the trial.	Levine ¹
Patient equipoise and informed consent	Patients, rather than clinicians, must be indifferent among the various treatment options when enrolling in a trial. Closely related to the view that the patient-subject’s informed consent, not the objective state of knowledge or physicians’ beliefs, is the primary ethical precondition for RCT participation.	Angell ⁴¹ ; Marquis ⁴² ; Lilford ⁴³ ; Ashcroft ⁴⁴ ; Veatch ⁴⁵ ; Menikoff ⁴⁶ ; Gifford ³⁹
Community equipoise	The locus of uncertainty or disagreement includes not just expert clinicians, but also patients and their representatives.	Karlawish & Lantos ⁴⁷
Uncertainty	The ethical precondition for enrolling a patient in a trial is a state of uncertainty—not necessarily of equal prior probabilities—on the part of clinician and patient about which of two or more treatments is preferred. Combines features of individual and patient equipoise.	Peto et al. ² ; Peto & Baigent ⁴⁹ ; Sackett ⁴⁸ ; Enkin ⁵¹
Alternatives to Equipoise		
Altruism	Patients’ desires to assist in learning something of value justifies their participation in RCTs.	Meier ⁵³ ; Royall ⁵⁴
Social contract	By virtue of the benefits they receive from prior research, persons have correlative obligations to participate in trials, even at some limited cost to themselves.	Wikler ⁵⁷ ; Gifford ⁵⁶
Consequentialism	Experimentation in RCTs cannot be reconciled with patients’ rights to optimum personal care. Only an ethic that looks to the greatest good for the greatest number can justify such trials.	Marquis ⁶²
Debate rests on false premises	Notions of equipoise are based on a misconception about the relationship between research and therapy in RCTs. It ought to be discarded in favor of a conception that is specific to research.	Miller & Brody ⁶⁶

should determine whether RCT participation is acceptable. Freedman’s 1987 description of *clinical equipoise*, which took this approach, was perhaps the most influential response to Fried’s challenge.³⁶ Freedman argued that physicians’ knowledge—and therefore the scope of their therapeutic obligations—is collective and professional rather than individual in nature. If so, he argued, clinicians who offer participation in RCTs are behaving ethically so long as there exists “an honest, professional disagreement among expert clinicians about the preferred treatment.”³⁶ In Freedman’s view, absent professional consensus, a clinician’s hunches or preferences pose no moral barrier to trial recruitment.

In a recent extension of Freedman’s work, Weijer noted that clinical research often includes some procedures “administered with therapeutic intent and others that answer the research question” (presumably, the experimental treatment under study in an RCT is among the procedures “administered with therapeutic intent”).^{37,38} He argued that the equipoise requirement applies specifically to these “therapeutic” procedures. Based on the work

of the U.S. National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, he advocated a “components approach” in which each element of a trial would be judged according to standards appropriate to its intent. Thus, a biopsy undertaken exclusively to address a scientific hypothesis would be acceptable if risks were minimized and were reasonable in relation to the knowledge gained (i.e., a research-specific evaluation standard). In contrast, administration of a promising new agent with therapeutic expectations in the context of a randomized trial would be acceptable if it met Freedman’s test of clinical equipoise.

Levine has argued that a trial is ethical if “there is no scientifically validated reason to predict that Therapy A will be superior to Therapy B. Further, there must be no Therapy C known to be superior to either A or B.”¹ This position bears a fundamental kinship with Freedman’s statement of clinical equipoise, because what constitutes a “scientifically validated reason” depends on community standards.

Although individual and clinical equipoise differ in a number of ways,³⁹ the contrast in moral locus of decision making is among the most salient. Recently, Miller and Weijer have suggested that the choice between equipoise at the individual or clinical community level represents a false dilemma; both may be ethically necessary.⁴⁰ They argue that clinical equipoise is a social condition that legitimates the initiation or continuation of a trial, whereas individual equipoise justifies the clinician-investigator's decision to offer or recommend trial enrollment to a patient. In practice, sorting through these conditions is often difficult. In Box 24.1, we describe a case in which, to the clinicians involved, neither level of equipoise seemed sufficient by itself to justify a trial.

A third important conception of the indifference requirement, hinted at by Fried and developed more fully by others, emphasizes the views of the patient-subject rather than the clinician-investigator.^{41–46} The acceptability of trial participation depends crucially on how the subject values the various probabilities and outcomes associated with trial enrollment, because it is the subject who will experience the consequences. Thus the subject, not the clinician-investigator, must be reasonably indifferent between the treatments offered in the trial.

Two features of the patient indifference perspective bear mention. First, because only the subject can provide ethical justification for trial participation, the argument rests entirely on valid informed consent. Proponents have not considered this principle's implications for RCTs, such as trials involving young children or occurring in emergency situations, in which autonomous consent is not possible. Second, this view highlights the need to think broadly about what endpoints we have in mind when we speak of being indifferent between two treatments. Clinician-investigators might be indifferent with respect to the trial's "hard" endpoints—mortality or major morbidity—but prospective trial participants are likely to consider factors such as quality of life and practical burdens as well.³⁹ Mastectomy and local resection with radiation may result in similar survival for most women with limited-stage breast cancer, but many women will have strong preferences depending on how they value such factors as disfigurement and the possibility of local recurrence. Lilford and Jackson have shown how one might model such tradeoffs to arrive at "effective" equipoise.²⁷

Box 24.1 A Case Involving Different Conceptions of Equipoise

In 2004, clinicians at Boston Children's Hospital discussed an RCT involving assignment of critically ill children to groups that would receive red blood cell transfusions at threshold hematocrits of either 21% or 27%. Though the current local practice was to transfuse at about 21%, no data existed to support this cutoff and practices varied across institutions. On the basis of this broader disagreement, a few clinicians argued for an ethical obligation to support the trial in order to help resolve this important question. Most, however, insisted that unless there was personal uncertainty, or at least disagreement within the local group, it would not be ethical to enroll patients. Thus three versions of the equipoise position were in play in this debate: (1) clinical equipoise, as described by Freedman; (2) equipoise within the *local* expert community; and (3) individual equipoise, as described by Fried.

Just as Freedman highlighted the role that lack of consensus within the expert clinical community plays in legitimizing an RCT, others have emphasized the importance of disagreement or indifference within the patient community.⁴⁷ According to this position, for a trial to be ethical, the community that must be in equipoise includes representatives of those who would be eligible for the trial. As with clinicians, individual patients and communities of patients may have complementary roles in legitimizing a trial.

A final group of authors argues that uncertainty, not equipoise, best articulates the ethical basis for RCTs.^{2,48–51} According to Peto and Baigent,

A patient can be entered if, and only if, the responsible clinician is substantially uncertain which of the trial treatments would be most appropriate for that particular patient. A patient should not be entered if the responsible clinician or the patient are for any medical or non-medical reasons reasonably certain that one of the treatments that might be allocated would be inappropriate for this particular individual (in comparison with either no treatment or some other treatment that could be offered to the patient in or outside the trial).⁴⁹

At first blush, it is not entirely evident how this "uncertainty principle" differs from some conceptions of equipoise. (Compare it with Levine's formulation above.) One important difference, however, is that, against Freedman, advocates of the uncertainty principle wish to place the moral onus back on the individual physician and patient who must decide about trial participation, rather than on the community of experts.⁵² Proponents of the uncertainty principle also reject the "etymological connotation of an equal balance between . . . the alternatives to be tested" inherent in the word *equipoise*.⁵¹ They insist instead that, for an RCT to be ethical, the metaphorical "confidence intervals" around one's hunches of benefit must include the possibility of no effect or of harm. This is a much less fragile conception than the individual equipoise described by Fried.⁵¹ Nevertheless, the uncertainty principle qualifies rather than radically revises the notion of equipoise.

Reconciling Clinical and Scientific Obligations in Randomized Trials

The justifications for RCTs reviewed above all invoke some version of the indifference requirement. However, some authors suggest that indifference may be neither necessary nor sufficient to justify trials. These commentators offer frameworks that—either alone or in combination with arguments from indifference—might provide alternative ethical foundations for RCTs.

One defense of RCTs appeals to patients' altruism to justify a limited loss of benefit associated with the possibility of randomization to inferior therapy.^{53,54} In Meier's words, "most of us would be quite willing to forgo a modest expected gain in the general interest of learning something of value."⁵³ Like the patient indifference approach, invoking altruism as a defense of trials rests heavily on valid consent and raises problems for trials involving those who lack capacity to consent.⁵⁴ It is also amenable to empirical investigation of participants' reasons for enrolling in trials.⁵⁵

A second justification appeals to the notion of social contract. Gifford, in a promising account, explored such an approach to

reconciling patients' self-interests and right to personal care with efforts to advance the common good. He suggested that "morality and political institutions are conceptualized as . . . cooperative ventures for mutual advantage, and each person can see that it is in his interest to have such an institution."⁵⁶ RCTs might be among the institutions that invite justification in this way. Wikler took a similar line, asking us to imagine a choice of "citizenship in one of two societies. In the first, doctors always give their patients the best care they can, whereas in the second, patients are sometimes slighted in the interest of medical progress. The state of the art of medicine, however, is more advanced in the second than in the first."⁵⁷ Many people, he argued, would choose citizenship in the second society. Several authors have considered the broader but related question, based in considerations of fair play and free ridership, of whether persons have *prima facie* obligations to participate in clinical research.^{58–61}

A third option invokes the consequentialist notion that the social benefits of trials outweigh their costs to individuals. For example, Marquis reluctantly suggested that an ethics of prescription, defended on consequentialist grounds, might be necessary to justify the conduct of these trials.⁶² Others have discussed the broader role of consequentialism in the ethics of medical research.^{50,63–65}

Finally, in 2003 Franklin Miller and Howard Brody posed a radical challenge to the central question underlying the equipoise debate. They argued that concerns about equipoise derive from the widely held but (they believe) incoherent "similarity position," which holds that "the ethics of clinical trials rest on the same moral considerations that underlie the ethics of clinical medicine."⁶⁶ In their view, this position contradicts the fundamental assumption of research ethics, as articulated in the Belmont Report of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research: "The ethics of clinical trials must start with the realization that medical research and medical treatment are two distinct forms of activity, governed by different ethical principles"⁶⁷ (see Chapter 14). According to the Belmont Report, clinical care involves activities "that are designed solely to enhance the well being of an individual patient or client and that have a reasonable expectation of success," whereas research denotes "an activity designed to test an hypothesis, permit conclusions to be drawn, and thereby to develop or contribute to generalizable knowledge."⁶⁷ To suggest that equipoise can unite the ethical conditions for these two activities represents a category mistake.

Rather than ask whether an RCT satisfies clinical equipoise, Miller and Brody would assess it against principles appropriate to the evaluation of research.⁷ The key question is not, as proponents of clinical equipoise argue, how the interventions offered in a trial compare with competent medical practice. Rather, investigators and reviewers must ensure that the study does not exploit subjects. This condition requires that the question is worth asking, the methods are sufficient to answer the question at hand, the risk-benefit ratio—integrating risks and benefits to individual participants with benefits to the community of future patients—is favorable, and subjects give valid informed consent. The most important implication of this view is that, to estimate the risk-benefit ratio of any study involving human subjects, one must incorporate considerations of societal benefit.^{67,68} The confusion at the heart of the various arguments from indifference lies in their denial that this is as true for RCTs as it is for other research designs.

Miller and Brody's framework is particularly helpful for analyzing and justifying studies, such as certain placebo trials, that offer some subjects less expectation of benefit than they might receive under standard care. However, conceptual questions and practical problems remain, and though the authors attempt to address these, it is not clear how their proposal will play out in the clinic.⁶⁹ For example, can we realistically ask individuals to trade the status of patient for that of subject when they enter a trial, or must we articulate a coherent vision of them simultaneously as patients and subjects? If patients, particularly those with serious illnesses, come to physicians with expectations of receiving optimum therapy, how will the explicit denial of therapeutic obligations affect subject recruitment and trust in research?^{70,71} On what normative grounds do we proceed when studying persons who cannot provide informed consent, such as children or patients involved in emergency exception research? Given these considerations, Weijer and Paul Miller counter that the components approach discussed above, which assesses research and therapeutic elements of a trial according to different criteria, better reflects the insights of the National Commission.⁷²

Practical Responses to the Problem of Reconciling Clinical and Scientific Obligations

As noted previously, various formulations of the indifference requirement offer potential solutions both to the problem of personal care and to the concern that some patients might be randomized to predictably inferior therapy. Conceptual debates focus mainly on the deontological issues related to personal care, and secondarily on the more consequentialist problem of assignment to inferior therapy. In contrast, discussions about practical ways to ameliorate these problems seek primarily to minimize the number of subjects who receive inferior therapy.

A historically important suggestion for ensuring indifference is to randomize beginning with the first person exposed to a drug.⁷³ This argument recognizes that preliminary, usually uncontrolled data available prior to the first RCT tend to disturb indifference sufficiently to make subsequent studies ethically and logistically challenging. Although theoretically plausible, in the real world there are valid reasons that new therapies do not reach the point of evaluation in an RCT until after they have been evaluated (sometimes extensively) in early-phase research.⁷⁴ By this time, evidence for their efficacy already exists. Nor does this suggestion resolve the practical problem caused by trends that emerge during the course of the study. Knowledge of such trends could lead to treatment preferences among clinician-investigators and potential subjects that could threaten study completion.

The practical challenge posed by interim data has led to the standard but controversial practice of withholding the information from investigators, referring physicians, and enrolled and potential subjects.⁷⁵ Veatch has written that withholding such information may sometimes be acceptable when subjects are aware of and consent to it in advance, but that "where the information really is crucial such consent to ignorance will be morally unacceptable."⁷⁶ Levine held that it is acceptable to "ask the subject to consent to . . . acceptance of the standards of proof agreed upon within the community of professionals" regarding emerging efficacy trends.¹ Freedman suggested that clinical equipoise alleviates the ethical difficulties caused by emerging trends, because until

the evidence is sufficient to convince the expert clinical community, clinical equipoise is maintained.³⁶ He further argued that, if clinical equipoise suffices to justify a trial, then withholding interim data should be unnecessary. (The routine concealment of such data suggests that, though investigators may endorse the abstract notion of clinical equipoise, they are unwilling to bet their own trials on it.) Finally, Lilford et al. argued against the withholding of interim results.⁷⁵

In concert with the practice of withholding interim results, data monitoring committees (DMCs)—also known as data safety and monitoring boards (DSMBs)—are widely used to deal with the problem of emerging trends⁵⁰ (see Chapter 53). DMCs, which should be independent of the sponsor and principal investigator, review interim data regarding toxicity and efficacy. They are charged with deciding when the accumulated evidence justifies closing the trial. Ideally, the decision to close a trial respects protocol-specified stopping guidelines that function to preserve both the scientific validity and the ethical integrity of the trial. DMCs may close trials early for several reasons, including poor accrual or other logistical problems, unanticipated toxicity in one or both arms, lack of an emerging difference between arms (futility), or unexpectedly strong evidence for a difference between arms (efficacy). In the context of the present discussion, their major role is to close a trial when the data are sufficient to answer the research question. The possibility of stopping early minimizes the number of subjects assigned to the less effective treatment, while permitting the better therapy to be offered sooner and to larger numbers of patients outside the trial. Decisions about early stopping, which are the subject of considerable statistical discussion, are among the most ethically charged in all of clinical research^{53,77–79} and will always generate controversy.^{80,81} In our view, they require greater attention from the research ethics community than they have heretofore received.

Decisions about when to stop an individual trial are obviously connected to judgments about when to declare uncertainty resolved and a particular line of inquiry closed. This critical issue has received only limited attention in the research ethics literature.⁸² Despite the concerns that they raise,¹ it has been customary to conduct confirmatory trials in many circumstances. Guidance from the U.S. Food and Drug Administration (FDA) states that “the usual requirement for more than one adequate and well-controlled investigation reflects the need for *independent substantiation* of experimental results. A single clinical experimental finding of efficacy, unsupported by other independent evidence, has not usually been considered adequate scientific support for a conclusion of effectiveness.”⁸³ Parmar has described Bayesian methods for making explicit decisions about when residual uncertainty justifies confirmatory trials.⁸⁴

A second strategy for minimizing the number of subjects exposed to the inferior intervention involves unbalanced randomization, with a ratio favoring the preferred arm.^{85,86} A more complicated approach has been called *adaptive randomization*, or “play-the-winner.”^{86,87} In this design, subjects are initially assigned to the experimental or standard treatment in a fixed ratio. However, as the data begin to favor one treatment or the other, the allocation ratio tilts toward the preferred arm. When there are large differences between treatments and results are available in the short run, such a design can be completed successfully.^{88,89} However, when differences are smaller or primary outcomes require long-term follow-up, adaptive randomization may not be feasible.

Although unbalanced randomization and play-the-winner strategies may reduce the number of subjects exposed to the inferior intervention, this advantage may be more than offset by the problem of justifying to those assigned to the nonpreferred arm why it is ethical for them to be recruited into the trial. Adaptive designs are also subject to methodological challenge, as changes in participants’ prognostic profiles over the course of the trial (e.g., lesser severity of illness late in the trial) might lead to differences between groups and confound the interpretation of treatment effects.⁹⁰

Yet another way to minimize suboptimal treatment for individual participants, as implemented by Kadane in a cardiac anesthesia trial,⁹¹ involves Bayesian strategies for assigning study participants to treatment arms. Before the start of the trial, a group of experts made treatment recommendations for hypothetical patients with various prognostic profiles. These predictions were used to develop computer models that could provide treatment recommendations for individuals meeting the trial’s eligibility criteria. Data that emerged over the course of the trial were used to update these models continually. If the experts’ (computer-modeled) recommendations for a particular eligible patient unanimously favored one arm, the patient was assigned to that arm. In contrast, if there was any disagreement among the recommendations, clinical equipoise was said to exist and the patient underwent random allocation. This method has the virtue of individualization and might reduce assignment of patients to predictably inferior therapy, but is labor intensive and has not found widespread acceptance.

Two other proposals for reducing the tension between experimental validity and personal care merit consideration. First, Peto et al.² have advocated the use of “large simple trials,” rather than the more typical and highly regimented “explanatory” designs.⁹² Such trials are distinguished by their broad eligibility criteria, reduced data collection requirements, and limited specification of treatments in the study beyond the particular intervention under evaluation.⁴⁹ From the point of view of reconciling research and treatment imperatives, such trials have the virtue of minimizing the experimental constraints and practical burdens that protocols place upon patients and physicians. As a result, they have many scientific advantages, including facilitating very large sample sizes, decreasing complexity and cost, enhancing the generalizability (external validity) of the study findings, and reducing the gap between the efficacy as measured in controlled settings and effectiveness as seen in ordinary practice.^{93–96} They also reduce the gap between personal and protocol care. Thus, for compelling ethical as well as scientific reasons, they merit serious consideration.

Finally, Veatch⁷⁶ and Silverman⁹⁷ have advocated “semi-randomized” or “comprehensive cohort” trials on both ethical and methodological grounds. In such studies, patients are offered the choice of Treatment A, Treatment B, or random assignment. Analytically, the primary comparison involves only the randomized subjects. However, subjects who choose direct assignment to Treatment A or Treatment B constitute useful observational cohorts. In particular, outcomes within these groups can shed light on whether the results of the primary comparison are generalizable to the population of persons who would not accept randomization (and who might differ in systematic ways from those willing to be randomized). This approach offers randomization as a genuine choice, reducing the need for physicians to choose

between fidelity to patients as unique individuals and allegiance to the experimental method. Although one might worry that few patients offered participation in such a trial would accept random assignment, such unwillingness might cast doubt on the ethical justification for randomization in the first place. Several comprehensive cohort trials have been successfully conducted.^{98–100}

Empirical Data

Though the relationship of normative to descriptive ethics is an uneasy one, some questions about the ethics of RCTs lend themselves to empirical answers.

How often do RCTs comparing experimental with standard therapies find the new treatment to be better? The observation that trials favor the experimental treatment most of the time would suggest the absence of systematic indifference within the institution of clinical trials. Knowledge of the proportion of past trials favoring the experimental treatment would also inform estimates of prior probabilities associated with future trials.¹⁰¹ Most such studies have not found strong advantages to experimental treatment. Reviewing surgery and anesthesia trials, Gilbert et al. found reasonable symmetry between studies favoring the experimental treatment and those favoring the standard.⁶⁰ Colditz et al. came to similar conclusions in trials of medical therapies.¹⁰² Chlebowski and Lillington observed that 16% of meeting abstracts describing RCTs of adjuvant therapy for localized breast cancer and only 2% of abstracts describing RCTs for metastatic breast cancer favored experimental treatment.¹⁰³ Machin et al. noted that 28% of published RCTs for solid tumors from the British Medical Research Council favored the experimental treatment.¹⁰⁴ Djulbegovic et al. reported that 44% of published RCTs for multiple myeloma favored the standard treatment, whereas 56% favored the innovation.¹⁰⁵ They also found that industry-sponsored and placebo-controlled trials were more likely than other trials to favor the innovation, raising concerns about systematic departure from indifference. Joffe et al. observed that 29% of adult cancer trials sponsored by a publicly funded U.S. cooperative group favored the experimental treatment, whereas only 3% favored the standard treatment; on average, experimental treatment was associated with a 20% improvement in anticancer efficacy when compared with standard treatment.¹⁰⁶ Finally, Soares et al. found no evidence that trials sponsored by a radiation oncology cooperative group favored the experimental treatment.¹⁰⁷

Do RCTs proceed despite compelling prior evidence that one treatment is better? Lau et al. used cumulative meta-analysis to evaluate the strength of evidence over time for or against 15 interventions for myocardial infarction.¹⁰⁸ For some interventions, trials continued years after benefits had been shown with high confidence. For example, 15 RCTs of intravenous streptokinase (SK) were reported and 32,095 subjects enrolled after 1977, by which time SK had been proven superior to control with Cumulative $P < 0.001$. Similar results have been seen in other settings.^{109,110} Such continuation of trials long after differences have been convincingly shown is difficult to defend on scientific or ethical grounds.

Do physicians have preferences for treatment arms, and do they affect recruitment? Though surprisingly few data are available, treatment preferences appear both to be common among physi-

cians and to reduce their willingness to enroll patients. For example, Taylor et al. surveyed surgeons participating in a slow-accruing trial comparing mastectomy with local excision for breast cancer.¹¹¹ About 20% believed that one or the other treatment was inappropriate for patients. Other work has shown that many physicians are uncomfortable with randomization, either because of treatment preferences or because it seems to violate the norms of the patient-doctor relationship.^{112,113} Alderson found that few health-care professionals thought indifference was possible for breast cancer trials.¹¹⁴ Cheng et al. described how prior beliefs led investigators to reject an RCT of a promising new therapy for melioidosis, a life-threatening infectious disease, despite considerable uncertainty about the new therapy's effectiveness.¹¹⁵ Finally, Clark et al. applied the term "jumping-the-gun" to refer to physicians' tendencies to treat patients off-protocol with interventions that have not yet been proven in RCTs, a phenomenon that probably reflects early loss of indifference among individual physicians.¹¹⁶

Do patients have preferences for treatment arms, and do those preferences affect their enrollment decisions? Few data characterize preferences among patients considering or enrolled in RCTs. Jenkins and Fallowfield asked approximately 200 cancer patients considering participation in RCTs about their reasons for accepting or declining trial entry.⁵⁵ Three-quarters of those interviewed decided to participate in the RCT. Approximately 80% of those who accepted the trial, versus 14% who declined, agreed that "either treatment in the trial would be suitable," suggesting that treatment preferences explain at least some patients' decisions not to enter the trial. Jack et al. observed similar effects.¹¹⁷ A review of the literature on trial accrual concluded that "patient preferences for one of the study treatments . . . appear to limit their willingness to take part in randomized trials."¹¹⁸ Finally, in a recent trial of a molecularly targeted agent for chronic myeloid leukemia, 18% of those assigned to the standard arm—versus only 2% of those assigned to the experimental arm—either withdrew consent or crossed over to the alternative treatment before meeting the study endpoint, indicating both strong preferences and a willingness to act on them.¹¹⁹

Beyond Equipoise: A Systematic Overview of Ethical Issues in RCTs

Although notions of equipoise have dominated debates over the ethics of RCTs, these trials raise many other challenging questions. A comprehensive discussion is beyond the scope of this chapter. Here, we attempt to identify issues of particular salience to RCTs, locate them within a general framework for judging the ethics of clinical research,⁷ and briefly review the relevant literature. Table 24.4 provides an overview.

Social or Scientific Value

In general, whether a research question is worth asking is independent of the study design, and therefore the requirement for social value has no special implications for RCTs. However, as discussed above, new trials sometimes begin long after any reasonable uncertainty about the preferred intervention is re-

Table 24.4
Randomized Trials and the Criteria for Ethical Research

Criterion	<i>Issues and Questions Relevant to Randomized Trials</i> TCH
Social or scientific value	Has the study question previously been answered? <ul style="list-style-type: none"> • Confirmatory trials • Cumulative meta-analyses • Objective of answering unresolved questions versus changing clinical practice
Scientific validity	How much incremental validity does the RCT offer, compared with alternate designs? What problems compromise the validity of RCTs in practice? <ul style="list-style-type: none"> • Subversion of randomization • Underpowered trials • Publication bias • Concerns about generalizability
Fair selection of participants	(No special problems related to randomized designs)
Favorable risk-benefit ratio	Do the study treatments satisfy the indifference requirement? <ul style="list-style-type: none"> • Loss of personal care • Loss of expected utility for some subjects Is there a generic benefit (trial effect) from RCT participation? When should a study be stopped? What should the control treatment be when there is no standard of care?
Independent review	(No special problems related to randomized designs)
Informed consent	Is informed consent always necessary? <ul style="list-style-type: none"> • Randomized consent (Zelen) design • Minimal-risk RCTs • Emergency exception research
Respect for potential and enrolled participants	Is withholding of information from trial participants acceptable? <ul style="list-style-type: none"> • Study arm assignment (blinding) • Interim results

solved.^{108–110} The question of when to conduct a confirmatory trial is controversial,^{1,84,120} and requires further normative exploration. The history of neonatal extracorporeal membrane oxygenation (ECMO) provides an illustrative example (see Box 24.2). Finally, performing a trial in hopes of influencing slow-to-change practice patterns, despite the fact that the study question has previously been answered, is ethically problematic.¹²⁰

Scientific Validity

The primary justification for randomization is its ability to minimize bias compared with alternative allocation strategies. Few deny that RCTs offer scientific benefits, but their exact magnitude is a matter of contention.¹²¹ Early reports suggested that studies using historical or concurrent nonrandomized controls overestimated benefits from experimental therapies, compared with RCTs, primarily because controls in RCTs often had better

outcomes than controls in other designs.^{102,122,123} Recent meta-analyses comparing randomized with nonrandomized studies, however, offer a more complicated picture. Concato et al.¹²⁴ and Benson and Hartz¹²⁵ found that effects observed in well-conducted nonrandomized controlled trials were similar to those seen in RCTs. In contrast, Ioannidis et al. found that discrepancies between randomized and nonrandomized trials were common, even when the latter were restricted to prospective comparisons.¹²⁶ Thus, in our view, further empirical work is needed to quantify the magnitude of the scientific benefits from RCTs.

Even assuming substantial incremental validity, several practical problems threaten RCTs’ claim to methodological priority. First, inadequate allocation concealment raises questions about the assumption of baseline comparability.^{127,128} Furthermore,

Box 24.2
Trials of Neonatal ECMO

By the early 1980s, uncontrolled case series suggested that certain critically ill neonates who were expected to die with conventional treatment could survive if treated with extracorporeal membrane oxygenation (ECMO), a complex, expensive, and risky new therapy. A group of investigators began an RCT to compare outcomes among infants treated with ECMO or conventional treatment.⁸⁸ Because the investigators’ prior expectations strongly favored ECMO (before initiating the trial, the investigators expected a 90% chance of survival with ECMO and 10% chance of survival with conventional treatment), they adopted several unusual design features to “soften the ethical dilemma.”⁸⁸ First, they employed single-consent prerandomization, whereby only parents of those infants assigned to experimental treatment (ECMO) were asked for permission to enroll their child.¹⁵⁸ Second, they used adaptive randomization (i.e., allocation probabilities increasingly favored the treatment that had been more successful among prior subjects).⁸⁷ When the study ended, 1 child had been assigned to conventional treatment and died, whereas 11 children had been assigned to ECMO and survived. This difference was statistically significant.

In 1986, investigators at Harvard initiated a second RCT of ECMO versus conventional treatment.¹⁵⁹ They justified another trial because “the disparity in group size [in the first RCT] provided little concurrent experience concerning the relative efficacy of the two therapies,” and because they were concerned that rapidly decreasing mortality rates with conventional treatment made using historical controls problematic. This trial also used single-consent prerandomization. In addition, it employed a different form of adaptive randomization whereby all infants were randomized to either ECMO or conventional treatment until there were four deaths in one arm, after which all subsequent infants were directly assigned to the favored treatment. In this trial, 6 out of 10 infants treated with conventional treatment, versus 19 out of 20 infants treated with ECMO, survived ($p < 0.05$).

Though ECMO subsequently entered standard practice in the United States, it was not accepted in the United Kingdom at the time. Thus U.K. physicians, dissatisfied with the methods employed in the trials described above, initiated a conventional RCT in 1993.⁹⁰ By the fifth interim analysis three years later, mortality was 54/92 (59%) in the conventional arm and 30/93 (32%) in the ECMO arm ($p = 0.0005$). Upon the recommendation of the DMC, the trial was closed. The appropriateness of conducting this trial, giving the prior evidence favoring ECMO, has been hotly debated.¹²⁰

participants in some blinded trials may make informed guesses about their treatment assignments, raising the possibility of unacknowledged postrandomization biases.^{129,130} Second, many RCTs are underpowered, increasing the prevalence of false-negative results.¹³¹ Third, evidence of publication bias (i.e., lower publication rates among negative than among positive RCTs) suggests that the literature systematically overstates the effectiveness of new treatments.^{132–138} Fourth, participants in RCTs are often unrepresentative of the populations to which inferences are made, raising concerns that study results may not generalize to nontrial practice.^{94,95,139–143} Fifth, despite RCTs' methodological rigor, bias may creep into authors' qualitative conclusions.¹⁴⁴

Finally, Wikler argues that the standard *P* value cutoff of 0.05 for declaring statistical significance is “not a medical or statistical truth, but a clinician's convention.”⁵⁷ It reflects a value-laden tradeoff between expected risks and benefits for present subjects and the degree of confidence desired before adopting new therapies. Also, as noted previously, because the *P* value fails to take into account the prior probability that the new treatment is superior to the standard, it can encourage misleading conclusions about the likelihood that an observed difference is a false positive.^{14,16} Various strategies to deal with the practical and inferential problems of the *P* value, including relaxing the traditional 0.05 cutoff for rare diseases or low-risk/low-cost interventions and using Bayesian or mixed frequentist-Bayesian analytic techniques, have been proposed.^{13,14,16,145–147}

Favorable Risk-Benefit Ratio

The Belmont Report enjoins us to consider risks and benefits to study participants, together with societal benefits from the knowledge gained, in evaluating the risk-benefit ratio of a particular study.⁶⁷ As Miller and Brody point out, the societal advantages of rigorous research design strengthen the ethical argument for RCTs, even when the indifference claim is weak.⁶⁶ On the other hand, RCTs open up the possibility that some participants may be disadvantaged by assignment to a predictably inferior therapy.²⁵ As we noted previously, the various conceptions of indifference in part represent efforts to resolve this conundrum. DMCs and early stopping rules are further efforts to walk the tightrope between advantages to society and costs to present patients.

It is difficult to estimate how much benefit, if any, subjects forgo by taking part in RCTs. Scant data indicate that experimental therapies in RCTs offer at best a small advantage over standard therapies.^{60,103–106} However, some claim the existence of a benefit from trial participation itself,^{25,148–150} though one of us has questioned the methodological basis for this conclusion.¹⁵¹ In any case, the weight of evidence suggests that in most cases one sacrifices little or nothing in terms of disease outcome by agreeing to participate in an RCT.

Recently, controversy has erupted over whether RCTs with mortality or major morbidity endpoints must include standard-care control arms.^{152–155} This debate, inspired by a trial involving patients with acute respiratory distress syndrome (ARDS), raises important questions of social value, scientific validity and risk-benefit ratio¹⁵⁶ (see Box 24.3).

In the ARDS trial, subjects were randomized to receive either large or small tidal volumes delivered by a mechanical ventilator,

in which either option was judged at the start of the trial to be within the range of acceptable care. This design presented at least three questions at the interface of ethics and scientific methodology: (1) In the absence of a routine-care control arm (that is, a third arm of the trial in which tidal volumes would have been determined by the bedside clinicians), could the trial determine whether either treatment under study was preferable to current practice? (2) Were subjects randomized to either arm put at unnecessary risk compared with routine care? (3) Did the absence of a routine-care arm hinder the DMC's ability to evaluate whether participants were experiencing adverse outcomes using interim data?^{152,157} Answering these questions is complex. Some have argued, for example, that a routine-care arm would not have been helpful in this trial, because routine care was not defined and was known to vary across a wide spectrum of practice. This lack of definition might have rendered any comparisons between the experimental arms and the routine-care control arm uninterpretable. At a minimum, the debate highlights the critical question

Box 24.3

The ARDSNet Controversy

In 1996, the Acute Respiratory Distress Syndrome Network (ARDSNet) initiated a multicenter randomized trial comparing mortality among critically ill patients treated with “traditional” high-volume mechanical ventilator breaths versus those treated with low-volume breaths.¹⁵⁶ At the start of the trial, practice varied considerably across intensive care units, with some preferring lower-volume and others higher-volume approaches. In addition, physicians generally adjusted their approach to mechanical ventilation based on the patient's clinical state. There was no consensus about the preferred ventilator strategy.

Against this background, trial participants were randomized to receive either high-volume or low-volume mechanical ventilation, with subsequent adjustments based on prespecified physiologic criteria. The high-volume strategy reflected approximately the 80th percentile of common practice, whereas the low-volume strategy reflected approximately the 3rd percentile.¹⁵³ About 860 subjects enrolled. In 1999, upon the recommendation of the Data Monitoring Committee (DMC), the trial closed early when convincing evidence for reduced mortality in the lower-volume arm emerged.

In July 2002, two critical-care physicians and two statisticians raised concerns about the trial, as well as about a second ARDSNet trial that was under way, with the Office for Human Research Protections (OHRP), which has regulatory jurisdiction over most U.S. human subjects research.¹⁵³ They argued that the absence of a routine-care control arm (either individualized ventilator management or volumes reflecting approximately the median in routine practice) potentially put subjects at increased risk. The additional risk could derive from the assignment of some participants to an inappropriate “control” arm, or from the inability of the DMC to monitor directly whether the participants in the two arms were experiencing poorer outcomes than they would have if they had received routine care. In response to this and other complaints, OHRP launched an investigation of the completed trial and requested that a second ARDSNet trial raising similar issues be suspended. Though ultimately it exonerated both trials and permitted the second trial to proceed, OHRP called for further debate about whether trials should be required on ethical grounds to include a routine-care control arm.¹⁵⁷

of what role research ethics should play with regard to considerations of scientific design.¹⁵⁵

Informed Consent

In general, informed consent to RCTs does not raise qualitatively different concerns from consent to other forms of intervention research. As with other designs, consent to RCTs is viewed by most as central to individuals' acceptance of the role of subject in addition to (or instead of) that of patient. However, several issues specific to RCTs have arisen.

Discomfort among physician-investigators with the mandate to obtain written informed consent has contributed to recruitment problems and even threatened the completion of some trials.¹¹¹ One response to this problem, advocated by Zelen, is to randomize eligible patients before requesting consent.¹⁵⁸ Investigators could then request consent only from those assigned to the experimental arm (single-consent design), or from those assigned to both arms (double-consent design). In either case, the trial would be analyzed on the basis of initial group assignment rather than treatment received (i.e., intent to treat). The single-consent approach, which withholds material information from some subjects, was deemed unethical by the U.S. National Institutes of Health when used in the Harvard Neonatal ECMO Trial.^{89,159} The double-consent strategy is more palatable, though it too has been challenged on both ethical and methodological grounds. For example, Ellenberg¹⁶⁰ and Altman et al.¹⁶¹ have argued that because of subject refusal and the need for intention-to-treat analyses, prerandomized trials may underestimate treatment effects and have reduced power when compared with conventional RCTs. Prerandomization is also inapplicable to blinded trials. Furthermore, it is possible that unbalanced presentations by investigators¹⁶² (i.e., emphasizing benefits to those assigned to experimental therapy and uncertainty or risks to those assigned to standard therapy) or investigators' glossing over the difficult issue of randomization itself might lead subjects to consent who would have refused under the conventional design. On the basis of these arguments, Marquis has condemned prerandomization as "either unnecessary or unethical."¹⁶³

Truog et al. have argued that informed consent to RCT participation may be ethically optional under limited circumstances, including (1) availability of all treatments outside the trial without the requirement for consent, (2) minimal incremental risk, (3) "genuine clinical equipoise," and (4) no basis for treatment preference among reasonable persons.¹⁶⁴ Middle-ground alternatives, such as opt-out consent designs,¹⁶⁵ are also available.

Trialists, ethicists, and regulators have recognized the impossibility of obtaining informed consent or proxy permission in some emergency trials, such as those for cardiac arrest¹⁶⁶ (see Chapter 27). In the United States, regulators have waived the requirement for informed consent to such trials if certain stipulations, including advance community consultation and notification, are met.¹⁶⁷ This emergency exception, although controversial, suggests that informed consent is not seen as ethically mandatory for all RCTs.

Empirical data on participants' or proxies' understanding of randomization are conflicting.²⁵ Several studies demonstrate problems with recognition of the method of treatment allocation

or the underlying rationale for its use.^{168–174} Other studies, however, paint a less pessimistic picture.^{175–178}

Respect for Potential and Enrolled Participants

Emanuel et al. suggest that respect for subjects includes permitting withdrawal, protecting privacy, informing subjects of newly discovered risks or benefits, sharing results, and maintaining subject welfare.⁷ For the most part, respect for subjects in RCTs raises no unique issues. One major difference, however, is that withholding information about treatment assignment and interim results is more common in RCTs than in other study designs.

Despite the fact that blinding challenges obligations of personal care as much as randomization (indeed, its methodological rationale is in part to preclude personal care),¹⁷⁹ it has received far less attention in the ethics literature. Clinicians who take part in blinded trials cannot easily make individualized dose adjustments, have difficulty interpreting adverse events, and may struggle with drug interactions. Although well-designed protocols will help investigators minimize risks to subjects as they navigate most situations, unanticipated circumstances can arise. Most commentators accept blinding if prospective subjects are aware of and agree to the fact that neither they nor the investigator will know their treatment assignment.^{1,180} Nevertheless, this reliance on consent raises problems for pediatric and other research that relies on proxy permission. In such trials, blinding (a clearly nontherapeutic procedure) might be ethically justified if it was both scientifically necessary and involved at most a minor increment over minimal risk.^{37,181}

Finally, respect for subjects would ordinarily include access to interim findings. The common practice of withholding interim results in RCTs further impairs personal care and increases the likelihood that subjects will receive a less effective treatment despite mounting evidence for its inferiority. At the same time, it may be practically necessary for trials to reach completion. As discussed above, withholding results is usually justified by reference to subjects' prior consent.^{1,76,180} Some commentators, however, argue that such "consent" to ignorance is invalid, at least in certain circumstances, and that trial results should be freely available.^{75,76} As with blinding, an alternate defense of the practice of withholding interim results might invoke methodological necessity and limited incremental risk.^{37,181}

Study Design and Policy Implications

The appropriate methodological and policy response to the debates over RCTs depends largely on whether one agrees with Freedman and his followers that clinical equipoise succeeds in reconciling perfectly clinicians' obligations to help advance medical science and to care for individual patients. The main practical effect of adopting this position is to prohibit trials, especially involving placebo controls, in which equipoise does not obtain.^{10–12} If, however, one believes as we do that RCTs (along with virtually all clinical research) may require accommodation between clinical and scientific commitments, the policy implications are more profound. At the extreme, viewing obligations to patients as absolute may require abandoning RCTs entirely.²³ Less radically,

one can seek to reduce inconsistencies between the clinical and scientific objectives of providing care within RCTs and to justify any compromises that remain. Several design and policy options merit consideration.

1. *Allocating treatments in ways that minimize losses to current patients:* Adaptive randomization and Bayesian allocation techniques might enhance expected utility for prospective subjects. Nevertheless, they do not entirely negate the charge that RCTs may require sacrificing the interests of some patients in pursuit of medical progress.^{28,57}

2. *Expanding the range of choices available to patients:* When experimental treatments are available outside trials, patients could be offered the choice of randomization or direct assignment to standard or experimental therapy.⁷⁶ This would diminish concerns that the withholding of patients' (or their physicians') preferred treatment compels enrollment in RCTs. However, few data indicate whether participation in the primary analytic (i.e., randomized) groups would be sufficient to make this design feasible in practice.

3. *Conducting pragmatic trials:* In some circumstances, pragmatic trials, including large simple trials, may help reconcile the competing aims of RCTs without compromising scientific rigor.^{2,49,93,182} In such trials, deviations from standard care are kept to the minimum necessary for experimental validity. In addition to the ethical advantages, proponents make scientific (enhanced generalizability) and logistical (lower cost, easier recruitment) arguments for such trials. Taken together, they form a compelling case for conducting a pragmatic trial when it can successfully answer the study question.

4. *Exploring Bayesian analytic techniques:* The implications of Bayesian statistical analysis for ethical conceptions of RCTs have received little attention. On the one hand, they might result in continuing trials beyond their stopping point under the frequentist paradigm, thus straining the indifference requirement past the point required by the $P = 0.05$ convention.^{14,16} At the same time, by reminding us that both patients and physicians generally hold prior probabilities, Bayesian approaches could force greater emphasis on disclosure of preferences and on patient choice than is currently the norm.⁴³

5. *Maximizing the return on investment from every RCT:* If the pursuit of scientific rigor through RCTs involves some concessions by present patients, then practical problems that compromise the quality of the information gained are especially troubling. Regarding publication bias, for example, one response envisions mandatory prospective registration of every RCT in a publicly accessible database.^{183–184} Efforts to ensure that trials are adequately powered and to assess their generalizability to the populations of interest are also warranted.

6. *Weighing alternate designs:* Fried argued that proponents of RCTs wrongly characterize their advantages over other designs as “a gulf as sharp as that between the kosher and the non-kosher.”²² Nonrandomized concurrent controls, historical controls, or continuous quality improvement may occasionally offer feasible alternatives when RCTs prove ethically or practically untenable.^{28,89,115,185} Shatz has written that “researchers ought to utilize alternative designs when they seem scientifically appropriate, and perhaps even when loss of scientific accuracy—which translates into possible losses for future patients—can be justified by reference to the interests of present patients.”²⁴ At the same time, recent trials of high-dose chemotherapy for metastatic breast

cancer¹⁸⁶ and of hormone replacement therapy for postmenopausal women¹⁸⁷ illustrate the dangers of relying on nonrandomized evidence. In our view, to avoid RCT orthodoxy investigators should consider alternative designs in each controversial case and provide specific justification for the decision to proceed with a randomized design.

Unresolved Ethical Issues and Data Requirements

Our review of the literature demonstrates four major areas that require additional data or greater conceptual clarity.

First, limited empirical evidence about the methodological or practical consequences of alternative designs exists. For example, how would comprehensive cohort designs affect trial enrollment and interpretation? How often do the restrictive eligibility criteria and tightly controlled conditions of many RCTs lead to answers that are internally valid but poorly generalizable to the population of interest?¹⁸⁹ How much bias is introduced by using concurrent but nonrandomized controls together with statistical adjustment techniques?^{124,125} Answers to these questions are crucially important to informed policy decisions about clinical research.

Second, the views of prospective participants about the tradeoffs inherent in RCTs are poorly understood. For example, we know little about how individuals who enroll in trials view their status as both patient and subject, how often they have preferences for standard or experimental therapy, what reasons they hold for accepting randomization, or how they view the relationship between their own medical care and contributing to medical progress.

Third, the choices we make when defining the boundaries of uncertainty require explicit justification in full view of their consequences for patients and subjects.⁸² Because they attempt to estimate treatment effects and their attendant uncertainties directly, Bayesian methods may prove especially fruitful here.¹⁶

Finally, despite the extensive debates over the past half-century, there is as yet no agreement on the fundamental justification for or appropriate use of randomized trials. Thus there is an overarching need for conversation among patients, methodologists, clinicians, and ethicists about the moral basis of RCTs. Existing writings, although rich and professionally diverse, do not always demonstrate the kind of interdisciplinarity or empirical grounding required to advance the debate. Because randomization largely highlights rather than fundamentally alters the dilemmas that are integral to most intervention studies, such conversation should transcend the narrow context of RCTs and aspire to articulate a solid ethical foundation for all clinical research.

The Ethics of Placebo-Controlled Trials

Randomized clinical trials test the efficacy of experimental or existing treatments by comparing them with a control intervention. The control group may receive a placebo disguised to appear indistinguishable from the treatment under investigation or standard treatment. Placebo-controlled trials have generated considerable ethical controversy and debate when they are used to evaluate treatments for patients with particular disorders despite the availability of proven effective treatment. Critics of placebo-controlled trials in these circumstances have argued that the use of placebos in the control group rather than proven effective treatment is unethical.^{1,2} It is alleged to violate the therapeutic obligation of physicians, by randomizing patients to an intervention known to be inferior to standard treatment. These placebo-controlled trials contravene the principle of “clinical equipoise,” which is widely held to be an ethical foundation for the design and conduct of randomized clinical trials.^{3,4} Defenders of such placebo-controlled trials have contended that placebo controls are ethically justifiable in these circumstances provided that sound methodological reasons support their use and that they do not expose research participants to excessive risks of harm.^{5–7} At the heart of the debate are fundamental issues concerning the nature and ethical justification of clinical research.

The ethics of clinical research has two objectives: promoting valuable and rigorous science in the service of human health and safeguarding the rights and well-being of research subjects.⁸ Because these objectives can conflict, ethical analysis of many difficult issues, including placebo-controlled trials, involves the careful weighing and balancing of competing considerations of scientific methodology and subject protection. Whether placebo-controlled trials can be ethically justified in research on disorders with proven

effective treatments depends on an understanding of the strength and weakness of alternative scientific methods for evaluating treatments. After introducing the rationale for placebo-controlled trials as a rigorous method of testing treatment efficacy, this chapter examines the methodological difficulties associated with active-controlled trials, especially those designed to test equivalence or “noninferiority.” It then reviews leading regulatory standards and codes of ethics relating to the use of placebo controls and undertakes a critique of clinical equipoise. This critique paves the way for developing an ethical framework for determining when placebo-controlled trials are justified despite the existence of proven effective treatment. Finally, the chapter discusses the difficult ethical issues concerning the use of placebo-controlled trials for “vulnerable” populations: children and cognitively impaired adults.

The “Gold Standard”

The history of the placebo-controlled trial has been traced to an experiment to evaluate the therapeutic efficacy of “animal magnetism” or “mesmerism” conducted in 1784 by a French royal commission headed by Benjamin Franklin.^{9,10} The randomized, double-blind, placebo-controlled trial, however, did not become a common method of clinical research until the mid-20th century.⁹ It is widely regarded as the most rigorous method for testing treatment efficacy.¹¹ A basic understanding of the rationale for testing treatments in placebo-controlled trials is necessary to appreciate the ethical debate.

Two distinctions are useful at the outset: (1) the distinction between absolute and relative efficacy and (2) that between

superiority and equivalence trials. Absolute efficacy is indicated by credible evidence that a treatment for a given disorder produces improvement in a relevant clinical outcome. It is typically measured by demonstrating a statistically significant and clinically important superiority of the treatment over a placebo control in a double-blind randomized trial. Relative efficacy is indicated by credible evidence that a treatment under investigation is better (or no worse) than a standard treatment with respect to a relevant clinical outcome, as measured by an active-controlled randomized trial. Thus, the primary purpose of the placebo-controlled trial is to ascertain whether a treatment under investigation for a defined group of patients with a given disorder has absolute efficacy. This is determined by observing specified clinical outcomes of patients randomly assigned to an investigational treatment or a placebo control. Placebo-controlled trials are typically conducted under double-blind conditions, with the aim of making it impossible for either patient-subjects or investigators rating trial outcomes to know whether the experimental treatment or placebo was received.

Superiority trials are designed to show that an investigational treatment is better than a suitable control treatment with respect to a relevant clinical outcome. Equivalence (or noninferiority) trials are designed to demonstrate that an investigational treatment is not inferior to a standard treatment. Placebo-controlled trials, which test absolute efficacy, are superiority trials. Active-controlled trials comparing two or more treatments may be designed either as superiority trials or equivalence trials. As discussed below, equivalence trials pose distinctive methodological problems.

The scientific merit of placebo-controlled trials can be illustrated by comparing them with “open label” trials—single-arm clinical trials without randomization, control groups, or masking of the treatment under investigation. Consider an eight-week open label trial of an experimental treatment T in patients diagnosed with major depression. Suppose that this trial demonstrates that 70% of the patients experienced a 50% or greater reduction of depressive symptoms, as compared with baseline measurement, using a standard rating scale. Does it follow that T is an effective treatment for depression? The patients improved, but did their reduction in symptoms result from taking T? This is a question of causation, the answer to which requires guarding against the fallacy of *post hoc ergo propter hoc* (after that, therefore because of that).

In the case of such an open label trial, the temporal sequence of an observed improvement following the administration of treatment does not imply that the treatment caused the improvement. The patients might have improved without T, owing to spontaneous remissions or the fact that depression has a characteristic pattern of waxing and waning symptoms. Alternatively, they may have improved because they hoped and expected relief from taking a new treatment, thereby manifesting a placebo effect. Similarly, the clinical attention of investigators from an esteemed research institution, involving diagnostic assessment and measurement of study outcomes, may also have contributed to improved mood reported by these patients. The fact that both the patients and the investigators knew that all trial participants received T may have biased the mood ratings in the direction of symptomatic improvement. Perhaps the patients reported feeling better because they wanted to please the investigators or thought that they ought to feel better after taking an antidepressant.¹² All these factors can confound judgments of treatment efficacy. The

purpose of the placebo-controlled trial is to conduct a rigorous experiment that controls for these confounding factors in order to make valid causal inferences about treatment efficacy.

A placebo-controlled trial of T would randomize patients with major depression to T or a suitable placebo control (PT). Ideally, the placebo-controlled trial administers test conditions that vary only in the fact that half the patients receive T (an agent with certain pharmacologic properties) and half receive an identically appearing “inert” placebo (for example, a sugar pill) without any known pharmacologic properties. If the patients receiving T are observed to have a significantly greater reduction in symptoms of depression than those receiving PT, then it is inferred that the pharmacologic properties of T are responsible for this result. For example, if half of the trial participants receiving T experience a 50% symptom reduction, as compared with one-quarter of those on placebo, and this difference is statistically significant, then T has therapeutic efficacy.

The placebo-controlled trial is not a perfect tool for testing absolute therapeutic efficacy. Most importantly, inferences about treatment efficacy may not be valid if the double-blind conditions of a trial are unsuccessful, such that trial participants or investigators are able to discern whether the investigational treatment or placebo has been administered. Nonetheless, there is no more rigorous method that is feasible for testing treatment efficacy with respect to disorders that lack treatment, or when existing treatments have not been proven effective.

Active-Controlled Trials

When proven effective treatment already exists for a given disorder, it is natural to think that any new treatment should be tested exclusively against the standard treatment. Apart from ethical concerns of protecting research participants, the use of placebo-controlled trials in this circumstance would seem to lack scientific or clinical value. Clinicians want to know whether an experimental treatment is as good or better than existing treatment, not whether it is better than “nothing.”¹ From this point of view, although first generation investigational treatments should be tested against placebo, second and subsequent generation treatments should be evaluated exclusively in comparison with existing treatments in active-controlled trials.² This perspective, however, can be challenged on methodological grounds.

Three methodological reasons support the use of placebo-controlled trials despite the existence of proven effective treatment. First, assessing the absolute efficacy of experimental treatments remains desirable, as distinct from evaluating relative efficacy in comparison with standard treatment. The new treatment may or may not be more effective than the standard treatment. However, the difference in efficacy between the experimental and standard treatments is likely to be smaller than the difference between the experimental treatment and placebo. Therefore, in order to have adequate statistical power to evaluate efficacy, a placebo-controlled trial would require fewer subjects than an active-controlled superiority trial, because the sample size needed to detect a difference between experimental and control interventions varies inversely with the anticipated magnitude of this difference. Indeed, if the anticipated difference between the experimental treatment and placebo is twice as large as that between the former and standard treatment, then approximately four times

as many subjects would be required for the active-controlled superiority trial.¹³ Accordingly, placebo-controlled trials are more efficient. Because they require fewer subjects, they can be completed more quickly and at less cost. This makes it advantageous to demonstrate the absolute efficacy of experimental treatments in placebo-controlled trials before planning larger scale active-controlled trials.

Second, as compared with active-controlled trials, placebo-controlled trials afford a more accurate determination of whether adverse events observed during a trial are caused by the pharmacologic properties of the investigational drug or reflect the symptomatic expression of the disorder.¹⁴ The lack of a control group not receiving pharmacologic treatment makes active-controlled trials less advantageous in this respect. To be sure, this assessment is complicated by the fact that placebo controls are often associated with reported adverse effects that mirror those of the investigational treatment; however, a higher incidence of adverse effects in the treatment arm as compared with the placebo arm can be attributed to the pharmacologic properties of the treatment.

Third, active-controlled superiority trials may not be feasible for testing new drugs, especially when they are not expected to be substantially more effective than existing treatment. Nonetheless, these new drugs may offer considerable clinical value if they have a more favorable side-effect profile. Furthermore, when existing treatment is only partially effective, providing measurable relief of symptoms for some but not all patients, the availability of new treatments can expand the range of therapeutic options, even though they are no better on the whole than standard treatment.⁶ Under these conditions, it is possible to conduct active-controlled trials designed to test the equivalence or noninferiority of an experimental and a standard treatment.

Active-controlled equivalence trials, however, are subject to serious methodological difficulties.^{5,6,15} A finding of no significant difference between the two treatments does not imply that the new treatment is effective. It is possible that in this particular trial neither the experimental drug nor active comparator was effective. Many standard, proven effective drugs are not uniformly effective in clinical trials. Without a placebo control to validate absolute efficacy, active-controlled equivalence trials may not be capable of discriminating between apparent and real equivalence. This difficulty can be surmounted when standard drugs are consistently and robustly effective, making it probable that the lack of observed difference amounts to equivalence. Otherwise, active-controlled equivalence trials, in contrast to superiority trials, do not permit valid inferences about treatment efficacy; that is, they lack “assay sensitivity.”⁵ This methodological limitation of the active-controlled equivalence trial is analogous to the more obvious inability of open label treatment trials to discriminate between true and apparent treatment efficacy. In both cases, the difficulty derives, in large part, from the use of a trial method that is not designed to determine the *superiority* of an experimental treatment to an appropriate control group.

These methodological considerations are ethically significant. The greater efficiency of placebo-controlled trials means that rigorous initial tests of efficacy can be conducted without exposing large numbers of subjects to potentially ineffective agents.¹⁶ These trials also provide clinically useful information on the side effects of new treatments as compared with an untreated control group. Moreover, serious problems can arise when active-controlled

equivalence trials are used as evidence for licensing or validating treatments in cases where active-controlled *superiority* trials would not be feasible. These equivalence studies could lead to licensing new treatments, or validating available treatments that previously have not been proven effective for a given disorder, when these treatments in fact are no better than a placebo intervention. Because most drugs cause unwanted and potentially harmful side effects, drugs that lack specific pharmacologic efficacy—therapeutic benefit beyond a placebo response—do not have an acceptable risk-benefit ratio.

Nevertheless, these methodological considerations, though ethically relevant, are not sufficient to justify the use of placebo-controlled trials to test treatments for a disorder when proven effective therapy exists. Further ethical analysis is necessary to evaluate whether placebo controls that withhold proven effective treatment are acceptable, and whether the risks from placebo assignment are not excessive and are justifiable by the value of the knowledge to be gained from the research. Though related, these are logically distinct issues. Some prominent critics of placebo-controlled trials have argued that use of placebo controls in these circumstances is morally wrong regardless of whether they are harmful.² Before undertaking a critical examination of these ethical issues, I review the guidance available from existing regulatory standards and codes of ethics.

Regulatory Standards and Codes of Ethics

Regulatory standards and codes of ethics differ in their guidance concerning placebo-controlled trials when standard, effective treatments exist. United States federal regulations governing research with humans contain no explicit prohibition or restriction of the use of placebo controls in clinical trials.¹⁷ Research involving humans can be approved by institutional review boards (IRBs) provided that several conditions are met, including the following: (a) “Risks to subjects are minimized . . . by using procedures which are consistent with sound research design and which do not unnecessarily expose subjects to risk”; (b) “[r]isks to subjects are reasonable in relationship to anticipated benefits, if any, to subjects, and the importance of the knowledge that may reasonably be expected to result”; and (c) “[i]nformed consent will be sought from each prospective subject or the subject’s legally authorized representative.”¹⁷

However, the *Institutional Review Board Guidebook* prepared by the Office for Protection from Research Risks (now the Office for Human Research Protections), which oversees research with humans, states, “A design involving a placebo control should not be used where there is a standard treatment that has been shown to be superior to placebo by convincing evidence.”¹⁸ Regulations and guidelines of the U.S. Food and Drug Administration (FDA) require “adequate and well-controlled” studies to demonstrate the effectiveness of drugs as a condition of approving their clinical use.¹⁹ Although the FDA does not require placebo controls, its policy gives a decided preference to placebo-controlled trials when such trials do not pose risks of death or serious harm. FDA regulations define an “adequate and well-controlled study” as one that “uses a design that permits a valid comparison with a control to provide a quantitative assessment of drug effect.”¹⁹ Among the variety of control conditions considered, the regulations mention placebo controls first. Concerning active treatment controls the

regulations state: “The test drug is compared with known effective therapy; for example, where the condition treated is such that administration of placebo or no treatment would be contrary to the interest of the patient.”¹⁹

It might be thought that FDA regulations should favor active-controlled trials whenever standard, effective treatment exists, because use of placebo controls in such cases is “contrary to the interest of the patient.” However, in a supplementary advisory on placebo-controlled and active-controlled study designs, the FDA points out the methodological limitations of active-controlled designs: “For certain drug classes, such as analgesics, antidepressants or antianxiety drugs, failure to show superiority to placebo in a given study is common. . . . In those situations active control trials showing no difference between the new drug and control are of little value as primary evidence of effectiveness and the active control design, the study design most often proposed as an alternative to use of a placebo, is not credible.”²⁰

The FDA position on the issue of placebo-controlled trials has been developed in detail by Robert Temple and Susan Ellenberg.^{5,6} They argue that in view of the methodological considerations favoring placebo-controlled trials, placebo controls are justifiable as long as patients randomized to placebo are not exposed to known risks of irreversible harm, such as death, disease progression, or permanent functional disability. This stance is also reflected in the guidelines for control group selection adopted by the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use, which formulates recommended regulatory policy for the United States, the European Union, and Japan.²¹

The Declaration of Helsinki, endorsed by the World Medical Association, is the leading international code of ethics for clinical research. In an influential article entitled, “The Continued Unethical Use of Placebo Controls,” Kenneth Rothman and Karin Michels appealed to the Declaration to support their position that placebo-controlled trials are unethical in disorders for which treatments of proven efficacy exist.¹ The relevant principle of the Declaration cited in favor of this ethical stance was the following: “In any medical study, every patient—including those of a control group, if any—should be assured of the best proven diagnostic and therapeutic method.”²² Critics of this ethical position have responded that the cited language would also appear to rule out any randomized clinical trial comparing a standard with an experimental treatment.^{23,24} The point of these trials is to determine if the experimental treatment is at least as effective as standard treatment. Patients randomized to experimental treatment are not assured “the best proven” treatment, because the efficacy of the experimental treatment has yet to be determined, and is the very issue under investigation in the trial.

The Declaration of Helsinki was extensively revised in 2000. Its prohibition of placebo-controlled trials when proven effective therapy exists was made unambiguous: “The benefits, risks, burden and effectiveness of a new method should be tested against those of the best current prophylactic, diagnostic and therapeutic methods. This does not exclude the use of placebo, or no treatment, in studies where no proven prophylactic, diagnostic or therapeutic method exists.”²² Nevertheless, a year later, the World Medical Association issued a Note of Clarification concerning the stance of the Declaration on the use of placebo-controlled trials, which states that placebo controls may be ethically justifiable despite the availability of proven effective treatment in two cir-

cumstances: “(1) [w]here for compelling and scientifically sound methodological reasons its use is necessary to determine the efficacy or safety of a prophylactic, diagnostic or therapeutic method, or (2) [w]here a prophylactic, diagnostic or therapeutic method is being investigated for a minor condition and the patients who receive placebo will not be subject to any additional risk of serious or irreversible harm.”²² The Declaration of Helsinki now appears internally inconsistent, containing a provision that prohibits placebo-controlled trials when proven effective treatment exists and a Note of Clarification that permits them under two conditions (see Chapter 13).

The latest version (2002) of the International Ethical Guidelines for Biomedical Research Involving Human Subjects promulgated by the Council for International Organizations of Medical Sciences (CIOMS) permits the use of placebo controls despite the existence of “an established effective intervention” under two conditions: “when withholding an established effective intervention would expose subjects to, at most, temporary discomfort or delay in relief of symptom;” or “when use of an established effective intervention as comparator would not yield scientifically reliable results and use of placebo would not add any risk of serious or irreversible harm to the subjects.”²⁵ This second condition provides more sound guidance than the comparable first condition in the Note of Clarification of the Declaration of Helsinki, because it limits the use of placebo controls when methodologically indicated to situations that do not pose serious or irreversible harm (see Chapter 16). The CIOMS guidelines also address the use of placebo controls to test interventions for use in less developed countries when an established effective intervention is not available. This controversial aspect of the debate over placebo-controlled trials is outside the scope of this chapter (see Chapters 64–67).

The lack of consistent guidance on the use of placebo-controlled trials in the extant regulations and codes of ethics reflects the unresolved ethical controversy over this issue. In any case, these documents have limited utility for ethical analysis, because they typically do not provide any systematic ethical rationale for the positions they adopt. The next section assesses critically the leading ethical argument against the use of placebo-controlled trials when proven effective treatment exists.

Clinical Equipoise

The principle or doctrine of *clinical equipoise*, first articulated by Benjamin Freedman, is widely regarded as central to the ethical justification of randomized clinical trials (RCTs)^{3,26} (see Chapter 24). To understand this principle and its bearing on the ethics of placebo-controlled trials, it is useful to place it within the context of philosophical inquiry concerning “the RCT dilemma.” During the 1980s, philosophers interested in research ethics recognized a tension between the obligation of physicians to offer optimal care to their patients (“the therapeutic obligation”) and the limitations on medical treatment provided in the context of randomized clinical trials. Don Marquis addressed this problem in a 1983 essay, “Leaving Therapy to Chance.”²⁷ The title is significant, suggesting that the randomized clinical trial is a form of therapy rather than an activity of clinical research ethically distinct from therapeutic medicine. Marquis began his essay, “Consider this dilemma: according to an argument that is hard to refute, the

procedure for conducting randomized clinical trials of anticancer drugs is incompatible with the ethics of the physician-patient relationship. If this problem is to be resolved, then either a key procedure for achieving scientific knowledge in medicine must be given up or unethical behavior by physicians must be tolerated.²⁷

Fred Gifford, following the lead of Marquis, examined the RCT dilemma in greater depth. He described the problem as follows: "The central dilemma concerning randomized clinical trials (RCTs) arises out of some simple facts about causal methodology (RCTs are the best way to generate the reliable causal knowledge necessary for optimally-informed action) and a prima facie plausible principle concerning how physicians should treat their patients (always do what it is most reasonable to believe will be best for the patient)."²⁸ Neither Marquis nor Gifford found what they regarded as a satisfactory solution, and neither considered the possibility that the ethical norms governing the therapeutic relationship between physician and patient may not be appropriate for guiding the ethics of clinical trials.

Freedman offered a solution to the RCT dilemma that gained widespread acceptance within bioethics and the medical world. In a landmark article published in 1987, he argued that in clinical trials, the tension between scientific experimentation and the therapeutic obligation of physicians could be overcome by means of the principle of "clinical equipoise."³ The term *equipoise* had been coined by Charles Fried to describe an ethically necessary condition for conducting a randomized clinical trial: physician-investigators must be indifferent between the therapeutic value of the experimental and control treatments evaluated in the study.²⁹ Physician-investigators not in a state of equipoise would be inviting patients to enroll in a trial allocating up to half of them to treatment they believed to be inferior.

Freedman argued that Fried's formulation of equipoise was unduly constraining and failed to reflect the nature of medicine as a social practice according to a professional standard of care. He labeled Fried's original concept of equipoise *theoretical equipoise* (sometimes called *individual equipoise*) and contrasted it with his favored concept of *clinical equipoise* (sometimes called *collective equipoise*). In the latter sense of equipoise, any individual investigator or physician might believe that one arm of the randomized clinical trial offers a therapeutic benefit over the other arm, but the medical profession as a whole remains divided as to which arm is the better treatment. According to Freedman, the trial would be ethical so long as the professional community has not yet reached consensus, which recognizes that "medicine is social rather than individual in nature."³ What makes clinical equipoise an ethical requirement of randomized clinical trials is that only when it is satisfied will patients be assured that they will not be randomized to treatment known to be inferior. In a later article, Freedman and his colleagues described clinical equipoise, and its implications for placebo-controlled trials, in the following way:

That principle can be put into normative or scientific language. As a normative matter, it defines ethical trial design as prohibiting any compromise of a patient's right to medical treatment by enrolling in a study. The same concern is often stated scientifically when we assert that a study must start with an honest null hypothesis, genuine medical uncertainty concerning the relative merits of the various treatment arms included in the trial's design. These principles allow for testing new agents when sufficient information has accu-

mulated to create a state of clinical equipoise vis-à-vis established methods of treatment. At the same time they foreclose the use of placebos in the face of established treatment, because enrolling in a trial would imply that a proportion of enrollees will receive medical attention currently considered inferior by the expert community.²

To evaluate critically the principle of clinical equipoise, it is important to appreciate the ethically significant differences between clinical research and medical care.^{30,31} In routine medical care, physicians are obligated to offer individualized therapy to particular patients consistent with the professional standard of care. Risks of diagnostic and treatment interventions are justified exclusively by the prospect of medical benefits to the patient. In contrast, clinical trials differ from medical care in their purpose, characteristic methods, and justification of risks. The randomized clinical trial is an experiment designed to answer a scientific question, not a form of personal therapy. Clinical trials aim at developing knowledge that can lead to improving the medical care of future patients, not at promoting the medical best interests of those enrolled in research. Unlike routine medical care, randomized clinical trials assign patient-participants to treatment (or placebo) by a random method; they are often conducted under double-blind conditions; and they typically restrict the dosing of experimental and control treatments and the use of concomitant treatments in accordance with the study protocol. These trials often contain a drug "washout" phase prior to randomization, designed to avoid confounding the evaluation of the investigational treatment with the effects of medication that patients were receiving prior to trial participation. Additionally, clinical trials include procedures designed to measure trial outcomes, such as blood draws, biopsies, lumbar punctures, and imaging procedures, which carry some degree of risk of harm or discomfort to participants without offering them compensating benefits. Similarly, outside the context of clinical trials, studies of patients designed to improve understanding of pathophysiology administer research procedures that pose risks without holding out the prospect of medical benefits to them. These risks of clinical research are justified by the value of knowledge to be generated. In sum, clinical research routinely incorporates features of study design that are not justifiable within the ethical framework of medical care.

These key differences between medical care and clinical research are ethically significant. In view of these differences, the ethical principles that guide medical care are not the same as those that guide clinical research. To be sure, in the abstract, the leading principles of beneficence and nonmaleficence (as well as autonomy and justice) apply to both activities.²⁶ However, the meaning of these principles differs importantly in the case of clinical research and medical care. Beneficence and nonmaleficence in medical care are patient-centered norms that guide physicians in the treatment of their particular patients. Together, they prescribe optimal medical attention, or, at least, conformity to the professional standard of care. In clinical research, beneficence concerns promoting the social good of improving health by means of producing generalizable knowledge; and nonmaleficence limits the risks to which research participants can be exposed for the sake of this goal. The investigator in conducting clinical research typically does not function primarily as the personal physician of enrolled patient-participants, and therefore is not subject to the same therapeutic obligations that govern medical care.

Although intuitively appealing, clinical equipoise is fundamentally mistaken. This principle conflates the ethics of clinical research with the ethics of medical care. The RCT dilemma, for which clinical equipoise was proposed as a solution, is a false dilemma. Clinical equipoise, and all other forms of equipoise, make sense as a normative requirement for clinical trials only on the presumption that physician-investigators who conduct these trials have a therapeutic obligation to the research participants enrolled in them. The “therapeutic obligation” of investigators, forming one horn of “the RCT dilemma,” constitutes a misconception about the ethics of clinical trials. The presumption that randomized clinical trials must be compatible with the ethics of the physician-patient relationship assumes erroneously that the randomized clinical trial is a form of therapy, thus misapplying the principles of therapeutic beneficence and nonmaleficence that govern clinical medicine to the fundamentally different practice of clinical research. It is impossible to maintain strict fidelity to doing what is best medically for individual patients in the context of ethical randomized clinical trials, because they are not designed for, and may conflict with, personalized care. The project of bridging the gap between therapy and research via the doctrine of clinical equipoise is doomed to fail.

Accordingly, clinical equipoise provides mistaken guidance about the ethics of placebo-controlled trials. Control groups in clinical trials that depart from a validated standard of medical care require justification but they are not inherently unethical. Placebo controls should be understood as no different in principle from any research procedures that pose risks to participants without a prospect of compensating medical benefit.³⁰ Placebo controls are unethical if they are not necessary to answer a clinically valuable scientific question, or if they pose excessive risks. However, the normative assumptions behind clinical equipoise—which evaluate clinical trials with respect to the prevailing medical standard of care—are ethically irrelevant to the situation of clinical research.

Clinical equipoise is also misguided because it confuses a valid methodological principle with a dubious stance on the ethics of selecting appropriate control groups for randomized clinical trials. Freedman and his colleagues have equated the methodological, and ethical, requirement that clinical studies have “an honest null hypothesis” and the ethical norm that physician-investigators have a therapeutic obligation to patient-participants, so that it is unethical to randomize them to known inferior treatment.^{2,3} These two components of clinical equipoise, however, are not equivalent. To have scientific and potential clinical value, all clinical trials require an honest null hypothesis. There must be sufficient uncertainty about the hypothesis being tested in a clinical trial to make it worth conducting. Randomized clinical trials comparing an experimental treatment with placebo typically are instituted to test an honest null hypothesis. It is not known whether the experimental treatment being evaluated would be superior to a placebo control with respect to study outcomes. Yet when proven effective treatment exists for the disorder under investigation, these placebo-controlled trials violate clinical equipoise because randomization to placebo involves treatment that is known to be inferior to available therapy.^{2,4} The critical assessment of clinical equipoise must detach the sound principle of scientific merit enjoining an honest null hypothesis from the erroneous ethical principle that control groups must always conform to the scientifically validated standard of medical care.

Charles Weijer, a leading advocate of clinical equipoise, has recently claimed that “[p]lacebo-controlled trials in the context of

serious illnesses such as depression or schizophrenia are ethically egregious precisely because no competent physician would fail to offer therapy to a patient with the condition.”³² But given the differences between the ethics of clinical research and the ethics of medical care, appealing to what competent physicians would do in medical practice has no inherent ethical bearing on what is justifiable in the context of clinical research. Instead, we should be concerned about the methodological rationale for use of placebo controls and the consequences to patient-participants of placebo assignment.

Ethical Framework for Placebo-Controlled Trials

Ethical evaluation of placebo controls as a scientific tool for testing treatment efficacy requires attention to five issues: (1) methodological rationale, (2) fair selection of participants, (3) assessment of risks from placebo assignment, (4) safeguards to minimize risks, and (5) informed consent.^{7,33} Participant selection is addressed briefly in the final section of this chapter devoted to placebo-controlled trials in children and cognitively impaired adults.

Methodological Rationale

The use of placebo controls must be methodologically necessary or desirable to achieve valid trial results. For the reasons indicated above, initial efficacy evaluation of experimental treatments in comparison with placebo controls is desirable, notwithstanding the fact that proven effective treatment exists, provided that the risks from receiving placebo are not excessive. Additionally, in comparing new treatments with standard treatments, placebo controls will often be necessary to assure the internal validity of trials designed to evaluate equivalence. Without a placebo control, it often would be difficult, if not impossible, to determine whether apparent equivalence reflected the efficacy of both treatments or the fact that neither was effective. This holds for chronic disorders with waxing and waning symptoms when existing treatments often are only partially effective, such as depression and anxiety, migraine headaches, multiple sclerosis, and stable angina. Randomized trials of these disorders evaluate treatments on subjective outcomes of symptom relief and have high rates of placebo response. Without placebo controls, trials showing lack of significant differences between experimental and standard treatments will not permit valid inferences regarding treatment efficacy.

When placebo controls are not methodologically indicated, they should not be used.³⁴ Two asthma clinical trials demonstrate the unnecessary, and therefore unethical, use of placebo controls. These two studies compared combination therapy with monotherapy as well as placebo.

The first study enrolled patients with “a history of at least 1 yr of intermittent or persistent asthma symptoms treated with inhaled corticosteroids for at least 6 wks before the prestudy visit.”³⁵ Patients were randomized to receive either the inhaled corticosteroid beclomethasone combined with the leukotriene antagonist montelukast (193 subjects), beclomethasone monotherapy (200 subjects), montelukast monotherapy (201 subjects), or placebo (48 subjects). The trial lasted 16 weeks.

The second study enrolled patients who “had a medical history of asthma . . . of at least 6 months’ duration that required

pharmacotherapy over the 6 months preceding the study.”³⁶ For this 12-week trial, patients were randomized to receive one of three treatments or placebo: the combination of the inhaled corticosteroid fluticasone propionate and the long-acting beta-agonist salmeterol (92 subjects), either of these alone as monotherapy (92 and 90 subjects each), and placebo (82 subjects).

Both studies were powered to detect significant differences between combination therapies and monotherapies. The statistical analysis section of the first study stated: “This sample size allowed detection, with 95% power (at $\alpha = 0.05$; two-sided test), of a 6.0 percentage point difference in FEV1 (percent change from baseline) and a 10.0% difference in daytime symptoms score (change from baseline) between the additivity and beclomethasone treatment groups.”³⁵

In these trials, there was no clear or compelling scientific or clinical rationale for placebo controls. Because both employed sample sizes powered to detect significant treatment differences between combination and monotherapy, placebo controls were methodologically unnecessary. They could, and should, have been designed as active-controlled superiority trials without placebo controls, thus avoiding the exposure of asthmatic patients in need of maintenance treatment to placebo for up to 12 or 16 weeks. In the article reporting the results of the first study, the authors stated, “The placebo group was included to validate the clinical benefit from inhaled corticosteroid treatment.”³⁵ However, demonstrating the *superiority* of the combination therapy to monotherapy would provide all the validation needed for this clinical trial. Moreover, because all the active treatments were approved medications that had been shown to be superior to placebo in previous clinical trials, comparison to placebo did not add valuable scientific information.

Demonstrating that the combination therapies were superior to placebo also lacks clinical value. Combination therapy should be administered in clinical practice only if it is likely to be more effective than monotherapy. In fact, both studies showed that combination therapy was superior to monotherapy—outcomes that could be demonstrated without comparison with placebo.

Why were placebo controls thought to be needed in these two studies evaluating combination therapy? One reason might be the belief that the FDA requires placebo controls for asthma clinical trials. This is suggested by the fact that the first study, which enrolled patients in 18 countries, included placebo controls only at U.S. sites. (The second study was conducted exclusively in the United States.) Although FDA guidelines appear to favor placebo controls whenever studies do not pose risks of serious, irreversible harm, they do not question the credibility of active-controlled superiority trials, in contrast to active-controlled equivalence trials.^{5,6,19} Hence, use of placebo in these two studies, which could have been executed as active-controlled superiority trials, without placebo controls, would not find any support in this appeal to FDA requirements.

Patients randomized to placebo in these two studies fared worse with respect to primary and secondary outcome measures including forced expiratory volume in 1 second at the end of the study compared with baseline, asthma symptom scores, withdrawal owing to asthma exacerbations, and use of albuterol. These results do not suggest that those receiving placebo were irreversibly harmed; however, they were placed at some risk of harm from asthma exacerbation and experienced symptoms associated with discomfort, which may have caused temporary functional

disability. Without a solid methodological rationale for placebo controls, it is impossible to justify exposing patient volunteers to the risks and discomforts of withholding or withdrawing effective treatment.

Assessment of Risks

The risks of placebo controls derive from the placebo intervention itself and from the risks of withholding proven effective treatment. When placebos consist of inert substances, ingested by mouth, the risks of the placebo itself generally are nonexistent or minor. Placebo injections and more invasive placebos, such as “sham surgery,” carry risks from the invasiveness of the placebo procedure and accompanying treatment such as anesthesia.^{37,38} Risk assessment here will focus on pill placebos, for which the risks of concern stem from lack of effective treatment.

It is important to recognize that a wide range of therapeutic benefits falls within the category of “proven effective” treatment. Therapeutic benefits include complete cures, more or less effective prophylaxis or symptom control, slowing progression of disease, and varying extent of symptom relief. Treatments may work in these ways for varying proportions of patients. Accordingly, the risks from withholding effective treatment will depend on the degree and probability of efficacy for patients receiving treatment and the severity of consequences for the health and well-being of patients in the placebo arm from lack of standard treatment during the course of trial participation. When existing treatments are only partially effective, or the benefit-risk ratio of standard treatment is marginal owing to relatively severe side effects, patients may not be disadvantaged by receiving placebo.

Assessing the risks of harm from receiving placebo in clinical trials requires attention to three dimensions of risk: (1) severity, (2) probability, and (3) duration of harm. At one end of the severity spectrum is the experience of mild symptoms with minimal threats to health, resulting from receiving placebo in trials of new treatments for conditions such as allergic rhinitis, heartburn, or headaches. At the other end of the spectrum, such as trials of cancer chemotherapy and antibiotics for a life-threatening infection, the use of a placebo control would pose substantial risks of serious irreversible harm, in view of illness severity and effectiveness of standard treatment. The use of placebo controls at the mild end of the severity spectrum is unlikely to evoke ethical concern, except for those who take a categorical stance that placebo controls are unethical whenever proven effective treatments exist. These studies are consistent with the Declaration of Helsinki’s permission for placebo-controlled trials in “minor” disorders in its recent Note of Clarification described above. On the other hand, everyone agrees that placebo controls are unethical if withholding available treatment would be likely to expose research subjects to death or irreversible morbidity. The more difficult cases lie in the middle range between the two ends of the severity spectrum.

Some commentators have taken the position that the only risks that raise concern about placebo assignment are death or irreversible morbidity.^{5,6} Yet discomfort or distress and temporary functional disability may reach a level of severity that makes them serious harms, to which research participants should not be exposed.⁷ An example is placebo-controlled trials of drugs administered to prevent nausea and vomiting caused by highly emetogenic chemotherapy to treat various cancers. In 1981, research

demonstrated robust and statistically significant differences between metoclopramide and placebo for the treatment of nausea and vomiting induced by cisplatin.³⁹ In the early 1990s, the new antiemetic agent ondansetron was tested in placebo-controlled trials for patients naïve to previous chemotherapy who were receiving cisplatin.⁴⁰ Because it was known that lack of prophylactic antiemetic treatment was likely to result in repeated vomiting in patients receiving cisplatin, and that an effective antiemetic agent was available, these trials were arguably unethical.^{7,8} Indeed, the need for placebo controls was doubtful, as a contemporaneous active-controlled trial demonstrated that ondansetron was superior to metoclopramide in reducing the incidence of nausea and vomiting in connection with cisplatin therapy.⁴¹ Although vomiting induced by chemotherapy is not life-threatening and does not cause irreversible disability, it represents serious, avoidable harm that is more than a minor discomfort. Nausea and vomiting induced by chemotherapy can be sufficiently severe to cause patients to refuse subsequent chemotherapy, or it may increase the risk of nausea and vomiting for those who undergo further chemotherapy.

The ethical concern over severe discomfort produced by trials that withhold antiemetic treatment was evidenced by a 1996 article written by seven investigators, including the lead authors of the previous placebo-controlled studies, entitled “Are More Antiemetic Trials With a Placebo Necessary?”⁴² They compiled the results of placebo-controlled trials of three antiemetic agents evaluated in connection with cisplatin chemotherapy. The article contained a table presenting the individual results for all 48 patients randomized to placebo in these trials. According to the pooled results, 98% of those receiving placebo experienced vomiting (median of six emetic episodes), as compared with 49% of those pretreated with one of the three antiemetic drugs. The authors concluded that “[c]andidate antiemetic agents should only be tested against active comparators.”⁴²

Accordingly, risks of concern for placebo-controlled trials should include short-lived but severe discomfort and temporary disability, as well as death and irreversible damage. What, then, counts as excessive risk? And who decides? There is no reasonable way to formulate exactly the probability, severity, and duration of potential harm that would make the risks of placebo controls excessive. The question calls for careful investigation and judgment. Such risk-benefit assessments are made by research sponsors, investigators, and most importantly by ethics review boards (ERBs) and research participants.

ERBs, charged with prospective approval of research protocols, must carefully assess the risks from placebo assignment when this involves withholding proven effective treatment. The review boards must determine that the risks have been minimized, that they are not intolerable or excessive, and that they are justifiable by the value of the knowledge to be gained by the study. Once placebo-controlled trials have been reviewed and approved by ERBs, patients make their own judgments about whether they are prepared to accept the risks of trial participation. In the case of chronic conditions for which placebo-controlled trials are common, patients are familiar with the symptoms of their disorder: For example, they know what it is like to experience symptoms of depression, anxiety, multiple sclerosis, or migraine attacks. Therefore, they are well placed to decide whether the risks of nontreatment, or less than standard treatment, are acceptable to them.

Some systematic data are available to inform risk assessments of placebo-controlled trials. A comprehensive review of placebo-controlled trials of chronic, stable angina showed that the risks of adverse events did not differ significantly between the drug and placebo groups.⁴³ A meta-analysis of antidepressant trials in the FDA database, encompassing thousands of patients, found that those depressed patients receiving placebo were not at significantly greater risk of suicide or attempted suicide.⁴⁴ In addition, the patients receiving placebo experienced a mean 31% symptom reduction during trial participation, as compared with 41% symptom reduction for patients who received investigational or active comparator drugs. Thus it appears that, in the aggregate, depressed patients receiving placebo controls in short-term trials are not made worse off or disproportionately disadvantaged as compared with those receiving pharmacologic treatment. A study of placebo-controlled studies in schizophrenia registered with the pharmaceutical regulatory authority of the Netherlands over a 10-year period ending on December 31, 2002, including more than 7,000 patients, also found no significant differences in suicide or attempted suicide between those patients receiving active drugs and those receiving placebo.⁴⁵ In contrast, there is some evidence from placebo-controlled asthma trials that patients maintained on inhaled corticosteroid treatment prior to trial entry who have treatment withdrawn by virtue of being randomized to placebo are more likely than trial participants receiving maintenance treatment to experience symptomatic worsening and to be withdrawn from research owing to asthma exacerbation.^{33,46} More systematic research is needed on the consequences of placebo assignment across the spectrum of placebo-controlled trials in disorders with proven effective treatment.

Safeguards to Minimize Risks

Careful screening of prospective patient volunteers for placebo-controlled trials is required to minimize risks. Severely ill patients at heightened risk of deterioration or of severe suffering from lack of treatment should be excluded. Prospective patient volunteers should be encouraged to consult with their physicians prior to deciding whether or not to enroll in a placebo-controlled trial.^{47,48} For those who lack a physician, consultation with a clinician not involved in the research project is desirable.

The duration of the placebo period should be limited to the shortest time required for adequate efficacy testing. During the conduct of the clinical trial, monitoring procedures are necessary to protect patient volunteers.⁴⁹ For severely ill patients, consideration should be given to limiting placebo-controlled trials to inpatient settings with constant monitoring and the ready availability of “rescue” medications in case of significant deterioration. In outpatient trials, investigators should maintain frequent contact with patient volunteers to assess symptomatic worsening and intervene appropriately. Consideration should be given to requiring research protocols to specify criteria for removing patient volunteers from clinical trials owing to symptom severity or other adverse consequences. In any case, clinical judgment will be necessary, and investigators should err on the side of patient safety.

Informed Consent

Elements of informed consent do not differ essentially in placebo-controlled trials from other forms of clinical research. Some points,

however, deserve emphasis. It is imperative that patient volunteers understand the nature of the study under consideration, how it differs from standard clinical practice, the meaning of *placebo*, the rationale for placebo use, random assignment, the probability of receiving a placebo, blinding of patient volunteers and investigators, alternatives for potentially effective treatment outside the research setting, and other pertinent aspects of study design. Among the risks that must be disclosed and understood are lack of improvement that patient volunteers randomized to placebo might have experienced if they had received standard treatment and the chance of symptomatic worsening during the placebo phase.

A variety of evidence indicates that many patients enrolled in randomized clinical trials are confused about, or fail to appreciate, the differences between routine therapy in medical practice and trial participation.⁵⁰ The invitation to enroll in treatment studies at medical institutions may foster “therapeutic misconceptions” that lead patients to believe that in clinical trials they are being assigned treatment according to clinical judgments about what is in their best medical interests.⁵¹ Consequently, special efforts are desirable to educate patient volunteers about the differences between clinical trials and personalized medical care. Educational aids may be helpful prior to the informed consent process for a particular study, such as computerized tutorials that explain the key elements of randomized, placebo-controlled trials.

Vulnerable Populations

Children and incompetent adults are vulnerable research subjects because they are not able to give informed consent. Children either lack or have not fully developed the capacities of understanding, reasoning, and making choices necessary for giving informed consent to research participation, or they have not reached the age of consent. Adults with various severe cognitive impairments have lost these capacities or may have never achieved them.

Placebo-controlled trials that would be unethical in the case of adults capable of giving informed consent obviously would also be unethical for children and incompetent adults. However, placebo-controlled trials that are ethical for adults may be unethical for individuals from these vulnerable populations. Two key ethical questions need to be addressed in determining whether it is justifiable to enroll children or incompetent adults in placebo-controlled trials. First, is it fair to enroll those unable to give informed consent? Second, should there be stricter limits on the risks of receiving placebo for trials enrolling children or incompetent adults than for competent adults? It is agreed that enrollment of children and cognitively incapacitated adults in research requires safeguards such as authorization by parents in the case of children and appropriate surrogate decision makers in the case of incompetent adults. Assent within the capabilities of the subject should also be obtained. Because these are generic safeguards for clinical research they will not be discussed here.

Children

As a general rule, it is unfair to enroll children in research when their participation is not necessary to answer the scientific question posed by the research.⁵² Some disorders occur solely or predominantly in children, such that clinical trials testing treatments for these conditions will require the enrollment of children.

Whenever possible, initial safety and efficacy testing should involve adults before proceeding to appropriate trials in children. However, just as unnecessary inclusion of children is unethical, excluding children from clinical trials may be morally problematic. Rigorous scientific knowledge about the safety and efficacy of treatment of adults with a given disorder is not adequate for guiding the care of children with the same condition, owing to biological differences between children and adults.⁵³ Excluding children from clinical trials on grounds of protecting the vulnerable can produce clinical vulnerability of children who must be treated by physicians without adequate evidence concerning the safety and efficacy of drugs tested only in adults.

Placebo-controlled trials of experimental treatments when no treatment is clinically available for a given disorder, or when existing treatments have not been rigorously evaluated, are just as acceptable in children as in adults, provided that the rule of initial testing in adults, when possible, has been followed. Can placebo-controlled trials testing experimental drugs enroll children when pharmacologic treatment that is proven effective in children exists? It might be argued that withholding proven effective treatment from a control group of children is unethical, because they cannot consent to forgo potentially effective treatment. The lack of informed consent makes these studies problematic in the case of children, as it does for all research with children that carries risks without the prospect of compensating medical benefits. Nonetheless, we should focus on the potential harm from receiving placebo rather than the fact of withholding treatment. If deviation from standard medical care is not inherently unethical for adults, it is not clear that it should necessarily be unethical for children.

Consider a placebo-controlled trial to evaluate a new treatment for allergic rhinitis. With children who regularly experience mild to moderate symptoms, the harms of forgoing treatment are likely to be minimal, provided that the trial is short term, the investigators have specified reasonable criteria for stopping trial participation in case of symptom worsening, and trial participants are carefully monitored. Accordingly, if placebo-controlled trials are methodologically necessary to test the absolute or relative efficacy of new treatments for childhood disorders, such as depression or anxiety, categorical exclusion of children is unreasonable.

Should there be a more stringent limitation of allowable risks in children from receiving a placebo control than for competent adults? As discussed above, the issue of where to set a risk threshold in adults is a matter of judgment. In the case of children, it is desirable to put some constraints on the upper limit of allowable risk. The U.S. federal regulations concerning research with children may be helpful in this regard. Placebo controls should be understood as “an intervention or procedure that does not hold out the prospect of direct benefit for the individual subject.”⁵⁴ So understood, subpart D of the regulations permits placebo-controlled trials in children when the risks of placebo assignment are more than minimal under three key conditions: “(a) the risks represent a minor increase over minimal risk; (b) the intervention or procedure presents experiences to subjects that are reasonably commensurate with those inherent in their actual or expected medical, dental, psychological, social, or educational situations; and (c) the intervention or procedure is likely to yield generalizable knowledge about the subjects’ disorder or condition that is of vital importance for the understanding and amelioration of the subjects’ disorder or condition.”¹⁷ Minimal risks are defined as those that children are likely to experience in daily life, making

a minor increase over minimal a small increment of additional risk.

The use of placebo controls to evaluate antidepressants in children with depression might fall within an acceptable risk threshold.⁵⁴ The justification of placebo, however, would depend on a reasonable determination that children are not exposed to more than a minor increase over minimal risk from the lack of pharmacologic treatment during short-term placebo-controlled trials. Placebo-controlled trials that exclude children suspected to be at higher risk of suicide, limit trial duration to the shortest period necessary to demonstrate acute efficacy, employ reasonable criteria for stopping trial participation in the event of serious clinical deterioration, and implement careful monitoring might qualify as providing placebo interventions that fall within a minor increase over minimal risk.

Additionally, to approve such a trial, an IRB would need to judge that the use of the placebo control would lead to generalizable knowledge of “vital importance.” Several considerations support such a judgment. Depression is a serious disorder of relatively high prevalence in children.⁵⁵ Comparatively few antidepressant trials have been conducted in children.⁵⁶ Treatments that are effective in adults are not necessarily effective in children, as trials evaluating tricyclic antidepressants have demonstrated.⁵⁵ High rates of placebo response, coupled with lack of strong and consistent efficacy of currently available treatments for childhood depression,^{55,56} provide the rationale for including placebo controls to generate valid efficacy data.⁷ Without a placebo control, the validity of antidepressant trials is open to question. The use of placebo controls in childhood depression appears consistent with criteria promulgated by the American Academy of Pediatrics, which permit placebo controls “when the disease process is characterized by frequent, spontaneous exacerbations and remissions.”⁵⁷

Incompetent Adults

The ethical considerations relating to appropriate enrollment of children in clinical trials and setting allowable risk limits are also pertinent to research with incompetent adults. Incompetent adults should not be enrolled in placebo-controlled trials unless their participation is scientifically necessary to test hypotheses about treatment efficacy. A major difference between children and incompetent adults is that children as a class are incapable of giving informed consent, whereas adults with disorders that put them at risk of lacking decisional capacity may or may not be capable of giving informed consent for research. In other words, diagnostic categories generally are not indicative of incompetence.⁵⁸ Because incompetent adults should not be enrolled in placebo-controlled trials when others who can give informed consent are available, some process of assessing capability to give informed consent is needed to determine whether or not cognitively impaired adults lack competence. For example, patients with schizophrenia on the whole score below normal controls on standard evaluations of capacity to give informed consent.⁵⁹ However, most, but not all, are capable of giving informed consent to research participation, especially when intensive educational efforts are employed.⁶⁰ The National Bioethics Advisory Commission recommended assessment of the capacity to give informed consent by professionals independent of the research team for all more than minimal risk research involving individuals with mental disorders that affect decision-making capacity.⁶¹

Placebo-controlled trials, however, may evaluate treatment appropriately targeted at severely ill patients who lack the capacity to give informed consent. Whether enrollment of incompetent adult patients is ethically acceptable will depend, in part, on the level of risks posed by the placebo control. The threshold of a minor increase over minimal risk might also be reasonable for incompetent adults. It is conceivable that higher risks from placebo assignment might be acceptable if those enrolled have formulated clear research advance directives authorizing their participation in greater than minimal risk research.⁶² In this case, the potential clinical value of the research and the methodological rationale for use of placebo would need to be compelling.

Conclusion

Over the past decade, the conduct of placebo-controlled trials in the face of proven effective treatment has generated intense controversy and debate. The points in contention are complex, including disputed methodological issues and competing ethical perspectives. Categorical rejection of such placebo-controlled trials, which invokes the concept of clinical equipoise, is subject to serious theoretical and practical problems. This chapter has presented an ethical framework for assessing the design and conduct of placebo-controlled trials that includes criteria for a sound methodological rationale, acceptable level of risks, informed consent or authorization by appropriate surrogate decision makers, and safeguards to protect enrolled participants. In permitting placebo-controlled trials despite the existence of proven effective treatment, provided that the trials satisfy suitable ethical criteria, this ethical framework aims at appropriately balancing the twin objectives of clinical research ethics: promoting rigorous research aimed at improving health and medical care, and protecting research participants from harm and exploitation.

Acknowledgments

Challenge Experiments

Challenge experiments are among the most controversial forms of clinical research. They involve experimental interventions aimed at perturbing the biological or psychological functioning of human beings for the purpose of developing scientific knowledge about diseases and their treatment. Challenge agents include drugs, inhaled or ingested substances, physical or psychological stimuli, and pathogens. No precise definition of challenge experiments has been developed, such that it is not always clear whether a particular investigation falls into this category. These studies characteristically offer no prospect of medical benefit for the enrolled participants. In this chapter we concentrate on two types of challenge studies: symptom-provoking experiments with psychiatric patients and infection-inducing experiments with healthy volunteers. Psychiatric symptom-provoking studies include administering challenge procedures known to evoke panic attacks, depressive symptoms, obsessions, and psychotic experiences.¹ Infection challenge experiments have induced diseases such as cholera, malaria, influenza, shigella, and *E. coli*.²

Psychiatric symptom-provoking studies have received considerable public and professional attention, owing to ethical concerns about research involving mentally ill patients that emerged in the mid-1990s. This prompted a report on this area of research by the National Bioethics Advisory Commission, *Research Involving Persons With Mental Disorders That May Affect Decisionmaking Capacity*.³ In contrast, relatively little attention has been devoted to the ethics of infection-inducing challenge experiments in the news media or in the medical or bioethics literature.⁴ Assessing these two forms of challenge experiments together offers a fruitful opportunity for reflecting on ethical issues presented by clinical re-

search that exposes volunteers to risks without the prospect of medical benefits.

Framing the Ethical Assessment of Challenge Experiments

Clinical research is typically designed and supervised by physicians with the use of medical equipment and procedures, and conducted in clinical settings. It is therefore commonly presumed that clinical research should be compatible with the ethical principles of therapeutic medicine, or that clinical investigation is morally problematic if it departs significantly from the ethics of medical care. In this light, challenge experiments appear morally shocking. How can it possibly be ethical for physicians to provoke symptoms of mental illness in psychiatric patients or induce infectious diseases in healthy individuals for the sake of scientific investigation? Isn't this the sort of abusive experimentation carried out by Nazi physicians? To be sure, the participants are volunteers, rather than concentration camp prisoners. Nonetheless, these challenge experiments involve physicians deliberately exposing humans to interventions that induce pathological conditions associated with physical or psychic distress and with the potential for lasting harm. The duties of physicians to care for the sick and avoid harm that is not compensated by medical benefit appear to be flagrantly violated by this form of clinical research.

Although understandable, this moral perspective on challenge studies is mistaken. It transports moral intuitions appropriate to evaluating medical care to the fundamentally different context of

clinical research.⁵ Medical care is devoted to producing therapeutic benefit to particular patients by means of diagnostic and treatment interventions. Clinical research, on the other hand, is devoted to producing scientific knowledge for the benefit of society that can aid in the understanding and treatment of disease. Whereas in clinical care, the risks of medical interventions to which patients are exposed must be justified by the potential for therapeutic benefit to them, in clinical research the risks of experimental procedures are typically justified, entirely or in part, by the value of the knowledge to be gained from the investigation. It follows that the ethical principles of beneficence and nonmaleficence applicable to both medical care and clinical research must be understood as having different implications for these two domains. In medical care, these principles are understood as having an individualized, patient-centered focus. In clinical research, by contrast, beneficence concerns the social value of scientific knowledge; and nonmaleficence places constraints on the level of risks to which it is ethical to expose research subjects for the sake of this social goal.

Nontherapeutic challenge procedures aimed at scientific knowledge would be morally egregious in the context of medical care. However, their use in clinical research must be assessed in accordance with the ethical requirements appropriate to this endeavor. The departure from, or symbolic violation of, the moral ethos of medical care posed by challenge experiments is, in itself, ethically irrelevant. What makes challenge studies morally problematic is their potential to exploit research participants for the good of society. As in the case of all clinical research, this form of experimentation stands in need of ethical justification in accordance with standard ethical requirements. To be ethical, challenge experiments must have scientific or social value; employ valid methods of investigation; select participants fairly; minimize risks and justify them by the potential knowledge to be gained from the research; be reviewed and approved by a research ethics committee; enroll participants who have given informed consent or with ethically appropriate surrogate authorization; and they must be conducted in a way that adequately protects the rights and well-being of research participants.⁶

In an ethical assessment of challenge experiments it is important to distinguish the use of challenge procedures as diagnostic tools in therapeutic medicine from their use as research probes in clinical research. Challenge procedures are commonly administered in the context of medical care for purposes such as determining sensitivity to allergens, airway reactivity, and as evidence of cardiac abnormalities. The purpose is to diagnose disease or dysfunction for the sake of guiding treatment. Challenge experiments in clinical research lack this patient-centered therapeutic purpose; they are administered to develop scientific knowledge about groups of patients with particular disorders.

Social Value

The first ethical consideration in assessing clinical investigation is the potential value of the knowledge it can yield. Valueless clinical research exploits human participants by exposing them to risks without the prospect of producing scientific knowledge. To be ethically justified, experiments that impose substantial risks or burdens must offer commensurate potential knowledge value.

Psychiatric symptom-provoking studies administer challenge procedures to patients and healthy volunteers to investigate the

pathophysiology of psychiatric disorders, with the ultimate aim of improving the diagnosis and treatment of mental illness. The study of evoked symptoms and associated neurobiological phenomena under experimental conditions has contributed to elucidating the role of neural circuitry and the functioning of neural transmitters in psychiatric disorders.⁷⁻⁸ For example, the roles of dopamine and glutamate in the symptomatic expression of schizophrenia have been explored by challenge experiments that have administered amphetamines and ketamine to schizophrenic patients. Tryptophan depletion experiments and the administration of alpha-methylparatyrosine (AMPT) have contributed to our understanding of the role of the serotonergic and noradrenergic neural systems in depression, respectively. It is hoped that this valuable method of scientific investigation, employed over the past 40 years, might eventually lead to diagnostic tests for psychiatric disorders, reliable indicators of optimal treatment selection, or new targets for treatment interventions. Whether or not such clinically relevant developments accrue directly from psychiatric symptom-provoking studies, improved knowledge of pathophysiology and response to treatment is likely to be produced by combining these experiments with brain imaging techniques and genetic tests associated with predisposition to psychiatric illness.

The social value of clinical research may extend beyond specific scientific knowledge. Psychiatric symptom-provoking studies have contributed to the social understanding of mental illness as biologically mediated brain disorders, bringing psychiatry squarely within the domain of somatic medicine. By identifying psychiatric disorders as “real” disturbances in biological functioning rather than purely mental or neurotic phenomena, this understanding has led to a decline in the social stigma of mental illness and the more widespread acceptance of pharmacological treatment. It has also helped absolve parents from misplaced guilt about causing severe mental illness, such as schizophrenia, in their children by means of childrearing practices. Although relevant to the historical assessment of symptom-provoking studies, the social value deriving from improved understanding of mental illness cannot justify any specific prospective experiment. This requires a judgment of potential scientific value relating to the hypotheses to be tested by the study in question.

By virtue of their role in vaccine development, infection-inducing challenge studies offer the prospect of contributing substantially to generating clinically relevant scientific knowledge.² These challenge experiments, which involve deliberate exposure of healthy volunteers to infectious diseases, have been used especially to evaluate initial efficacy of experimental vaccines before conducting large-scale field trials. Once human challenge models are developed, such that they can reliably and safely transmit infectious disease, they are typically used in experiments comparing those who receive candidate vaccines with unvaccinated controls. Preliminary indications of efficacy are determined by the differential responses of vaccinated and unvaccinated research participants to the infection challenge.

Expedient development of effective vaccines can help spare many people from morbidity or death associated with infectious diseases. Pilot data on the efficacy of an experimental vaccine obtained by means of infection challenge experiments can limit the exposure of thousands of humans in field trials to only the most promising vaccine candidates. By weeding out candidate vaccines that do not demonstrate the ability to protect challenged participants, the use of a challenge model can significantly in-

crease the efficiency of vaccine development by reducing the time and cost of testing candidate vaccines. Accordingly, infection-inducing challenge experiments can contribute substantially to public health. In addition to their role in initial efficacy testing of vaccines, infection challenge experiments have been used to elucidate the pathogenicity of microbes and to understand factors contributing to protective immunity, disease acquisition, and disease severity.^{2,4}

Participant Selection

Both psychiatric symptom-provoking and infection challenge experiments raise issues of fairness in selecting research participants. By virtue of aiming to improve the understanding of the pathophysiology of psychiatric disorders, symptom-provoking studies must necessarily recruit patients with mental illness. However, targeting severely ill patients who may have compromised capacity to give informed consent is unethical if the research questions that symptom-provoking experiments are designed to address can be answered by studying fully capacitated patients.⁹ Nonetheless, some valuable research questions can be answered only by recruiting those who are incapable of giving informed consent. Ethics review boards must determine whether the potential scientific value and the risk-benefit ratio of proposed experiments justify enrolling incompetent individuals with informed authorization by family members. Similar issues of participant selection are raised by psychiatric or infection challenge experiments designed to enroll children.

Infection-inducing challenge experiments recruit healthy volunteers who are financially compensated for research participation. No systematic data are available on the volunteer population for these experiments. To the extent that these studies are more likely to recruit economically disadvantaged individuals, concerns may be raised about the fairness of participant selection. However, a blanket policy of excluding such individuals would arguably be discriminatory.

Risks of Challenge Experiments

A key ethical issue in the assessment of challenge experiments is whether the risks to participants can be justified by the value of the knowledge to be gained from the research. The risk of greatest concern is death, which might arise from the unexpected adverse consequences of the challenge agent, from suicide provoked by exacerbated psychiatric symptoms, or by the complications of induced infectious disease. For example, in the famous yellow fever experiments in 1900, supervised by Walter Reed, the first volunteers were members of the research team.¹⁰ Volunteers were deliberately exposed to the challenge of mosquito bites in Cuba with the aim of establishing the transmission of yellow fever. One of the researchers died and another recovered after a serious bout of yellow fever. Over the past 30 years during the era of prior review of clinical research in the United States by Institutional Review Boards (IRBs), there had been no reports of death or lasting harm from either psychiatric symptom-provoking or infection challenge experiments. However, an asthma challenge experiment conducted at Johns Hopkins University resulted in the death of a young, healthy volunteer in 2001.¹¹

Contemporary infection challenge experiments are almost always limited to those diseases that resolve on their own without adverse consequences or that can be fully eradicated by treatment. According to a retrospective review of 18 challenge experiments involving the infection of 128 healthy volunteers with malaria via mosquito challenge, no participants had lasting sequelae.¹² However, 97% of participants experienced one or more symptoms. The most common symptoms were arthralgia or myalgias (79%), headache (77%), chills (68%), and fever exceeding 38° C with a median duration of two days (61%). With adequate procedures for monitoring and treatment, the risks to volunteers from infection challenge experiments are mainly physical discomfort, which may be severe. For example, in a study administering cholera bacteria to determine an optimal challenge model for future efficacy testing of candidate vaccines, 34 of 40 volunteers developed diarrhea, which was classified as “severe” in ten participants.¹³

Short-lived discomfort, rather than lasting harm, is also the major risk of psychiatric symptom-provoking studies. In these experiments, the discomfort takes the form of psychic distress. For most symptom-provoking studies the symptoms that they produce are typically of brief duration and of mild to moderate intensity: for example, a panic attack lasting a few minutes, temporary increase in anxiety and obsessive thoughts in patients with obsessive-compulsive disorder (OCD), or short-lived depressive symptoms; however, some participants experience more pronounced symptomatic responses. Articles presenting the results of symptom-provoking experiments usually report only aggregate data describing the mean degree of change in symptom rating scales produced by a challenge stimulus as compared with a placebo control. These data do not indicate symptom severity of individual participants or the level of distress experienced by those with provoked symptoms. Systematic investigation of psychic distress produced by various psychiatric challenge paradigms would aid in risk-benefit assessment of prospective studies. Some articles, however, include narrative descriptions of more intense reactions, which illustrate the potential of these studies to cause psychic distress. Three examples are presented below.

*Metergoline Administered to OCD Patients*¹⁴

The magnitude of the change during the metergoline study period was within the subclinical category as assessed by the NIMH Global Anxiety Scale (4 to 6) for all but two patients. Over the four-day metergoline period, one patient (patient 5) developed gradually mounting anxiety, which remained unabated for three days, after the study was terminated. Another patient (patient 7) who was well-controlled on clomipramine, reported a similar experience peaking in the evening of day 3 of metergoline administration. She reported being “frantic,” “agitated,” and very fearful and noted a dramatic increase in compulsive checking. On the evening of day 3, she reported three hours of moving repeatedly in and out of her house during a severe thunderstorm to check on a specific item in her backyard. This sudden attack of anxiety and compulsive behavior was very unusual and distressing for her, as she had not experienced similar symptoms for months.

*Tryptophan Depletion Following Treatment for Depression*¹⁵

She began to cry inconsolably and described her emotions as being “out of control.” She said that she did not know why she was crying but could not stop. She also described psychic

Figure 26.1. Scanning Electron Micrograph (SEM) of *Anopheles stephensi*. Source: BSIP/Photo Researchers, Inc. Reproduced with permission.

anxiety, difficulty concentrating, loss of energy, loss of self-confidence, and a sense that nothing was worthwhile. She felt as if all the gains she had made over the past few weeks had “evaporated,” and her HDRS [Hamilton Depression Rating Score] increased to 34. . . . By the following morning she said that she felt “back to herself,” with an HDRS score of 9. She commented that the previous day had been a “nightmare” but that she had learned that the depression was not her “fault.” She also noted that, although she would not want to repeat the test, it had been worthwhile because of what she learned about her illness.

*Lactate Infusion in Vietnam Veterans With Posttraumatic Stress Disorder*¹⁶

Except for patient 6, all the men became depressed and felt guilty during flashbacks. . . . Patient 7 burst into tears during a lactate flashback as he saw his best friend blown up by a booby-trapped grenade.

One potential indicator of severity of distress caused by psychiatric challenge studies is the need for treatment to manage symptoms caused by the experimental provocation. Whether or not counteractive treatment was administered is not typically reported in research articles. One article describing an amphetamine challenge of 16 patients with borderline personality disorder reported, “Two patients had a significant psychotic experience following amphetamine on the first day and were treated with neuroleptic.”¹⁷

Studies addressing the safety of psychiatric symptom-provoking studies have seldom been conducted. A recent report of the outcome of 30 schizophrenic patients receiving 90 ketamine challenge infusions is encouraging.¹⁸ The patients in the aggregate experienced a 30% increase in psychotic symptoms, with a return to baseline 90 minutes after the infusion. No serious adverse events occurred following any of the ketamine challenges. Outcomes for 25 of these patients were matched to a comparable group of 25 patients who did not receive ketamine, over an average

follow-up period of 265 days. No differences were observed in measures of psychopathology, psychiatric care, or amount of antipsychotic medication.

Minimizing Risks

Achieving an acceptable risk-benefit ratio requires that research risks are minimized to the extent possible. The requirement to minimize risks does not mean that risks must be eliminated, for that would make almost all clinical research impossible to conduct. Risks are to be minimized with respect to the task of answering valuable scientific questions by means of scientifically valid methods. Study designs should be evaluated to determine if they can be modified to pose less risk to participants without compromising or undermining the scientific validity of data to be generated by the study.

Challenge procedures must be sufficiently potent to answer research questions without placing participants at excessive risks of harm. Multiple dimensions of the design and conduct of challenge experiments are relevant to the requirement of minimizing risks. For pharmacologic challenge studies, careful attention must be given to the dose of the challenge agent, its route of administration (for example, intravenous versus oral), the frequency of administration, and invasiveness of the challenge procedure. For a scientifically successful and ethically appropriate symptom-provoking experiment, the challenge procedure must be potent enough to elicit characteristic symptoms but not so strongly provocative as to cause severe or long-lasting distress. Generally, infection challenge studies should be limited to inducing infections that are self-limiting or can be fully eradicated by treatment without lasting adverse consequences. Supportive care, such as adequate hydration, is required to protect participants from avoidable complications. Review of the literature and communication with other investigators may help determine safe challenge procedures. The investigator who supervised the asthma challenge experiment that led to the death of a volunteer was criticized for not under-

taking a thorough literature review of the risks of administering hexamethonium, a ganglionic blocker that was not licensed for clinical use.¹¹

Risks are also minimized by careful determination of eligibility criteria aimed at excluding those who might be at higher risk of harm from the challenge experiment. In the case of psychiatric symptom-provoking studies, avoiding the provocation of suicidal behavior is of paramount importance, which calls for screening to exclude those with known risk factors for suicide. For infection challenge experiments, eligible subjects must be determined to be in good health and without any compromise to their ability to fight infection.

To protect participants during the course of challenge experiments, adequate procedures for monitoring their condition are required. Whenever risks of challenge procedures are substantial, these studies should usually be conducted in in-patient settings staffed with competent clinicians and equipped with the medical resources required to respond to any adverse events.

Infection-inducing challenge experiments may pose risks to individuals who are not research participants, because volunteers may transmit infectious disease to others with whom they come into contact. Careful screening of prospective volunteers can reduce the risk of disease transmission to those most vulnerable to infection: for example, by excluding pregnant women and volunteers who live in households with infants. Volunteers, furthermore, must practice adequate contraception while capable of transmitting infection. Infection control procedures for research and clinical staff who come into contact with volunteers and isolation of volunteers while they remain infectious may be indicated for some challenge experiments.

Justifying the Risks of Challenge Experiments

Should there be any limit to the level of risks that are justifiable in challenge experiments? The question is most pertinent to high-risk infection challenge studies that would form an integral part of a vaccine development program that has a compelling public health rationale. Consider the prospect of challenge experiments inducing infectious diseases for which treatment is nonexistent or not effective in fully eradicating disease, symptoms are severe, and/or serious morbidity or mortality is likely to result: for example, smallpox, SARS, HIV, or hepatitis C. Although the U.S. federal regulations governing research with humans do not place any upper limit on allowable research risks,¹⁹ it is unlikely that any public funding agency or ethics review board would endorse such an experiment. However, it is worth pondering whether the famous experiments with healthy volunteers conducted by Walter Reed on the transmission of yellow fever—then a potentially lethal disease without treatment—would be considered ethical by our contemporary standards.

The Nuremberg Code, developed in the wake of the brutal Nazi concentration camp experiments, states the following: “No experiment should be conducted where there is an *a priori* reason to believe that death or disabling injury will occur; except, perhaps, in those experiments where the experimental physicians also serve as subjects.”²⁰ The qualification of an *a priori* reason is critical. Because a research participant dies as a result of a medical experiment, it does not follow that the research was unethical. For example, one’s ethical conclusions about the asthma challenge

experiment at Johns Hopkins—in which a healthy volunteer died—will depend on what was antecedently known or knowable about the risks of the challenge procedures proposed for use in the study.

The Nuremberg Code’s suggestion of an exception to the upper limit for justifiable risk in the case of self-experimentation by investigators raises an interesting question. It is doubtful that inclusion of self-experimentation would, by itself, make a high risk study ethical that would otherwise be judged unethical. Nonetheless, self-experimentation deserves ethical attention. In justifiable, higher risk studies involving healthy volunteers, such as some infection challenge studies, should members of the research team be prepared to volunteer to demonstrate their willingness to assume the same risks and discomforts that they ask of healthy volunteers?

Most commentators would probably take the position that the risks of lasting harm from some possible challenge experiments are so great that they cannot be justified regardless of the potential social value of the research. Whether there should be any upper limits on temporary discomfort not associated with lasting harm is more questionable. Some would argue that there should be no limit on how much discomfort is allowed in such research, because competent adults presented with adequate information about an infection-inducing challenge study have the right to decide how much discomfort or inconvenience they are willing to accept. Others, including the authors, would contend that some studies might be likely to produce such a magnitude of discomfort that it would be unethical to recruit volunteers.

How can it be determined whether the potential value of knowledge to be gained from a given study can justify the risks posed to healthy volunteers? There are no formulas available. The assessment calls for carefully considered and deliberated judgments by research sponsors, investigators, and ethics review boards. Ethics review boards must assess each protocol for challenge experiments on its own merits, weighing the benefits of potential scientific knowledge and possible future clinical applications against the severity of risks of lasting harm and temporary discomfort that the challenge procedures are likely to produce.

Informed Consent

Challenge experiments do not raise unique issues relating to informed consent. As in other forms of psychiatric investigation, psychiatric symptom-provoking studies prompt concerns about the ability of various groups of psychiatric patients to give informed consent for research participation. Clinical experience and the research literature do not support the view that, as a class, psychiatric patients have compromised decision-making capacity.²¹ On the whole, diagnostic categories are not reliable indicators of the capability of individual patients to give informed consent. Paul Appelbaum and his colleagues found that a group of 26 female outpatients with major depression performed well on the MacArthur Competence Assessment Tool—Clinical Research (MacCAT-CR), which evaluated their capacity to give informed consent to a study of maintenance psychotherapy.²² William Carpenter and his research team used this same capacity assessment instrument to evaluate the decisional capacity of 30 patients with schizophrenia with respect to a hypothetical randomized trial of a novel antipsychotic medication.²³ A comparison group of normal

volunteers was assessed with the MacCAT-CR for a comparable clinical trial. Those with schizophrenia performed significantly worse on the Understanding, Reasoning, and Appreciation scales of the instrument. However, following an educational intervention, those with schizophrenia performed as well as the normal volunteers.

For patients considered at risk of compromised decision-making capacity, adequate safeguards should be implemented to assure that they give informed consent to participation in challenge experiments. The National Bioethics Advisory Commission³ has recommended capacity assessment by independent professionals for all research studies involving those with mental disorders that may affect decision-making capacity that present greater than “minimal risk”—defined in terms of the type of risks “ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests.” The alternative requirement that prospective participants pass a test of comprehension of symptom-provoking studies may be no less effective and more efficient.²⁴

The context and timing of informed consent for some symptom-provoking studies deserves attention. In a number of studies, amphetamine and methylphenidate challenges have been administered to patients with schizophrenia shortly after psychiatric hospitalization, during a period when they were acutely psychotic and before they received treatment.¹ This linkage between treatment and symptom-provoking studies has the potential to interfere with informed consent. Acutely ill patients in need of treatment for psychotic disorder may lack the capacity to give informed consent at the time of hospitalization and prior to antipsychotic treatment. Additionally, patients who are seeking treatment may not fully appreciate the nontherapeutic nature of the symptom-provoking experiment. They may believe that its purpose is to obtain clinically relevant information about their condition. Finally, they may view research participation as a condition of receiving treatment, thus compromising the voluntariness of their choice to enroll in the challenge experiment. Compelling reasons must justify symptom-provoking studies under these circumstances. If an ethics review board approves such research, tests of comprehension and perhaps an independent capacity assessment would be indicated.

In our experience as members of an IRB reviewing mental health research, we have found that informed consent documents prepared by investigators for IRB review have often failed to be explicit about the purpose of symptom-provoking studies. It is especially misleading to describe symptoms produced by these challenge experiments as “side effects.” The aim of eliciting characteristic symptoms to study psychiatric disorders should be clearly articulated at the beginning of consent forms. It is also necessary that these documents describe the symptoms anticipated to be provoked and the fact that the experiment is being used solely for research and not to generate information relevant to the diagnosis or treatment of individual patient-participants.

Infection challenge experiments enroll healthy volunteers who are not at risk of impaired decision-making capacity. In view of the burdens imposed on those participating in these studies, a thorough process of information disclosure prior to research enrollment is critical to assure that prospective volunteers understand the purpose of challenge experiments; the procedures involved, including isolation if relevant; the risks of the induced infection and measures taken to minimize these risks; the type, level, and

duration of discomfort likely to be experienced; what can or will be done to alleviate discomfort; and the fact that there are no individual health-related benefits from research participation.

The major ethical concern relating to informed consent for these studies is the potential adverse effects of payment as an inducement to participate. Sometimes a high level of payment is characterized as “coercive,” but this confuses threatened penalties for not participating with an incentive to volunteer. The term “undue inducement,” often used to describe incentive payments for research thought to be excessive, is also problematic. Because it is not clear what counts as due inducement to participate in research, determinations of undue inducement are apt to be arbitrary. Ezekiel Emanuel has persuasively argued that when the necessary ethical requirements for clinical research are satisfied, then there are no grounds for assessing any level of inducement as undue.²⁵

Nevertheless, when substantial payment is offered to volunteer for an infection challenge experiment, safeguards need to be in place to protect individuals from the prospect that the payment might impair their judgment about research participation. Two issues are of concern in this context. First, the offer of payment may cause people to lie about risk factors that would exclude them from study participation. To the extent possible, objective tests should be used to determine study eligibility. When risk factors can be identified only from history-taking, careful assessment is required and confirmatory medical evidence is desirable. Prospective participants must be counseled about the personal importance of truthful communication and informed about the specific health risks of participation if they possess various risk factors. Second, the offer of payment may prompt prospective participants to discount the risks of the challenge experiment.²⁶ This problem can be counteracted by requiring that individuals pass a test of comprehension, including the major risks of study participation, prior to permitting research enrollment. A similar requirement is appropriate for psychiatric symptom-provoking studies when treatment is offered as an inducement to participate.

Patients typically have not been paid as an inducement to, or compensation for, research participation. Consideration should be given to providing modest payment for participating in psychiatric symptom-provoking studies as a way of signifying the difference between research participation and medical care.²⁶ This could help dispel any confusion that the research is being conducted to generate diagnostic information for the benefit of patients.

Right to Withdraw From Research

In some infection challenge studies, volunteers are isolated for a period of time following the induced infection in order to prevent transmitting the infection to others. Such restriction on the freedom of research volunteers should not be permitted unless it is judged by investigators and IRBs to be necessary to protect the public health. Isolation or constraints on the ability to leave the research facility conflicts with the norm of research ethics that volunteers are able to withdraw from research participation at any time without interference or penalty. However, restrictions on freedom to withdraw from research participation or a research facility are not unique to infection-inducing challenge experiments. For example, psychiatric patients in studies that withdraw their medication may not be free to leave the research facility if they are judged to be a danger to themselves or to others.

Challenge experiments using isolation should limit the time volunteers spend in isolation to that necessary to eliminate the risk of infecting others. The need for isolation places an added burden on the process of informed consent. All volunteers must be fully cognizant of and agree voluntarily to the isolation requirements. Although participants may not be allowed to leave the research facility for a specified period, this does not preclude their right to withdraw from further exposure to infectious agents and/or other unwanted research procedures.

Conclusion

Challenge experiments constitute a valuable form of clinical investigation. They are perceived as ethically objectionable, in large part, because of misguided moral intuitions that evaluate these studies in the light of ethical norms appropriate to medical care. As in the case of all clinical research, challenge experiments must be carefully planned, prospectively reviewed, and conducted with the aim of promoting valuable research and protecting participants from harm and exploitation.

Emergency Research

History

Research that enrolls people with acute, serious, and life-threatening illnesses without their informed consent, referred to as emergency research, presents substantial ethical challenges. These challenges focus on how to justify enrolling critically ill persons when the investigator cannot obtain informed consent from either the participants or their proxies. Many Western nations have struggled to define the appropriate regulations to guide this kind of research. Perhaps the most illustrative of these efforts occurred in the United States during the 1990s.¹ The controversy over appropriate regulations became so contentious that for three years there was a moratorium on the research while researchers, institutional review boards (IRBs), and research regulators debated whether the principles of research ethics were adequate to justify a waiver of informed consent, and if they were, how such a waiver should be implemented.^{2,3}

Ultimately, the U.S. Food and Drug Administration (FDA), an arm of the Department of Health and Human Services (DHHS), issued a set of regulations in 1996 that outlined conditions for the waiver of informed consent in emergency research, after which clinical trials resumed.⁴ Although the policy arguments were waged in nuanced debates over the precise wording and intent of the government's basic clinical research regulations, known as the Common Rule,⁵ the controversy and its resolution are an excellent case study in issues that transcend the particulars of regulatory language. The issues include the openness of IRB review, who should participate in research review, the justification of research risks, and the role of proxy informed consent.

Clinical trials involving emergently ill persons who are unable to provide informed consent themselves are a relatively recent event in the history of research with humans. The scientific and clinical infrastructure to launch large trials studying important questions in the care of the acutely ill were not capable of facilitating research until the late 1970s—when researchers in cardiology, neurology, emergency medicine, and critical care began to discover the mechanisms of acute, serious, and life-threatening conditions such as myocardial infarction and head injury. Motivated by data that suggested plausible hypotheses for interventions, these investigators and the emergency medical system established an infrastructure for clinical trials to test potential treatments for emergently ill patients.

Some of this research produced dramatic successes. The randomized controlled trials of drugs that opened up clotted coronary arteries demonstrated a reduction in mortality from heart attacks.⁶ These “clot buster” drugs rapidly became the standard of care for acute myocardial infarction. In contrast, other trials demonstrated that some initially promising interventions, such as hypothermia for acute head injury, were not effective.⁷ In these studies, informed consent was often impossible to obtain from research participants, but the research continued nonetheless, under a variety of rationales for waiving consent.

In the mid-1990s, the U.S. clinical research infrastructure and the DHHS agencies charged with human participant protections came into sharp conflict. The problem was the ethical appropriateness of enrolling people with emergent illness who could not provide informed consent and who had no legally authorized representative available to do so. Clinical investigators and research

regulators disagreed over the adequacy of human participant protections for the waiver of both patient and proxy informed consent. The judgment of research regulators in the DHHS that there existed no regulatory guidance for the waiver of informed consent placed a moratorium in 1993 on all emergency research involving a waiver of informed consent unless it was approved by the Secretary of the DHHS.⁸

Prior to this moratorium, how did investigators justify emergency research? They relied on at least one of three justifications: (1) deferred consent; (2) a waiver granted by the FDA for testing an emergency investigational new drug (IND); or (3) a waiver based upon a series of requirements in the Common Rule anchored to the construct of minimal risk. Individually, each of these solutions was ethically inadequate, but collectively they contained many of the elements of the ethical principles used to permit emergency research with a waiver of informed consent.

Deferred consent meant obtaining consent from participants or their proxies to remain in a research protocol after the investigator had already enrolled them in the research.⁹ Although researchers who used deferred consent argued that it fulfilled the requirement for informed consent,^{10,11} the practice only gave the participant (or proxy) an opportunity to withdraw after enrollment. Hence, it lacked one of informed consent's key components—the ability to choose prior to enrollment. Although deferred consent arguably respected a person's autonomous choice to continue participating in a study, it did not substitute for an informed prospective consent.

A second justification researchers used to waive informed consent in the late 1970s and 1980s was the repeated application of the FDA's rule for the use of an intervention in an unplanned, emergency situation for the benefit of a patient, known as an IND waiver.¹² Investigators argued that they could invoke the IND waiver multiple times for each eligible patient and that it thereby constituted a legitimate mechanism for waiving informed consent. Although this repeated practice of the IND waiver does capture the investigator's judgment that the intervention is potentially beneficial, the waiver refers specifically to a treatment situation. Research may contain components that are given with therapeutic intent, but it inherently includes components to generate knowledge about the efficacy and safety of the intervention. Hence, a waiver of informed consent for treatment purposes cannot be extended to justify exposing a person to research procedures such as randomization.

The third rationale that investigators used was the Common Rule's guidelines for the waiver and modification of informed consent when, as is the case in emergency research, the research could not occur without the waiver.¹¹ These guidelines required that the research risks were minimal, the waiver would not adversely affect the participants' rights and welfare, steps would be taken to inform the participants of the research, and the research could not be practicably carried out without the waiver.⁵ But the Common Rule, first promulgated in 1981, did not clearly articulate what risks *minimal risk* applied to and how to interpret the definition of minimal risk. Substantial disagreement over these issues meant that a waiver on the basis of minimal risk could not settle the controversy.

For three years, emergency research in the United States was halted because federal research regulators argued that no adequate participant protections existed for the waiver of informed consent

in emergency research. Until regulations were written that could justify it, all such research was prohibited unless the secretary of the DHHS authorized it. Although the secretary's permission may have granted an investigator legal authority, it did not address any of the unresolved ethical issues. These issues were finally addressed and the moratorium ceased in October 1996 when the DHHS issued regulations that established conditions to permit research with the waiver of an informed consent, the so-called emergency research regulations.⁴ These regulations established criteria for the review and approval of emergency research done under a waiver of informed consent (see Table 27.1).

The 1996 emergency research regulations describe a process that engages the investigator, study sponsor, IRB, and general public and that affects the spectrum of activities in the design and conduct of research. This process includes (1) consultation with the leaders of the community about the research design and plans; (2) informing the community about the research; (3) preparing three kinds of informed consent forms—a standard informed consent form for the participant, a form for the family or legally authorized representative to provide proxy informed consent, and a form for consent to continue in the research; and (4) informing the community of the study's results.

These requirements included substantial innovations. Although the new regulations made no effort to clarify the minimal risk controversy, they introduced a novel risk-benefit assessment, namely, that research had to be "potentially beneficial" to the participants. The process of informed consent was expanded to include a role for family rather than the narrowly defined "legally authorized representative." Finally, the process of research review and approval was extended beyond the usual institutional structures. The

Table 27.1
Requirements for Waiver of Informed
Consent in U.S. Emergency Research

Necessity: Evidence supports the need to do the research, and the proposed participants are the only population that could reasonably participate in the research.
1. Informed consent from the participant or the participant's legally authorized representative is not practical.
2. Risk-benefit assessment: The research is "potentially beneficial" to the participants.
3. Engagement of the community of potential participants at the beginning and close of the research: The community of potential participants has input into the research design and conduct to determine its social worth and learns about the research results.
4. IRB-to-IRB communication: If one IRB fails to approve the research, the sponsor should inform the remaining IRBs of this fact.
5. Ongoing review of the research: A data safety and monitoring board is in place.
6. Due diligence to obtain consent from participants or their proxy is exercised.
7. Respect for proxy or participant assent and dissent after enrollment.
8. Regulatory review: The FDA and investigator meet to discuss study design and whether the research could be conducted without a waiver of informed consent, and, if the research could not be practicably done without a waiver, how to apply the regulations to the proposed study design.

regulations required consultation with leaders of the community from which research participants would be drawn and required that the community be informed of the proposed research and its results. "Community consultation" was probably the most innovative and controversial of the new regulations' requirements.

The emergency research controversy was a unique opportunity in the ethics of research with humans. By removing the usual protection of informed consent from the participant or a proxy, the research community had to engage a core issue: What are adequate protections for research with humans when the core protection of informed consent is absent? The controversy that brought emergency research to a halt in the United States was resolved by a set of regulations specific to emergency research. Although the problem was solved and the research resumed, this resolution missed an opportunity to settle the general issue of the responsible conduct of research that involves noncompetent adults.

Core Conception and Methodological Rationale

The core concept of emergency research is based on two attributes: (1) the characteristics of enrolled participants; and (2) the impact of the timing of the intervention on the ability to obtain informed consent from either the participants or their proxies. A research project is emergency research when the participants have an acute, serious, and life-threatening condition; the investigator must administer the intervention to the participants within a limited amount of time; and this time limit prevents the research team from obtaining informed consent from either the participants or their proxies.

This definition is conceptually sensible, and investigators can usually apply it. Assume that the first criterion is fulfilled, namely, that the potential participants have an acute, serious, and life-threatening condition. An investigator can generally obtain informed consent for a study whose intervention can be given over the course of days after the acute event. Participants have days to consider the option of enrolling and, in the event a person is not competent to consent, the investigator has time to locate a proxy. Such a study is not emergency research. At the other extreme, an investigator generally cannot obtain informed consent for a study from the patient or the patient's proxy when the intervention must be delivered within minutes of an acute and entirely unexpected event. Such a study is emergency research. But in between these extremes, when does the timing of an intervention transform the research from nonemergency research to emergency research?

Much of the controversy over this question has to do with how one interprets the judgment that it is not practical to obtain informed consent from either the participant or the participant's proxy.^{13,14} For example, a study of diaspirin cross-linked hemoglobin for traumatic hemorrhagic shock had a 30-minute window of intervention to randomly administer either the study intervention or blood to patients with acute hemorrhage.¹⁵ Even under these conditions, the investigators enrolled 6% of the participants with prospective informed consent. Hence, informed consent is *possible* with as little as a 30-minute window. But how should an investigator and IRB decide whether this is practicable?

An assessment of the practicality of obtaining prospective informed consent from the participant or the participant's proxy requires a consideration of at least four factors: (1) whether the onset of becoming eligible for a research study can be anticipated

in advance; (2) the proximity of the participant or a proxy to the study site; (3) the financial and personnel resources needed to obtain informed consent from either the participant or a proxy; and (4) the impact of different consent methods on the scientific value of the study. The following two cases illustrate how these factors interact to determine the economic and scientific costs of a requirement for informed consent from either the person prior to illness (advance informed consent) or from a proxy after the person is ill.

In both cases, the studies proposed to recruit persons who were admitted to hospital and then suffered acute cardiac arrest. Under these conditions, advance informed consent from the person is possible. That is, at the time of admission to the hospital, the patients grant consent to be enrolled if they should become eligible for the study. In the first case, the study compared manual chest compressions to a new device to perform chest compressions during cardiopulmonary resuscitation.¹⁶ The study used advance informed consent from the participants who were admitted to hospital.¹⁶ This informed consent practice enrolled 18 participants out of 2,131 prospectively consented patients screened from 7,100 patients. Thus, among participants who granted advance informed consent, approximately 1% were enrolled. With this enrollment rate, the investigators estimated that the study would take 16 years to complete.

In the second case, the study proposed to compare two drugs for cardiac resuscitation.¹⁴ In planning the practicality of advance consent, the investigators identified 85 patients out of 8,000 patients admitted to telemetry units who might have been included over a 14-month enrollment period.¹⁴ As in the other case, the ratio of people granting advance consent to enrolled participants would be approximately 1%. These two cases demonstrate that it is possible to obtain informed consent, but the costs can be substantial. These costs include the number of study staff and sites needed to screen and discuss the study with potentially eligible participants, and the time needed to enroll participants.

Another cost of informed consent is scientific. Specifically, the requirement for informed consent can selectively reduce the enrollment of certain subpopulations. This in turn limits the generalizability of the results because underrepresented populations are excluded from the study, thereby diminishing the social worth of the research. For example, investigators conducting a study of hypothermia for persons with acute brain injury initially used prospective informed consent and then changed to a waiver of informed consent after it became lawful to do so in 1996.¹³ The time during which the intervention could be administered was eight hours. During the period of prospective informed consent, the study enrolled 7.2 participants per month. In contrast, during the period when enrollment occurred under a waiver of informed consent, the study enrolled 10.6 participants per month. Whereas the other studies cited above reported enrollment rates of 1% to 6% using informed consent, in this study, a reasonable proportion of participants could be enrolled with prospective informed consent. From the perspective of cost, a requirement for informed consent increased study costs, but not prohibitively.

But the investigators noted differences in the characteristics of the persons enrolled under the requirement for informed consent versus those enrolled under the waiver of informed consent. During the period of prospective informed consent, minority groups were underrepresented by 30%. This gap was closed when the requirement for informed consent was waived. Hence, the

informed consent requirement had an impact on the generalizability of the results because the study could say nothing about populations similar to those who were excluded under the informed consent requirement. The requirement for informed consent diminished the social worth of the research.

The economic and scientific costs of informed consent are also interdependent. Even if the financial resources did exist to conduct a 16-year study, the results of such a study might not be valid. The added sites might not be qualified to do the research, and as the duration of a study grew, the administration at study sites would change and interest might wane. Collectively, these factors could compromise the quality of the data collected. In addition, a 16-year study would substantially delay production of useful data and publication of potentially valuable knowledge to the clinical community.

Emergency research is controversial because it suggests that society is willing to trade off a core research participant protection— informed consent—in the pursuit of efficiency and the interests of society. The claim that a project counts as an instance of emergency research is a judgment that must be made through negotiation with all interested parties. In fact, the finding that a protocol is emergency research may vary from site to site. At one site, the consensus may be that a project is not emergency research because prospective informed consent is practical. For example, an urban medical center may find that families are likely to be available in time for an informed consent discussion and thus a waiver of informed consent is not necessary. In contrast, a rural medical center may find that the distance between the families and the hospital is so great that the costs of enrolling only those whose families or proxies can provide informed consent are not acceptable. At that site, the same project would be thought of as emergency research.

Ethical Issues

The voluntary choice of the competent person to enroll in research is a core protection that fulfills the requirement of respect for persons.¹⁷ But is this protection an absolute requirement for the responsible conduct of research? During the 1970s in the United States, the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (National Commission) addressed whether it was possible to ethically conduct research in which the participant's signature on an informed consent form is either impossible or unnecessary. The National Commission addressed the ethics of research that involves selected populations and its recommendations were subsequently written into federal regulations for research that involves the following groups: children who are by law not competent to consent,^{5(subpart D)} prisoners whose captive environment substantially restricts their voluntary choice,^{5(subpart C)} and persons with mental illness severe enough to warrant institutionalization.¹⁸ The National Commission also developed guidelines that resulted in federal regulations for research in which written informed consent from the participant was either infeasible,^{5(46.116(d)(1–4))} such as research involving deception, or seemed excessively protective, such as a study that used existing samples initially gathered for clinical purposes without written informed consent.^{5(46.117(c)(2))}

The conceptual framework the National Commission developed to address research that involves vulnerable persons or research in which written informed consent from the participant

was infeasible or seemed excessively protective was a substantial step away from the strict requirement of informed consent. By relaxing informed consent as an absolute requirement for all research with humans, while at the same time preserving core protections, the National Commission established a new standard that recognized that the social worth of research could outweigh a strict adherence to the informed consent requirement. In sum, vulnerable persons should have access to research and its potential benefits, and many kinds of valuable research not otherwise practicable without a waiver or modification of informed consent were permissible.

The conceptual framework relied on nuanced applications of the principles of beneficence and justice.¹⁹ Waivers and modifications of written informed consent from the participant are permissible if the research risks and potential benefits fulfilled specific criteria. Parental, prisoner, or proxy consent was appropriate if the research presented no more than minimal risk, or in the case of greater than minimal risk research, if the research either had a reasonable prospect of potential benefit to the participant, could produce results relevant to the class of participants, or had been reviewed and approved by a national panel. The National Commission also articulated the *necessity requirement*. This term described the finding that the research was relevant to the vulnerable population and could not be otherwise done with a nonvulnerable population. The National Commission was thus developing a framework that justified research risks based on balancing study risks against either the potential benefits to the participants or against the importance of the knowledge that could reasonably be expected to result from the research.

This conceptual framework was consistent with two of the National Commission's recommendations in its general guidelines for research with humans. First, its guidelines for IRB review of research required that the IRB judge risks reasonable in relation to the potential benefits to participants and to the importance of the knowledge that could reasonably result from the research. Second, the framework was consistent with the guidelines for waivers and modifications of informed consent in the general conduct of research. An IRB could modify the elements of informed consent, such as the requirement for the participant's signature, or even waive informed consent entirely, if the research risks were minimal, if the waiver or modification would not adversely affect the participants' rights and welfare, and if the research could not be practicably be carried out without the waiver or modification.

This model suggests that although the National Commission never specifically addressed the waiver of informed consent in research that involves persons with critical illness, it articulated many of the elements that might justify waiving informed consent in emergency research. But the model is incomplete. Specifically, the National Commission never addressed two shortcomings. These shortcomings remain the source of substantial disagreement in the ethics of research that involves noncompetent adults.^{1,19,20} First, although the National Commission rejected the distinction between therapeutic and nontherapeutic research, it never clarified what risks should be balanced against the potential benefits to participants and what risks should be balanced against the importance of the knowledge to be gained from the research. Second, the National Commission did not clearly articulate how to interpret its own definition of minimal risk that was subsequently adopted by federal regulators when they wrote the Common Rule: "*Minimal risk* means that the probability and magnitude of harm or

discomfort anticipated in the research are not greater in and of themselves than those ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests.”^{5(46.102(i))} A clear limitation in this definition is the absence of a comparison group to which an IRB could refer when answering the question of to whose daily life the risks of research should be compared. Should the IRB compare the risks of the research to the risks encountered in the daily lives of the potential participants of the research or in the daily lives of healthy persons? A previous version of the regulations stated healthy persons but this was edited out to yield the unanchored definition in the Common Rule.²¹ The commentary to the Common Rule stated that the edited definition referred to the risks faced by the potential participants of research.²¹

The authors of the Common Rule would later explain that this edit to the minimal risk definition was intended to permit a waiver of informed consent for research that involved persons with head injury, that is, emergency research.²² Unfortunately, this was a quick fix without the necessary public discussion of a substantial modification in the nature and intent of the rules for waiver and modification of informed consent. Both politically and ethically, it was ambitious but naive to think that a single word modification in the definition of minimal risk, with an explanation in the commentary section, would settle the issue of when it is appropriate to waive informed consent. Such limited treatment of the issue by the federal officials who wrote the regulations was insufficient when the National Commission had never tackled the general issues of research that involves persons who are cognitively impaired as a result of either physical or mental illness, or the waiver of informed consent in research that involves these participants. In the end, the National Commission’s particular recommendations for research that involves the institutionalized mentally ill were never adopted into regulations.

As a result of these shortcomings, investigators and IRBs had little if any explicit guidance for the conduct of emergency research. The Common Rule required that an investigator obtain informed consent from participants or their legally authorized representatives,^{5(46.116)} and it directed that when a research project enrolled “vulnerable subjects,” the IRB should ensure that additional safeguards are included.^{5(46.111(b))} But no detailed procedures existed for obtaining consent from a legally authorized representative, or what to do if such a representative is not available, or what additional protections IRBs and investigators should consider. This limited guidance and the shortcomings in the standard for assessment of research risks precipitated much of the emergency research controversy, the moratorium, and the need for further regulations.

Despite these limitations, the National Commission’s conceptual framework was significant for establishing that informed consent was not an absolute requirement and that it could be relaxed when other protections were adequate. The strategies IRBs and investigators did take to justify emergency research—deferred consent, treatment IND waiver, and waived informed consent on the basis of minimal risk—were arguably insufficient. But collectively they suggested that the National Commission’s conceptual model could be adapted along with other considerations to create adequate participant protections to permit the waiver of informed consent. The emergency research controversy was a chance to pick up where the National Commission and the authors of the 1981 Common Rule left off. Unfortunately, the

emergency research regulations that were issued in 1996 did not do that. Specifically, the regulations did not address the shortcomings in the application of the minimal risk definition and the justification of research risks.

The 1996 regulations focused on four elements: (1) risk-benefit assessment based on the necessity requirement and potential benefit; (2) a process to assess risks and benefits that emphasizes open, public, and ongoing review; (3) a continued role for informed consent; and (4) the ability to opt out of research.

Risk-Benefit Assessment Based on the Necessity Requirement and Potential Benefit

A core defense of the waiver of informed consent was the principle of beneficence. Investigators consistently asserted that there was legitimate uncertainty in the expert community as to the correct approach to manage emergently ill patients. They designed their research projects to settle this uncertainty and determine the benefits of promising interventions for participants who suffered substantial morbidity and mortality even after receiving standard care. Investigators noted a common framework in the provisions of the Common Rule for research that involved children and in the Commission’s draft regulations and proposed guidelines for research that involved noncompetent adults that permitted proxy consent in the case of research risks that were minimal or research that was potentially beneficial. However, these regulations and guidelines set out standards for when it is permissible to obtain the informed consent from a parent or proxy, not the waiver of informed consent.

The 1996 emergency research regulations created a novel category of permissible research risk and benefit called a “potential . . . to provide a direct benefit to the individual subjects.”⁴ The regulations instructed IRBs to judge whether a study met this standard based on a tripartite risk benefit assessment: “risks associated with the investigation are reasonable in relation to (1) what is known about the medical condition of the potential class of participants, (2) the risks and benefits of standard therapy, if any, and (3) what is known about the risks and benefits of the proposed intervention or activity.”⁴

The standard suggests three risk assessments. Risks are to be compared to the severity of the medical condition, the risks and benefits of standard therapy, and the risks and benefits of the proposed intervention. There are a number of shortcomings in this tripartite standard.²⁰ First, it does not articulate which risks are to be used in each of these assessments. Research includes risks that are part of interventions that may help participants (so-called therapeutic components, such as the proposed intervention), and it also includes risks that are part of the intervention but done solely to generate generalizable knowledge (so-called non-therapeutic components, such as additional blood draws and randomization). Second, the first assessment—risks compared to the severity of the medical condition—suggests that the sicker the participant population is, the more justifiable are increased research risks. Although this is accepted in clinical care, it is not at all appropriate that increasing vulnerability justifies increasing research risks, in particular risks that are associated with non-therapeutic components. Third, the balancing of “risks associated with the investigation” with “risks and benefit for the proposed intervention” is at least vague and even incoherent. What risks of the investigation are distinct from the risks of the proposed

intervention? Fourth, the balance between risk and the importance of the knowledge that may reasonably result is entirely absent. In summary, although the spirit of the requirement reflects the principle of beneficence, the requirement is vague in instructing an IRB how it should assess the research risks and potential benefits in order to arrive at the judgment that the research has a “potential . . . to provide a direct benefit to the individual subjects.”

This is a substantial shortcoming in the regulations and a missed opportunity to settle the loose ends of the National Commission's work. It resurfaced in 1998 when the National Bioethics Advisory Commission (NBAC) proposed regulations for research that involves adults with impaired decision-making capacity.²³ Those regulations, like the 1996 emergency research regulations, should have stipulated clearly what kinds of research risks could be justified by potential benefits to the participants and what research risks were justified by the importance of the research questions. A model to guide this assessment is “component analysis” and was developed by Charles Weijer¹⁹ and adopted by NBAC in 2001 in its summary recommendations for the revision of U.S. human participant research regulations.²⁴

Component analysis recognizes that clinical trials characteristically include activities intended to benefit the participants and procedures to evaluate such activities. In other words, research has therapeutic and nontherapeutic components. Dividing research into these respective components assists in justifying research risks. In the case of therapeutic components, the essential consideration is whether legitimate uncertainty exists over which approach to manage emergently ill patients is the preferred one. This epistemological condition, called *equipose*,²⁵ describes a consensus that the available evidence suggests, but is not sufficient to support the claim, that an intervention is at least as effective and safe as existing treatments. A clinical trial is necessary to gather that evidence.

In contrast, the nontherapeutic components of research are the procedures that are done to assure that the study fulfills the requirements of generalizable knowledge. Such procedures include techniques such as randomization, blinding, and tests and questionnaires that are not normally included in standard care of persons with the condition under study. The risks of these components are justified by the value or importance of the knowledge that the research is expected to produce.

How much risk in nontherapeutic components is appropriate in research that enrolls participants without participant or proxy informed consent? The risks justified by nontherapeutic components should be no more than minimal risk, or to avoid the contentious definition, an increment of *acceptable risk*. In accord with the principle of justice, this increment of risk should not be based on the severity of the participant's illness because that would effectively mean that sicker participants could be exposed to greater risks because they are sick. It should be based on the standard of a reasonable person.

A Process to Assess Risks and Benefits That Emphasizes Open, Public, and Ongoing Review

In addition to creating a new conceptual model of research risk and benefit assessment, the 1996 regulations created a process for assessing research risks and benefits. The regulations require the

study sponsor and investigator to consult with representatives of the communities from which participants will be drawn and, prior to the start of the research, to publicize to these communities plans for the research and its risks and expected benefits. In the event an IRB at one proposed study site does not approve a study, the regulations require the IRB to document its refusal and require the sponsor to disseminate this report to investigators and IRBs at other sites. During the course of the research, a data safety and monitoring board (DSMB) should review the conduct of the study. Finally, at the close of the research, the sponsor should disclose the results to the community in which the research was conducted. The general theme of this process is an open and public discussion of the risks, potential benefits, and social worth of research.

Among these requirements, the most innovative are the requirements for community consultation, public disclosure, and sharing the determinations of other IRBs. This model of democratic deliberation is novel to the social structure of research review, approval, and monitoring. Typically, in nonemergency research, studies are designed by the expert medical community based on its consensus that *equipose* exists. The IRB at each study site reviews the research risks and potential benefits and determines whether they are appropriate. IRB membership includes a representative of the community and the IRB is empowered to bring in additional members as necessary to assist in reviewing a study. The IRB does not routinely seek the input of the participant community. The results of IRB review are not routinely shared with other IRBs reviewing the same protocol. Public disclosure of results is not expected, and in the case of some research, especially research done for advancing corporate interests, disclosure may not occur.

The requirements for community consultation, public disclosure and the sharing of IRB determinations alter this social structure. The requirement that the sponsor and the investigator consult with representatives of the community from which participants will be drawn include suggestions for public meetings to discuss the protocol, the creation of a panel of community members as consultants to the IRB, and the addition to the IRB of community members who are not affiliated with the institution. The goal of these efforts is to promote the public's comprehension of the study and the proposed waiver of informed consent and to elicit community opinions and input. Although there is no formal requirement that the community approve the research, the acts of consultation and disclosure provide the community the opportunity to weigh in on what are permissible risks in the pursuit of research to develop new therapies. Sharing the results of an IRB's deliberations with other IRBs opens up the scope of IRB deliberations to other IRBs. The net effect of all of these requirements is a more public discussion of the research.

In principle, these proposals have substantial merit and conceptual sense. The history of AIDS research suggests that there is good reason to proactively involve the community of potential participants in the process of research review.^{26,27} In AIDS research, patients with the disease sharply and vocally disagreed with the standard approach that investigators proposed to determine whether a drug should be used to treat a person with AIDS; in early trials, the proposed endpoints to establish an intervention's efficacy included reducing the number of deaths. Although such an endpoint provides solid proof of efficacy according to the expert medical community, people with AIDS argued that it meant clinical trials exposed them to unnecessary risks in the pursuit of

generalizable knowledge and slowed the process of developing effective therapies. Instead, they successfully argued that trials should measure intermediate endpoints that were used in clinical decision making, such as CD4 cell count. Such involvement expands the community that assesses the therapeutic components from an expert medical community to a more democratic community that includes potential participants. In other words, clinical equipoise becomes community equipoise.²⁷ One could imagine a similar dialogue occurring in a discussion of an emergency research protocol. For example, the community might have input into the judgment that death is the appropriate endpoint to assess an intervention's efficacy or whether the waiver of informed consent was necessary on the basis of the costs and social worth of the research.

Some of the rhetoric to justify community consultation was that it was the "consent of the community."²⁸ However, the use of the term *consent* in this context does not mean that community consultation replaces the individualized ethic of informed consent. Informed consent is designed to respect an individual's autonomy. A group consultation simply cannot do that. Instead, the ethical issue raised by the requirement for community consultation and disclosure in the emergency research regulations relates to the principle of justice and whether the social structure of research is sufficient to assure that the rights and interests of participants are adequately protected. In the case of AIDS research, patient advocacy groups proactively sought a place at the table and as a result revised the social structure of AIDS research. But the emergency research controversy did not start with public outcry, and the requirement for community consultation did not come from the public asking for a role in research review. This may reflect the fact that the community did not know about the issues, and even when the community did know, that it did not care. The limited coverage in the popular press of the emergency research controversy and the lack of public engagement in spite of the press reports suggests this. But it is also possible that the failure of the public to demand a place in the social structure of research reflected the lack of an organized community to make that demand. In other words, community consultation and public disclosure at the start and end of a study were meritorious proposals but without a clear social structure to support them.

This lack of a social structure was revealed when investigators attempted to fulfill the requirement of community consultation. They struggled with identifying who is the community, and who are its representatives, and who can legitimately speak about the social worth of research. Investigators were faced with the unusual exercise of looking closely at how their eligibility criteria defined who they would recruit, how they would identify leaders who could speak for the community, and what the dialogue with those leaders would involve. In some kinds of studies, the eligibility criteria define a well-circumscribed group, such as narcotics addicts who would be recruited for an intervention for acute overdose. This is a group that can be reached through addiction counseling centers, the courts, and even popular venues for drug trade. But who are their leaders? Other kinds of studies defined increasingly heterogeneous groups such as persons at risk for a heart attack or persons at risk for an automobile accident. Are the leaders of these communities persons who provide health care, politicians, or those who speak up when suitably informed? Finally, the press and other media showed that they were not accustomed to playing a role in the social structure of research.

Poststudy disclosure of studies that were halted on the basis of safety took the form of sensational stories about the waiver of informed consent rather than balanced presentations of the study results.²⁹

A Continued Role for Informed Consent

The core of the emergency research controversy was the claim that obtaining informed consent—whether from the participant or from the participant's legally authorized representative—was not practicable. But this is a judgment based upon scientific and economic factors. In some cases, informed consent may not be practicable, but it is possible. The 1996 regulations require that investigators and IRBs address this possibility. The investigator should have IRB-approved informed consent forms in place for the participant and the participant's legally authorized representative in the event informed consent might be obtained at either the time of enrollment or even prior to eligibility using the mechanism of advance informed consent.

This requirement sends a mixed message about the adequacy of the other participant protections. The regulations require that although the balance of the risks and potential benefits and the process to assess them support a waiver of informed consent, the investigators should still make an effort to get informed consent. But if the original judgment was that informed consent is not practicable and its waiver is justified on the basis of a public finding of permissible risks and social worth, why is informed consent thought necessary? This requirement illustrates the unresolved tension in the very definition of emergency research: whether it is appropriate to say that informed consent is not practical, and if it is appropriate, what considerations should enter into the judgment?

Because the regulations require procedures to obtain informed consent when it is possible, they raise the question of what counts as a reasonable effort to secure consent. This suggests that sites should set benchmarks for the expected proportion of participants who will provide informed consent. This benchmark would be informed by previous studies and pilot studies of the proportion of eligible participants who are either themselves capable of informed consent or who will have proxies available to provide informed consent.

The Ability to Opt Out

The regulations require that the investigator locate the legally authorized representative or family of the participants who are enrolled under a waiver of informed consent to disclose that the patient is in the study and obtain "consent to continue in the study." Although this is not informed consent, it does permit a participant the opportunity to withdraw from the study. It is a sensible protection for those who find participation in research objectionable in principle and therefore wish to withdraw their data or cease receiving ongoing study interventions.

Empirical Data

The public's reaction to the emergency research regulations was largely quiet. This may in part reflect the lack of a clear group that

represents persons with an emergent illness. It may also indicate that the public did not have the same concerns as researchers and regulators. The few studies of public attitudes that have been conducted suggest that the waiver of informed consent in emergency research does not elicit substantial public concern.³⁰ More than half of people questioned are willing to participate in such research, and most are willing to allow a family member to serve as a proxy. The experience with actual emergency research protocols suggests that people are typically willing to remain in the research and do not feel that the failure to obtain informed consent is an indignity.¹⁵ What people do express concern over is focused more often on the fairness of selecting their community as the study population, the risks of the intervention, and who will profit from the research.³¹

The Process of Public Disclosure and Community Consultation

Experience with the process of community consultation and public disclosure generally shows that investigators do not regard it as a valuable part of the design and review of their research. Instead, they regard it as a hassle¹⁴ and have difficulty in delineating the requirements and responsibilities for implementing the rule.³² Most of the communication with the public is informing the public without discussion or exchange of information, so-called one-way communication.³³ One-way communication to announce discussions generally results in limited attendance at public forums. For example, advertisements in a newspaper with a daily circulation of 250,000 to a metropolitan area of 1.5 million people resulted in 12 calls, 20 preregistrations, and 25 attendees at a community consultation meeting.¹⁶ Experience suggests that there may be a vocal minority who want the option to prospectively state their dissent to enrollment using medic alert bracelets or notations on a driver's license similar to the indication for organ donation.³¹ The experience with two-way communication suggests that the investigators and IRBs should ask the community the following questions: Does the community recognize the problem the research is designed to address? Are the research risks reasonable with respect to the potential benefits and the importance of the research problem? Finally, given previously voiced concerns about who will profit from the research, investigators should have a clear answer to this question when meeting with members of the public.

The Role and Function of the DSMB

One of the requirements for an emergency research protocol is a DSMB. As important as this board is for the ongoing monitoring of study risks and benefits, there is limited data on how well DSMBs function to protect participants. The case of an emergency research protocol shut down by its DSMB because of substantial numbers of deaths in the intervention group²⁹ raised two issues that are common to the design and conduct of DSMBs but for which limited data or standards exist to guide investigators.³⁴ The first issue is DSMB membership. Specifically, what proportion, if any, of the membership of the DSMB should include representatives of the community? A plausible case can be made that just as community consultation is necessary at the start of the trial, it is necessary over the course of the trial. Hence, community repre-

sentation on the DSMB may be appropriate. However, who should serve in this role and what expertise should be required are not evident. The second issue is how the DSMB should balance protecting the interests of the participants with preserving the credibility and integrity of the research. Although unplanned subgroup analyses to assess interim risks, benefits, and results are potentially informative, they may lack sufficient credibility on which to base decisions about whether to stop a trial. One potentially useful strategy to help a DSMB work through the balance between participants' interests and study credibility is an upfront discussion among the members about how they would respond to various kinds of scenarios over the course of the trial.³⁵ Such a group exercise would force members to express their views on what counts as credible evidence and the degree of risk to which they are willing to expose participants in order to get these data.

Policy Implications

The inability to obtain informed consent to research from emergently ill persons challenges nations to address whether they will relax a core protection for participants in the interests of other patients and society. Although the regulations developed in the United States make such research possible, they present investigators, IRBs, study sponsors, and research regulatory agencies with a number of requirements that researchers generally regard as burdensome. A retrospective review of the number of cardiac arrest trials published during the period of 1992 to 2002 documents a temporal decline in the proportion of studies conducted in the United States compared with all other countries that corresponds to the issuance of the 1996 regulations.³⁶ This decline suggests that the regulations present a burden to sponsors and researchers, especially researchers who wish to conduct small, single site studies that typically lack the resources to fulfill the requirements for a waiver of informed consent under the 1996 regulations. Or it may reflect that sponsors are taking their research overseas to countries that do not have similar regulatory requirements. Although fewer small and single-site studies may increase the quality of emergency research studies, it does limit the opportunity for innovation and rapid development and testing of new treatments which can occur as a result of small and single-site studies.

The second policy implication is a potential weakening of trial sponsors' ability to protect proprietary data. The regulations' requirements for public disclosure, community consultation, and informing other IRBs if one institution's IRB rejects a project potentially open up the largely private world of research to wider scrutiny of preclinical data, intellectual property ownership, and research results. Such scrutiny might inhibit a private sponsor from supporting an emergency research project.

Study Design Implications

An inability to waive informed consent for research that involves emergently ill persons would have substantial impact on the design of studies to develop interventions to improve the care of these patients. In many cases, the research simply would not be done. Instead, evidence would be gathered by case reports, animal models, and inferences from interventions for related conditions

in persons who can provide informed consent or prospective non-randomized cohort studies that examine the outcomes of variations in the standard of care (assuming such variations exist). Each of these kinds of studies has substantial limitations when compared with the randomized controlled trial.

If informed consent is an absolute requirement, there would be some cases when a small portion of the participant population could either provide prospective consent or have a legally authorized representative available to do so on their behalf. In these studies, participant recruitment would be slow and costly. At the close of such studies, the data would be difficult to interpret because of changes over time in the standard of care and legitimate concerns regarding the quality of the data that arise because study sites that enroll participants infrequently are likely to have mistakes in data gathering and the training of study personnel.

The 1996 regulations allowed investigators to avoid these problems. The implications of these rules on study design include allowing investigators to use techniques such as randomization, control groups, and blinding.

Conclusion

The U.S. controversy over emergency research was dramatic, contentious, and resolved with a set of regulations that many researchers regard as cumbersome and an impediment to valuable research and some ethicists regard as a weakening of the structure of human participant protections.

European Union countries have regulations suggesting that a waiver of informed consent would be illegal unless the "direct benefit to the patient outweighs the risks."³⁷ But this position is ethically questionable. It mistakenly applies to *research* a set of conditions that justify the waiver of informed consent for *treatment*. This approach cannot, however, ethically justify research because study protocols have components that are not intended to benefit participants.

Addressing three unresolved ethical issues might close this disquieting gap between scientific practice and ethical norms. First, there is a need for a coherent conceptual framework to assess research risks and benefits. A framework based on component analysis that separately examines the risks of therapeutic and non-therapeutic procedures seems the most sensible framework. Second, there is a need for a conceptual framework to guide the judgment that informed consent is not practicable. Particular attention is needed to examine cases when informed consent is possible but costly and a threat to scientific value and validity. The third issue arises at the intersection of ethics and political science. The requirement for community consultation suggests that existing local and national structures may not adequately represent the interests of potential participants in the design and review of research. But community consultation is a vague construct without clear institutional structures to support it.

Empirical studies can inform the discussion of these ethical issues. Studies of both researchers and the public should explain how people perceive the moral harm of waiving informed consent in the conduct of research that involves nontherapeutic research risks, the acceptability of waiving informed consent on the basis of considerations of science and costs, and the consequences of changes to the institutional structures for the design and review of research that are intended to expand community input.

Research With Biological Samples

The collection and storage of human biological samples has become integral to health research. The number of stored samples, estimated to be in the hundreds of millions, if not billions, increases daily as researchers and clinicians routinely obtain samples and store them for research purposes.¹ To identify an appropriate consent process for research with human biological samples, commentators have relied largely on theoretical considerations. Not surprisingly, this approach has led to divergent practices² and conflicting recommendations.^{3–13}

Some commentators endorse prospective consent, whereas others argue that individuals should provide consent for each new study at the time the study is proposed. There is also disagreement among those who endorse prospective consent. Some advocate asking individuals to authorize future research on the disease being studied, and to separately authorize research on other diseases.¹⁴ Others propose to offer individuals even more choices, including how the samples will be stored, which investigators may use the samples, and what types of research may be performed on them.^{15,16} Finally, some hold that consent is not needed at all for research with biological samples that poses minimal risk.¹⁷

Reliance on different consent practices has the potential to undermine the scientific value of human biological samples and greatly increase the costs of conducting such research. Divergent consent practices require investigators to track the various types of consent obtained for different samples and may preclude the pooling of samples. One way to avoid these problems is to consider whether data on individuals' views support an ethically appropriate and uniform consent process that could be adopted across institutions and around the world.

Relevance of Empirical Data on Individuals' Views

Empirical research has yielded substantial data on individuals' views regarding consent for research with human biological samples,¹⁸ yet few studies have considered the implications of these data for consent practices. This paucity of analysis may trace in part to concerns over the so-called "is-ought" gap between empirical data and moral conclusions. Briefly, the is-ought gap refers to the view that empirical data concern the way the world is, whereas moral conclusions concern the way the world ought to be. Hence, it is unclear to what extent empirical data can shed light on moral controversies and debates. To address this concern, it is important to understand the ethical relevance of empirical data on individuals' views for consent practices.

Any consent process must respect individuals' autonomy and values, and protect them from serious risks. If only one kind of consent process for research with human biological samples were consistent with these ethical goals, appeal to empirical data would be unnecessary. Institutions, investigators, and institutional review boards/research ethics committees (IRBs/RECs) could simply adopt the ethically preferred approach.

Analysis reveals, however, that these ethical considerations are consistent with a number of consent practices. For example, respect for autonomy implies that individuals should be allowed to make their own life decisions. Yet, respect for autonomy does not clearly favor a single kind of consent process. It does not, for example, clearly support prospective consent for unspecified future studies versus asking individuals for consent at the time each new study

Figure 28.1. Stored Tissue Repository. Source: Guido Sauter, University Medical Center Hamburg-Eppendorf. Reproduced with permission.

is proposed. When theoretical considerations alone do not identify a unique approach, data on individuals' views can be useful, in several ways, to identifying a best practice among the ethically acceptable options.

First, empirical data on individuals' views can be vital to determining which of the ethically acceptable approaches are supported by the so-called reasonable person standard. The reasonable person standard can be understood as a response to the fact that even straightforward research studies involve more information and more choices than any single person could possibly absorb and understand. This fact raises the question of what information and which choices should be offered to individuals as part of the informed consent process. According to the widely held reasonable person standard, investigators should make these decisions based on the preferences of the reasonable person: What information does the reasonable person want to make this decision, and which choices does the reasonable person want to be offered? Empirical data can be useful for helping to estimate the views of the reasonable person. In particular, by identifying areas of general consensus, empirical data can provide insight into the views of the reasonable person.

Second, moral analysis implies that investigators should respect individuals' fundamental values. Empirical data can be useful in this regard by identifying fundamental values as they pertain to research with biological samples. For example, empirical data might reveal that the collection of certain types of biological samples, such as semen or ova, conflict with the values of some groups but not others.

Third, respect for persons provides a reason to respect their preferences. All things being equal, investigators should respect the preferences of research participants, even when the preferences

in question do not rise to the level of fundamental values. This is also true when the preferences are not widely shared, in which case they may not be addressed by considerations related to the reasonable person standard, which focuses on preferences that apply to most individuals. Empirical research provides an important mechanism for identifying even relatively uncommon preferences regarding research with biological samples. For example, empirical data might reveal that a certain group of individuals does not want to contribute samples for research purposes, even though the majority of individuals are willing to have their samples so used. This finding could alert investigators to restrict the use of samples obtained from individuals who belong to this group.

To assess the policy implications of empirical data on individuals' views, it is important to recognize that all empirical studies have limitations. The results of survey research in particular can be sensitive to numerous aspects of a given study, including which groups were surveyed, framing effects of the questions, current events at the time the survey was administered, and the possibility that individuals may not have understood some questions or may simply have provided the answers they thought the interviewers wanted to hear. To address these limitations, it is vital to determine the extent to which the data are consistent across studies that surveyed different groups, and whether different questions and methodologies were used.

Literature Search

A comprehensive search was conducted using PubMed for studies published in English that report data on individuals' views regarding consent for research with biological samples (see Appendix 28.1 for details). Studies about individuals' views on research with embryos, as well as studies about the use of biological samples for clinical purposes, were excluded. This search identified 2,483 articles. The titles of all the identified articles were reviewed by the author for any terms related to individuals' views regarding consent for research with biological samples. The abstracts of articles with any relevant terms or phrases were retrieved and reviewed, and the full texts of all potentially eligible articles were reviewed to determine whether they included quantitative or qualitative data on individuals' views regarding consent for research with biological samples. This process yielded 29 unique articles. Finally, references and bibliographies of the 29 articles were reviewed using the same method. This search yielded 2 additional articles.

Empirical Findings

The literature search identified 31 studies that provide empirical data on the views of more than 33,000 individuals regarding consent for research with human biological samples. A summary of these studies is presented in Table 28.1. Most of the studies were quantitative, with a few qualitative studies, hearings, and focus groups. The studies, conducted in the United Kingdom, France, India, Japan, Singapore, Sweden, Uganda, and the United States, assessed the views of employees, religious leaders, patients, current research participants, past research participants, parents of research participants, relatives of deceased individuals, and the general public. Fourteen studies assessed the views of research

Table 28.1
Individuals' Views on Consent for Research With Biological Samples

<i>Respondent Type; Donor/Nondonor</i>	<i>Author, Year</i>	<i>Population; Response Rate</i>	<i>Willing to Provide Sample for Research</i>	<i>Willing to Allow Study of Other Diseases</i>	<i>Comments</i>
Subject; donor	Matsui, 2005 ¹⁹	5,361 Japanese; 98.0%	> 90.0%	N/A	Willingness to provide sample for genetic research 5–9% lower
	Hoeyer, 2005 ²⁰	1,200 Swedes; 80.9%	N/A	N/A	48.5% want results; 35.5% not aware they gave a sample
	Chen, 2005 ^{21§}	1,670 U.S.; 100%	90.8%	87.1%	6.7% refused all research
	Wendler, 2005 ^{22§§}	347 Ugandans; 98%	95%	85.0%	54% want results; 4% think may be used for nonresearch
	McQuillan, 2003 ^{23#}	3,680 U.S.; 79.7%	85.3%	85.3%	84% agree to genetic research; minorities slightly less willing
	Stegmayr, 2002 ²⁴	1,409 Swedes; 95.2%	93.0%	N/A	3% oppose industrial research; 22.3% recontact for new projects
	Malone, 2002 ²⁵	7,565 U.S.; 100%	93.7%	86.9%	4% lower consent rate for less detailed consent form
	Wendler, 2002 ^{26###}	814 U.S.; 94% / 47%	N/A	91.9%	88% want results; consent more important for clinically derived samples
	Nakayama, 1999 ²⁷	120 Japanese; 88%	98.5%*	N/A	92% remembered donating; 61% thought it was for clinical care
Patient; donor	Pentz, 2005 ²⁸	315 U.S.; 70%	95%	95%	76% prefer consent once; 14% state consent is unnecessary
	Jack, 2003 ²⁹	3,140 English; 100%	98.8%	N/A	Only 2 individuals concerned about commercial research
	Moutel, 2001 ³⁰	170 French; 30%	100%	N/A	None thought that DNA “storage duration should be limited”
	Hamajima, 1998 ³¹	583 Japanese; 95.7%	95%	N/A	Some decliners concerned about spreading their disease
Public; donors	Womack, 2003	106 U.K.; 71.0%	100%	N/A	5% stated family or deceased opposed tissue donation
	Kozlowski, 2002 ³³	3,383 U.S.; 70%	18%	N/A	Study solicited genetic samples by mail from random individuals
Patient; nondonors	Start, 1996 ³⁴	450 U.K.; 91.0%	83%†	N/A	Some concerned with spreading their disease
	Goodson, 2004 ³⁵	100 English; 100%	82.0%††	N/A	35% want results; 75% “not happy” to contribute to cloning
Public; nondonors	Roberts, 2005 ³⁶	63 U.S.; N/A	N/A	N/A	Support genetic research; concern about children/prisoners
	DeCosta, 2004 ³⁷	59 Indians; 96.6%	86.0%	N/A	14% fewer willing to provide sample of child's blood
	Hoeyer, 2004 ³⁸	1,000 Swedes; 59.6%	N/A	N/A	48% “feel respected” if get results
	Wong, 2004 ³⁹	708 Singaporeans; 70.3%	49.3%	N/A	38.1% unwilling to donate due to fear of needles/injections
	Ashcroft, 2003 ⁴⁰	155 U.K.+; N/A	100%	N/A	Want control; oppose cloning; want new consent for new tests
	PSP, 2002 ⁴¹⁺⁺	16 U.K. focus groups; N/A	N/A	N/A	Support research; willing to contribute biological samples
	Stolt, 2002 ⁴²	21 Swedes; N/A	N/A	N/A	Support research on other diseases; some want results
	Asai, 2002 ⁴³	21 Japanese; N/A	N/A	N/A	Support research; concerned about risks; some want results
	Schwartz, 2001 ⁴⁴	1,383 U.S. Jewish Am.; 20%	> 80.0%	> 80.0%	Want consent for each study, but not offered general consent
	Wang, 2001 ⁴⁵	3130 U.S.; 84%	79%	79%	21% not willing to donate nor store blood for genetic research

Table 28.1 (Continued)

Respondent Type; Donor/Nondonor	Author, Year	Population; Response Rate	Willing to Provide Sample for Research	Willing to Allow Study of Other Diseases	Comments
	Welcome Trust, 2000 ⁴⁶	16 U.K. focus groups; N/A	N/A	N/A	Most would provide sample; prefer disease-specific research
	NBAC, 2000 ⁴⁷	7 U.S. hearings; N/A	N/A	N/A	Support research, including for profit; endorse one-time consent; concerned about confidentiality
	Merz, 1996 ⁴⁸	99 U.S.; 0–20%	60%	87%	26% want results; 30% would restrict drug company access
	Phan, 1995 ⁴⁹	21 U.S.+++; 48.8%	N/A	N/A	90.5% support genetic research; concerned about confidentiality

N/A = Indicates that the study does not provide quantitative data on the relevant question. § Denominator varies for different questions. §§ Respondents were guardians who donated children's blood samples. # Using year 2000 data. ## Most respondents were subject donors; the remainder were public nondonors. * Of the 96 respondents who participated in the follow-up survey. ** Donated deceased family members' tissue. † Percentage who would agree to their left over tissue being used for *medical research*; †† Percentage who were "happy" for tissue to be used for *cancer* research. + 35 individuals in focus groups; 120 in individual interviews. ++ Also interviewed clinicians, patients, community leaders and organization spokespersons. +++ Respondents were religious leaders from the Midwest.

participants, patients or members of the general public who had donated samples for research purposes; 17 studies assessed the views of patients or members of the general public who had not donated a sample for research.

Taken together, the studies yield consistent findings, despite being conducted around the world, over a 10-year period, in different groups, using different methods. The studies reveal that the vast majority of individuals want to decide whether their biological samples are used for research purposes. When given a choice, 80–95% of individuals are willing and 5–10% are not willing to contribute a biological sample for research purposes.

Most objections to providing samples are due to factors other than their use in research. For example, some individuals expressed concern regarding the method of obtaining samples. Only 50% of respondents in one study were willing to provide a sample for research, but 38% of those who were unwilling cited a fear of needles or injections as their reason.³⁹ Similarly, in another study, most respondents who declined even to consider the possibility of providing a sample of their deceased relative's tissue cited the time required for the discussion.³² Only 18% of the respondents in yet another study provided a genetic sample for research.³³ However, these individuals were contacted through random digit dialing by investigators unknown to them. In addition, respondents were required to complete a telephone interview, agree to receive a kit for obtaining genetic samples, follow the instructions in order to use the kit themselves, and mail the sample back to the investigators. The low rate of donation in this study likely traces, at least in large measure, to the fact that respondents were contacted by strangers and providing a sample would be time consuming and difficult.

Consistent with the finding that most objections trace to factors related to obtaining the samples, rather than the actual research use of the samples, all six studies that focused exclusively on leftover samples found extremely low opposition to samples being used for research purposes. More than 90% of the respondents in five of the six studies were willing to donate their leftover samples for research purposes.^{24,25,28,29,31} In the remaining study, 83% of patients were willing to donate their leftover tissue for

research and only 2% were unwilling.³⁴ The other patients skipped the relevant question in the survey or were unsure of their views regarding donation. Furthermore, many of those who were unsure or unwilling to donate expressed concern over the possibility of spreading their disease to others.

Studies that investigated different consent options found that the vast majority of individuals who are willing to provide samples for research are willing to provide samples for research in general, without restriction regarding the type of research for which their samples would be used. Even the five studies that assessed research on potentially stigmatizing diseases found that most individuals are willing to provide their samples for such research. Two studies found that individuals are equally or slightly more willing to provide samples for research on potentially stigmatizing conditions (Alzheimer's;²⁸ HIV²²); two others found that individuals are slightly less willing (Down syndrome;³⁵ Alzheimer's²⁵); and one study found mixed results (mental illness, equally willing; homosexuality, slightly less willing).⁴⁴ The only proposal that elicited consistent opposition in the four studies that assessed the issue was the use of samples in research aimed at cloning human beings.

In seven studies that explicitly addressed the issue, the majority of individuals were willing to provide one-time general consent and rely on IRBs/RECs to determine when their samples would be used in future research projects.^{20,22–25,28,38} The apparent exception to this acceptance of one-time general consent found that approximately 70% of respondents thought consent was needed for each project. However, as the authors note, these respondents were not offered the option of one-time consent.⁴⁴

Three studies assessed commercial research, finding that individuals are only slightly less willing to provide a sample for commercial compared to academic research.^{24,29,48} Finally, nine studies assessed whether individuals want information on the studies for which their samples will be used. A significant percentage, ranging from 26%⁴⁸ to 88%,²⁶ want such information. Because the studies tend to ask about information in general, it is unclear whether individuals want information on the goals of the

studies, their own results, grouped results, or some combination of these types of information.

Implications for Informed Consent

Contemporary commentators, following the philosopher David Hume, often cite a gap, the so-called is-ought gap, between empirical data and ethical conclusions.^{50,51} Empirical data concern the way the world is; ethical conclusions concern the way the world ought to be. To assess the implications of empirical data on individuals' views, it is important to recognize the is-ought gap, yet not overstate its significance. The is-ought gap does not imply that empirical data are irrelevant to ethics. Instead, this gap implies that it is impossible to derive moral conclusions about what we ought to do or which policy we ought to adopt from empirical data alone. To derive ethical conclusions, empirical data must always be supplemented by and analyzed in the context of the relevant moral considerations.

Moral analysis establishes that any consent process should respect individuals' autonomy and values and that it should protect them from unwarranted risks. However, these considerations are consistent with a number of consent processes for research with biological samples. In this context, empirical data on individuals' views provides a way to identify which consent process is best supported by the reasonable person standard and best respects individuals' fundamental values.

The data reveal consistent and strong evidence that individuals around the world want to control whether their biological samples are used for research purposes. When given a choice, the vast majority of individuals choose to provide a sample, whereas a small minority of individuals do not want their samples used for research purposes. The data also reveal that the vast majority of individuals endorse one-time general consent and are willing to rely on IRBs/RECs to determine when their samples will be used in future research projects.

Because these data are so consistent across surveys and survey populations, they provide an estimate for the consent process best supported by the reasonable person standard. Specifically, these data suggest that the reasonable person standard supports a default practice of offering individuals a simple, binary choice of whether their samples may be used for research, with the stipulation that future decisions regarding research uses will be made by an IRB/REC.^{52,53} In addition to respecting individuals' autonomy by allowing them to decide whether their samples are used for research, this approach respects the small minority who do not want their samples used for research by allowing them to keep their samples out of the research pool. This approach also protects individuals by ensuring their samples are used for future research only when the reviewing IRB/REC finds that the research project poses no more than minimal risk, including any risk of group harms.

Although this consent process should be suitable for most studies, there may be compelling reasons to modify it in some cases, either by waiving consent or soliciting more detailed consent. The consistency of the data implies that the default of offering a simple, binary choice should be modified only in rare cases. Specifically, the fact that individuals want to control whether their samples are used for research implies that consent typically should be obtained even when samples will be anonymized. Conversely, the fact that individuals are willing to have their samples used for

research on all conditions—including potentially stigmatizing conditions and conditions from which they do not suffer—implies that only rarely will there be a need to detail the different kinds of research for which their samples might be used.

Implementation

To implement this approach, the consent form and process should include at least the following five elements: (1) request to obtain samples for future research; (2) risks, if any; (3) absence of direct benefits; (4) information, if any, to be provided to individuals; and (5) reliance on IRB/REC to review and approve future research provided it poses no greater than minimal risk (see Box 28.1).

Several studies found that individuals often assume samples obtained for research will be used for their own clinical care.²⁷ To address this confusion, the consent process should inform individuals that the research will not benefit them. The finding that many individuals would like information regarding future research studies implies, at a minimum, that individuals should be told what information will be provided to them regarding future studies.

The consent process should also include additional elements as appropriate (see Box 28.1). In cases in which individuals retain the right to remove their samples from the research pool, they should be so informed. When samples are obtained as part of clinical care or other research, individuals should be told whether their decision regarding samples will have any impact on their clinical care or research participation.

Box 28.1. Suggested Wording of Consent Forms

A. Possible Wording

"We would like to use your blood (tissue) sample in future studies to learn how to improve people's health. The researchers conducting these studies will not contact you for more information. Your sample will be used only when an independent group, called an institutional review board [research ethics committee], determines that the research is important and ethical, and poses no more than minimal risk to you. These future research projects will not benefit you personally, and are not part of your medical care. All information you provide will be kept confidential as far as possible. However, there is always a very small chance that some information may be released."

B. Possible Additions When Relevant

Optional provision: "No matter what you decide, it will not affect how we treat you."

Individual information: "We will provide you with any information from future studies that may have an impact on your health."

Study information: "Information on the nature [findings] of future research projects will be posted on our website [provided in some other way]."

Future removal: "If you decide in the future that you no longer want to allow your sample to be used for research, please contact the study doctors and any remaining sample will be removed."

The data reveal that many individuals want information about the studies for which their samples are used. The data do not indicate whether individuals want information on the research goals of the studies, pooled results, individual results, or some combination of these types of information. These data also do not address why individuals want this information, for instance, whether they are curious or think the information might be relevant to their clinical care; nor do the data address how individuals might balance receiving information with protecting their confidentiality, and the possibility that some information might cause them anxiety. Recommendation of a uniform approach to this issue will require further research and analysis.

IRBs/RECs should not approve research projects that involve using individuals' samples for purposes that conflict with the individuals' fundamental values. The several studies that assessed the issue reveal that many individuals are opposed to their samples being used for research dedicated to cloning human beings. Hence, investigators should not be allowed to use samples for this type of research without first obtaining specific informed consent. Finally, the vast majority of studies focused on blood and tissue samples. Individuals may be more willing to provide some types of samples, such as hair or sweat, and less willing to provide other types of samples, such as semen or placenta.⁵⁴

Implications for Ethics Review

Most commentators argue that research with human biological samples should be subject to ethical review and approval. Most guidelines agree with this approach. In 2004, however, the U.S. Office for Health Research Protections ruled that if the samples were not obtained specifically for the research project in question, and if an arrangement was in place to keep investigators from obtaining the identities of the donors, then the samples are considered not identifiable—and therefore are not subject to U.S. regulations or IRB review.⁵⁵

The existing data indicate that the vast majority of individuals are willing to provide biological samples for research purposes and to rely on IRBs/RECs to protect them from risks. The data do not indicate, however, whether individuals would be willing to rely on investigators to decide when their samples are used for research purposes in the absence of IRB/REC review and approval. Until future research is conducted on individuals' views, and on whether investigators would provide sufficient protections without IRB/REC oversight, the existing data support requiring IRB/REC review and approval. Hence, in the absence of compelling considerations to the contrary, it seems reasonable to argue that ethics review should be required.

Conclusion

Many proposed approaches to consent for research with biological samples are consistent with the moral considerations of respecting individuals' autonomy and values, and protecting them from untoward risks. In this context, empirical data can help to identify the preferred approach by estimating the views of the reasonable person and identifying individuals' relevant values and preferences.

The existing empirical data reveal that the vast majority of individuals want to control whether their samples are used for

research purposes. The vast majority of individuals also endorse one-time general consent. These data support offering individuals a simple binary choice of whether their samples may be used for research purposes, with the stipulation that an IRB/REC will decide when their samples are used. This approach respects individuals' autonomy and is supported by the reasonable person standard for informed consent. In particular, this approach allows all individuals to control whether their samples are used for research, and allows the minority who do not want their samples used to keep them out of the research pool. This approach has the additional virtues of not burdening individuals with unwanted choices, and avoiding unnecessarily burdening institutions with the need to track the specific choices that attach to individual samples under other approaches to consent.

Acknowledgments

Thanks to Bernice Elger, Benjamin Wilfond, Rebecca Pentz, and Ezekiel Emanuel for their helpful comments on earlier versions of the manuscript. The opinions expressed are the author's own. They do not represent any position or policy of the National Institutes of Health, Public Health Service, or Department of Health and Human Services.

Genetic Diagnostic, Pedigree, and Screening Research

Interest in genetic approaches to biomedical research problems has been high for almost 100 years, since Archibald Garrod used Gregor Mendel's rediscovered theory of inheritance to explain human "inborn errors of metabolism" in 1908.¹ From the point of view of clinical research ethics, sadly, many chapters of this history are viewed today as examples of how biomedical science can be exploited by social prejudices to the detriment of marginalized people. Borrowing from the successes of both stock breeding and the germ theory of disease, early human geneticists moved quickly from biased pedigree studies and racist anthropologies to draconian prescriptions for preventing hereditary disease and improving the public's health. In the United States, policy makers translated these *eugenic* conclusions into selective immigration restrictions and involuntary sterilization programs; Germany under fascism took them further, to coercive selective breeding programs and genocide.²⁻⁸ By mid-century, the Nuremberg trials had transformed *eugenics* into an epithet and launched our contemporary concern with clinical research ethics on the lessons of the medical experiments undertaken in its name⁹ (see Chapters 2 and 12).

Over this same period, biochemists, cell biologists, and geneticists working with animal and plant models were steadily illuminating the cellular and molecular mechanisms of genetic inheritance.¹⁰ Since World War II, the resulting field of molecular genetics has inspired new waves of interest in research that might produce a *genetic medicine* for the future.¹¹ With the elaboration of the genetic code and the role of DNA mutations in *molecular disease*, a new discipline of medical genetics was able to use molecular markers to track and predict health problems in families and populations, and with the development of methods for manipu-

lating DNA, a new *biotechnology* made it possible to contemplate a comprehensive molecular analysis of the human genome. Today, in the wake of the Human Genome Project and the human genetic research it makes possible, clinical scientists whose specialties range from infectious disease to psychiatry are conducting family studies to isolate genetic variants, developing diagnostic tests based on those variations, and screening populations with those tests to assess the variants' prevalence and distribution.

With the widespread adoption of genetic approaches to biomedical research problems has also come new attention to the ethical issues that human genetic research can raise. Against the historical backdrop of eugenics, genetic researchers have reason to be sensitive to the potentially stigmatizing power of genetic information and acutely concerned to fulfill their obligations to respect the rights and interests of the individuals, families, and groups they study. Their challenge has been that, although genetic family studies, testing trials, and population screening surveys have been conducted for decades, there has been little consensus about how they should be designed and conducted from an ethical point of view.

As new research teams take up genetic approaches, investigators and institutional review boards (IRBs) alike quickly discover that both the federal research regulations and the research ethics literature are only beginning to explore this area. If anything, the prevailing standards seem to assume that cohorts of biomedical research subjects usually consist of individual strangers, rather than people who live with each other as families and communities. At the same time, a variety of homegrown practices and policies have evolved within the human genetics research community to

address these challenges.¹² Unfortunately, these precedents can be wilder as easily as they illuminate. Although homegrown approaches to specific problems are often defended passionately by their advocates, almost all these approaches have their critics as well.

In 1993, the federal Office for Protection from Research Risks (OPRR; now the Office for Human Research Protections, OHRP) issued a second edition of its *Institutional Review Board Guidebook*, which included a new section addressing human genetic research. That section opens with the caveat: “Some of the areas described in this Section present issues for which no clear guidance can be given at this point, either because not enough is known about the risks presented by the research or because no consensus on the appropriate resolution of the problem yet exists.”¹³ In fact, 10 different open research policy questions can be found in that section, under two broad headings: issues in recruitment for and consent to genetic studies, and issues in information disclosure and control.¹⁴ The *Institutional Review Board Guidebook* has never been updated, but many of the questions it raises have been the subject of research and policy discussion over the last decade. For some questions, a consensus has emerged that provides a way forward for researchers. Other questions have been substantially superseded by new ones. Still others remain hotly contested. Five topics warrant special consideration:

1. The status of research participants’ relatives as “human subjects” in pedigree and genetic diagnostic studies
2. Protecting the voluntariness of research participation in pedigree and genetic diagnostic studies
3. Respecting the rights and interests of communities in population screening studies
4. Defining researcher obligations to disclose research findings to participants in both family and population-based genetic studies
5. Defining participant rights regarding the control of genetic materials and research results in both family and population-based genetic research

This chapter reviews each of these five topics with three aims in mind: (1) to identify further empirical research needs; (2) to draw out any public policy implications of its discussion to date; and (3) to suggest lessons for the design and conduct of genetic research studies. The next section begins by explaining the core conception and rationale for each of the three kinds of genetic research that raise these issues: genetic family studies, diagnostic genetic testing research, and population-based genetic screening studies. This will help display the common genetic etiology of the issues to be reviewed and the different ways they manifest themselves in different contexts.

Core Conception and Methodological Rationale

Genetic Family (Pedigree) Studies

The oldest form of genetic research is to observe the pattern of inheritance of a particular trait across multiple generations of a family. Today, these genealogical *pedigree* studies are used to help pinpoint the chromosomal location of the DNA coding regions, or *exons*, that seem most closely tied to an inherited trait, or *pheno-*

type, in order to seek clues into the phenotype’s causes. By comparing the inheritance of a panel of known molecular markers in the DNA with the familial occurrence of a particular inherited trait, specific markers that have been transmitted through the family in the same pattern as the trait can be identified. This is a sign that the DNA markers and the exons most tightly correlated with the phenotype reside together on the same section of chromosomal DNA. Where a causal hypothesis can explain the relationship between the proteins prescribed by these exons and the phenotype, the coding regions can be collectively identified as the gene for the familial trait. Once *mapped* in this way, the causal gene can be isolated by even more fine-grained techniques and deciphered, or *sequenced*, at the molecular level, providing a key clue to the pathogenesis of the clinical problem.¹⁵

As higher resolution marker maps become available, such genetic *linkage studies* involving large families are becoming increasingly common across the biomedical research landscape. They are already being used in attempts to discover the etiology of health problems as diverse as deafness, heart disease, colon cancer, and schizophrenia.¹⁶ They have become particularly important in the etiology of diseases such as breast cancer, which are understood to be predominantly environmentally caused, but which also seem to run in some families. In these cases, the hope is that if the inherited germ-line mutation can be isolated in families, it may shed light on the environmentally induced somatic cell mutations that are its sporadic counterparts. With the Human Genome Project’s production of comprehensive, fine-grained genetic marker maps beginning in the 1990s, and the first complete sequencing of the human genome in 2003, the pace of these gene-identification studies has increased dramatically¹⁷ (see Figure 29.1).

Genetic Diagnostic Testing Research

Genetic linkage studies produce a measure of the proximity between a trait’s correlated markers and its causal gene known as a *lod score*.¹⁸ Flanking markers that have lod scores indicating that they are 1,000 times more likely to be physically linked to the relevant coding regions are considered reliable indicators of the location of the causal gene. This means that they can also be used as clinically detectable surrogates for the gene long before tests can be developed that directly target the relevant DNA exons themselves. Then, if specific molecular mutations can be identified within the exons as necessary and sufficient conditions for the emergence of the clinical phenotype, molecular probes for these versions of the genes (or *alleles*) can be quickly developed as powerful prognostic tests for use within at-risk families.¹⁹

For individuals who have a familial risk of carrying alleles that are causally correlated with health problems for themselves or their children, the identification of these genes or their markers through clinical testing can provide the benefit of increased certainty about their personal genetic status. For those who are found not to carry the deleterious alleles, this benefit is reassurance and relief. For those who *test positive* for the targeted mutations, the benefit depends on how well they can use the knowledge of their carrier status to prevent or prepare for its ill effects. Genetic diagnostic research, usually involving pilot studies of clinical testing protocols with high risk families, attempts to optimize this process by gathering evidence on its dynamics and sequelae before the tests are introduced into general clinical practice.²⁰

Source: National Human Genome Research Institute (<http://www.genome.gov/Pages/News/PaceofDiseaseGeneDiscovery.pdf>).

Population Screening Research

The rationale for identifying and tracking the inheritance of genetic variants in particular families also fuels research interest in studies of genetic variation at the level of human groups and populations. Since the beginning of the Human Genome Project, there have been calls to systematically map the genetic variation within our species.²¹ The initial interest was primarily genealogical: Physical anthropologists and population geneticists would use comparative genotyping to produce the molecular clues they need to reconstruct more completely the global history of human migration and differentiation. But today interest in the ways in which human groups vary at different genetic loci is much broader within biomedicine, as scientists apply the fruits of genome research to their work in epidemiology,²² molecular diagnostics,²³ pharmacogenetics,²⁴ and the analysis of complex genetic traits.²⁵ Much of this interest is driven by the prospect of a *genomic medicine*, in which diagnostic protocols, therapeutic interventions, and preventive measures could be tailored to each patient's genetic profile.²⁶

Whatever its focus, all population genomic research involves collecting DNA samples from individual members of different human groups, genotyping them (through marker mapping or DNA sequencing) at one or more loci, and comparing the results. Almost by definition, a complicating feature of many population genomic studies is the fact that this research is increasingly cross-cultural and international. Large genetic variation studies like the Haplotype Mapping Project are increasingly collaborative efforts between scientists in different countries who collect and compare DNA from populations chosen for their phenotypic diversity. Even genetic studies that involve mainstream U.S. immigrant communities, such as African Americans or the Ashkenazim, can quickly

take investigators all across the globe. As a result, cultural, linguistic, and socioeconomic factors complicate population genetics research in much the same way they complicate international epidemiological research, raising questions about the collective interests of the human groups being studied, and their decision-making role in this context.

Ethical Issues

"Secondary Subjects" and Informational Privacy

Conceptually, family-based gene-hunting studies start with the identification of a person who expresses the inherited trait in question (a *proband*, or *index case*), and then reconstructs as much of the trait's pattern of inheritance within the proband's extended family as possible. This genetic pedigree is used to distinguish family members who carry the causal gene from those who do not. For most well-defined genetic conditions, linkage study subjects are recruited from clinical practice settings in which multiple family members have become involved in genetic evaluation and counseling, and the family pedigree for the condition is already at least partially established. As one researcher has noted,

It takes an immense amount of time and detective work to construct a pedigree: to check the genetic relatedness of individuals, hunt down clinical information (such as clinical work-ups of living members and autopsy reports on those who have died) and obtain blood, tissue and other samples from family volunteers. Doing the genetic marker studies—

the laboratory work—is relatively expeditious compared to constructing the pedigree and getting the samples from family members.²⁷

Ethical questions, however, arise even in the initial stages of this process. The proband can provide investigators access to his or her own clinical records, which may well include family medical histories compiled for clinical purposes. But does the provision of information by the proband about family members for research purposes involve them involuntarily in the research, potentially breaching their privacy? This issue came to the forefront in 1999 when the father of a participant in a genetic twin study being conducted by behavioral genetic researchers at Virginia Commonwealth University (VCU) protested the fact that personal and medical information about him had been solicited from his daughter in the course of the study. In its resulting investigation, OPRR suggested that the VCU IRB should have considered the probands' family members as "secondary" research subjects, and should have required the investigators to secure the family members' consent before collecting this information about them. Because the OPRR and the FDA used this rationale to temporarily suspend all human subjects research at the Virginia Commonwealth University, genetic researchers and IRBs around the country reacted to this ruling with considerable alarm. Scientists complain that the "reality is that restricting the ability of a researcher to collect family history data without obtaining informed consent from family members will result in many projects being abandoned for logistical and financial reasons."²⁸

Appropriating clinical family history information to launch a new genetic family study is a practice so traditional that it was ethically invisible within the research community until this case raised the issue. But at stake is not only the privacy of the genetic information disclosed about other family members, but also the voluntariness of their involvement in the study.

Empirical Research

To date, there has been little systematic study of the relative consequences of constructing pedigrees with or without the consent of the family members involved. However, there is a good bit of data on the public's general attitudes toward the use of medical records for research purposes without consent. Coy summarizes a series of five public opinion polls conducted between 1993 and 2001, before the VCU case raised the profile of this issue. A significant majority of the public consistently expressed opposition to the prospect of researchers using their medical records without their consent, even when research confidentiality safeguards were emphasized.²⁹ On the other hand, one survey found that 64% of respondents would, if asked, consent to the use of their medical records by "researchers at a university conducting a study about a medical condition that had affected some of the respondent's family members."³⁰

This data needs to be followed up with more specific studies in the genetic research context, but it does suggest that the public is interested in having control over the research uses of personal medical information, particularly as that use moves further away from direct clinical care for themselves or their family members.

Policy Implications

The federal regulations governing clinical research define *human subjects* as living individuals about whom investigators collect in-

formation that is both identifiable with the individuals and private (45 CFR 46.102(f)).³¹ One early policy response to the VCU case was a statement from the American Society of Human Genetics, which argued that, although the family history information gathered in constructing pedigrees was identifiable, it was not private, because it was usually known to other family members.³² But as Botkin notes, "there are different spheres of privacy and a decision to share information with close friends and family does not imply a willingness to share information more broadly."³³

In 1993, although acknowledging that "no consensus on this issue has yet been reached," OPRR suggested that IRBs might "draw a distinction between information about others provided by a subject that is also available to the investigator through public sources (for example, family names and addresses) and other personal information that is not available through public sources (for example, information about medical conditions or adoptions)."¹³ IRBs could then allow investigators to collect only the former, public facts about the family in the index case. This strategy has been promoted and expanded by several commentators in the wake of the VCU case.³³

If the information gathered from family members is both identifying and private, thus categorizing them as human subjects, IRBs and investigators must determine whether informed consent can be waived. This process begins by asking if the research involves more than minimal risk to secondary subjects. Botkin argues that the collection of highly sensitive private information, such as psychiatric history or sexual orientation, may indicate that a study poses more than minimal risk. Botkin also recognizes how advances in genetic research may raise particular concerns regarding potential stigma or discrimination based on genetic risk information. This is especially true for studies in which new knowledge is generated that may indicate genetic risks for disease in healthy individuals.³³

Study Design Implications

The recruitment strategy that flows most naturally from the "secondary subject" discussion is to have the proband provide a bare family tree (one that contains information already publicly available elsewhere), and for the investigators to convert this tree into a genetic pedigree by soliciting relevant health data from each relative directly. In order to pursue the linkage analysis further, investigators must request and collect DNA (usually from a blood sample) from as many members of the extended family as possible. This recruitment approach anticipates the fact that the relatives will all have to be contacted eventually anyway if the study is to proceed to the next stage. If the investigator's solicitation includes an invitation to contribute the preliminary genetic data as well as blood, the subjects' ability to control their own involvement in the study is enhanced.³⁴

Other researchers take stronger measures to insulate prospective subjects from premature involvement. Some investigators do not construct family trees immediately, but have the probands carry letters to their relatives explaining the study and inviting them to contact the investigators if they want to become involved.³⁵ As a result, the researchers only receive pedigree information from those family members who actively volunteer for the study. Although this approach does the best job of giving the potential subjects control over the situation, it is important to note its imperfections. If enough family members volunteer for the study,

even those who declined to participate may find themselves involved, as information about them is inferred from analyses of their offspring and forbears. This approach may also potentially decrease overall participation of family members in studies; however this effect has yet to be determined empirically.

This approach, moreover, highlights a second issue: In some cases it may be the proband's own privacy that the recruitment process puts at risk. This concern arises primarily for genetic studies of socially stigmatizing conditions like psychiatric disorders, the diagnosis of which may not be generally shared within an extended family.³⁶ To rely on a proband to contact and recruit members of his or her extended family is to assume that the proband's diagnosis is one that can be shared with relatives without prejudice; for this reason most psychiatric geneticists take the responsibility to contact the family themselves. Here, the imposition on the family is justified out of a concern to protect the proband's privacy.³⁷

Unless it is handled adeptly, this strategy quickly meets limitations. Without a reference to the proband's diagnosis of, for example, schizophrenia, how do the investigators adequately explain to a proband's cousin why they are interested in her participation in their family linkage study of this disease? One approach to this problem involves discussing the importance of preserving confidentiality for every participant within a family study. This educational approach may also give the family member the chance to learn more about the illness being studied while both keeping the proband's diagnosis confidential and reducing the confusion of a family member concerning why this family was chosen for the study.³⁷

Finally, a different kind of family privacy and consent question comes up at the conclusion of a genetic study when investigators are preparing to publish their results. To present their data, investigators must publish the pedigrees on which they based their work. It is easy enough to present the pedigrees anonymously, but the family trees they provide are readily decipherable by family members and those who know them. It is thus possible for family members to learn not only about the carrier status of other relatives, but also other facts relevant to the genetic analysis, such as adoptions, stillbirths, and instances of misidentified paternity.

One common practice within human genetics is to scramble pedigrees for publication by changing the gender and birth order of family members in order to disguise their identities, yet preserve the essential genetic story the pedigree tells.³⁵ The original data is then kept available for inspection only by other *bona fide* researchers. As linkage analysis spreads into other medical fields, this approach is meeting increased resistance: Although the traditional publication practice of placing bars across the eyes of patients obscured information irrelevant to the topic, this approach also modifies the scientific data in question. A National Institutes of Health (NIH) research team learned this lesson to its chagrin when it published a "disguised" pedigree of an Egyptian family that disclosed the existence of two children in which "paternal genotype inconsistencies" were identified.³⁸ The results of this disclosure within the immediate family were disastrous, and led to new guidance to the NIH IRBs that, when misidentified paternity is uncovered in a genetic family study,

if the disease is rare with few subjects available, and it is scientifically impractical to discard the pedigree, then the results of the data analysis could be published without publishing the pedigree itself, with the pedigree made available to *bona fide* investigators who request it. If the pedigree must be

included in the publication, the nuclear family in which the incompatibility occurs could be left out of the pedigree. If it is necessary to publish the complete pedigree, an approach could be made to the family to elicit admission of non-paternity and to request permission to publish.³⁹

This approach, in fact, is the one that would be most compatible with other existing guidelines for protecting the privacy of clinical research subjects in the medical literature.⁴⁰ But it challenges the time-honored convention of using pedigree diagrams as a convenient graphic summary of family study data, and it leaves open important ethical questions. From whom should the investigators solicit permission from within the family? Everyone represented in a pedigree? Only those who carry the mutation in question? Only family members with special interests at stake, like the two Egyptian children and their parents? Although each of these approaches has its advocates, none is entirely satisfactory. Moreover, they all give rise to an additional question: What should investigators do in the face of intrafamilial disagreements over permission to publish data about their family?

A recent empirical study attempted to assess how investigators and journals are addressing the various challenges of publishing pedigrees while attempting to protect the privacy of family members.⁴¹ The three-part study examined the attitudes and experiences of human genetics researchers regarding privacy and confidentiality issues related to the publication of pedigrees. It also surveyed editors of biomedical journals concerning their policies and practices regarding pedigrees, and reviewed recent articles from a number of prominent journals that publish genetics research to assess the documentation of consent and information available to authors with respect to published pedigrees. The study found a wide array of practices among both journals and investigators with respect to the protection of privacy and confidentiality in the publication of pedigrees.

For example, 36% of investigators reported that family members were not informed that their pedigrees would be published and 78% did not obtain consent specifically for pedigree publication. Additionally, 19% of investigators reported that they had altered pedigrees to protect the privacy and confidentiality of family members; however, of those respondents, 45% did not disclose these alterations to journals. Of the 14 journal editors that responded to the survey, only three had specific policies for dealing with potential identifying information in pedigrees, and in the two-year review of journal articles, none had explicit documentation of informed consent for pedigree publication.

The results of this study demonstrate that practices by investigators and journals are not conforming to established recommendations regarding the protection of privacy and confidentiality of human subjects in pedigree research. The current practice of pedigree alteration may also affect the integrity of scientific communication. The authors involved with this study recommend more explicit policies for informed consent, documentation, and peer review regarding pedigree publication, including an active stand against pedigree alteration and better management of identifying information in published pedigrees.⁴¹

Recruitment Strategies

Enlisting research subjects to help recruit their relatives has been defended as a means to enhance family members' ability to make

voluntary choices regarding participation in genetics research. However, families are not composed of equal peers. In many situations, the subject-recruiter or family facilitator is recruited from the charged atmosphere of the clinic. These subjects, who are motivated by their clinical need to find “their gene,” usually proceed as advocates of the research. Thus the pressure of compelling family relationships may simply replace the researcher’s influence in recruiting potential subjects.⁴² This problem may be greater for cohesive, hierarchically organized families from cultural groups that have not yet been affected by the 20th century breakdown of the family, families whose size also tends to make them ideal subjects for linkage analysis.

One response to this problem is for researchers to approach families collectively by presenting their research projects at large gatherings like family reunions, and inviting all interested individuals to contact them to become involved.^{37,43} Some teams of researchers also rely on lay organizations, like genetic disease support groups, to make the initial contact with families in the context of the community support they are providing.⁴⁴ However, these approaches also pose risks to the goal of achieving autonomous participation: Family members may actually feel less free to demur in large group settings, and lay-led support groups vary in expertise, understanding, and objectivity (particularly when they are helping to fund the research itself).

Empirical Research

There have been very few empirical studies of participant reactions to different recruitment approaches.⁴³ A study of proband and parental assistance in identifying relatives for cystic fibrosis carrier testing research found 30.1% of 203 eligible families declining to provide contact information for relatives,⁴⁵ and a focus group study of cancer genetic research participants reported reluctance to serve as an intermediary for the researcher.⁴⁶ On the other hand, the literature includes many calls by genetic health voluntary and advocacy organizations for participant-led recruitment efforts, and many family studies proceed in this fashion.⁴⁷

Policy Implications

Some argue that because the family is the proper clinical unit of analysis (and allegiance) for geneticists who counsel patients, most questions about the disclosure of intrafamilial genetic information should not be regarded as problems about confidentiality in professional practice.⁴⁸ If that argument succeeds for genetic counseling, should it not also apply to genetic research? Similarly, others now argue that taking the family seriously means that IRBs or investigators should not attempt to police the inevitable psychosocial forces that come into play in familial decision making, any more than they would second-guess an individual volunteer’s internal deliberations. Researchers would do better, they argue, to monitor their own influence and leave the family’s internal dynamics intact.⁴⁹ Whether the family should be regarded as an entity that can justify these arguments that may discount the privacy and autonomy of individuals is, of course, the question.^{50–52}

Study Design Implications

Whether individual family members or the family as a whole are considered the unit of analysis in a family linkage study, the recruitment of family members should be part of the original

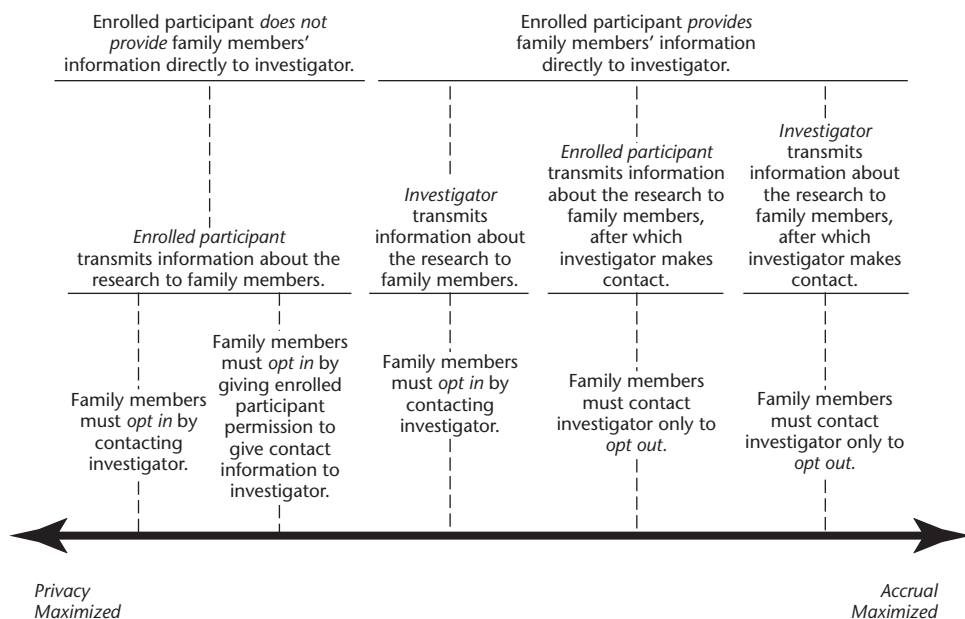

protocol and study design, and must involve thoughtful consideration regarding the confidentiality of both the proband and other participating family members. The nature of the particular study, recruitment goals, and family dynamics should also be taken into consideration when developing a recruitment strategy. It is important that these strategies balance the research quality and the need for adequate participant accrual to achieve scientific validity with potential harms to family participants such as invasion of privacy, unwanted disclosure of disease risk information, or familial pressure to participate. These issues should be highlighted during all stages of a recruitment process including identification, contacting, and actual recruitment of family members.

In 2004, a multidisciplinary ad hoc expert group was convened by the Cancer Genetics Network to explore the scientific and ethical issues surrounding the recruitment of participants for familial genetic research. This group reviewed the various recruitment methods used in family studies with regard to privacy, confidentiality, and participant accrual for each stage of the recruitment process (see Figure 29.2).⁴³ Initial contact with potential participants may be conducted by the study’s investigators or by enrolled participants who may wish to contact family members themselves in order keep their identity confidential until they agree to be in the study. Although the latter approach may maximize privacy, it may also put undue burden on the participants and thus lower accrual. Alternatively, although investigator-initiated contact may raise accrual rates, some family members may feel that because an investigator has contact information, and possibly some health information, their privacy has already been invaded. A third, intermediary approach would be for enrolled participants to inform family members about the study and that an investigator will be contacting them to discuss participation. This approach takes the actual burden of recruitment off the shoulders of participants, but allows them to take the family’s best interest into account.

Unfortunately, none of these approaches deals with the problem of unwanted disclosure of information to family members before an informed consent process can take place. In dealing with this issue, it is increasingly important that the researcher consider the family dynamics of potential participants. Kathleen Bonvicini claims that it is important to pay attention to “individual family roles, level of cohesiveness, levels of power/influence, and family interactions” when designing a recruitment strategy. For example, the recruitment of a family leader from an older generation may help in the recruitment of subsequent generations of family members. Bonvicini also explains that the informal communication between family members, such as the family “grapevine,” can also help in the dissemination of information about the study and recruitment.³⁷

Once initial contact is made and basic information concerning the study is given to potential participants, they are usually given the opportunity to be further contacted by the investigators regarding participation using either an *opt-out* or *opt-in* approach. In situations in which enrolled participants make the initial contact, family members must opt in by contacting the investigator in order to receive more information about the research. Alternatively, family members can also opt in by permitting their contact information to be given to the investigator. In situations in which the investigator makes the initial contact, family members may be asked to opt in by contacting the investigators directly if they would like further information about the research, or may only need to

contact investigators to opt out if they do not wish to be further contacted. Although the opt-in approach maximizes the privacy of family members, an opt-out approach may increase accrual rates for a study. The decision to use either of these methods may depend on both the needs and goal of the study and the families involved in the research.⁴³

Community Interests

Genetic research projects that are framed in terms of identified human groups can have repercussions for all the groups' members, even when not all are directly enrolled in the study.^{53,54} In fact, it is only through their group identity that the harms of population genomic research can come back to haunt individual subjects.⁵⁵ As a result, some commentators have begun to argue that where genetic studies impose group-level risks, a decision to incur shared risks is most appropriately made at the level of the group as a whole. Some have proposed that this moral concern be translated into a fourth principle for clinical research ethics (in addition to the Belmont Report's respect for persons, beneficence and justice) called "respect for communities."⁵⁶

The principle of respect for communities is often put into practice through a call for "community engagement" as a prerequisite for population-based genetic studies. Over the last decade, such calls have come from a wide range of potential research participant groups, communities, and research policy makers,⁵⁷ and there have been some anecdotal reports of participant attitudes and researcher experiences with community consultation exercises.^{58–62} To date, however, there has been very little empirical research evaluating different approaches to community engagement or documenting its consequences for participating communities and groups.

The idea of community engagement has its origins in practices employed in a wide variety of research areas that recruit subjects because of their membership in a certain population, including public health research,⁶³ cultural anthropology,⁶⁴ research on

emergency medical procedures, and research with sovereign nations like Native American tribes.⁶⁵ Community engagement has been brought into discussions of population genetic studies relatively recently, however, largely in response to the collapse of one of the earliest proposed sequels to the Human Genome Project, the ill-fated Human Genome Diversity Project (HGDP).

In 1991, a group of population geneticists and physical anthropologists released a plan to sample DNA from the "world's most ancestrally representative" human populations, to create a global data and tissue bank for human genetic variation studies.⁶⁶ The proposal was originally framed as an attempt to preserve genetic material from "vulnerable" and "vanishing" human populations before assimilation and oppression drove them to extinction. When the planners released a list of 400 isolated ethnic, linguistic, and tribal groups they felt met this criterion, the project encountered a firestorm of critical reaction from advocates of indigenous peoples. The advocates pointed out that none of the listed groups had ever been approached about their willingness to be included in the research and, to the extent that the groups were vulnerable to extinction, the preservation of their DNA would not be their first concern.^{67–69} The HGDP never survived this political controversy beyond its planning stages. However, a rear-guard attempt to redress the disaster by the North American advocates of the project did create the starting place for current discussion of community involvement in genetic variation research.

The North American Committee (NAAmC) for the HGDP developed a "model protocol" for DNA sample collection that "requires that researchers participating in the HGDP show that they have obtained the informed consent of the population, through its culturally appropriate authorities where such authorities exist, before they begin sampling."⁷⁰ For the NAAmC, this requirement essentially meant ratcheting up all the protections that are afforded to individual human subjects in biomedical research to the group level, on the ground that "the group—whether one family, a set of family, a genetic disease organization or an ethnic group—is really the research subject."⁵³

The NAMC vision of group consent is a robust way to recognize the principle of respect for communities. The model protocol gives groups the rights to grant or deny investigators access to their members, to withdraw from research at any time, to have their group identity protected as a matter of confidentiality, and to negotiate the ways in which their DNA samples will be studied and used. It even instructs researchers to let refusals at the group level trump the informed consent of individual members who might otherwise volunteer.⁷⁰

The NAMC concept of group consent is best exemplified by the kinds of negotiations that occur between researchers and self-governing groups like the American Indian nations. These were the “ancestral populations” of interest to the HGDP in North America, and many tribes already have formal legal mechanisms for vetting research proposals involving their communities. The Navajo, for example, not only review all biomedical research proposals at the tribal level before giving scientists access to their people, but insist on the right to censor all publications emanating from any research they approve.⁷¹ On the other hand, the indigenous American Indian peoples are still sovereign nations in their own right, and can impose such requirements quite independently of whether or not researchers recognize a moral need for population-based consent. For these groups, in other words, the NAMC protocol works well, but is also largely irrelevant.

Unfortunately, for other kinds of populations, in which the group consent would be a new protection, the protocol is less apt. In fact, the committee recognizes that “researchers can only seek consent from a broader representative of a population if such a representative exists.” For study populations larger than single families or the residents of a specific locale, it argues, the need for group consent “depends necessarily on two things: the population’s view of its identity and the existence within the broader group of entities that the population itself recognizes as culturally appropriate authorities.” Apart from Native American and Canadian peoples, the committee concludes, “most other ethnic groups in those two countries do not have those kinds of cultural identities or group-wide culturally appropriate authorities.”⁷¹

Very few of the populations of interest for current genetic variation research have political structures that can claim to be their culturally appropriate authorities, and all of the populations of interest will be larger than the populations of specific families or sampling sites. Attempting to apply this full-blooded concept of group consent to nonsovereign genetic populations encounters major conceptual, ethical, and practical difficulties, which have been more extensively discussed elsewhere.⁷² In brief, such an attempt would founder on two fronts: First, both our practice of nesting local groups within larger social communities and the global diasporas of most human populations mean that no socially identified group with the culturally appropriate authority to do so can have the reach to speak for all those in a given genetic population who might become research subjects.⁷³ No matter how careful researchers are to get permission from the right authorities in a local self-identified social group, as long as that group is nested within a larger genetic population, the group’s ability to protect itself from the consequences of the research will be compromised by any other subpopulation’s decision to participate, and its decision to participate will in turn put those other groups at risk. In response to this, some advocates argue that researchers must attempt to consult with the largest supervening group relevant to the research problem.⁵⁴ In doing so, of course, they will inevitably find

themselves dealing with populations that transcend ethnic, national, and even continental borders.

Second, suggesting that any socially identified group could speak for such populations would reinforce (by tacitly endorsing) the view that there really is a biological justification for the social boundaries we draw around and between each other—a view population geneticists don’t believe and expect to discredit.⁷⁴ Whatever moral standing the human superfamilies of interest to population genomics may have, in the modern world it will only very rarely be the moral standing of sovereign nations.

These concerns have convinced most advocates for group interests in genetic research that simply treating populations as if they were individual research subjects is naive, and that more nuanced interpretations of what it means to respect communities in this context will be required.⁵⁴ Under various labels, two models of community engagement are beginning to appear in various official recommendations to genetic variation researchers. Although both models conform better to the realities of population genomic research, both also remain haunted by the same kinds of issues that limit the utility of the NAMC protocol for group consent.

Policy Implications

The first approach is to reframe the process of community interaction to retract the gatekeeping role of group consent. Because genetic populations are not the sorts of groups that can claim autonomy as moral communities, it makes no sense to hinge the recruitment of their members on some corporate permission. Thus, for example, the “Points to Consider for Population-based Genetic Research” developed by the NIH stresses that: “Community consultation is not the same as consent. In the majority of cases, communities in the United States are not required to give consent or approval for research in which its members participate, nor is it reasonable to attempt to obtain community consent or approval.”⁷⁵

Instead of consent or approval, the NIH guidelines explain that “community consultation is a vehicle for hearing about the community’s interests and concerns, addressing ethical issues and communicating information about the research to the community.”⁷⁵ The purpose of this interchange is to solicit the study population’s help in identifying any “intracommunity” or “culturally specific” risks and potential benefits, so that the research can be designed in ways that best protect the group’s interests.⁶⁵

This interpretation of community engagement places much more emphasis on preserving the special values and cultural lifeways of a given population than on treating the population as a politically autonomous entity. The ethical emphasis has shifted from respecting the group to protecting its members as research participants vulnerable to group-related harms. Nevertheless, the ethical requirements continue to share with the group consent model the importance of identifying and interacting with consultants who can accurately and fairly represent the population’s values.⁶⁴ As Marshall and Rotimi point out, this can be difficult:

Despite the obvious benefits of community advisory boards, there are limits and constraints on their ability to represent the values of diverse community members. . . . In some cases community leaders on advisory boards may be politicians. Community activists represent another powerful group who might serve on such boards. Religious leaders or local celebrities also might be asked to participate on the boards. Investigators must be sensitive to the social and political agendas

of members on community advisory boards and try to minimize the potential for addressing priorities that may be relevant to only a minority of the local population.⁶⁴

Of course, the increasing dispersion of human populations around the world means that in fact most human superfamilies no longer share common “culturally specific risks” and benefits. This leads even the staunchest advocates of community engagement to the counterintuitive point of arguing that, for study populations like “general ethnic, racial or national populations, e.g., Ashkenazi Jews, American Indians, Puerto Ricans, etc.,” the lack of distinctive common interest and structured social interaction means that “community review may not be required and even for geographically dispersed populations that share distinctive beliefs and practices, like the Amish or the Hmong, limited social interactions between members of the study population make intra-community risks unlikely.”⁵⁴

Study Design Implications

Diverse, dispersed genetic superfamilies of the sort useful to genetic variation studies will not often enjoy the level of organization that can make representative consultations possible. For these cases, Sharp and Foster suggest that all that may be required is the form of community engagement they call “community dialogue”: an effort to interact with the local communities and institutions at the specific site from which members of a given genetic population will be recruited, in order to acquaint them with the investigators’ mission in advance of individual subject enrollment.⁵⁴ The key move in this interpretation is to acknowledge the complexity of human population structure by sacrificing the ambition to protect all members of a genetic population from the potential harms of the research, and to refocus on the particular families and locale from which investigators hope to solicit DNA samples.

Instead of attempting to respect the genetic population as a moral community, or attempting to protect all its individual members from potential harm, the practice of community engagement is reinterpreted by this approach to be simply a matter of establishing a viable political collaboration with the local community in which the recruitment of individuals for DNA sampling is to take place. Because this does not even require that the community representatives bring any special expertise to the research design, the language can shift from “consultation” and “review” to “dialogue” and “engagement”—terms more often used to describe attempts to teach than to learn. In fact, as the range of “local” risks and benefits widens for any specific genetic population across the global spectrum of cultural, political, and social environments, the utility of any specific advice becomes diluted to the vanishing point, until only the most generic biomedical design considerations become relevant to researchers.⁷⁵ As the NIH “Points to Consider” warn,

Community-wide “buy-in” to the goals of the research project may improve the ability to recruit study participants. However, community consultation is not a substitute for careful, systematic preliminary studies that provide the foundation for choosing the study population, developing sampling or recruitment plans, designing protocols and measurement tools, and planning analytic strategies. A wide variety of social science methods and statistical data are available for assessing the characteristics of communities. Investigators must be

cautious about relying on anecdotal information gained in the course of community consultation to guide the development of their research plans.⁷⁵

Narrowing the focus from broad study populations to localized communities does make the prospect of community engagement more plausible. Localized communities will be able to produce representatives authorized to speak for their membership more easily than unorganized populations. Local communities are more likely to face common intracommunity risks and needs that might be usefully communicated in designing the research at that site. And to build trust and negotiate access to community members, it will be much more effective to work at the local level.

Nevertheless, it remains important to appreciate the limits of this approach. The kinds of study populations that are of most interest to genetic variation researchers, the international human superfamilies whose genetic variations disclose the patterns of disease susceptibilities within the species, will be those least well served by the practice of community engagement. If the concern is to give those larger population groups some involvement in research that may affect them, even negotiating a full-blown “community partnership” with one localized subset of the population is as likely to be an example of the problem as it is a step toward justice: To the extent that the researcher does not confine his scientific claims to the local community at hand, that community’s decisions about participation preempt the interests of the rest of the population.

Moreover, for these same reasons, investigators cannot honestly let local communities speak for the population, and cannot promise that local research designs will protect the communities from population-related harms incurred by studies at other locales. Thus, in this most attenuated model of community engagement, even the local communities to which the principle of respect for communities could apply cannot be afforded a robust interpretation of that ideal.

Reporting Research Findings to Participants

So far, the issues we have described all arise at the outset of a new genetic study, during the process of recruiting and enrolling subjects. As human genetic studies progress and begin to yield results, however, other questions emerge. These questions all concern the management of the information that investigators uncover about their subjects.

Most human genetic studies begin as basic research projects in molecular and human genetics, and often have relatively indirect connections with the kinds of clinical services that are relevant to the education and counseling of individuals regarding the results of genetic tests. Thus, one traditional approach to managing findings has been to condition subjects’ participation on the understanding that no individual findings will be disclosed to subjects under the auspices of the study. This approach was justified, in part, by the slow pace of research that isolated disease genes, which allowed the clinical community to prepare for the translation of research findings into clinical practice further in advance. Even when researchers are confident that the information they have uncovered is reliable, they are often uncertain about their own obligations to provide the clinical services required to convey it back to their subjects. The traditional view has been that,

clinical researchers may minimize potential harm to subjects by separating, as thoroughly as possible, their research role from clinical roles. If a genetic test reaches the level of reasonable medical certainty, and a subject wishes presymptomatic testing to learn the risk of carrying a particular defective gene, the subject can be referred to a qualified clinical genetic counselor for provision of such information (rather than obtaining genetic liability test results in the research setting).³⁶

Hence, for example, the linkage studies that localized markers for the Huntington's disease gene established the policy of withholding preliminary research results from all subjects until the level of scientific confidence in the reliability of the markers justified the establishment of pilot clinical testing programs.⁷⁶

Others, however, question whether the traditional separation of research and clinical roles is in the participant's/patient's best interest in these situations. Information transferred to regular medical records would become more widely accessible to insurance companies and employers, exposing the family members to increased socioeconomic risks as a result of their research participation.⁷⁷ Moreover, the pace of research to isolate genes is quickly putting pressure on this traditional approach. Many investigators now find themselves in possession of information that seems to be reliable enough to use clinically in the absence of a developed program for delivering the information. In addition, individuals and families sometimes request early results directly from the researchers, and their requests are supported by those who argue that subjects should have the right to information about themselves at all stages of the research, particularly when it could have a bearing on clinical decision making.⁷⁸ For example, one team reports that,

We believe that the major responsibility of this type of investigation (to their subjects' welfare) is formal education of the affected individuals, particularly those newly diagnosed, their families and their physicians. . . . As part of the education component in our study, a detailed session is conducted during the study visit; all local subjects are afforded a clinical visit to review all data with the polycystic kidney disease (PKD) physician; and all patients and all doctors receive a detailed letter describing the data obtained.⁷⁹

This position reflects a growing view that the relationship between genetic researchers and research participants should be one of collaboration and codiscovery, rather than simply one of scientific observer and participants observed. On the strongest version of this view, even the clinical significance of the research results is not particularly relevant: Research participants simply enjoy a basic right to know everything that the researcher knows about them. In fact, legal concerns have already been raised about "look-back liability" on the part of investigators who hold, but do not communicate, important findings.⁸⁰

Policy Implications

Three different kinds of research results prove particularly troubling to researchers in defining the limits of their obligations to inform their participant partners: unanticipated findings that are potentially stigmatizing; findings that have clinical implications for health problems unconnected with the research topic; and

preliminary findings of possible clinical relevance that remain to be validated for clinical use.

Unanticipated findings. One of the more common unanticipated consequences of tracing the inheritance of DNA markers within a family can be the inadvertent disclosure of misidentified paternity. This is not a new issue for clinical geneticists, who encounter it in the context of prenatal testing and carrier screening for recessive diseases.⁸¹ However, for clinical researchers from other specialties interested in late onset diseases of adults like breast cancer, this risk is still underappreciated. Longstanding recommendations to address that risk up front in the informed consent process are rarely followed outside of traditional medical genetic settings.^{82,33}

For many people, ancestral relationships are as important to their identities as their living relations. Despite our modern belief that individual human potential transcends genealogy, biological lineage continues to provide most people in many cultures with their names, their inheritances, and their connections to history.⁸³ This is why population genetic studies that promise to confirm, enrich, or extend the ancestral lineage stories of particular families are of such interest, and why the interpretation and communication of their results can be so controversial.⁷³ The seduction of genetic genealogies has already tempted governments and tribes to propose DNA-based tests to secure lineage-based membership in indigenous tribes for political purposes,^{84, 85} and led religious communities to use genetic markers to adjudicate the orthodoxy of aspirants' claims to be coreligionists.⁸⁶ As often as not, those efforts will be inconclusive or exclusionary.

In both ancestry and paternity cases, genetic studies can exacerbate the problem of genealogical essentialism, in other words, "the view that the genealogical family is the 'real' one and that knowing blood kin is essential for establishing a stable personality and identity."⁸⁷ In challenging either our remote or immediate origin stories, genetics provokes the same question: What does it mean to be a "descendant," and what role should biology play in determining the rights and privileges that should attend the role?⁸⁸

Pleiotropy. The second set of problematic results from genetic studies reflects the fact that some clinically significant alleles will be "pleiotropic" in their expression, meaning that a single gene or allelic variation has multiple phenotypic effects. Pleiotropic alleles may convey risks for very different health problems with different prospects for treatment. For example, consider the preliminary but highly public association of APOE genotypes with risk for Alzheimer's disease (AD). APOE genotyping is also under investigation by cardiologists as a risk factor for hyperlipidemia and its clinical sequelae, atherosclerosis and myocardial infarction. In fact, the same allele of the APOE gene, the 4 allele, seems to convey the highest risk for both coronary artery disease (CAD) and AD.^{89,90} Presumably, the ethicolegal requirements of informed consent now require cardiologists to disclose to their research subjects that information on AD risk will be contained in the results of any APOE genotyping they perform.

Moreover, the researcher's commitment to candor and the patient's "right to know" would also seem to require that researchers divulge the AD risk results when patients ask for that information after testing has already been conducted as part of a study in cardiovascular genetics. And, of course, the researcher's professionalism means that all of those disclosures should be performed according to the professional standards of care established for that task. Unfortunately, if those standards follow the

recommendations emerging from the neurologists' current discussions of APOE genotyping for AD risk, it will be difficult for other researchers, like cardiologists, to conduct APOE testing in the setting of their research without becoming professionally competent to counsel participants about the meaning of the test for their AD risks as well.

This difficulty arises because most of the new practice guidelines on APOE genotyping for AD risk take as their model the protocols developed to govern the clinical introduction of prognostic testing for Huntington's disease,^{91,92} for which no effective treatment exists. This paradigm sets the ethical standards for APOE genotyping for AD risk quite a bit higher than they have been to date in cardiological research contexts, because the model's focus is on protecting the patient from the psychosocial risks of testing rather than on preventing the harms it predicts. Moreover, these psychosocial risks do not depend on either the subject's awareness of the information or its ultimate scientific validity. If parties outside the research relationship, including the patient's family and clinicians, labor under the belief that APOE genotyping will predict AD risk, their reactions can still harm the patient. Thus, the most recent recommendations regarding APOE genotyping urge that "in deciding whether or not to carry out APOE genotyping for any purpose, physicians and patients should bear in mind that genotype disclosure can have adverse effects on insurability, employability, and the psychosocial status of patients and family members."⁹² Thus, they conclude that "future clinical applications of genotyping should be offered only when pre-test and post-test counseling, education and support are available."⁹²

In other words, to be consistent with the most relevant current recommended policies and practices regarding genetic testing, it appears that all research uses of a versatile genetic test like APOE genotyping will have to be governed by the protocols required by its most problematic use. This means that, in order to protect participants in cardiovascular research from the psychosocial sequelae of having their APOE genotype interpreted as a risk predictor for Alzheimer's disease, cardiologists must perform their testing according to the guidelines devised by neurologists for AD risk assessment—guidelines that the neurologists themselves are not yet ready to implement because of the scientific uncertainties that still haunt the association.⁹² As genome research yields an increasing number and variety of such "spoiler associations," it will become important for biomedical researchers to coordinate their efforts across specialties, so that important research tools are not hamstrung by similarly contentious professional policy claims.

Preliminary findings. Finally, because gene-hunting has been an incremental affair, using maps and sequence data to triangulate our way to alleles of interest and then assessing the expression of those alleles in populations, it almost always generates tentative conclusions along the way. Where these findings seem to hold the promise of clinical relevance, bench scientists and epidemiologists find themselves concerned about their obligations to warn participants of these findings.

In part, this issue reflects the need for a better translational bridge between the laboratory and clinical practice, a need that has spurred the dramatic growth of genetic diagnostics research. In the absence of effective therapies, the promise of accessible genetic information lies in its ability to allow individuals and their families to identify, understand, and sometimes control their inherited health risks. That ability, in turn, depends on two conditions: the

validity of the clinical risk predictions that the information provides and the patients' ability to assess that validity realistically. This means that the decision to declare a particular genetic test ready for use as a clinical decision-making tool depends on much more than guaranteeing the test's ability to reliably identify its target mutations. It also requires a professional judgment about the clinical significance of the test results and the concomitant risks of that information for patients and their families: the features that comprise what some call a test's "clinical validity."⁹³

Assessing those features of the test, and developing testing protocols that can optimally address them, requires answering epidemiological, psychosocial, and health services research questions that go well beyond the usual purview of molecular genetics.^{16,93} Over the last decade, at the recommendations of policy bodies like the National Academy of Sciences¹⁶ and the Department of Health and Human Services Secretary's Advisory Committee on Genetic Testing, the field of genetic diagnostic research has emerged to provide the evidence needed to craft safe and effective protocols for the clinical delivery of genetic risk information.⁹⁴ Professional policy statements like those governing the disclosure of APOE4 risk information are often precautionary placeholders in the absence of such data.

Study Design Implications

Despite the development of policies and protocols for the careful translation of genetic research findings into clinical practice, however, bench scientists often feel obligated to disclose accidental or expected research results that they find clinically or socially important for participants to know. This has led to attempts to develop practical approaches to deciding when to disclose research results, even in advance of well-developed clinical protocols. Three types of approaches are increasingly common.

One approach is to establish decision-making guidelines by suggesting the variables that should be considered in each instance. For the most part, these algorithms track the risk/benefit calculus familiar in clinical medicine. For example, one early report recommended that investigators make their decision about the disclosure of early finding on the basis of the following three variables: (1) the magnitude of the threat posed to the subject, (2) the accuracy with which the data predict that the threat will be realized, and (3) the possibility that action can be taken to avoid or ameliorate the potential injury.⁹⁵ These are the principles that typically govern decisions to disclose information in clinical medicine, and routinely dominate medical ethical discussions of clinical truth-telling, the limits of confidentiality,⁹⁶ and professional obligations to offer unsolicited medical advice.⁹⁷ Most recent recommendations on the question of reporting research results to subjects simply elaborate on these consequentialist principles.^{98–100} Thus, one reviewer concludes:

Thus in the end perhaps genetics research is best served by the routine practices of disclosure utilized in the medical treatment area. Disclosure of results, which are material to a patient's decision-making in the areas of health and reproduction could become the standard of care so long as the information is reasonably believed to offer some clinical benefit to the subject. Disclosure to family members may also fall under a materiality standard, with disclosure becoming a duty if the genetic infirmity is susceptible to treatment or prevention. As the study of the human genome gives way to

the practice of genetic medicine, our sensibilities about disclosure may follow in its path.¹⁰¹

For all its strengths, this approach faces two major objections. The first is that it ignores the ideal of “partnership” to which many researchers and participants aspire. For those who view genetic research as a robustly “collaborative enterprise” between scientists and volunteers, titrating disclosures against a risk/benefit algorithm may not show enough respect to the participants’ right “to know everything the investigator knows about them.”¹⁰² The second objection is that, in practice, the prerequisites imposed by applying clinical standards of care, such as the clinical validation of test results, the use of Clinical Laboratory Improvement Amendments (CLIA)-approved laboratories, and the observance of Health Insurance Portability and Accountability Act (HIPPA) privacy regulations, may, as in the case of APOE4 genotyping, make it inappropriate for researchers to disclose many of the findings that they feel compelled to report to their volunteers.¹⁰⁰ Applying clinical standards suitable to the therapeutic relationship, in other words, may mask or distort distinctive elements of the researcher/volunteer relationship that both parties would be loath to sacrifice.

A second, procedural approach to these issues is to recommend the creation and use of committees that would be comparable to the data safety and monitoring boards (DSMBs) used by clinical trials.¹⁰³ These committees (often misnamed as project ethics committees) are charged with deciding when study findings are clinically reliable and useful enough to disclose to the research subjects.¹⁰⁴ To the extent that they involve research subjects, family representatives, or community members from the study populations, these committees may potentially offer a useful middle ground between paternalistic and client-centered views. This approach has been particularly successful when researchers are working with organized communities and disease groups, although it faces many of the same challenges discussed above for other forms of community engagement at earlier stages in the research process.⁶⁴ Although these committees may utilize similar standards for clinical evaluation as other researchers or policy makers, they are in a unique position to help define the magnitude of potential threats to their communities, provide more accurate information on key social variables, and evaluate study criteria in light of their own values.

Finally, a third approach is to plan research communications in a stepwise fashion. In this model, participating families or communities are brought into the planning of research studies early on so that they can have as full a sense as the researchers of the potential information that might be generated, even before they agree to participate in the study. This process allows the study team both to alert the participants to the possibility of unexpected, uncertain, or unhappy findings, and at the same time to gain a sense of their expectations regarding information reporting and a more refined understanding of what results would be considered problematic by their volunteers.⁵⁴ Then, as data is collected and analyzed, the research team communicates aggregate results to the participants, via newsletters or reports, in progressively more refined and validated form. This approach shapes the disclosure in keeping with the volunteers’ own values, but also shifts to them the responsibility for ascertaining their individual results.¹⁰⁵

Increasingly, as tests for genetic factors in more complex diseases become available, the question will become less whether one has the mutation in question, but what that means for one’s future.

To be able to use the results of genomic research intelligently, research participants will need to be able to think even more than they must today in terms of shifting ranges of probabilities that are influenced by both genes and environmental factors.¹⁰⁶ As they learn to do this, both subjects of research and investigators will find themselves swimming upstream against our culture’s tendency to interpret genetic risk factors in a deterministic, even fatalistic fashion.¹⁰⁷ It is this willingness to read too much into genetic risk assessments that raises the stakes of the researcher’s decision to disclose preliminary research results, because it both drives the interest of participants and exacerbates most of the ancillary psychosocial risks they might face. Part of the clinical researcher’s job in optimizing the personal utility of genetic information will be finding ways to counter this misleading inclination.

Control and Benefit-Sharing

Returning research results to participants inevitably raises their expectation of being able to control the consequences of their participation, especially when communication is cloaked in the language of “partnership.” Partnerships are usually characterized by shared decision making and mutual benefit. But this leads to a final set of issues for genetic researchers: How much control and what kinds of benefit-sharing can genetic researchers honestly promise?

For example, research participants are routinely told that they are free to withdraw from studies at any time. Yet in genetic family studies, their participation consists of their presence on a pedigree and their DNA in a freezer. Traditionally, most researchers have regarded DNA samples like other donated human biological material, as material over which the sample sources no longer hold a claim. For example, one group draws on the *Moore v. Regents of the University of California* case¹⁰⁸ to argue, “According to a 1990 California Supreme Court case, a cell line is ‘factually and legally distinct’ from the cells taken from a subject, and therefore cannot be considered the ‘property’ of that subject.”³⁶ However, unlike most donated tissue, DNA samples in a family collection gain their research value precisely to the extent that they continue to represent their donors. Thus, when another group considered the issue, it determined the following:

Participants at the conference agreed that subjects in pedigree studies have the right to refuse to participate any further in the research, and should be able to have their names removed from a pedigree. There was also a consensus that the subjects could withdraw their personal DNA sample or require that it not be used in any further research, assuming that they had not formally transferred ownership to the researchers. However, subjects were not considered to have any control over the information obtained by investigators from their DNA samples, and researchers are free to use such information for further analysis consistent with approved research protocols.⁵²

For investigators contemplating publication, this consensus yields mixed advice. The “names” of family members who deny permission to publish data should not be included, but does this extend to the anonymous symbols that signify them in the chart as well? Or are those symbols, conveying gender, genotype, and family relationships, simply “information obtained by the investigators,” over which family members have no further control?⁴⁴

Part of the reason the “ownership” of research data and materials becomes a question in genomic studies is that the pedigree information and DNA samples collected in the course of particular gene-hunting projects can often be used to support subsequent projects. Traditionally, tissues and blood samples donated for research have been considered to be available for further study by researchers. Many consent forms for linkage studies make this assumption explicit to their subjects by having them provide blanket permission “for further research” with their samples. An increasingly common view today, however, is that “the day for informal donations of DNA samples is past,”¹⁰⁹ and that new molecular studies of collected samples should be subject to the same requirements as the original family study that generated the resource. The strongest view is that the participants should know and agree to any molecular studies conducted on their DNA samples that were not specifically discussed under the initial consent without a “blanket consent” option. One statement of this position appears in the institutional guidelines developed by the IRB of the Johns Hopkins University:

A subject cannot give consent to participate in a future experiment of unknown risk. Prior to recontacting donors who have either agreed to future testing or whose samples are stored and with whom consent for future testing was not discussed, investigators must seek an opinion from the . . . IRB regarding the appropriateness of the risk:benefit ratio and possible impact of test results on the subjects. . . . If consent is given for genomic screening using a particular set of probes—identified as probes for a particular disease under study—probes identified with other diseases may not be used unless further consent is obtained for the study of the individual’s DNA with those new probes.⁷⁹

Of course, one category of research that has traditionally been exempt from the regulations that apply to research involving humans has been research with anonymous human tissue, and most of the human cell lines that are used for biomedical research are distributed through the genetic research community without any traditional personal identifiers attached.¹¹⁰ As genetic mapping, DNA sequencing, and genotyping technologies progress, however, the adequacy of that practice will continue to be pressed by our increasing ability to retrospectively link samples to their human sources. Because DNA profiles are themselves remarkable personal identifiers, there may be no way to completely “anonymize” individual DNA sequence data. Foreseeing the day when it may become valuable to research to post complete “personal genome projects”¹¹¹ on the Internet as open source research resources, calls for “health information altruists” are already being made.¹¹²

In addition to questions about the limits of participant control of samples and information, there has been increasing discussion of the need for a variety of forms of “benefit sharing” with genetic research participants, at both family and group levels. Three different models of benefit-sharing are emerging, although they are not often well distinguished: (1) profit-sharing plans, in which the research participants negotiate intellectual property rights and financial stakes in any commercialized outcomes of the research; (2) health-care dividend plans, in which participants are provided with privileged access to any health-care products or services generated by the research; and (3) “reciprocity” agreements, in

which participants are given benefits unrelated to the research itself, in recognition of their contribution to the research. Each of these approaches has strengths and weaknesses, and they are only just beginning to be evaluated empirically.

Policy Implications

Most genetic researchers strive to avoid profit-sharing approaches by having participants relinquish claims to any commercial benefits of a study. However, in recent years a number of the voluntary health organizations of families at risk for particular genetic conditions have begun experimenting with the profit-sharing approach.¹¹³ Again, this trend has been galvanized by a dispute: In 1997, Miami Children’s Hospital obtained a patent that covered all diagnostic and therapeutic uses of the gene for aspartoacylase and its mutations, which cause Canavan’s disease. The research leading up to this discovery had been organized largely by families of children with Canavan’s disease, who recruited the scientist Reuben Matalon, raised the funding, and participated as DNA donors in the research. The families sued Miami Children’s Hospital, arguing that the use of the patent to sell genetic testing back to the community that made it possible was unfair and likely to restrict access to the test.¹¹⁴ In the wake of that case, other organizations—like PXE International, devoted to another rare genetic disease, pseudoxanthoma elasticum—have taken care to negotiate material transfer agreements with researchers, retaining rights to patent ownership for discoveries related to “their genes.”¹¹⁵ The Genetic Alliance, an umbrella group for rare genetic disease organizations, has now launched a Biobank initiative modeled on the PXE International profit-sharing approach.

The rationale for the profit-sharing approach is two-fold. On one hand, disease groups argue that they make material contributions to the research, well beyond the DNA samples that their family members may contribute. They are often the ones who bring scientific attention to their disease, maintain the registries of families that are key to research recruitment, facilitate that recruitment, and sometimes even fund the research. Second, by preserving a financial stake in the research, these groups strive to protect access to any health-care services that result from the research for their constituents.

As a policy matter, however, the profit-sharing approach does raise some challenges. First, it risks imputing ownership of particular mutations or alleles to the participating group. Unlike populations, these genetic disease advocacy groups are “genetic communities” in the sense that their membership is defined by a genotype many members share. Unlike clans, the families that constitute them are not genealogically related. When such a group patents “its” gene after underwriting the gene’s discovery, the group explicitly adopts the “ownership” paradigm, even when it does so defensively and on behalf of its constituency. But what obligations to that constituency flow from this move? Little attention has been given to how competing interests within such groups should be adjudicated by researchers in negotiating the disposition of this intellectual property, or whether the advocacy group itself acquires any different obligations of accountability to people carrying “its” genotype than scientific or corporate patent-holders would. What does it mean to be a loyal member of such a community, when different scientific research groups come courting, or when rival advocacy groups claim to be one’s representative?

Because the main stated interest of disease groups in advocating profit-sharing approaches is to gain access to health-care benefits, another popular model has been to condition group participation on privileged access to research-related health care, regardless of ownership. For example, in 2000 the revised Declaration of Helsinki endorsed the view that “[a]t the conclusion of the study, every patient entered into the study should be assured of access to the best proven prophylactic, diagnostic and therapeutic methods identified by the study.”¹¹⁶

The “health dividends” approach is defended as a realistic way to recognize a family’s or community’s role in assuming the risks of research, and of allowing researchers to do what is in their power to help redress the lack of health-care access that research participants from disadvantaged communities may face. It does, however, face two dangers that are familiar to investigators in other clinical research settings. The first is that by promising health-care benefits from basic genetic research studies, the researchers may foster unrealistic expectations among participants, encouraging the “therapeutic misconception” (see Chapter 58). Perhaps even more important, where there are foreseeable benefits, this approach can establish a forced choice dilemma for disadvantaged participants, compromising the voluntariness of their participation in any particular study.

One response to these challenges has been to attempt to disconnect the health benefits provided by researchers from the topic of the research itself. For example, in its policy statement on benefit sharing, the international Human Genome Organization says that, in addition to research-related health dividends, “immediate health benefits as determined by community needs could be provided . . . and that profit-making entities [should] dedicate a percentage (1–3% of their annual net profit) to healthcare infrastructure and/or to humanitarian efforts.”¹¹⁷ Often, such benefits are negotiated by communities during or after their participation in research as a gesture of “reciprocity” on the part of researchers.

The reciprocity approach has several important policy advantages. It does not impute “ownership” of particular genetic patterns or variants to the participants. It does not risk unrealistic expectations about the therapeutic outcomes of genetic research. It can provide collective benefits to both participating and nonparticipating segments of the group. And it can be better adapted to meet the highest priority local needs. On the other hand, it does raise some important questions. For example, is there a community that can benefit? Does the proposed reciprocity constitute extortion or bribery? Is the proposed reciprocity proportional to the group’s contribution?

Although the first wave of contemporary literature on this topic portrayed genetic information as “the common heritage of humankind,”¹ and thus unsuited to ownership and exploitation by subsets of the species, the organization of genetic research in terms of community membership is shifting the tone of the ownership debate dramatically. Although the ownership framework continues to be debated in international policy circles,¹¹⁸ as human communities have come to be (mistakenly) identified with unique human superfamilies, such communities seem to have begun to accept the idea that their genes are akin to the natural resources under their local control.¹¹⁹ Complaints of “biopiracy,” and pleas for “benefit-sharing” and “reciprocity” on behalf of communities under genetic study, as well as charges of unfairness and neglect by

those left out of genetic diversity research, all suggest a rising sense that, in fact, subsets of the species do have claims on the genetic information that distinguishes them and should be compensated appropriately for its use by others.¹⁰²

Conclusion

Genes (and their variations) seem to have acquired the status that germs held in Archibald Garrod’s day a century ago, as the most promising causal factors to investigate in addressing questions of human health and disease.² As these investigations gather momentum in the clinical research arena, they are provoking reassessments of the traditional conventions of human genetics research and pioneering new questions for research ethics. So far, the discussion of these issues has proceeded largely without the benefit of the evidence that might help their sound resolution. Fortunately, there is a growing interdisciplinary community of researchers devoted to gathering this evidence, and support from the scientific community for their efforts.¹²⁰ Our review suggests a four-part agenda for further empirical and policy research by this community, addressing four questions that cut across all the issues identified above.

What Does It Mean to Participate in Human Genetic Research?

As genomics makes possible increasingly fine-grained studies of human genetic variation, both globally and locally, it will become more important for genome researchers and science policy makers to become sophisticated students of human cultural, social, and political variation as well. Understanding research participants’ beliefs and attitudes about themselves, their family relations, lineage, community, and ethnic identity will be critical to the success of this science. These beliefs and attitudes shape the participants’ interpretation of the research experience and lay the foundation for any research risks or possible benefits that might emerge.

What Social Values Influence the Pace and Direction of Genomic Research?

Questions about the translation of new genetic knowledge into practical health benefits sometimes get relegated “downstream” from genetic research ethics, as issues in the clinical delivery or dissemination of genetic discoveries. However, studies of academic/industry relationships in genomics make it clear that entrepreneurial thinking about the prospect for application occurs quite early in the human genetic and genomic research process. The increasing interest in benefit-sharing arrangements with research participant communities is also encouraging basic scientists to design research with practical outcomes in mind. Finally, behind these incentives, most scientists are motivated by more or less well formed public health goals. Careful empirical and policy studies of benefit-sharing, the commercialization of cutting-edge science, the regulatory system that governs the translational pathway in the United States, and the public health goals of genetic medicine, will provide useful perspectives on regulatory regimes at the institutional, governmental, and international levels.

What Challenges Can We Anticipate From the Frontiers of Genetic Science?

New advances in genome-wide analysis will increase the speed and scope of genetic research exponentially over the next decade, making it possible for clinical investigators to take genomic approaches to complex traits and conditions that have been hitherto beyond their reach. New sequencing technologies promise to propel this work even further by dramatically lowering research costs, and their combination with improved gene transfer technology will open up new horizons for molecular medicine. Novel issues will be generated for clinical investigators and research participants when these tools begin to be used in human studies, challenging current conventions regarding individual informed consent, research participant privacy, research risks, and research aimed at “genetic enhancement.” Anticipating and identifying these new issues in advance is the exercise of scientific moral imagination that can be informed by careful empirical forecasting of scientific progress.

What Are Responsible Policy Options in Designing and Conducting Human Genetic Research?

Experiments in policy making for genetic research ethics are proliferating, as investigators, bioethics scholars, professional societies, and regulatory bodies suggest and implement different approaches to the issues we have reviewed. Now the data from these experiments needs to be analyzed. Comparative assessments of genetic research projects with families, communities, and populations operating under different regimes can help provide empirical evidence of researchers’ and participants’ actual experience with them, and help inform more careful ethical and legal critiques of the alternatives.

It is not a coincidence that genetic research attracts special attention within clinical research ethics, even when its issues are common to other parts of biomedicine. In addition to the historical shadow under which it operates and the scientific excitement about its promise, the intrinsic subject matter of human genetics—our biological differences and relationships—will always provoke ethical issues. Genetics is a science that speaks to the very traits that animate our most profound and volatile human rights issues and it will challenge clinical researchers and the research participants who work with them as long as our genetic identities are important ingredients in human assessments of social standing.¹²¹

Deception in Clinical Research

Testing research hypotheses and answering scientific questions are sometimes accomplished by deceiving research participants. Deception is most commonly associated with psychological and social science research, in which data suggest that investigators often deceive participants. However, deception also occurs in a broad range of clinical research.¹ For example, clinical trials designed to assess the impact of expectancy on drug-craving and drug-taking behaviors sometimes deceive participants. One testing paradigm involves asking research participants to perform various manual tasks, for instance, responding to a red light on a computer screen, after receiving an injection of a drug such as cocaine. To distinguish drug effects from expectancy effects, this paradigm administers the drug in only half of the testing sessions and administers saline in the other sessions, but tells participants that they will receive the drug in all the sessions.

In some cases, clinical investigators may deceive research participants for what is perceived to be the good of the participants themselves, for instance, suggesting that an individual's disease has not progressed to the point that research testing reveals. Such deception raises obvious ethical concerns, but not issues that are unique to clinical research, and we will not address them here. We will instead focus on the question of whether and under what conditions it might be ethically acceptable to deceive research participants for scientific purposes.

Most commentators agree that deceiving research participants for scientific purposes is *prima facie* unacceptable. Most commentators also agree that the deception of research participants for scientific purposes can be justified in some cases—that is, that such deception is not, in practice, always ethically unacceptable. Much of the debate, then, focuses on the conditions under which

deception might be acceptable. Not surprisingly, the extent to which one finds deception in clinical research acceptable depends on how problematic one takes deception to be, which, in turn, depends in large measure on the extent to which one thinks that deception harms or wrongs research participants.

Many researchers assume that deception typically is relatively harmless and conclude that any restrictions on its use should be modest. These individuals would allow deceptive research for a broad range of studies, and would allow deception in cases in which nondeceptive methods are possible but would be more burdensome or onerous, perhaps requiring more participants or a longer study. Many commentators assume, in contrast, that deception is seriously unacceptable, and should be permitted only in extraordinary circumstances, if at all. These commentators often conclude that deception should be allowed for scientific purposes only when the research has very significant social value and would be impossible to conduct using nondeceptive methods.

Behind much of the debate over the ethical acceptability of deception in clinical research is the assumption that the use of deception necessarily conflicts with respect for participant autonomy. Either participants can provide valid informed consent, or investigators can rely on deception, but not both.^{2–5} Against this assumption, some writers have argued that investigators can conduct deceptive studies while respecting the autonomy of the research participants by prospectively informing them that will be deceived, but not informing them of the nature of the deception. For example, in the deceptive studies of drug-craving and drug-taking behaviors, participants might be informed that the study has not been described accurately in all its details, without telling them which details have been misdescribed. Here too, as in a good

deal of the deception debate, more data would be instructive, data on how deception and its alternatives affect participants and the validity of scientific findings.

The Nature of Deception

Deception occurs when investigators communicate—understood broadly to include written, spoken and behavioral communication—in ways that can reasonably be expected to result in some participants developing false beliefs. For example, investigators might tell participants that they will all receive active medication when only half of them will receive active medication and the other half will receive placebo. Deception in the clinical setting typically is intentional. That is, the investigator intends to deceive the participant and communicates in a way that is expected to lead to false beliefs on the part of participants. Moreover, the investigators rely on the fact that the participants are likely to develop false beliefs. It is the fact that the participants develop false beliefs in the drug testing paradigm mentioned previously that allows the investigators to distinguish expectancy effects from drug effects. Typically, we consider deception especially problematic when it involves the deceiver intentionally deceiving another person and then relying on the deception for the benefit of individuals other than those deceived.

Deception typically occurs as the result of investigators providing false information to participants. For example, in a study of continuous positive airway pressure (CPAP) versus placebo in sleep apnea, participants were told that the inert placebo pill was “intended to improve airway function.”⁶ The investigators used a misdescribed placebo pill as the control out of concern that those familiar with CPAP would have been able to distinguish CPAP from sham CPAP.

Investigators also may deceive participants by withholding pertinent information from them. In a study of chronic obstructive pulmonary disease (COPD), investigators attached a chronolog to participants’ inhalers to measure whether they were “dumping” study medications.⁷ To ensure accurate measurements, participants “were not informed of the chronolog’s date- and time-recording capabilities.”⁷

Whether a given instance of communication or failure to communicate constitutes deception depends upon what it is reasonable to expect individuals to conclude on the basis of the communication (or lack thereof). For this reason, reasonable people may disagree on whether a given instance of communication constitutes deception. To assess the impact of expectancy, one research design tells participants that a light will appear on their computer screen and then they will receive an injection of a drug. The design assesses expectancy by delaying the injection of drug for some time after the light appears. This design relies on the fact that participants expect to receive the injection just after the light appears. Is this design deceptive?

It is deceptive if it is reasonable to expect that participants, told that they will receive an injection of drug after the light appears, will conclude that they will receive an injection *immediately* after the light appears. If it is reasonable to expect that participants, told that they will receive an injection of drug after the light appears, will conclude that they will receive an injection at some time relatively soon but not necessarily immediately after the light appears, then the design may not be deceptive, depending upon how long the delay happens to be. Because our expectations re-

garding the beliefs reasonable individuals will develop may not be clear in this case, it may be unclear whether this design involves deception.

To consider a more prominent example, what does the present analysis imply about whether placebo-controlled studies are inherently deceptive? A typical blinded placebo trial randomly assigns some to receive drug and others to receive placebo, while withholding from participants information regarding which they are receiving. Furthermore, active steps are taken, such as double blinding and placing drug and placebo in identical capsules, to ensure that participants do not discern whether they have been assigned to receive drug or placebo. Clearly, then, placebo trials withhold important information from participants, and as a result participants often end up with false beliefs about what they are taking. Some end up with the belief that they are taking drug when, in fact, they are receiving a placebo. Are these trials therefore inherently deceptive? (Critics of placebo trials claim that participants typically are able to discern whether they are receiving active drug or placebo, allaying one’s concerns regarding the potential for deception, but raising concerns regarding the scientific usefulness of placebo-controlled studies.)

Placebo-controlled trials in which all participants are told that they will receive an active drug clearly are deceptive. A trial that simply withheld any information regarding the contents of the research “tablets” would arguably be deceptive as well. In the absence of information to the contrary, one expects that tablets provided in the context of a clinical trial contain active medication. It is less clear that placebo-controlled trials are deceptive when participants are informed that placebos are being used, and that they will not be told whether they are receiving active medication or placebo. If participants are provided this information, it seems the reasonable response would be to remain agnostic over whether they are receiving medication or placebo, implying that standard placebo-controlled designs are not inherently deceptive.

Trials involving sham procedures, in contrast, sometimes involve an element of deception. In these trials, researchers manipulate the sham procedure, not so that participants will remain agnostic over whether they are receiving the real or the sham procedure, but in such a way as to engender the false belief in the participants that they are receiving the real procedure. Thus, even though participants are informed in advance that they will receive either a real or a sham intervention, active steps are taken to convince all the participants that they are receiving the real treatment.⁸

The Milgram Experiments

The contemporary debate about deception in clinical research was fueled by Stanley Milgram’s experiments on obedience in the early 1960s.⁹ In the wake of the disclosure of horrific acts during World War II, perpetrated by ostensibly ordinary Germans who claimed simply to be following orders, Milgram designed a series of experiments to assess the extent to which ordinary Americans would likewise obey authority figures.

Milgram recruited participants and paired them with a second individual who was identified as another participant, but in fact was working with Milgram. The “confederate” was placed in what was described as an electric chair and given a series of tasks to perform. This individual intentionally made a series of mistakes.

At each mistake, the participants were instructed by a researcher in a white coat to administer shocks of increasing severity to the individual. The accomplices in the chairs would feign increasing levels of agony as the participants were instructed to give, and often complied with giving, greater and greater shocks.

Milgram's widely criticized experiments were clearly deceptive. Participants were told that they were delivering actual shocks, and the actors strapped in the chair reacted in ways to reinforce this belief. Milgram's experiments led to widespread discussion on what precisely are the harms of deception in clinical research. Milgram responded to his critics on several occasions, and even conducted follow-up research on the participants to assess the extent to which they had been harmed.¹⁰ Many of the participants reported to Milgram that they did not experience long-term harm as a result of their participation and were supportive of the research. Critics have questioned whether long-term harms are the relevant metric and whether participants can be trusted to report accurately whether they experienced serious trauma, especially when asked by the very individual who perpetrated the deception in the first place, raising further questions about the best methods for empirically assessing the possible harms of deception for scientific purposes.

What Makes Deception in Scientific Investigation Ethically Problematic?

At the outset, it is useful to appreciate the conflict between the ethos of science and the use of deceptive techniques. Science aims to discover and communicate the truth about the natural world and human conduct. There are sound methodological reasons for using deception to probe the truth about human attitudes and beliefs, and their effects on behavior. It follows, however, that when deception is used, a conflict between the means and ends of scientific investigation ensues: The end of discovering the truth is pursued by the means of deliberate untruth.

It might be argued that deception in scientific investigation is no more problematic than the pervasive and accepted use of deception in daily life and social contexts.¹¹ In a 2004 news article reporting advances in the design of computers to simulate human responsiveness, Clifford Nass, a professor of communication at Stanford University, is quoted as endorsing the use of deception in research: "We spend enormous amounts of time teaching children to deceive—it's called being polite or social. The history of all advertising is about deceiving. In education, it's often important to deceive people—sometimes you say, 'Boy you are really doing good,' not because you meant it but because you thought it would be helpful."¹²

Deception in ordinary life typically is justified on the grounds that it is for the benefit of the individual who is being deceived. For instance, the "polite" and "social" deception that Nass cites is justified on the ground that it is better to deceive someone slightly than criticize them or hurt their feelings. Notice, however, that this condition is not relevant to deceiving research participants for scientific purposes and the benefit of society in general, through the development of generalizable knowledge.

A major ethical concern with deception in research is its potential to violate legitimate trust. Individuals generally trust that the research in which they are invited to participate is worthwhile, that it will not expose them to undue risks of serious harm, and

that they will be treated fairly. When participants discover that they have been deceived, which typically occurs during the process of debriefing at the end of study participation, they may lose trust in scientific investigation. As we argue below, the issue of trust is likely to be especially important for research involving patient subjects conducted in clinical settings.

Deception of research participants also clearly conflicts with the ethical norms governing clinical research.^{1,13} First, it violates the principle of respect for persons by infringing the right of prospective research participants to choose whether to participate in research based on full disclosure of relevant information. Second, it may manipulate individuals to volunteer when they would otherwise not have chosen to do so had they been informed accurately about the nature of the research, including its use of deception. For these reasons, deception as it is currently practiced in many clinical research studies is incompatible with informed consent.

Finally, deception in research raises ethical concern because it can be corrupting for the professionals who practice it and for those who witness it. According to an ancient perspective in moral philosophy, moral character depends on habits of conduct.¹⁴ The use of deception in research may interfere with the disposition not to lie or deceive persons. This problem is compounded when the study design requires deception at the initiation of the trial, as well as maintenance of the deception during the conduct of research. Those who witness deception, especially if performed or sanctioned by professionals in positions of authority, may develop skewed perceptions of the ethics of deception, which may have negative consequences for the development of moral character. For these reasons, deception in research is *prima facie* wrongful.

The Harms of Deception and the Value of Deceptive Studies

The previous section concludes, as most commentators assume, that deception in clinical research is *prima facie* unethical, but can be justified in some circumstances. Hence, much of the debate concerns the extent to which deceptive studies should be permitted: Should deceptive studies be allowed in a relatively broad range of cases, or in extraordinary circumstances only? This debate over balancing the costs of deception against the value of deceptive studies occurs for two general kinds of studies.

First, in some cases investigators must deceive research participants to answer the scientific questions posed by the study. Earlier, we considered some examples of drug expectancy studies that pose just this dilemma. Assuming that there is no way to assess the effects of expectancy without deceiving the research participants, institutional review boards (IRBs) must determine whether the value of answering these questions justifies the harms of the deception involved. This is a difficult calculation to make; it is an impossible calculation to make unless one has some estimate for the potential harms of deception. It is worth noting that this calculation is made all the more difficult by the fact that an individual study rarely, if ever, definitively answers any given scientific question on its own. Only a series of studies, including future studies that may or may not occur, and which are usually not under the purview of the reviewing IRB, can answer the scientific questions posed by most trials.

A second, less examined need to balance the potential harms of deception against the anticipated value of deceptive research arises with respect to studies in which the use of nondeceptive means is theoretically possible, but is to varying degrees difficult or impractical. For example, one experimental paradigm for studying aggression in humans challenges participants to accumulate points by typing into a computer that, they are told, is connected to another computer operated by someone who may steal some of their points. In fact, the participant's computer is programmed to occasionally, and arbitrarily, subtract points from the participant's accounts. The investigators measure aggression as a function of how participants respond to these "thefts" by attempting to steal points from their "opponents." There are nondeceptive alternatives to this paradigm. Most simply, the researchers could hire assistants to sit at a second computer that is connected to the participants' computer. This person could type in the responses that the computer program now enters, thus producing a nondeceptive study. Should IRBs require investigators to adopt this methodology instead? Is this study feasible and effective? Presumably, the person entering the data will make more mistakes than the computer and may not end up entering truly random responses. It follows that this alternative study design will require more resources. It will require hiring assistants and setting up a second computer in a different room. In addition, given the uncertainty regarding the data entry of the "responding" research assistant, the alternative study design will likely yield somewhat less powerful results.

Whether an IRB should mandate this alternative design depends on the balance of the potential harms of deception against the anticipated value of the study and the costs of requiring an alternative design. Some might argue that the risks of the study amount to the potential harm that might result from the participants' having their points stolen and how they respond to these thefts. The use of deception does not increase the risks of the study, hence there is no reason to require the investigators to pursue a more costly nondeceptive approach. In response, one could just as easily argue that this design offers a clear example of a deceptive study with a feasible, and effective, nondeceptive alternative. Granted, the alternative design introduces an extra variable. But the alternative study is relatively straightforward and the mistakes that the computer operator makes could be isolated and controlled for. Thus, on this view, one might conclude that the investigators should be required to pursue the nondeceptive alternative. To resolve this debate, we need to determine to what extent deception harms research participants.

Empirical Data on the Harms of Deception

A number of studies have found that deception does not upset most participants.^{15–18} In a study of participants who had been deceived in psychology experiments, Epley and Huff found "little negative impact." Indeed, Smith and Richardson report that those who had been deceived in psychology experiments rated their overall experience as more positive than those who had not been deceived. Although these findings seem to suggest that deception itself poses no risk to participants, thus seeming to confirm Milgram's findings that the deception he used did not harm his participants, there are reasons to question the data and their relevance to clinical research. First, the data focus on healthy college un-

dergraduates participating in psychology experiments. Yet healthy college students may have a different attitude toward being deceived than patients participating in clinical trials.¹⁹ Second, it is estimated that approximately one-third to one-half of psychology experiments use deceptive techniques.^{20,21} Given the prevalence of deception, combined with widespread debriefing, college students may *expect* psychology experiments to be deceptive.^{22–25} Hence, the existing data may reflect the attitudes of participants who expect to be deceived, not the attitudes of those who assume they are participating in nondeceptive research.

Third, the relationship between investigators and participants in psychology studies may minimize the impact of deception. Deception is morally problematic in part because it involves a violation of trust in a relationship. The trusted deceiver manipulates the beliefs of the deceived and thereby undermines their ability to make autonomous decisions. On this analysis of the harm of deception, one would expect that the degree to which individuals are bothered by deception will depend in part on the extent to which they are dependent on the deceiver.^{26–28} We expect those we trust and depend on to look out for our interests and support our making decisions for ourselves. As a result, we are more vulnerable to deception by them.

Young, healthy college students are unlikely to rely a great deal on psychology experimenters, whereas patients often invest a great deal of trust and hope in clinical investigators. Thus, deceiving patients in the research setting has the potential for greater harm, especially if it undermines patients' trust in physicians in general. For instance, in a study by Fleming and colleagues concerning alcohol use (discussed below), a majority of the individuals who were upset by being deceived stated that the use of deception would "lower their trust in the medical profession." In this way, investigators deceiving participants seems to conflict with physicians' obligations to earn and maintain the trust of their patients.²⁹

Fourth, the majority of these studies assess the impact of deception by deceiving participants, debriefing them, and then asking whether they found the deception troubling. Because people do not like to view themselves as victims, under the control of others, they may downplay the effects of deception, particularly when asked by the individual who deceived them in the first place.^{30,31} Finally, some of these studies assessed the impact of the deception after some time had elapsed. This is most clear in the case of Milgram's follow-up studies, which occurred years after the original experiment. It seems plausible to assume that any harms caused by deceiving participants would diminish over time.

These differences suggest that the psychology data provide little insight into the impact of deception on participants in clinical research. Moreover, despite the long history of deceiving participants in clinical research, few clinical investigators have attempted to gather data on its effects. To assess the generalizability of these data, IRBs that approve deceptive clinical studies should consider obtaining data on the impact of the deception, perhaps as part of the debriefing process. Indeed, it seems reasonable to argue that IRBs that approve deceptive studies should require the investigators to collect such data. These studies are being approved on the basis of assumptions about the harms caused by the deception. It seems reasonable for investigators and IRBs to systematically collect data to assess whether the IRBs' assumptions in this regard are accurate. Until such data are collected, assessment of the extent to which deceptive clinical research harms research participants must be based on more theoretical considerations.

It is worth noting a potential conflict between reducing the harms of deception versus reducing its wrongs. One might argue that debriefing remedies the wrong of deception to some extent by informing research participants that they were deceived. Debriefing may also limit the social harms of deceptive research by establishing a clear policy by which deceptive actions are disclosed, thereby notifying research participants in general that deception is not widespread and unreported. Debriefing, however, is likely to increase the extent to which deception harms research participants. Presumably, research participants who never realize and are never told that they were deceived will not experience psychological harm. Hence, some might argue that investigators should err on the side of no debriefing as a way to protect research participants from experiencing harm.

Theoretical Harms of Deceptive Clinical Research

Studies that fail to inform participants prospectively of the use of deception conceal the possibility that participants may experience distress once they are deceived. Those who learn that they were deceived may also lose trust in investigators, reducing the pool of potential research participants. Research participants may be harmed even when they are not upset by the use of deception. Being in control of one's life is central to human dignity and self-respect; hence, the fact that investigators fail to respect the autonomy of research participants by deceiving them may be harmful. The knowledge that medical researchers are sometimes deceptive may undermine the public's trust in the research enterprise. Finally, deceiving participants may have an adverse effect on clinicians, who are trained to promote the best interests of their patients.^{32,33} These burdens may be exacerbated when participants inadvertently inquire about the misdescribed aspects of the study. To avoid such situations, researchers may minimize the opportunity for participants in deceptive studies to ask questions, further vitiating the informed consent process.

These concerns, although genuine, are largely theoretical. Hence, they leave IRBs in the position to choose, in the absence of sufficient data, whether to allow deceptive clinical research or not. Stopping all deceptive clinical research until sufficient data are collected would halt important research. Moreover, the effects of deception may be impossible to assess in the absence of deceptive studies that deceive participants and then assess the effects. Continuing to conduct deceptive clinical research also seems problematic, especially given social norms against deception and the possibility that use of deception may cause serious distress to some participants.

Regulations and Guidelines Governing Deception in Research

National and international guidelines regarding research with humans uniformly require participants' informed consent in most cases. Guidelines that mandate informed consent without exception may inadvertently prohibit deceptive research. For example, guidelines that require participants to be informed of the purpose of the research may effectively prohibit research whose validity depends on participants not being prospectively informed of the study's purpose.

Many guidelines do not address deception explicitly, but allow investigators to alter some or all of the elements of informed consent in some circumstances, typically when the risks are minimal. For example, U.S. research regulations allow IRBs to approve research that "does not include, or which alters, some or all of the elements of informed consent" provided that several conditions are satisfied, including the requirements that the risks are minimal and the research could not "practically" be carried out without the alteration.³⁴ Hence, IRBs may approve deceptive studies provided they find that the studies pose no greater than minimal risk to participants.

Other guidelines address the issue of deception explicitly, typically leaving the decision of whether to approve the deception up to the reviewing IRB or research ethics committee. The research guidelines from Nepal state, "A special problem of consent arises when informing participants of some pertinent aspect of research that is likely to impair validity of the research. Such circumstances should be discussed with the [ethical review boards] who will then decide on the matter."³⁵ Similarly, the Brazilian regulations state that "when the merit of the research depends on some restriction of information to the subjects, such facts should be properly explained and justified by the research and submitted to the Committee of Ethics in Research."³⁶ And according to the Tanzanian guidelines, participants must be informed that treatments will be allocated at random, although "[e]xceptional cases are where there is an argument for not telling the patient the truth, and must be subject of the IRECs [institutional research ethics committee]."

Some guidelines draw a distinction between deception by lying to participants versus deception as the result of withholding pertinent information. The Indian guidelines state that "[d]eception of the subject is not permissible. However, sometimes information can be withheld till the completion of the study, if such information would jeopardize the validity of the research."³⁸ Guideline 6 of the guidelines produced by the Council for International Organizations of Medical Sciences (CIOMS; see Chapter 16) has one of the most extensive discussions of deception in research, arguing, "[a]ctive deception of subjects is considered more controversial than simply withholding certain information."³⁹ The CIOMS guidelines further state, "[d]eception is not permissible, however, in cases in which the deception itself would disguise the possibility of the subject being exposed to more than minimal risk" and stipulate that the "ethical review committee should determine the consequences for the subject of being deceived." The same approach is suggested by the Belmont Report (see Chapter 14), which allows investigators to "indicate to subjects that they are being invited to participate in research of which some features will not be revealed until the research is concluded." Importantly, the Belmont Report allows withholding information only when necessary and does not allow it in "cases in which disclosure would simply inconvenience the investigator."⁴⁰

One of the most detailed guidelines regarding deception in research is the *Ethical Principles of Psychologists and Code of Conduct* produced by the American Psychological Association.⁴¹ The *Principles* allow investigators to deceive subjects when the following four conditions are satisfied:

1. The use of deception is justified by the study's significant value.
2. Any equally effective, nondeceptive approaches are not feasible.

3. Deception is not reasonably expected to cause physical pain or severe emotional distress.
4. Any deception is explained to participants, preferably at the conclusion of their participation, but no later than the conclusion of the research, and participants are allowed to withdraw their data.

The second condition's requirement of *equal* effectiveness seems to conflict with the assumption that deception is *prima facie* unacceptable. If this assumption is correct, it follows that we might prefer a nondeceptive study even if it is somewhat *less* effective, because the harm incurred by the decrease in effectiveness might be outweighed by the good that is achieved in avoiding the deception.

The third condition attempts to address the concern that deception conflicts with respect for participants' autonomy by requiring that participants are not deceived in the context of studies that are reasonably expected to cause physical pain or severe emotional distress.

Briefly, we can think of harms as states of affairs that conflict with the interests of the individual harmed. For instance, physical integrity is in most individuals' interests. Therefore, states of affairs that involve destruction of physical integrity harm the person in question. States of affairs that conflict with individuals' moral interests, in contrast, are standardly understood not as harms, but as "wrongs." The third condition attempts to ensure that, as long as the use of deception does not conceal the potential for physical pain or severe emotional distress, it will not alter the enrollment decisions of prospective participants. In other words, as long as this condition is met, one might assume that participants who consent to a deceptive study would have consented even if that study had not been deceptive. This then leaves IRBs with the task of determining whether the social value of the research justifies the use of deception. One might assume that as long as the deception does not conceal risks of physical pain or severe emotional distress, then studies with essentially any social value can justify the deception, because the use of deception will not increase the risks to participants. This line of reasoning, however, ignores the possibility that the deception itself might pose a risk to participants.

Assessing Participants' Desire for Control

There are some data relevant to assessing the extent to which deception itself harms individuals. One example comes from alcohol research. Gathering accurate data on alcohol abuse is complicated by the fact that alcoholics often provide misleading information when asked direct questions about their alcohol use. To address this problem, some investigators have studied the acceptability of concealing the intent of alcohol abuse questionnaires by including questions about smoking, weight, exercise, and drug use. Under this design, participants are provided with "general health" questionnaires without being informed that the investigator's research interests are limited to the alcohol use questions.

At the end of one study, the investigators debriefed the participants and assessed the impact on them of the deception itself.²⁹ The data reveal that one-third of the participants were upset by the deception, but of these, two-thirds supported the study and said that they would be willing to participate again. The authors regard

the relatively high number of participants who were willing to participate again, combined with the importance of accurate information on alcohol abuse, as showing that these kinds of deceptive studies are ethically acceptable.

But as previously noted, there are reasons to question whether individuals, once deceived, will accurately report how much the deception bothered them. Leaving that concern to the side for the moment, these same results tell us that one-ninth of the participants were upset by the deception to the point of refusing future participation. Importantly, these individuals had been told in advance the truth about the nature of the study, including its risks, the lack of expected benefit, the procedures involved, and the possible alternatives. The deception involved the minor point that the researchers were interested in a specific aspect of the participant's health, rather than the participant's health in general. And yet, a significant percentage of the participants were bothered enough to be unwilling to participate in such research again.

Presumably, many of these participants were upset not by the fact that the researchers were interested in alcohol use, but by the use of deception itself. This conclusion supports a piece of common sense: At least some people are upset by the mere fact of being deceived, independent of the nature of that deception, especially when the deception is for the benefit of others. It follows that no matter how carefully we minimize the *extent* of deception, for example along the lines of the American Psychological Association's *Principles*, deception still poses risks to some participants without their consent. Of course, most guidelines allow the use of deception only when the risks are minimal. However, this assessment is typically made by considering whether the deception conceals any significant risks from the participants, thus ignoring the possibility that the use of deception itself may pose risks to some participants.

Individuals who are upset by the use of deception *per se* are, presumably, those who place a high value on being in control of their lives. Therefore, taking control of these individuals' lives by deceiving them without their consent involves a contradiction of one of the values that is most important to them as persons. The fact that at least some are upset by deception *per se* establishes that even if the deception involved in a particular study does not conceal any risks that are present independently of that deception, the deception itself introduces a new risk into the study. And allowing studies that fail to inform participants of this risk contradicts the requirement that participants may not be put at risk without their consent. The most obvious way of avoiding this harm would be to treat the risk presented by the use of deception in exactly the same way that we treat all the other risks involved in research participation: Inform participants of the presence of that risk. The possibility suggests the need for "authorized" deception.

The Principle of Authorized Deception

It is widely assumed that deceptive clinical studies force investigators and IRBs to choose between respecting personal autonomy and collecting valid data. This assumption neglects the possibility that prospective participants can be informed of the deception and asked to consent to its use, without being informed of the nature of the deception. For instance, investigators who conduct deceptive research could include the following statement in the informed consent document:

You should be aware that the investigators have intentionally misdescribed certain aspects of this study. This use of deception is necessary to conduct the study. However, an independent ethics panel has determined that this consent form accurately describes the major risks and benefits of the study. The investigator will explain the misdescribed aspects of the study to you at the end of your participation.

For studies designed to deceive participants by *withholding* information, as opposed to providing false information, the first sentence might read: "You should be aware that the investigators have intentionally left out information about certain aspects of this study."

We have seen that deception *per se* presents a risk to participants; at least some are harmed when they are deceived, and others may have relevant idiosyncratic concerns that never get revealed because of the deception. Authorized deception warns participants of these risks. Therefore, potential participants who are bothered by deception *per se* will be able to avoid deceptive studies, those with idiosyncratic concerns will have the opportunity to reveal them, and others will have the opportunity to consent to being deceived. Authorized deception also removes any harm to the research team that is incurred when members of the team are required to deceive participants without their consent.

By alerting participants to the use of deception, authorized deception goes as far as possible in respecting the autonomy of research participants while permitting deception needed to generate scientifically valid data. Authorized deception also blocks the undermining of participants' and the public's trust in science and medicine by flagging those studies that are deceptive, and it justifies exposing participants to deception not in terms of the potential benefit to others but in terms of the participants' consent to that deception.

Objections to Authorized Deception

There are a number of possible objections to the use of authorized deception in clinical research. We raise and respond to three broad areas of concern below.

Concerns About Informed Consent

Some might argue that valid consent requires that participants know the exact nature of all the procedures they will undergo. On this view, people cannot provide valid consent, even when informed of the use of deception, because they do not know the true nature of the misdescribed procedures. In order to provide fully informed consent, they would have to know the nature of the deception as well. They would have to know what they are being deceived about.

We can grant that participants cannot provide fully informed consent as long as they are unaware of the nature of the deception and as long as we understand "fully" in a literal sense. However, as is widely acknowledged, participants never know everything there is to know about any study. There is simply too much to know. Therefore, in order to argue that authorized deception precludes informed consent, one would have to show that the information participants fail to obtain as the result of deception casts doubt on their consent in a way that the other information they never re-

ceive does not.⁴² For instance, prospective participants need to be informed of the risks and potential benefits of study medications because most people care about this information and it might affect reasonable persons' willingness to participate; however, they typically need not be informed of the precise doses of the medication because this is a technical detail that is unlikely to affect their willingness to participate. This widely accepted analysis suggests that investigators can conduct deceptive clinical studies and still obtain valid consent as long as they do not deceive participants about any aspects of the study that would affect their willingness to participate or aspects of the study that individuals are likely to want to know prospectively.

To implement this approach, IRBs must decide which aspects of a given study might affect participants' willingness to participate. Because enrollment decisions depend upon the risks and benefits of the research, IRBs should approve deceptive studies only when the deception does not conceal significant risks or misleadingly promise significant benefits. The burden of proof should be on investigators to show why any deception regarding risks or benefits is necessary. In some cases, it may be acceptable to deceive participants about minimal risks.

When reviewing deceptive clinical research, IRBs should also consider whether the potential participants have idiosyncratic concerns that might affect their willingness to enroll. For instance, deceiving participants about the ingredients in a study drug typically would not affect their willingness to enroll. Yet such deception might be problematic if it conceals ingredients to which the participant population would strongly object, such as bovine-derived products for a Hindu population.

Authorized deception requires IRBs to use their judgment to assess what aspects of a given study might affect participants' willingness to participate. Of course, IRBs might get these judgments wrong in certain cases, and allow investigators to deceive subjects about aspects of the study that would have affected their willingness to participate. Given this possibility, IRBs should err on the side of caution, requiring investigators to accurately inform participants of all aspects that, in the judgment of the IRB, might affect their willingness to enroll.

Granting the potential for mistakes, it is important to note that this potential is not unique to deceptive studies. Informing participants of every aspect of a given study, including all the ingredients of every drug and every remote theoretical risk, would only confuse participants and undermine their informed consent. For this reason, investigators and IRBs must decide which aspects of the study might affect participants' willingness to participate every time they decide what information should be included in a consent form.

Similarly, most regulations allow IRBs to waive the requirement for informed consent when the research poses no greater than minimal risk and there are good reasons not to obtain informed consent. Assuming it can be ethical to conduct clinical research that the IRB deems to pose only minimal risks without consent at all, it seems acceptable to conduct otherwise ethically appropriate, deceptive research when the IRB judges that the use of deception poses no greater than minimal risks to participants.

Some might respond that this analysis ignores the fact that deceiving participants is different from withholding information from them. In cases of deception, participants fail to have certain information not because there is too much information to convey,

but because they are being deceived. As a result, participants end up with false beliefs about the studies in which they are participating. Clearly, there is a difference between the two cases. However, it is not clear that this difference makes an ethical difference. Authorized deception informs participants of the use of deception, and provides them with the opportunity to consent to its use. Therefore, the deception per se will not make an ethical difference between the two cases. The participant, not the researcher, is in control of deciding whether the person participates in a deceptive study. In addition, the fact that the participant ends up with false beliefs, rather than no belief at all, does not seem to make an ethical difference either. It all depends on whether the issue in question is relevant to providing informed consent. And, as we have seen, relevance to informed consent gets decided using the same method in both cases: Is the information relevant to the participant's decision to enroll? If the answer is "no," then in both cases withholding that information does not cast doubt on the person's informed consent.

In some cases, however, there may be an important difference between a study that uses authorized deception and one that simply does not inform participants of particular aspects of a study, on the assumption that the aspect is irrelevant to the decision of whether to enroll. In the latter case, investigators can solicit from prospective participants any individual concerns that might be relevant to the research. Of course, it may not occur to participants that a particular concern of theirs is relevant to the research. Hence, this approach is not guaranteed to uncover concerns. Yet some participants would likely reveal concerns. For instance, some Jehovah's Witnesses might present their views regarding receipt of various blood products.

In the case of research using deception, however, individuals might not reveal idiosyncratic concerns that happen to coincide with the aspects of the study relevant to the deception. If the study's informed consent form explicitly and inaccurately stated that participants would not receive any blood products or bovine-derived products, it seems unlikely that participants would reveal these concerns. The use of authorized deception might partly address this concern. When told that they are being deceived about some aspects of the study, potential participants might think to reveal these concerns. When it is felt that some participants might be especially bothered by some aspects of the study over which they are being deceived, the IRB could consider requiring a focus group of relevant participants to assess their views. For instance, a recent study of the impact of direct-to-consumer advertising on physician prescribing behavior failed to state in specific terms the purpose of the study.⁴³ It is unclear whether this is something that would bother these participants, a question that could be addressed by conducting a preliminary focus group of similar physicians.

Concerns About Study Data

Others might object that authorized deception could confound a study's data if informed participants tried to discover which aspects of the study have been misdescribed. Granting this possibility, the fact that many participants currently recognize the existence of deceptive studies suggests that this possibility may already be present.⁴⁴ Just as participants in placebo-controlled trials may try to guess whether they received the study drug or placebo, so informing participants about the use of decep-

tion might stimulate them to try to guess the nature of that deception.

There are several ways in which this effect can be reduced. First, researchers should make a clear offer of debriefing at the study's end. Knowing ahead of time that they can eventually learn the nature of the deception should reduce participants' desire to discover it for themselves. In addition, by disclosing the use of deception and explaining that it is necessary to generate valid data, researchers might enlist participant cooperation in maintaining the deception. For instance, participants can be asked ahead of time to focus on the procedures specifically asked of them, and researchers can explicitly limit any probing questions.

Some experimental evidence indicates that authorized deception would not necessarily bias the responses of research participants. For example, two groups of psychology students were exposed to a deceptive experiment in which they were falsely informed that they would receive two to eight "painful electric shocks" at random times after a red signal light appeared.⁴⁵ No shocks were actually administered. Measures of self-reported anxiety and physiological arousal (pulse and respiration rates) were obtained. Prior to the deceptive shock intervention, one experimental group was informed that deception is occasionally used in psychology experiments to assure unbiased responses. The other group exposed to the deceptive shock intervention did not receive any information about the possibility of deception. No outcome differences were observed for participants informed of the possibility of deception versus those not informed.

The information about deception in this experiment, however, falls short of the authorized deception approach that we recommend. It disclosed to prospective participants that deception is a possibility in "a few experiments" rather than informing them that deception would actually be employed for all or some participants in the particular experiment in which they were invited to enroll. In contrast, Wiener and Erker directly tested the authorized deception approach, described as "prebriefing," in an experiment evaluating attributions of responsibility for rape based on transcripts from an actual rape trial.⁴⁶ Participants (68 undergraduate psychology students) were either correctly informed or misinformed about the jury verdict regarding the defendant's guilt. Half of participants received an informed consent document stating "You may be purposefully misinformed." The other participants were not alerted to the possibility of deception. No differences on attribution of responsibility were observed depending on whether or not the participants were prebriefed about the use of deception.

The results of studies that use authorized deception, however, may not be comparable with the results of previous studies that did not use this approach. This is a genuine methodological concern, which must be weighed against the countervailing ethical concern. When preservation of data comparability is an issue, IRBs should decide whether it is of sufficiently compelling value to warrant waiving the requirement for authorized deception.

The use of authorized deception also may reduce accrual if people refuse to participate in studies they know to be deceptive. This possibility could undermine the generalizability of the data, especially if particular groups are more likely to avoid deceptive studies. Conversely, the use of authorized deception may increase the available pool of research participants in the long run, by reducing the number of those who refuse to participate in future research after being deceived. Currently, there are no data to make

this assessment either way. On the other hand, there is clear evidence that deception upsets at least some people, violates respect for personal autonomy, and may cause problems for the research team. In addition, even if it turns out that authorized deception adversely affects accrual, it does not necessarily follow that authorized deception should be rejected. A finding that authorized deception substantially decreased accrual would suggest that people are especially bothered by the use of deception. Hence, we would have even more reason to argue that the use of deception *should* be revealed during the consent process.

Concerns About Harms

The argument for authorized deception assumes that people accurately gauge the extent to which being deceived will bother them. If this is not so—if, for instance, awareness of the use of deception concerns participants far more than actually being deceived would bother them—then authorized deception would make research less effective without making it significantly less harmful. In general, participants are more likely to be upset by the prospect of deception if they think that the deception might be concealing some risks involved in the study. The solution (to the extent that this is actually a problem) would be to explicitly state that the deception involved in the study does not conceal any risks. In the end, which alternative we should adopt depends upon how participants react to the use of authorized deception. Thus, a final decision will have to await the appropriate studies called for previously.

Conclusion

Deception in clinical research and valid informed consent are not necessarily incompatible, as is widely assumed. However, IRBs should consider allowing deceptive research only when the following conditions obtain: (1) the use of deception is necessary to achieve the goals of the study; (2) the use of deception is justified by the study's social value; (3) people are not deceived about aspects of the study that would affect their willingness to participate, including risks and potential benefits; (4) people are informed of the use of deception and consent to its use; and (5) people are informed of the nature of the deception at the end of their participation. To be sure, deception about the purpose of a study that is authorized in advance by participants is not *strictly* compatible with informed consent, because accurate disclosure about a study's purpose is a basic element of informed consent. However, if there is no reason to think that prospective participants would decline to participate if they knew the true purpose of the research, then authorized deception is compatible with respect for autonomy and thus with the spirit, if not the letter, of informed consent.

The use of authorized deception—an approach that generally has been neglected by researchers and IRBs—respects personal autonomy by putting participants in control of whether they are deceived; it minimizes the harms of deception to the participants; it removes the possibility that the use of deception will undermine one's willingness to participate in clinical research; it minimizes the possibility that the use of deception will undermine public trust in research; and it minimizes the burdens of conducting deceptive research on the research team.

Epidemiology

Observational Studies on Human Populations

“Everyone wants to be an epidemiologist,” declared the former chair of epidemiology at Harvard University. This rather bold claim, part of a plenary speech at a recent international meeting of epidemiologists, may come as a surprise to those who, quite happy with their current vocation, had never considered epidemiology a career option. The underlying premise of this distinguished cancer epidemiologist’s message was that epidemiologic studies are increasingly at the center of nearly every public discussion of health and medicine. AIDS, SARS, avian flu, Agent Orange, Gulf War syndrome, the safety of silicone breast implants, and the value of hormone replacement therapy (HRT) are only a few examples of recent issues with epidemiologic studies at the center of the controversy. Add to this list the usual culprits responsible for most of the death and suffering of any community—heart disease, cancer, diabetes, injuries, accidents (now called unintentional injuries, as opposed to intentional injuries), conditions related to aging, and infectious diseases—and epidemiology’s special relevance to public health becomes clearer.

Epidemiology, focusing its scientific method on the etiology and prevention of human disease, matters to the health of individuals and populations in a unique and powerful way. Those concerned about their health and the health of their communities need to appreciate the role that epidemiology plays in the science and practice of preventive medicine and public health. Epidemiologic methods, how results are interpreted, and what interventions arise from them have become increasingly important components of the education and training of health professionals. Physicians, nurses, public health practitioners, public policy makers, and those who will call themselves professional epide-

miologists spend years learning the concepts, methods, and interpretative processes of epidemiology.

The legal profession is also interested in what epidemiologists do and what epidemiologic research means for their clients. Epidemiology rates its own chapter (alongside others on statistics, toxicology, and DNA evidence), in the Federal Judicial Center’s *Reference Manual on Scientific Evidence*.¹ The epidemiologist’s expertise in designing and interpreting studies of disease etiology and prevention has become a central (and often contentious) problem in deciding who should be compensated in toxic tort liability cases. Relating the population-based findings of epidemiologic research—general causation—to the cause of disease or death in an individual—specific causation—is at the heart of this difficult legal matter, with significant financial incentives for defendants, plaintiffs, and for their legal teams. The multibillion-dollar tobacco settlement is an excellent case in point.²

Epidemiology is also of great interest to the media. In the final weeks of writing this chapter, television, print, and web-related news companies reported the findings of a large epidemiologic study showing an association between taking antibiotics and subsequent increased risk of breast cancer. Reporters asked the investigators whether women should reconsider taking these medications if they are concerned about their risk of breast cancer. The long-winded answer (too long for the television sound bite) is that this finding could be a false alarm or it could be an early fair warning to women; deciding which explanation is more likely will require a careful examination of the results of other (earlier) studies, future analyses of similar data from different populations of women, and considerations of the so-called biological plausibility

of the systematically collected and summarized findings, the time course of the relationship between onset of antibiotic usage and onset of cancer, and a host of other considerations to be discussed later in this chapter. Simply put, there is a sense—some might call it a misconception—in the media and in the public at large (two groups with relatively little understanding of the complexities and difficulties of interpreting observational epidemiological research) that a single “scientific” finding—in this case, an epidemiological finding—is true enough to warrant immediate public action. Rarely is that the case. More often, a single study provides the professional public health community with a starting point for further research, considerable discussion and debate, and (hopefully) the correct judgment regarding what should be done about it.

It is fair to say that misconceptions abound about the importance and nature of epidemiology among scientists and laypersons alike. Physical and biological scientists often have the impression that epidemiology is a severely limited, “soft” science, too weak to provide reliable, objective knowledge.³ The public, on the other hand, is jokingly perceived among the ranks of epidemiologists as being so ignorant that it confuses the study of epidemics, disease causation, and disease prevention with dermatology (the medical specialty treating skin diseases). The media, whose role in society is to inform the public of interesting stories, does not have the responsibility for teaching the fine points of epidemiologic study design, analysis, and especially interpretation. Part of the problem is that epidemiology has traditionally been taught primarily at the graduate level as a specialty topic for health-care professionals and for those who will use its population-based findings in public health or preventive medicine practice, as well as for future research epidemiologists. Small wonder the public is confused about the relevance and significance of epidemiologic findings.

Against this backdrop of wide relevance, keen interest, and unfortunate misunderstanding, we discuss the ethics of epidemiology. Understanding the ethics of epidemiologic research is important because, as we will describe in detail, public and private values and norms are intimately linked to the science and practice of epidemiology in public health and preventive medicine. For those who recognize epidemiology as their profession and for those who use epidemiologic methods, it is important to perform, interpret, disclose, and apply the results of these studies in the best ethical tradition. We believe therefore that there is a need to develop a deep understanding of the ethics of carrying out epidemiologic research and the ethics of applying that knowledge for the prevention and control of disease and for the promotion of health.

In this chapter, the ethical issues are discussed from the perspective of those who carry out the studies and those who practice epidemiology as a professional vocation. Not everyone who employs the methods of epidemiologic research—generally, observational methodologies—is a member of the profession. This situation leads to some interesting and provocative problems involving the societal roles and responsibilities of epidemiologists to be discussed later in this chapter.

What Is Epidemiology?

It is important to understand the definition of *epidemiology*. Epidemiology is the study of the distributions and (causal) determi-

nants of health states in human populations and the application of the knowledge gained to health promotion as well as disease prevention and control.⁴ Epidemiology is sometimes more narrowly defined in terms of its characteristic methods, but we will resist that temptation, emphasizing that for us epidemiology is a professional practice with its own evolving terminology, cardinal concepts, a characteristic methodological framework, and significant social responsibilities. We will not, however, describe its concepts and methods in detail, other than to distinguish observational studies (the sorts of studies referred to as *epidemiological*) from randomized controlled trials, whose ethical issues are discussed elsewhere in this text. The terminology of epidemiology and glossaries of ethical terms relevant to it can be found in recent publications,^{4–6} and several textbooks provide excellent descriptions of epidemiological methodology.^{7–13}

Epidemiologic studies are typically observational; the investigator does not intervene on an individual participant under study beyond physical measurements (such as drawing blood for analysis, taking blood pressure, or measuring height and weight) or questions about demographics (age, gender, ethnicity), social factors (income, education, marital status), lifestyle factors (diet, exercise, smoking) and medical history (previous heart attacks). For communities, epidemiologic studies assess environmental and contextual factors such as air quality, social cohesion, housing, availability of public health programs, and public policies. Epidemiologic study methodologies can be used to examine the impacts of interventions imposed upon (e.g., mandatory immunizations) or chosen by individuals (e.g., smoking cessation), communities (e.g., water treatment), and populations (e.g., dietary changes).

Epidemiologic studies are typically categorized as surveillance studies, cross-sectional surveys, case-control, and cohort studies with subtypes of each. They can be either retrospective (looking back in time) or prospective (looking forward). They can include measurements of molecular phenomena (e.g., the expression of DNA repair genes), personal habits (e.g., smoking behavior), environmental phenomena (e.g., air pollution), or social phenomena (e.g., income differentials between ethnic groups). Indeed, the genius of the epidemiologic approach is that it can integrate a broad range of potential health determinants and outcomes; in the past few years subspecialty areas within the discipline have emerged such as molecular epidemiology,¹⁴ clinical epidemiology,^{15–17} and social epidemiology,^{18,19} adding to the traditional disease-oriented subdisciplines of chronic disease epidemiology,²⁰ psychiatric epidemiology,²¹ and infectious disease epidemiology,^{22,23} to name a few. Most epidemiologists pride themselves on their methodological expertise; a few have undertaken the task of describing the theoretical and philosophical foundations of the field; not many more have examined the ethical foundations of their practice. Indeed, a concerted effort to discuss ethics in epidemiology arose primarily within the professional ranks only as recently as the late 1980s.

Ethics is but one of several philosophical disciplines relevant to epidemiology. Epistemological problems and other issues related to the acquisition of knowledge and interpretation of evidence have received attention in the epidemiological literature.^{24,25} Ontological and conceptual issues, such as the nature of causation, health, and disease, have also been examined. It is sometimes difficult to divorce epistemological and ontological issues fully from ethics, especially when discussing how epi-

miologic studies should be designed and how epidemiologic results should be applied to populations. Underdetermination and its cousin, uncertainty, have important influences on any scientific discipline whose findings are applied and have such a profound impact on the well-being of human populations.²⁶ We will nevertheless focus primarily on ethics.

Major Categories of Ethical Concerns and a Brief History of Ethics in Epidemiology

For ease of presentation, we will discuss two major categories of ethical concerns: ethical issues in the conduct of observational studies, and ethical issues arising from the application of the scientific understanding—the knowledge—that emerges from epidemiologic research. It will be helpful to begin with a brief history of ethical inquiry applied to epidemiology.

One of the fundamental principles of bioethics is respect for persons, grounded in the Kantian imperative that people should always be treated as ends in themselves and never *merely* as means to an end. It is the major foundation for the obligation for informed consent in research and treatment, but it also informs decisions concerning study design and implementation.⁵ (The emphasis is added to indicate that research participants are, in fact, means to an end, but they should not be treated *solely* as instruments for our ends.) In most bioethics discussions of this principle, the emphasis is on respecting autonomy, typically in the form of self-determination and freedom from coercion, and protecting persons with diminished autonomy. That is, people should be free to decide for themselves for or against a treatment or participation in research, and the decision must be voluntary, without coercion or fear.

Beyond this aspect of respect for persons, however, there is respect for the dignity of the individual, which means that research is culturally sensitive and refrains from demeaning or disrespectful actions or situations as well as from intentional physical harm, reflecting yet another bioethical principle: non-maleficence. Nowhere in the history of epidemiology are these concerns for dignity, respect, and avoiding intentional harm more relevant than in what is widely considered to be the most infamous observational epidemiologic study ever undertaken: the Tuskegee Syphilis Study that came to public attention in 1972 (see Chapter 8). It is a classic example of an ethically reprehensible study and remains a sober reminder of the need for the appropriate ethical conduct of any scientific investigation of human subjects. There are many important ethical issues that arise from the Tuskegee experience: the choice of hypothesis, consent and coercion, the absence of benefit to participants, frank harm, a miscarriage of justice, and the responsibilities of professional “scientific” investigators toward the study participants. To this day, African Americans are reluctant to participate in some research studies due to the lingering effect of the Tuskegee disaster.

Yet despite the ethical importance of the Tuskegee Study as an exemplar, and despite the intense interest in it that was generated in the early 1970s, knowledge of its ethical significance remains outside the learning curves of many public health students; only 19% of graduate students surveyed at a major public health school in 1996 were aware of the ethical significance of the Tuskegee Study.²⁷ Part of the problem is that ethics in epidemiology has not yet been well incorporated into the curriculum of graduate epi-

demology programs. In addition, ethics in epidemiology was not widely discussed in the literature before 1990 when a conference was held on the topic and a set of ethical guidelines was proposed by academic and industry leaders in the field, assisted by Tom Beauchamp and other leading scholars.^{28–30} Several sets of ethics guidelines have appeared since that seminal conference,^{31–35} and more recently the broader public health community in academia and government has produced codes and guidelines, books, and scholarly articles on related topics.^{36–44} Other parallel developments such as the growth of the institutional review board (IRB) system, mechanisms for ensuring research integrity, and new federal privacy regulations on health-related information also impact the ethical practice of epidemiology.

The Nature and Ethics of Epidemiologic Studies

Contrasting observational epidemiological study designs to experimental (clinical trial) designs is a frequent point of departure for understanding the nature of epidemiologic studies and the ethics of conducting them. Observational epidemiologic research differs from clinical trials and community intervention trials primarily in the relationship of the investigator to the individuals or communities being studied. In trials, the protocol rather than the investigator determines the exposures given to research participants. In observational studies, as the name implies, the investigator only observes the effect of exposures or characteristics and does not manipulate or determine whether, how, when, where, and to what extent participants are exposed. The primary ethical implication of this difference has to do with the limitations on the exposures to which persons can be subjected in intervention trials research.

However, to assume that observational studies are thereby of less interest or have fewer ethical obligations is to overlook a number of rather profound issues. First, most intervention trials are undertaken with the possibility, if not the expectation, that at least some participants will derive benefit from the intervention. There are not similar added benefits from observational studies. That is not to say, however, that there are no benefits from observational studies. Sometimes observational study designs are used, for example, to study the impact of a voluntarily selected exposure with preventive potential, such as use of sunscreen as a skin cancer preventive. Typically, the direct benefits of observational research are small.⁴⁵ These studies are often justified in terms of the benefits to other persons similarly situated or to society more generally because of increased scientific understanding. However, the altruistic contribution of participating in a study for which one gains no direct therapeutic benefit can itself be a benefit to those who value making such contributions to society. Further, if the findings from the study are shared with the research participants, there is potential benefit both in increased understanding and, perhaps, even in risk reduction.

Another, less frequently emphasized difference between intervention trials and observational studies is that intervention trials assume a model of causality and test whether intervening in that causal web reduces adverse outcomes or enhances positive outcomes. Observational studies, in contrast, are typically directed toward elucidating the etiologic associations that make up the theoretical causal web, with much less attention paid to the form of the causal hypothesis in question. Counterfactual and other

causal definitions are matters of interest for more theoretically inclined epidemiologists, but these have not had a major impact on the design or interpretation of epidemiologic studies to date.⁴⁶

It is important to note that observational studies may involve sufficient contact with research participants that an intervention effect occurs. This goes beyond the classic Hawthorne effect (or the Heisenberg uncertainty principle as applied metaphorically to human research). There has been an assumption in some clinical circles, especially in cancer research, that patients enrolled in clinical trials have better outcomes, regardless of the arm to which they are randomly assigned, than those who are not trial participants.⁴⁷ However, the evidence for this “trial effect” is weak and, when it does occur, it seems to result from implementation of clear clinical protocols rather than participation in a clinical trial itself.^{48,49} The latter explanation supports the possibility of this effect occurring also in observational studies. This is especially evident in cohort studies or studies requiring several phases of data collection or monitoring. For example, the enrollment and tracking of a cohort of participants over several years requires frequent contact and reinforcement to maintain the participants’ continuing commitment to the study. That contact and the affirmation inherent in it constitute in themselves a kind of intervention. Newsletters may be used to maintain contact and as a way of providing feedback or useful information to participants.

Further, as the Tuskegee study so well illustrates, it is unethical for investigators managing an observational study to fail to respond if they detect adverse health problems in the study population. This means, for instance, that participants who suffer a serious problem during the course of a study should be referred for treatment. Even though such activities, along with the methods for tracking and retention, are not part of an intervention trial, they constitute a kind of intervention that might not otherwise have occurred for these participants. This means that investigators cannot assume that the natural history and etiologic associations observed in the study would directly duplicate the experience of a similar cohort who had not been part of such a study. However, the results would be applicable to participants if similar methods of screening, detection, diagnosis, referral, and continuing contact were to become general policy in communities, just as the use of standard clinical protocols in randomized trials may produce a “trial effect” that goes beyond the placebo effect. Such effects should also pertain to patients outside trials who receive the same protocol-driven treatment.

At the heart of the practice of epidemiology are methods and methodological decisions that often involve selection, trade-offs, evaluation, judgments, or other issues that evoke values or obligations and deserve ethical attention. The selection of a target population for an epidemiologic study requires considerations not only of suitability to the questions of interest and the availability or willingness of participants to be participants, but also the history of the populations. Is this a population that has been overburdened by research, without commensurate benefit or input into objectives, methods, implementation, or dissemination or application of results? Or is this a group that has been excluded or underrepresented in previous research, and therefore about which little is known?

Interest in understanding and addressing disparities in health status across population subgroups has grown in recent years. When previously overlooked groups are included in epidemio-

logic studies, such disparities become evident, as do avenues for research into causes of the disparity. In the United States, there are numerous examples of African Americans being excluded from research, especially clinical trials, or exploited in research.^{50,51} This history of exclusion or exploitation has not only deprived the African American population and public health community of the benefits that could have resulted from ethically and methodologically sound studies, but has also contributed to the mistrust and reluctance to participate that make such research now more difficult.⁵²

The principle of justice, as a basis for bioethical analysis, has two major domains, both related to distributive justice. The first has to do with the allocation of resources and the second with the burdens and benefits of research. It is this second aspect of the principle that concerns us here, though the first is relevant. For biomedical and epidemiologic research, this form of the principle of justice states that the burdens or risks and benefits of research should be fairly distributed within and across populations. No person or group should be asked to assume a greater share of the burden of research participation or the risks attendant to it without some ethical justification for that increased burden and without greater potential benefit commensurate with the increased burden or risk. All this assumes that the burden and risk is undertaken without coercion or deception and with full understanding, not only of what is being asked and of the attendant risks, but also that this person or group has been targeted for this research, and the justification for that focus.

Epidemiologists conducting observational studies should be sensitive to the history of populations studied and the risks and burdens they are asked to assume by participation, including risks of stigma related to findings. Further, researchers have an obligation to provide whatever benefit can be derived from the study to those who participate in the research. The nature of that benefit varies according to the nature of the study and the population, the resources available, and the findings. Indeed, a major argument of this chapter is that what we do with results of observational studies is an ethical issue deserving of greater attention.

In general, study design should take into account the particular needs and concerns of the population under study.⁵³ The elderly constitute another example of a population often either excluded or unnecessarily burdened by research because of a failure to account for their special needs or concerns. Special efforts may be required to respect their dignity, avoid embarrassment in data collection, or protect them from harms that might be of little concern to younger participants. Researchers should attend especially to issues related to consent, vulnerability, justice, and respect. Concerns of competence and comprehension may be obvious, but even considerations such as font size used in printed materials, allowing more time for building trust and for data collection, and providing a comfortable, reassuring setting may be critical.

The elderly may be particularly susceptible to even subtle coercion—a factor that should be taken into account during the consent process and in the wording and presentation of the research proposal. In addition to vulnerability related to consent, some elderly candidates may be at increased risk for harm from data collection that would otherwise be considered minimal risk, such as tests of balance, sensitive questions, and activities that could cause bruising. The special needs of the elderly may lead some researchers to exclude them, but that also raises questions

concerning the implications of excluding a population subgroup who may have very different outcomes, exposures, or associations. On the other hand, the burdens of research may be viewed rather differently by elderly participants, some finding the data collection onerous or embarrassing, and others finding it stimulating, exciting, or providing them with a sense of contributing to science. As with all populations, the question must be raised, to whom do benefits accrue?

Finally, as with all persons, elderly research participants should be treated with respect and care. This means protecting their dignity as well as protecting them from physical and psychological harm. Engaging the elderly participant as a partner in research not only may enhance the quality of the data obtained, but also may contribute to greater participation rates and provide a benefit to the participant.

Data in observational research is often collected by interview or questionnaire. Epidemiologists focus on how to obtain valid and reliable data, especially on sensitive topics, but the ethical issues often receive less attention. If we recognize that research participants are the source of the data on which our work depends, and that their provision of very personal information is a significant contribution to that effort, then their role as participants gains value. The relationship of researcher and research participant then becomes one of mutual trust and confidence, which entails certain obligations on the part of the researcher. This perspective is grounded in a view of the researcher-respondent relationship as one of voluntary mutual trust and commitments. This concept of mutual trust and obligations may require some elaboration because, although it is implicit in the informed consent process, it is not typically made explicit.

When a person agrees to participate in a research project—whether a clinical trial or an observational study—that person places trust in (and sometimes entrusts his or her life to) the researcher. The typical requirements for disclosure, comprehension, competence, absence of coercion (voluntariness), and consent are expressions of respect for the autonomy and dignity of the person, but they are also the grounds on which the potential research participant bases a decision to place trust in this researcher. (Beauchamp has seven elements at three levels, adding a recommendation for a plan and dividing consent into the decision and the authorization, but the implication is the same.⁵⁴) By consenting, the participant indicates a level of trust that the researcher has provided the information that is needed and will conform to the protocol outlined.

That we require justification for any deviation, such as deception, indicates that there is an implicit assumption that the participant can trust the researcher. Further, if participation in research carries risk or causes harm, then the researcher has an obligation to minimize the risk and rectify the harm, and that includes being sensitive to the impact the research may have on participants. If questions or procedures may evoke stress or anxiety, then the researcher is obligated by the relationship of trust to provide assistance. Studies that raise questions about or ascertain either mental problems (such as suicidality) or physical problems (such as abuse or disease state) should have in place procedures to respond, including additional measures for further assessment and referral.

Because the researcher typically is exposed to much less risk and stands to gain much more benefit in the way of information vital to his/her task than the participant in observational research,

then the greater obligation falls to the researcher. However, we contend that there are also certain obligations for the participant. Though there are always provisions for the volunteer to withdraw the consent, the agreement implies that, while participating, he/she will take part in all aspects of the protocol that are appropriate and not objectionable. There is, then, a level of commitment on the part of the research participant, though the commitment is less binding because the voluntariness of the commitment allows for the option of withdrawal.

The researcher enrolls a subject trusting that this person will, indeed, participate and will provide honest and accurate information to the extent possible. The researcher trusts that a participant will not intentionally subvert or sabotage the research and will not provide false or fabricated data. The researcher also trusts that the participant, when requested, will not disclose aspects of the research that may be proprietary, confidential, or could compromise the collection of data or recruitment of new participants. One example is in the conduct of qualitative research in which focus groups are employed. Participants are typically asked to maintain confidentiality of comments made in the group. This is an obligation to protect confidentiality on the part of research participants parallel to the obligation of the researchers themselves. Both the researchers and the other group members trust each participant to keep that information confidential.

We are suggesting that mutuality in the relation of investigator and research participant is important in the conduct of epidemiologic research and that both our ethical sensitivity and our epidemiologic methods can be enhanced by moving beyond the paternalism of the expert and embracing greater reciprocity in our relations with those we would study.

Beyond the principle of respect for persons, the values of human dignity and autonomy, and the obligations implied in a mutual agreement, there are also issues of character and the role of the virtues in ethical judgment and action. Good—ethically correct—research requires integrity, honesty, compassion, and trustworthiness among investigators.^{5,6,55} Researchers should ask, “Are we presenting the process honestly?” “Are we considering the impact on the respondent?” “Are we acting so as to engender trust in us and in other researchers who may come after us?” To act ethically requires not only that we know how to determine the right thing to do, but also that we are disposed to act in conformity to that judgment. It is moral character that provides the impetus to do what is right. The formation of character is beyond the scope of this chapter, but it cannot be ignored as a critical component of ethics.

If epidemiologists embrace and strive to achieve the goal of improved health and well-being for the population, then steps toward that goal require continuing accumulation of knowledge about the determinants of health and disease in individuals and populations. Observational research comes into play because we cannot subject persons to randomization from the start, nor can we impose risk factors on persons, and the broad underlying structures and contexts that we increasingly understand to be critical for differences in incidence across populations do not lend themselves to randomized intervention research.

One of the chief advantages of randomized trials compared to observational studies is that randomization among the treatment groups is assumed to reduce confounding and some other types of bias. (Bias is a systematic error that may be due to study design or implementation, such as selection bias or information bias.)

Confounding can occur when there is a factor associated with both the outcome of the study and a specific factor of interest, such as exposure (like asbestos or pesticides), or personal characteristics (like income or education), or behavior (like diet or exercise). These associations, if not controlled for in either the design or analysis, can produce a biased estimate of the effect. Randomization is especially effective in preventing uncontrolled confounding. Randomization also reduces information (or misclassification bias) and is intended to protect from selection bias, although the rigid inclusion and exclusion criteria may mean the results will not apply to other population groups or the broader patient group that eventually receives a treatment. In general, it can be said that randomized controlled trials enhance the internal validity of a study, often at the expense of external validity. That is, the estimates are less likely to be biased with regard to the population actually studied, but may not apply to populations less rigorously selected.⁵⁶

Random variability is quite distinct from bias, and applies to both randomized controlled trials and observational studies. Bias is a form of nonrandom variation. Random variations in measurements and estimates of effect do not constitute bias because they are not the result of systematic error, but they do contribute to our uncertainty about the accuracy of those measures. Researchers rely on statistical methods, with certain assumptions, to quantify uncertainty due to random variability. For randomized trials, that usually takes the form of hypothesis testing: Is treatment A better than treatment B (or better than no treatment)? The study typically proposes a null hypothesis that the two (or more) treatments are equally effective, or that a new treatment is no more effective than placebo. The researchers may believe the new treatment is superior; indeed, it is unlikely they would be conducting the trial if they did not have some evidence for a potential treatment advantage. If there is a difference observed between the two (or more) arms, then the researcher must decide if the difference is likely to be the result of random variability alone or reflects a real difference in effect.

Even if two randomized groups are given exactly the same treatment, we are likely to observe some difference in the point estimates of the outcome measures merely because of random variations in the measures. This is where statistical tests come into play. If the probability of obtaining a difference as large as or larger than the one actually observed (the *P*-value) is smaller than a previously established level of certainty (the alpha level) then the null hypothesis is rejected and we judge that the difference is unlikely to be due to chance. Note that the alpha level is determined ahead of time; that is, the researcher chooses the alpha level. (It is often set at 0.05, but the researcher must explicitly affirm that or another level.) If one rejects the null hypothesis, judging that there is a difference in treatments when, in fact, there is no difference, it is called a Type I error. If, on the other hand, one fails to reject the null hypothesis when it is false, meaning that the statistical test does not support a difference in treatment even though there really is one, it is called a Type II error. One can set the alpha level very low, reducing the likelihood of a Type I error, judging there to be a difference when there is none, but this increases the likelihood of a Type II error, judging there to be no difference when in fact one treatment is superior. The Type II counterpart to the alpha level is called beta, and 1-beta is the power, the probability of rejecting the null hypothesis when it is false.

In randomized trials and in observational studies, there is a trade-off between Type I and Type II errors. The trade-off is not simply a statistical one of balancing the seesaw of probabilities for one error or the other, but it is also potentially an ethical one. What is the cost of judging that a treatment is more effective when it actually is not, versus the cost of judging that a treatment is not more effective when in fact it is? What resources may be expended for a new treatment that provides no advantage, and what needs go unaddressed because of the diversion of those resources? Conversely, what suffering goes unmitigated because a treatment's advantage is not recognized?

The discussion thus far has used clinical trials to illustrate the potential ethical issues involved in what is typically thought to be purely statistical trade-offs in hypothesis testing, but similar concerns arise in observational studies, especially when they are used as the basis for decisions concerning policy and practice. Observational studies increasingly emphasize estimation with confidence intervals rather than hypothesis testing as a means of indicating the precision of the estimates; that is, how much confidence we have that an estimate of effect falls within some range of random variability. This approach may seem to reduce the concern over tradeoffs of Type I versus Type II error. However, when clinical decisions or public health policy decisions are made on the basis of observational studies, the concern about Type I versus Type II error becomes more pressing.

At some point a decision may be forced, and at that point we consider the trade-offs of one versus the other in light of the precision of our estimates and relative weighting of the cost of one type of error versus the other. It is easy to adopt alpha of 0.05 and beta of 0.2 (the predetermined critical probability of a Type II error) and some arbitrary difference in means or proportions or strength in the measure of association assumed to be clinically meaningful. More difficult is probing what difference it might make in policy or clinical decision making if the null hypothesis were erroneously rejected or, conversely, the null were not rejected when in fact there were true and meaningful differences or associations.

When one implements a decision to change some characteristic, program, or policy based on evidence that it will make a difference in the health of individuals or the population, when in fact it will make no difference, then resources are wasted that might otherwise have been used more effectively and, perhaps, lives are changed in unnecessary ways. On the other hand, if one fails to implement such changes because the evidence for an association does not meet some predefined, but arbitrary alpha level, when the changes would indeed result in enhanced individual or population health, then those people and the population are deprived of the benefits of healthier life and resources are expended that might otherwise be conserved to address the poorer health status. Deciding between these scenarios requires reflection on the resources and the values of those affected by the decision, as well as the obligations of those making the decision.

Power calculations are often used to estimate the probability of detecting a real difference of a certain size, if there is one, given a certain population size, or to estimate the sample size needed to observe an effect that is clinically meaningful at predetermined alpha and beta levels. There are a number of statistical assumptions required for power calculations, but our argument is that statistical analysis, even power calculations, as well as discussions of findings, require reflection on the implications for policy anal-

ysis or clinical decision making that rely on the data. Such reflections inevitably invoke values, principles, and obligations that are inherently ethical in nature. This raises the question of whether community input is needed even in observational research, not only concerning risks and benefits but where to err in judgments of effect. Consider research to determine the effectiveness of alternative programs that may subsequently be implemented as a matter of policy: Should the community be able to factor into their risk/benefit deliberations the probability of assuming that an ineffective intervention is effective, or conversely, assuming that an effective intervention is not?

Similar concerns can be raised in screening programs. For many screening tests, decisions must be made about appropriate critical values that define a positive test. The sensitivity measures how well the test detects the condition and is the probability the test will be positive given the person has the condition being screened (or the proportion of those with the condition who will have positive tests). The specificity measures how well the test screens out those without the condition and is the probability the test will be negative given the person does not have the condition being screened (or the proportion of those without the condition who will have negative tests).

For some tests, the critical value that defines a positive test can be chosen, typically to increase sensitivity at the expense of specificity or vice versa. These decisions must find a balance of sensitivity and specificity that is optimal for the outcome and population being studied. Although sensitivity (and $1 - \text{sensitivity}$, the false negative proportion among those with the condition) and specificity (and $1 - \text{specificity}$, the false positive proportion among those without the condition) are theoretically independent of the population, the predictive value of a screening test (the probability a person has the condition given a positive test, or the proportion of those with a positive test who actually have the condition) is a function of the pretest probability (the assumed probability that person has the condition before the test is given, or the prevalence of undiagnosed disease in the screened population). Decisions must be made on the relative importance and cost (in human terms as well as resources) of false negative versus false positive results.

It is commonly acknowledged among public health professionals that screening programs as a form of prevention should not be undertaken in the absence of demonstrated treatment options for those identified or other clear benefit as a result of screening. However, there is less agreement about the appropriateness or obligations of researchers conducting observational studies that function as de facto screening programs because of their identification of persons with (or likely to have) a disorder. We have previously argued that we believe researchers conducting observational studies that identify problems in participants have an obligation to have in place procedures for referral of those so identified.

Interpreting and Applying Observational Evidence: Ethics of Decisions and Interventions

We assume that the overarching purpose behind performing observational research (in the form of epidemiological studies) is to generate scientific understanding of disease etiology. There are, of course, other important purposes for epidemiologic studies:

For example, surveillance of disease incidence and mortality—measuring the demographics of disease of populations—is also an observational research activity. Similarly, monitoring the outcomes of medical (typically, therapeutic) interventions—often referred to as health outcomes research or health services research—relies heavily upon epidemiological methodologies and concepts. Our focus here will be on the use of epidemiological evidence for primary prevention—that is, the interpretation and application of epidemiological evidence to assess whether public health measures should be implemented for the identification and removal of disease-causing factors (exposures).

Although epidemiological research is at the center of the process of scientific interpretation, rarely are questions of causality answered solely with observational evidence on human populations. Evidence from other scientific disciplines, using quite different methodologies, notably biological (laboratory) studies, is often examined alongside epidemiologic evidence. One of the increasingly important considerations in causal interpretations of scientific evidence is *biological plausibility*, as discussed below.

It is also important to point out that certain categories of preventive interventions—for example, early disease detection technologies such as sigmoidoscopy for colon cancer, mammography for breast cancer, and many vaccinations for infectious diseases—are typically tested in randomized controlled clinical trials, a topic examined in detail elsewhere in this book. Active chemopreventive medications such as tamoxifen or raloxifene for the prevention of breast cancer, finasteride for the prevention of prostate cancer, and aspirin for the prevention of coronary heart disease are also tested in randomized trials, although these trials typically are undertaken after a variety of other types of studies have been performed, including laboratory, epidemiological, animal model, and preclinical studies for toxicity and acceptability.

Our focus here is on the interpretation and application of epidemiological evidence (often supplemented with evidence from biology) for primary prevention, the identification and removal of disease-causing factors and/or the promotion of so-called lifestyle factors and the social forces that affect them, such as physical activity (exercise), dietary interventions (e.g., eating fruits and vegetables), and safety devices such as seat belts or bicycle helmets.

Responsibility for Interpreting and Applying Epidemiologic Evidence for Primary Prevention

It may seem obvious that there are public health professionals willing to take on the responsibility of deciding whether the scientific evidence demonstrates a need for interventions or whether more evidence is needed before acting. By *need for interventions*, we mean that sufficient evidence exists to consider a factor a hazard and thus available for considerations of interventions, given that any intervention must also take into account the impact of the intervention on the community and on individual freedoms or rights, the benefit/risk horizon of the intervention, as well as a consideration of the populations who may warrant preferential consideration for intervention because they are vulnerable, underrepresented, or otherwise special.

However, the issue of responsibility for prevention has been hotly debated within the ranks of epidemiology, and it is one with prominent ethical roots.⁵⁷ Being responsible in this context means

being accountable for decisions to intervene and being committed to improving the public's health, including but not limited to the health of individuals and the health of the communities in which they live.^{58,59} Although it is widely accepted, for example, that physicians and other health-care professionals are responsible for decisions to intervene therapeutically—decisions ideally made with the full consent and cooperation of patients—it is less clear whose responsibility it is to prevent disease by offering preventive interventions to individuals not already ill or to populations with varying incidence rates or prevalence of disease, injury, birth defects, or other health-related conditions. In contemporary society, primary prevention is undertaken (even advocated for) by a host of different players: individual health professionals, some of whom are clinically trained and others who are not, institutions such as the American Cancer Society or the American Heart Association, government health agencies at the local, state, and national levels, regulatory bodies such as the Environmental Protection Agency, grass roots advocacy groups concerned about air or water pollution, and private, for-profit companies that, for example, impose no-smoking policies in the workplace.

As practicing professional epidemiologists, we have argued that we are responsible for directly connecting our research results with our communities through the complex and value-rich process of interpreting and applying epidemiologic evidence in preventive public health practice.⁵⁹

Not everyone agrees. Some professional epidemiologists have countered that their responsibility ends with the causal interpretation of scientific evidence, providing information regarding the certainty with which one might accept or reject a given causal hypothesis, but providing no recommendation for public health (preventive) action.^{57,60,61} A range of reasons for keeping epidemiologists free of the role of public health practitioner—some practical, others ethical—have been carefully examined elsewhere.⁶² Among these are concerns that epidemiologists lack expertise in public health policy making, that advocating for public health policies negatively affects one's scientific objectivity, and finally, that the observational nature of epidemiologic science militates against applying that science to the real world. But these are not compelling reasons for limiting the role of epidemiologists to a scientific practice devoid of application.

Epidemiologists regularly participate in research and education policy making and therefore cannot be ignorant of the basics of policy making that is needed for public health practice. In addition, it has been argued that participation in public health policy making (and other forms of advocacy) may actually enhance epidemiologists' scientific objectivity by encouraging them to improve their methods of research synthesis, that is, their methods of causal inference. And finally, it has been noted that public health applications regularly emerge from observational research, often coupled with evidence from the laboratory or clinical sciences. Decisions about interventions are unlikely to be solely dependent upon epidemiologic findings, but that fact does not mean that epidemiologists should not participate in (much less have a responsibility for) applications because the science is observational. Nevertheless, it is interesting and important to point out that some have recently argued for a rather strict separation of the role of researcher from that of clinical practitioner.⁶³ As Brody and Miller write, "There is an irreducible ethical tension between the roles of treating physician and investigator. In most

settings, this tension is best dealt with by *requiring* that the same physician not serve in both roles [emphasis added]."⁶³

Such tension exists as much in prevention as it does in treatment scenarios, although the prime conflict appears to be the conflict between the duty to do one's best for a patient and the disruption in that duty that randomization creates in a clinical trial. Put another way, observational (epidemiological) research on treatment, or on factors that may cause or prevent disease, does not conflict with a practitioner's obligation to do his or her best for a patient or a community. Observational research does not disrupt the choice of intervention or the opportunity to avoid exposure that would be part of the joint responsibility of the health professional-researcher.

Causal Claims and Preventive Recommendations: Conceptual Rationale

The level (or strength) of evidence required to recommend a preventive intervention is not, in theory or practice, fixed. Clearly, if there is very strong evidence that some factor is causal and manipulable, then one must do all that is necessary to intervene to prevent further disease through further exposure. On the other hand, it would be in error to argue that "very" strong evidence of causation is necessary before any action to remove a purported causal factor can be recommended. In practice, those who are responsible for such recommendations need to know enough—just enough—to provide a warrant for the recommendation, taking into account, as described briefly above, the concomitant issues of the expected reduction in risk, the potential harm of the intervention, the acceptability and intrusiveness of the intervention, and the population or community the intervention will affect. In addition, we must consider the implications of being wrong in our recommendation, as noted in the discussion of Type I versus Type II errors. For all these reasons, we cannot act in a vacuum of information. We need to know something about the purported cause and its effects including the level of certainty we assign to our understanding.

We recognize that for different purported causal factors, the level of evidence required is likely to be different. We recognize that for some situations we may require an extensive understanding of the disease mechanisms, including how a purported causal factor such as exposure acts within those mechanisms. We recognize that for other situations we may require much less evidence. In terms of responsible action for prevention, we are, in essence, in a constant state of asking ourselves with each new piece of the evidentiary puzzle: Is it time to act, time to recommend a preventive intervention? Another way of putting this is to presume that we are looking for the least amount of evidence for causation, wherein that threshold (in any given situation) may be quite high indeed.

Causal Claims and Preventive Recommendations: Methodological Rationale for Interpreting Epidemiologic Evidence

Before describing the methodologies used in interpreting epidemiological evidence, it is important to point out that the practice of making causal claims and from them, preventive recommenda-

tions, is not only characterized by uncertainty, in a probabilistic sense, and by the epistemological condition of underdetermination, but also heavily influenced by values, both scientific and extrascientific. Although ideally one would expect an interpretative assessment of carefully collected scientific evidence to be objective and free—as much as possible—from the subjective influences of any individual reviewer, this may not be the case in the interpretation of epidemiologic evidence. Indeed, examples of non-scientific norms, such as antiabortion sentiments, affecting the process of causal interpretations of epidemiologic evidence, have been documented. The reason that such values can have such an effect is an important problem. The origin of this problem lies in the structure of the methods used to make causal claims, a mix of quantitative and qualitative strategies and components, as described below.

Causal claims are most often made in what are referred to as reviews of the scientific literature in which the available scientific evidence is summarized after a systematic collection from published sources. Some authors of reviews may choose to include previously unpublished (or nonpeer-reviewed) studies. Guidelines for systematic reviews emphasize the importance of clearly defining which studies were included (i.e., inclusion criteria), the methods used in summarizing the results of multiple studies (e.g., through pooled analyses or meta-analysis), and the overarching purpose of the review (e.g., to make research recommendations, causal claims, and/or preventive recommendations).

The most important types of observational study designs relevant to causal interpretations are the so-called analytic case-control and cohort studies. In a systematic review, these are tabulated separately with special attention paid to the characteristics of the study population, exposure measurements, results (often in terms of the relative risk of disease or death, estimated in case-control studies by the odds ratio), and a measure of statistical uncertainty, typically provided by a *P* value, or confidence interval, or both. The number of studies included in these tables depends upon factors such as when the reviewer happens to have undertaken his or her review in the historical context of studying the relationship between the exposure factor of interest and the disease or condition it is purported to cause; well-studied “associations” can generate tables with dozens of entries.

The interpretation of this body of evidence includes an assessment of statistical uncertainty and an assessment of the extent to which the findings (across all studies represented in the review) can be explained either by systematic biases or by unmeasured confounding factors. Although observational studies cannot, by their very nature, provide strong assurances that all potential confounders have been accounted for, or all other biases prevented or eliminated, a prominent part of the process of making causal claims from observational evidence is judging the extent to which the results could be “higher” or “lower” due to controlled confounding or presence of other biases. Though the possibility of bias affecting results is typically acknowledged in published epidemiologic studies, it is usually given less weight in evaluating the reliability of the results than the uncertainty due to random variability.

It is not uncommon for absolute decisions about associations to be based on whether *p* values exceed arbitrary alpha levels even when the degree of uncertainty can be quantified. The presence of bias, on the other hand, is often discussed in rather general terms and the impact of the bias on results is rarely assumed to

negate the findings. Though methods of sensitivity analysis to quantify the impact of bias are available, they are only occasionally incorporated into the reporting of epidemiologic findings, whereas one can hardly conceive of an epidemiologic study being published without either *p* values or confidence intervals, sometimes both.

Assuming that a body of evidence successfully makes it through this initial assessment of statistical uncertainty, potential bias, and confounding, the reviewer then examines it from the perspective of what are referred to as causal “criteria,” although the discipline recognizes that only one (of several used) can be considered a true criterion in the sense that it must be satisfied if causation is to be claimed. That criterion is temporality; the condition that a factor must precede its effect in time to be considered causal. Depending on the user’s preference (and to an extent, the published source of these criteria), there are as many as eight and as few as no additional criteria used in causal assessments in practice. In theory—in other words, in the texts describing this methodology—there are typically nine criteria in all, including experimentation, by which it was meant a randomized controlled trial. This list includes the following: consistency, strength, dose-response, biological plausibility, specificity, coherence, temporality, experimentation, and analogy. A detailed description of each of these is not important for the purposes here. What is important is that each of these so-called criteria has an implicit rule of inference associated with it that can be easily manipulated by the individual (or group) writing the review. Put another way, causal claims from epidemiological evidence (and from the biological evidence used to assess the single criterion of biological plausibility) are dependent upon the rules assigned to these criteria as well as the number of criteria used and the priority assigned to them. Differing (often opposite) causal claims from the same epidemiological and biological evidence originate primarily from different interpretations of—that is, different rules of inference assigned to—these so-called causal criteria.²⁶

Ethical Considerations in Translating Causal Claims Into Preventive Recommendations

Areas of ethical tension emerge when discussing the ethics of translating epidemiologic research into preventive action.⁶⁴ The first involves the balancing act between that which we need to know and that which needs to be done. Public health action aspires to be based on a strong foundation of scientific knowledge; evidence-based decision making has increasingly become the approach taken for all types of preventive (and most therapeutic) interventions. But science is a complex interdisciplinary phenomenon, neither fixed in stone nor free of subjectivity. Uncertainty flows through our understanding of human biology and pathophysiology at the individual and population levels encompassing biological, lifestyle, and social determinants of health and disease. The scientist’s claim to objectivity is primarily supported by the validity and reliability of methodologies. Yet, as discussed above, the interpretation of evidence generated by observational methods of epidemiology requires not only judgment but often (if not always) consideration of evidence from biological (or social) sciences. The interpretative methods themselves are more qualitative than quantitative, allowing for subjectivity and a range of values to potentially influence those judgments.

Our search for what counts as truth (however tentative) and our duty to act to promote health and prevent disease in persons and populations are an important source of ethical tension. At its core lies a concern that we not err in our recommendations for preventive interventions. We should act neither too rashly nor too late. Unfortunately, there is no well worn path to assess our success or lack of it. It is one thing to say that we recommend an intervention because we are convinced of the causal attribution of the factor we plan to “remove” from a community so that a reduction in incidence or mortality can follow. It is quite another to demonstrate such a success, documenting the reduction.

Another source of tension involves the intervention itself—how the risks are balanced by the benefits and, perhaps most importantly for public health interventions, the extent to which individual freedoms have been sacrificed in the name of the common good. A contrast between individuals and populations is a prominent feature of most discussions of public health ethics, within which we place the ethics of epidemiologic practice. Observational research is characteristically performed on groups, sometimes defined by geography (e.g., women living in New York City), by occupation (e.g., nurses), or by social class (e.g., migrant farm workers). Although it is true that these groups are composed of individuals and that measurements are often (though not always) taken on each individual, the research results are characteristically presented in terms of the possible causal (or preventive) effects of the exposure on the population studied, rather than on any individual within that group. In a classic epidemiological paper contrasting research practices and preventive interventions for sick individuals and sick populations respectively, Rose made a strong point about the need for studying different populations that may be exposed, by choice or not, to quite different environmental factors and that could, as a result, manifest quite different disease distributions, impossible to discern within each population.⁴⁵

Similarly, interventions are undertaken at the individual or population level for prevention, with smoking cessation (or tobacco control) a well worn but excellent example. Individuals can be encouraged to stop smoking in one-on-one sessions with therapists or physicians or friends, just as populations can be encouraged to stop smoking by regulations disallowing smoking in public places or worksites. It is this latter situation in which the ethical tension exists when the freedoms accorded to individuals in most contemporary societies are curtailed in the name of promoting the health of the community as a whole.⁶⁵ Starker examples involve preventive interventions that few individuals can avoid, such as fluoridation and chlorination of public water supplies, childhood immunizations, and seat-belt laws. Because the relationship with individual participants and populations is less direct and the benefits more distant or abstract for many observational studies, the ethical issues may not be as obvious.

Summary

The ethical issues facing epidemiology range from obligations to individual participants to epistemological challenges, reflections on causality, and policy formation. Epidemiologists, by the very nature of their research, cannot work in isolation from the populations they study, nor can they assume that the fruits of their labors are merely possible answers to interesting scientific puzzles.

Epidemiology is at the very heart of public health, providing a major cornerstone in its scientific foundation and taking responsibility for preventive action. The obligations this entails—to individuals, to populations, to the community of science, and to public health professionals and the entities where they work—are wide-ranging and profound.

Behavioral and Social Science Research

Ethical issues in the conduct of behavioral and social science research with human participants involve considerations that are as diverse as the range of disciplines and fields that constitute these sciences. The methods, study populations, and issues being examined in studying behavioral and social processes all come into play in designing and implementing ethically sound research. This chapter provides an overview of the history of ethical considerations in the conduct of behavioral and social science research; addresses underlying ethical considerations that animate these fields of inquiry; unpacks the complexity of making ethical determinations, especially in the context of challenging circumstances, study populations, or methods; and raises issues—some unresolved—that merit consideration in planning for and reviewing research.

For all fields of human research, ethical determinations about the rights and interests of human research participants are an integral part of the research enterprise. Behavioral and social scientists undertaking research are informed by professional codes of ethics,^{1–4} formal guidance enunciated in the Belmont Report,⁵ and the Department of Health and Human Service's (DHHS) Policy for Protection of Human Research Subjects (45 CFR 46).⁶ In the context of such guidance, scientists planning and implementing studies must make judgments about research participants, and thus need to apply ethical principles and rules responsibly to real-life circumstances in advance of and during the ongoing research process. This chapter examines how assessments about risk, harm, and benefit; confidentiality and privacy; disclosure and the processes of informed consent unfold in behavioral and social science research in relation to the substance of the study, the target population, and the specifics of the research method and design.

The social and behavioral sciences refer to a broad rubric of disciplinary and interdisciplinary fields dedicated to the scientific study of behavioral and social phenomena. Permeable at its boundaries, the term embraces fields ranging from anthropology, economics, political science, psychology, and sociology to linguistics, geography, demography, sociolegal studies, and education research, among others. Some disciplines like psychology have produced disciplinary subfields such as cognitive psychology or developmental psychology that also are quite interdisciplinary. Other fields, such as neuroscience, have interacted to create new arenas of scientific discovery and explanation. The richness and complexity of the behavioral and social sciences, the interdisciplinary synergism across these fields, and their growing interaction with the biological sciences can be seen in the conceptual framework used in volumes as early as the 1988 National Research Council report, *The Behavioral and Social Sciences*,⁷ and more recently in the 2001 *International Encyclopedia of the Social & Behavioral Sciences*.⁸

In terms of health-related research, the Office of Behavioral and Social Sciences Research (OBSSR) at the National Institutes of Health (NIH) similarly conceives of behavioral and social science research to be a “large, multifaceted field” that is “not restricted to a set of disciplines or methodological approaches.”⁹ The OBSSR statement emphasizes the breadth of methodological approaches in these sciences, including surveys and questionnaires, interviews, randomized clinical trials, direct observation, physiological manipulations and recordings, descriptive methods, laboratory and field experiments, standardized tests, economic analyses, statistical modeling, ethnography, and evaluation. All of these methods come into play in behavioral and social science research on

health—whether it is in the context of fundamental studies designed to further understanding of behavioral or social functioning or in the context of clinical research designed to predict or influence health outcomes, risks, or protective factors. Indeed, it is the methodology, rather than the specific field or purpose of the study, that tends to signal ethical issues worthy of attention.

The literature on ethical considerations in behavioral and social science research involving human participants focuses on the shared methods and complementary interests that cut across these fields. In work that was published during the same period that the Belmont Report and the federal regulations were issued, the emphasis was on methods, ethical concepts, and the newly emerging federal role in human research regulation. For example, chapters in the 1979 volume *Federal Regulations: Ethical Issues and Social Research*,¹⁰ edited by Wax and Cassell for the American Association for the Advancement of Science Selected Symposium Series, addressed the complex ethical issues involved in qualitative as well as quantitative research. Similarly, contributions in the 1982 volume *Ethical Issues in Social Research*,¹¹ edited by Beauchamp, Faden, Wallace, and Walters, or in the two 1982 volumes edited by Sieber under the overarching title *The Ethics of Social Research*^{12,13} focused on how ethical issues present themselves in the context of different research methods and examined key concepts such as benefit and harm, deception and consent, and privacy and confidentiality. More than 20 years later, in 2003, the National Research Council report *Protecting Participants and Facilitating Social and Behavioral Sciences Research*¹⁴ also emphasized the link between research methods and key ethical concepts.

Emergence of Ethical Considerations

Ethical considerations in behavioral and social science research became an explicit topic of attention during the 1960s and 1970s. During this period, four types of activities emerged that over time intersected in terms of both substantive issues and networks of behavioral and social scientists working in these domains. Each contributed to heightened interest in research ethics. First, there was the emergence of a subfield of research (largely located within social psychology) giving systematic attention to the study of behavioral and social science research as a social process worthy of investigation. Second, researchers and scientific societies in behavioral and social science fields began focusing on the ethical practices and the ethical responsibility of researchers to human research participants. Some high-profile studies brought attention to these issues. Third, the federal government, largely in the context of biomedical research, but also including behavioral and social science research, turned to addressing the regulation of research with humans. Fourth, and not unrelated, interest in the regulation and ethics of research as well as the establishment of formal mechanisms stimulated some social science research addressed to these issues.

Social Psychology of Research

The social psychology of research involves examining the dynamics of research as a social process and the factors that could affect or bias results.¹⁵ Research that commenced in the 1960s focused on the unintentional effects on research participants' re-

sponses of the investigators' knowledge of the hypotheses and experimental conditions (i.e., expectancy effects),¹⁶ the impact of the nature of the information (e.g., the form or the wording of language) on outcomes,¹⁷ the influence on results of simulated behaviors (e.g., role-playing behaviors of shorter or longer duration), and even whether volunteering or assumptions about the likelihood of deception (irrespective of ethical considerations) may reduce research participants' level of engagement with the research questions or tasks.¹⁸ The desire of research participants to help, the social influence exerted in the situation, perceptions of the research participants and the researcher regarding socially appropriate responses,¹⁹ participants' concerns about negative evaluations (i.e., not being a sufficiently "good" participant),²⁰ and the demand characteristics of the research situation are some of the factors that interested behavioral and social scientists because of their possible consequences for the validity of research.^{21,22} Although most of this research focused on laboratory experiments (the context of much social psychological research), the questions being asked were germane to both fieldwork and social surveys. In addition, although this arena of research was directed to understanding the research enterprise and what contributes to, or erodes, its validity, the social processes being studied were quite central to ethical considerations (e.g., the amount of information disclosed to human participants and the social influence of research situations on participants' autonomous behavior).

Heightened Attention to Ethical Considerations

At about this same time, another strand of research in the behavioral and social sciences was directly addressing topics related to human values (e.g., conformity, obedience, stereotypes).^{23,24} This work sought to better understand the impact of social situations, influences, and norms on human behavior using compelling research designs and tools. The visibility of such studies and the broader attention in this post-World War II era to the treatment of participants in research also led scientific associations, including professional societies in the social and behavioral sciences, to address ethical considerations in the conduct of research.

High-Profile Research

Much of the debate that unfolded about human research ethics in the behavioral and social sciences had its roots in notable work done in this period. A number of substantive studies raised questions about the appropriateness of the research procedures from the vantage point of the research participants. Although raising ethical questions about a study is distinct from judging a study to be ethically questionable, these two responses were frequently confounded. In many respects, the several studies that were particularly high profile were exemplars of a genre of behavioral and social science research of that time. Three studies—cutting across laboratory and field contexts—are most highly cited for leading those in the behavioral and social sciences to explore what constitutes viable ethical practices in their research and the conditions and criteria that should be applied in making such determinations.^{25,26}

In the 1960s, experimental studies of obedience undertaken by Milgram involved research participants "believing" that they were administering painful shocks to others in the context of

memory research. In reality, no shocks were being administered at all, despite participants being told that they were causing painful consequences to others.^{27,28} The actual purpose of Milgram's research was to understand compliance with authority figures under varying conditions and to identify the factors that engendered resistance. The artificially constructed experimental situation encouraged participants to comply with authoritative instructions and continue to administer what they believed were painful shocks.

The scientific and social significance of Milgram's findings—that is, the propensity in certain situations for persons to obey authorities and override their sense of right and wrong—is generally acknowledged. Nevertheless, both the stress effects on participants of such compliance (resulting from “inflicted insights”²⁹) and the deceptive scenario that placed them in this position, spawned significant discussion and debate in the research community, including by Milgram himself.^{30–33} In many respects, Milgram was ahead of his time in explicitly addressing investigator's responsibilities to research participants. In his 1961 grant proposal to the National Science Foundation, for example, Milgram emphasized debriefing to put subjects at ease and to assure them of the adequacy of their performance. Conducting follow-up studies, he is credited with the first use of postexperimental procedures.²³ Although these studies showed that the vast majority of participants valued being in the study and only a few wished they had opted out, controversy continued to surround this research.

The 1971 prison simulation study by Zimbardo and associates^{34,35} also framed ethical questions that engaged the attention of the research community.^{26,36} Although there was no deception in this research, the long-term simulation of the role of prisoners or guards produced physical and psychological aggressive behaviors in “guards” and submissive behaviors in “prisoners.” Participants became emotionally involved in their roles, leading to the experiment being terminated by the principal investigator because of concerns about psychological consequences.³⁵ Zimbardo's attention to research participant stress and the fact that he ended the study after six days are evidence of the care taken in the execution of this research. Though follow-up work identified no lasting adverse effects and yielded self-reports of benefits to participants, the study highlighted the larger ethical question of simulating behaviors that *could* induce sustained identity stress and potential psychological harm. How to weigh the potential risk of more than transitory stress in relation to the benefits of this form of research was, however, less a point of conversation than the behaviors that this simulation evoked.

The third inquiry conducted by Humphreys from 1965 to 1968 used participant observation and interview methods to study men who engaged in impersonal acts of fellatio in public restrooms (the “tearoom trade”).³⁷ The research also included tracing car licenses to the homes of men Humphreys did not interview in the field in order to interview them subsequently without disclosing his true identity. He took this step to offset any social class bias, based on his observation that better educated men are more willing to talk about their lives and these sexual experiences in the field. Although the study contributed to understanding a highly stigmatized behavior and to reducing stereotypes about homosexuality, it simultaneously created considerable controversy about covert observation, deception, and potential harm, from emotional and interpersonal to legal.^{38–40} Like the Milgram and Zimbardo studies, this field research generated debate in the behavioral and

social science community about the research procedures that Humphreys used. Although Humphreys sought to explicate the benefits of the research and reported that none of the participants subsequently expressed concerns about the deception or reported any harms, criticism about informed consent and deception eclipsed other issues.

Behavioral and Social Science Societies

During the 1960s, professional associations in the behavioral and social sciences also turned to a consideration of the ethical dimensions of research. The promulgation of ethics codes is perhaps the most tangible indicator of a commitment to articulate normative standards to guide and inform researchers in these fields. In taking up this task, scientific societies realized that periodic review of ethics codes would be necessary as knowledge evolved, methods developed, and contexts and issues emerged for study.

The American Psychological Association (APA) was the first professional association to take up this work and to use empirical methods to develop a code. The APA's critical incident method requested firsthand reports from some 7,500 members of decisions having ethical implications.^{41,42} Instead of relying on a committee to identify issues, APA asked members to describe situations with ethical implications that they knew firsthand and to specify the ethical issues requiring decisions. Published in 1953, this code focused largely on psychologist-client relationships, in which the preponderance of incidents were reported.⁴³ In 1966, the APA established a Committee on Ethical Standards in Research that, also using the critical incident method, produced *Ethical Principles in the Conduct of Research With Human Participants*, which was adopted by APA Council.⁴⁴ The *Principles* became a new component of the APA Ethics Code published in 1972⁴⁵ and in all subsequent code revisions during that period.⁴⁶ The *Principles* was revised and reissued in 1982.⁴⁷ In 1992, the APA adopted a further revision of the code,⁴⁸ which was buttressed by publications related to human research participants.^{49,50} The most recent revision of the Ethics Code appeared in 2002.¹

By the late 1960s, other behavioral and social science societies took up this task as well. In 1967, the American Sociological Association (ASA) reactivated a process that had commenced in 1960, and by 1969, a Code of Ethics was approved by 88% of eligible members voting.⁵¹ The ASA also saw its code as a dynamic document, with revisions being approved in 1982 and 1989, and enforcement procedures put in place by the ASA Council in 1983.⁵² A major revision was approved in 1997.² The American Anthropological Association (AAA) initially addressed ethical issues in its 1967 Statement on Problems of Anthropological Research and Ethics.⁵³ By 1971, the AAA had adopted an ethics code, *Principles of Professional Responsibility*,⁵⁴ which was followed by amendments and a revision in 1990^{55,56} and a further revision in 1998.³

The American Political Science Association (APSA) also addressed ethics in human research in the late 1960s. The APSA Committee on Professional Standards and Responsibilities issued a report in 1968 entitled “Ethical Problems of Academic Political Scientists,” with a Standing Committee on Professional Ethics being established as a consequence.⁵⁷ Not until 1989, after a period of evolution, were these standards formalized;^{4,58} they were further revised in 1998.⁴ With funding from the Russell Sage Found-

dition in 1975–76, the APSA led 12 other social science associations⁵⁹ in undertaking a survey about confidentiality in social science research that yielded a statement, entitled “The Scholar’s Ethical Obligation to Protect Confidential Sources and Data,” and recommendations were approved by the APSA Council in 1976.⁶⁰

Overall there was progress commencing in the late 1960s and 1970s in social and behavioral science societies’ initiating activities and formalizing codes.¹¹ Nonetheless, some of the same ambivalence and tensions articulated by individual researchers about the balance between strengthening human research ethics and over-regulation were also evident. Thus, the deliberations taking place in professional associations revealed an impulse to lead, but also to crystallize an evolving consensus in the formulation of ethical standards. Over time, for example, codes of ethics became much more explicit about informed consent⁶¹ and about the use of students in research.⁴¹ The evolution of federal regulations in this area similarly reflected an evolving consensus about ethical practices and how they should guide operational research.

Inclusion of Behavioral and Social Sciences Research in Federal Policy Making

Even in the earliest language and consideration of federal policy related to human research protection, discussions made reference to behavioral and social science research. Gray^{62,63} traced the first inclusion of social and behavioral research back to a July 1966 revision of the February 1966 U.S. Public Health Service (PHS) policy that required institutional review of human research in all PHS awards.⁶⁴ Quoting from Gray,⁶² the July 1966 revision stated that

there is a large range of social and behavioral research in which no personal risk to the subject is involved. In these circumstances, regardless of whether the investigation is classified as behavioral, social, medical, or other, the issues of concern are the fully voluntary nature of the participation of the subject, the maintenance of confidentiality of information obtained from the subject, and the protection of the subject from misuse of the findings. . . . [social and behavioral sciences sometimes use procedures that] may in many instances not require the fully informed consent of the subject or even his knowledgeable participation.

Any ambiguity as to the intent of this language was further clarified in December 1966, when the U.S. Surgeon General, in response to a question, stated that the policy “refers to all investigations that involve human subjects, including investigations in the behavioral and social sciences.” Furthermore, PHS policies issued in 1968 (“Public Health Service Policy for the Protection of the Individual as a Subject of Investigation”) and 1969 (“Protection of the Individual as a Research Subject: Grants, Awards, Contracts”) explicitly included behavioral and social science research, focusing in particular on risks that might be incurred due to breaches of confidentiality and misuse of findings. By 1971, in response to requests for better understanding of policy and the need for more uniformity in institutional review, the Department of Health, Education, and Welfare (DHEW), which preceded the DHHS, issued “The Institutional Guide to DHEW Policy on Protection of Human Subjects.” This Guide dealt with concerns about

physical, psychological, sociological or other harms and explicitly addressed harms, beyond physical harms, that could arise in behavioral and social science research.

The National Research Act of 1974 established the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (National Commission) and required the establishment of a board to review biomedical and behavioral research involving human subjects at institutions that apply for funding from the PHS. The Act also affirmed the new DHEW regulations for the protection of human subjects (codified at 45 CFR 46) that required research to be reviewed and approved by committees as a prerequisite to funding. The behavioral and social science community expressed concerns about the potential suppression of research on controversial issues under the guise of ethical considerations; about the emphasis on a written document as part of informed consent, especially given ambiguous statements about waivers and documentation of consent; and about whether the regulations would be meaningfully extrapolated from biomedical and clinical settings to some of the challenging contexts and issues that animate social and behavioral science research (e.g., studying socially harmful behaviors or unsavory topics or persons). Concerns were also expressed about the very limited involvement of behavioral and social scientists on the National Commission or staff, although a number of papers were ultimately requested from these scientists by the National Commission.⁶²

Over the four years that the National Commission worked (1974–78), behavioral and social scientists’ level of engagement in research ethics increased. By 1979, when proposed revised regulations were published for comment in the *Federal Register*, the behavioral and social science community was better situated to respond. Comments ranged from encouraging ethical guidance that was better aligned with the designs and methods of the behavioral and social sciences to completely resisting any regulatory policy for social and behavioral science research. The federal regulations adopted in 1981 reflected the strengths of the National Commission’s work and the urgings of the behavioral and social science community to specify a more nuanced understanding of risk, types of harm, and categories of review. Areas of research that could be exempt, areas that could be handled through expedited review, the capacity to waive documentation of consent, the definition of human subjects research to include *living* persons and identifiable *private* (not public) information were improved features of the 1981 revision. The National Commission’s articulation of the core principles that formed the basis of the Belmont Report (i.e., respect for persons, beneficence, justice) as well as its openness to comments were important to the fuller integration of behavioral and social science research in federal policy.

Literature at that time^{62,63,65} and later^{14,66,67} provides an overview of the evolution of the 1981 federal regulations and the role of the National Commission in the development of these regulations. During the 1980s and the period that led to the adoption of the Common Rule (subpart A of the regulation) by federal agencies in 1991, behavioral and social science research operated within federal policy without much profile. By the late 1990s, with heightened public and policy attention to human research protection and the role and functioning of institutional review boards (IRBs), some of the same concerns expressed in the 1970s about one-size-fits-all solutions, the dominance of the biomedical model, and hyperregulation resurfaced in the behavioral and social sciences.^{68,69}

Emerging Empirical Research on the Ethics of Research

Since the late 1990s, in addition to formal institutional responses in the form of new federal advisory committees, new National Academy of Sciences' committees, and initiatives of scientific societies, there have also been calls for better empirical knowledge about ethical aspects of human research in light of the methods and practices in these fields.^{14,68,70} Assumptions about about such issues as what research participants consider to be personal or private information, what they consider to be of risk or benefit, and what they believe they need to know before agreeing to participate in certain forms of research. To date, the literature on human research ethics largely remains more analytic or assumptive than empirical.

Work in the arena of survey research, addressed primarily to consent and confidentiality, is a major exception. Singer's work in particular stands out in this regard. Since the late 1970s, Singer has undertaken extensive research on such issues as the effect of the amount of information on consent and the impact of the request for and timing of written consent and confidentiality assurances (with sensitive and nonsensitive information) on response rates and response quality.⁷¹⁻⁷⁴ Singer reported that 8% of her sample refused to sign consent forms, but were willing to be interviewed—a finding consistent with a study by Ellikson and Hawes.⁷⁵ She also reported that when sensitive information is involved, confidentiality assurances matter in terms of willingness to respond and response quality, but confidentiality assurances have no significant effect when the content is not sensitive, complementing the findings of Turner⁷⁶ and of Boruch and Cecil.⁷⁷

Much of the research in the 1970s was stimulated by the Privacy Act of 1974 and the 1974 federal regulations for the protection of research participants. In reflecting on this research in two review studies published in the 1990s,^{78,79} Singer called for far more empirical inquiry on ethical issues in research. Over a wide range of issues and areas, the number of studies continues to be small in relation to the ethical questions about human research that could be informed by a critical mass of work. Singer's 2004 research, for example, has turned to the important issue of examining willingness to participate in surveys given perceptions of risk of disclosure, perceived harm, and perceived benefit.⁸⁰ Focusing on children and youth, Fisher has undertaken research on such issues as adolescents' assessment of investigators' use of varying options (such as maintaining confidentiality, reporting to parent/adult, encouraging self referral) under hypothetical conditions of investigators observing adolescents at various levels of jeopardy.⁸¹ She has also been studying the capacity of children and youth to understand their rights, with younger children comprehending information but having less comprehension of their rights as research participants.⁸² Others, like Hull and colleagues, are studying strategies for recruitment of family members in research in addition to the indexed participant.⁸³

There has also been a resurgence of interest in studying IRBs, a topic that—despite its inherent interest and value—has received scant research attention⁸⁴ since the University of Michigan surveys undertaken by Gray and associates^{63,85,86} as part of the work of the National Commission. Since the late 1990s, there have been additional commissions⁸⁷ and government reports⁸⁸ about IRBs that utilize or make reference to studies or data, but, over almost

30-year period, only a modest number of studies has surfaced across a spectrum of issues. For example, in 1985, Ceci, Peters, and Plotkin reported on an experimental study of IRBs' responses to hypothetical proposals that differed in sociopolitical sensitivity and ethical concerns (e.g., presence or absence of deception, debriefing).⁸⁹ They found that when the purpose of the research was presented to IRBs as nonsensitive, the protocol was twice as likely to be approved. In 1995, Hayes et al. reported on a survey of IRB members at research universities, finding that over half received minimal or no training.⁹⁰ In 2003, Wagner, Bhandari, Chadwick, and Nelson reported on the costs of operating IRBs and economies of larger IRBs.⁹¹ And in 2006, two studies were published that focused on investigator experiences, understandings, and perceptions of IRBs.^{92,93}

Renewed attention and calls for empirical research on research ethics have been matched by some federal funding initiatives. In particular, the DHHS Office of Research Integrity commenced an extramural program of support in 2001. Also, the inauguration in 2006 of the *Journal of Empirical Research on Human Research Ethics* (JERHRE), dedicated to publishing empirical research and reviews of empirical literature on human research ethics, can be expected to further catalyze attention to inquiry on these issues.⁹⁴

Ethical Issues in Research Contexts

The dearth of scientific knowledge about human research ethics adds to the challenge of undertaking research in all of the human sciences, including in the behavioral and social sciences. Nevertheless, absent deeper empirical knowledge, ethical considerations need to be weighed sensitive to the contexts of study and the fundamental principles of beneficence, respect, and justice specified in the Belmont Report and in codes of ethics. Key to making ethical decisions is to assess choices as part of the process of specifying the research design and methodology.

Complexity of Ethical Considerations

Behavioral and social science research draws on a range of research designs and methods in examining the complexities of human behavior—individually, in groups, in organizations and institutions, and in communities. Although different social science methods may be more frequently used or relied on by different behavioral and social science disciplines, almost every method is used to some degree in each behavioral and social science field. In addition, scientists increasingly draw on multiple methods in designing their research, even if there is primary reliance on a particular method.⁹⁵ The range of methods and multiple methods used in behavioral and social science research, the diverse populations under study, and the spectrum of issues (from mundane and everyday to highly sensitive and personal) make ethical considerations challenging and not amenable to easy characterization, generalization, or solution.

An emphasis on design and methods helps to identify ethical considerations across the behavioral and social sciences and between these sciences and the biomedical sciences—whether weighing autonomy, privacy, trust, benefit, or harm. Levine effectively dissected such issues in his 1976 paper “Similarities and

Differences Between Biomedical and Behavioral Research,”⁹⁶ prepared for the National Commission, and in his now classic volume *Ethics and Regulation of Clinical Research*.⁹⁷ Macklin also made an early and helpful contribution in her examination of disclosure in social science research.⁹⁸ Most comparisons between behavioral and social science research and biomedical research implicitly contrast the former to biomedical experimentation. It is from that vantage that behavioral and social science research is typically characterized as more likely to involve minimal risk for human participants because interventions in biomedical research have far greater potential for physical injury, harm, or adverse reaction.^{14,99,100}

Leaving aside the additional complexity of research on special populations (e.g., children, prisoners), much of behavioral and social science research involves little interaction or intervention that could elevate risk beyond the minimal level, taking as the standard that the “probability and magnitude of harm or discomfort anticipated in the research are not greater in and of themselves than those ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests.”⁶ Nevertheless, assessment of risks and benefits still comes into play in planning and implementing behavioral and social science research. Although the potential for physical harm or discomfort are rare, the risks are considered when appropriate—as is the potential for psychological, social, economic, or legal harm.^{101,102} In some instances, the research activity itself could produce psychological discomfort or harm from feelings of being inconvenienced, embarrassed, or tired or from transitory stress or anxiety to more traumatic emotions or experiences. In most instances, risk of social, economic, or legal harms follows from insufficient protection of private information during the actual research or from breaches of confidentiality (including a person’s anonymity) thereafter.

As suggested by the above, the substantive topics of inquiry may themselves cause psychological stress—from minor and transitory to more serious. For example, a research study on obesity that asks participants about their eating habits may cause minor and transitory stress. Research examining social support after the death of a loved one could cause a greater level of stress for participants because it evokes deep memories of sadness. Similarly, a retrospective study of adults who suffered child abuse could stimulate recollections that produce stress that is more than transitory or exceeds what persons would experience in everyday life. Research topics may also create the possibility of reputational, economic, legal, or physical harm that would exceed standards of low or minimal risk were there to be a breach of confidentiality. For example, a study of physicians charged with medical malpractice could produce reputational, economic, or legal harm were the identity of the physicians or the information they provided to researchers become known outside of the research setting. In each instance, precautions need to be taken to ameliorate or reduce the level of risk.

The biggest risk in behavioral and social science research most often relates to disclosure of a person’s identity and information about him or her. Even in nonsensitive matters, a promise of confidentiality is typically part of the process of obtaining consent from research participants. How such consent will be obtained, whether the information will be preserved and for what purposes, who may have access to such data, and the consequences to research participants of any breach, even with seemingly quite ev-

eryday issues (e.g., a study of exercise practices at a gym that might reveal to an employer that the research participant was not home sick that day) need to be weighed in order to honor the explicit or implied agreement between research participant and researcher.

The next sections of this chapter address the operational processes involved in weighing ethical issues in research involving human participants. The emphasis is on considering the potential for risk and strategies for risk reduction in the context of planning and implementing research because, even in areas of minimal risk, it is incumbent upon researchers to design their research in ways that maximize benefits and reduce risk as well as protect against circumstances that could inadvertently raise risk levels. At least in principle, the responsibilities of investigators in this regard are generally quite well understood.

The attention to risk in these sections is not to eclipse consideration of the very real benefits that can flow from behavioral and social science research and that need to be weighed in a risk/benefit assessment. Indeed, behavioral and social science research can provide a wide range of benefits, including insights into human behavior or the practices of a particular culture, determinations regarding best therapeutic methods or educational practices, or strategies for addressing developmental challenges for children and the elderly. The results of this research may have a direct benefit for participants (e.g., decisions regarding work hours in an organizational setting) or may benefit society more generally by influencing broader public policy decisions (e.g., limited hours for workers in high-risk occupations). The benefits that derive from research are an important part of the equation in reviewing research and assessing risk and risk tolerance under varying circumstances.

A Heuristic Model for Guiding Ethical Considerations

A number of scholars have recognized the complexity of weighing ethical considerations and have sought to map the relationship between types of research and ethical issues. Kelman, for example, schematized the relationship between types of research, the concrete interests of participants, and potential effects of the research on participants and on larger social values.²⁶ Cassell also depicted the relationship between investigator, research participants, and research in the context of studies ranging from biomedical and psychological experimentation to fieldwork, nonreactive observation, and secondary analyses of data.¹⁰³ She characterized the contexts in which investigators have more (or less) power as perceived by participants or have more (or less) control over the context or setting of research. Using a more complex framework, Sieber, too, graphed how the assessment of risk (from mere inconvenience and social risk to legal, psychological, or physical risk) can best be assessed in the context of a scenario that takes into consideration aspects of the research activity (e.g., the research processes, use of research findings), the risk-related factors (e.g., privacy and confidentiality, deception and debriefing), and the vulnerability of the persons and institutions involved (e.g., those visible or public, those engaged in illegal activities).¹⁰⁴

This chapter benefits from the ideas presented in these frameworks, but presents a three-dimensional model to inform ethical decision making that is more centrally focused on the core elements of the research: the methods, characteristics of the study

population, and the type of inquiry. As noted in the introduction to this chapter, the ethical issues raised by the use of various methods are closely tied to the population under study and the type of inquiry. Figure 32.1 depicts the interaction between the degree of substantive sensitivity of the study, the level of methodological intervention, and the degree of vulnerability of the human participants. This three-dimensional model views the potential degree of risk to follow from a combination of the method used, person characteristics, and the nature of the research.

In Figure 32.1, the y axis characterizes the level of methodological intervention in relation to research participants. It varies from no interaction (e.g., the use of extant public data or records), to indirect or direct contact (e.g., survey or interview) to intervention (experiments). This continuum generally reflects the centrality of the intervention or interaction to the definition of human subjects research, as specified in 45 CFR 46.102(f).⁶ Methods vary in the level of intervention with human participants (or their environments), and the level of research intervention can introduce risk. However, risk associated with methods is not a function only of the degree of intervention. Methods also vary in the amount of control an investigator has over the potential for risk (e.g., laboratory settings provide for a higher degree of investigator control than field studies) and in the degree of actual invasiveness

(e.g., video recordings in public places can be more invasive than a laboratory intervention on a relatively mundane issue). In selecting methods, investigators should weigh the scientific appropriateness of certain approaches cognizant of the value of minimizing or ameliorating the level of risk.

The x axis is the research population gradient and represents the level of human participant vulnerability. Any number of factors (biological, social, psychological, cultural) may influence where a research participant falls on the continuum. Federal law recognizes the vulnerability of certain populations of study (pregnant women, fetuses, and neonates; prisoners; and children), creating additional regulations for research involving these groups. The representation of participant vulnerability on a continuum allows viewing these and other potentially vulnerable groups (e.g., students, those in low-income brackets) on the same scale. It also permits depicting participants' vulnerability to heightened risks as a function of the characteristics of the population under study as distinct from any normative judgment about the desirability of protecting that population (e.g., studies of doctors engaged in insurance fraud or pharmacists engaged in illegal drug sales) or whether that population should otherwise receive any direct benefit at all. The responsibility of the investigator is to ensure that the vulnerability of human participants is not increased by virtue of being a part of the

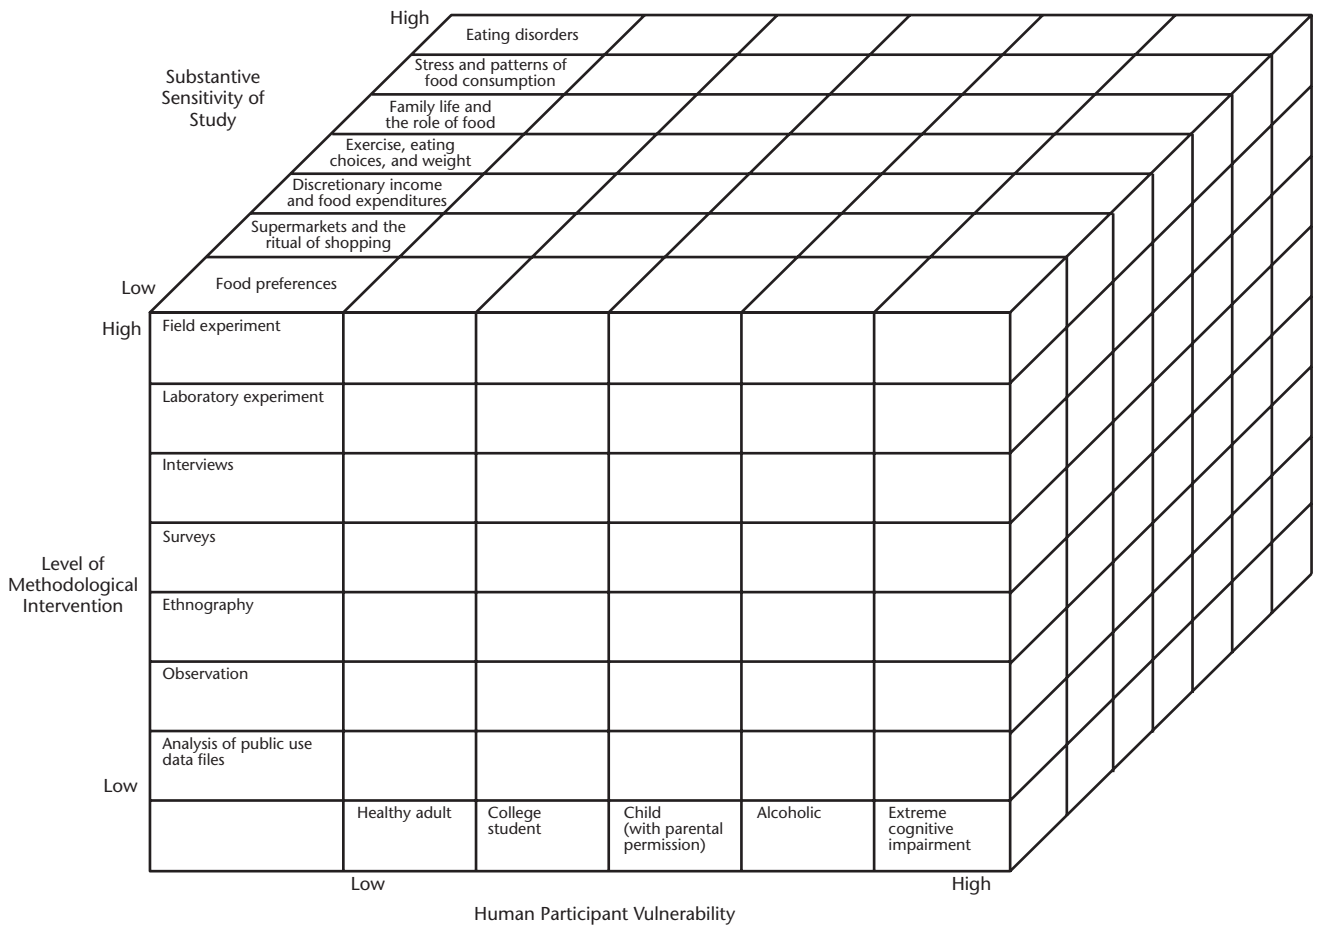

Figure 32.1. Risk in Research as a Function of Substantive Sensitivity of Study, Level of Methodological Intervention, and Human Participant Vulnerability.

research and being willing to contribute to the advancement of important knowledge.

The third dimension (z axis) displays the sensitivity of the study topic using, for heuristic purposes, illustrative studies about human interaction regarding food and consumption behavior. The sensitivity or the invasiveness of the research topic affects the level of risk in behavioral and social science research—from discomfort or embarrassment through anxiety, legal liability, and so forth. Figure 32.1 shows that risk level in matters of substance also interacts with the populations under study and the methods being employed. Although the invasiveness of the inquiry is often viewed alone in an analysis of risk, in reality it operates in concert with other factors that together shape risk.

The three dimensions highlighted above—level of methodological intervention, human participant vulnerability, and sensitivity of the study topic—interact to determine the level of risk. The next sections focus on factors that influence the risk of harm and consider the implications for the informed consent process and issues of confidentiality from the vantage point of different methodological approaches: experimental, observational, survey, interview, ethnographic, and analysis of public data files. The reader should note that although methodologies may overlap in any single study (e.g., the use of observation in experimental research), for purposes of clarity, each method is discussed separately.

Ethical Challenges

Experimental Methods

The experimental method provides a direct way of testing the cause and effect relationship between variables. Behavioral and social science experiments can occur in laboratories or in external field settings, including the school, community center, hospital, workplace, or neighborhood, to name but a few. This method, widely used by both biomedical and social scientists, is defined by the manipulation of a variable of interest, random assignment of participants, comparison of treatment or intervention and control conditions, and control of extraneous factors.

Take, for example, an experiment designed to test cognitive functioning under stress in older adults. The investigator gives experimental participants a task that is designed to tax their working memory and compares the results to those of a control group. First, the introduction of a manipulation of the environment alone raises ethical issues because such an intervention would not otherwise be experienced by the research participants. Because the researcher is changing the situation to which people would ordinarily be exposed, he or she has an obligation both to minimize any risks involved and to make those risks known to potential participants during the informed consent process.

The researcher who introduces and manipulates a variable must take care to examine the nature of the variable—its intensity and duration. In experimental research, investigators search for the level of intensity and duration that will produce an effect akin to what would occur in the lives of participants (referred to as experimental or mundane realism). An intervention may be positive, neutral, or negative and should not be assumed to be adverse. For example, the effect of relaxation exercises on workplace productivity for those in high stress jobs could be a very pleasant and satisfying intervention. The effect of group size and composition on problem solving may be a neutral manipulation. With inter-

ventions that may stimulate adverse states—such as tedium, anger, or performance anxiety—examination of the nature of the variable (both its intensity and duration) provides insights into the amount of invasiveness and its contribution to overall risk. If risk of an adverse state is beyond what might be expected in everyday life, the researcher may reduce the intensity of a planned intervention with the more limited goal of identifying triggers and mechanisms without risking substantial adverse behavior.

In planning and implementing experiments, the investigator needs to consider possible psychological and emotional consequences when germane. How is the manipulation of the situation viewed by the participant? Is the impact of the intervention (whatever its intensity or duration) transient? What will research participants be told about the research in advance of the study? Will debriefing return participants to their preexperimental state? In other words, does the manipulation increase risk for the research participant, and, if so, does the debriefing reduce it?

The design of the experiment can also have an impact on ethical considerations. A long-term sustained intervention may, in some instances, increase risk for research participants. For example, in an experiment designed to test the impact of images of aggression (e.g., shouting, pushing, hitting) on teenage behavior, those images that more closely approximate what teenagers experience in their daily life may pose less risk than those that exceed what they typically experience. Furthermore, the intensity and duration of the exposure may have an impact irrespective of the typicality of the depictions. Repeated exposure to a series of aggressive images may increase the level of fearfulness or of engaging in aggressive behavior. How participants may be affected by repeated exposures will be determined not only by characteristics of the methods, but also by individual factors. In this example, the risk to teenagers who have been abused or live in violent neighborhoods may be different in unknown directions than the risk to teenagers who have not had these experiences (e.g., at-risk teenagers may be desensitized or alternatively reaffirmed by the images).

Field experiments include randomized control trials and quasi-experimental designs that aim to test how modification of conditions can change behaviors or beliefs of individuals or groups. Experiments in the field alter the external environment (e.g., types of drug counseling, alternative strategies for teaching reading) that can affect the lives of those exposed to a treatment or control. The same ethical guidelines that apply to clinical medical trials apply here (e.g., one treatment should not offer more of a known benefit than another). Although experiments in the laboratory allow researchers to achieve a high degree of internal validity through careful controls, field experiments are introduced into real-world settings and thus have the potential for far greater external validity. Field experiments with randomized control designs are much more complex to plan and implement (from access to sites and agreements about the form of a manipulation to continuing follow-up to ensure consistent implementation of the treatment). Quasi-experimental designs are often introduced in the field when the context may require some alteration of a strict experimental design to be feasible. The classic texts by Campbell and Stanley¹⁰⁵ and by Cook and Campbell¹⁰⁶ provide more detailed descriptions of experimental and quasi-experimental design.

A field experiment might compare, for example, a novel intervention aimed at reducing risky sexual behaviors among teens with a control group that receives a standard educational

intervention. The introduction of a variable into a natural as opposed to laboratory setting raises some unique ethical challenges: How is the variable introduced into the setting (e.g., individual education sessions or community wide)? Is the intervention visible to others, thus posing additional risks for human participants (e.g., being seen by neighbors or friends entering a clinic for treatment)? Does the intervention have a broader or spillover effect? If so, is the effect transient? Is the effect of the intervention desirable or undesirable? If the experiment is occurring in a natural setting, is there sufficient attention to privacy protection? If people are unaware that the research is occurring, is there sufficient respect for the autonomy of research participants to determine whether they wish to be part of the research? If research participants are members of a vulnerable group (e.g., prisoners, teens, at-risk teens), how, if at all, does this increase risk?

Naturalistic experiments also arise in the conduct of social and behavioral science research. A change in legal regulations about drug use, for example, may provide an apt opportunity for a before-after design or a case-control comparison to sites that have not had such change. Interventions may be person-made (as in the case of a change in regulations, policy, or practice) or may be naturally occurring. A naturally occurring event like a hurricane or other disaster affords an opportunity to study certain aspects of human behavior with a before-after design or through comparison (e.g., a study of the reactions of people at varying distances from the site of a disaster). In such an instance, risk in the form of emotional trauma may vary in terms of research participants' locations. It may be more intrusive to ask people to participate in a study than to observe their interactions with neighbors, police, or clergy. The researcher needs to examine carefully the methods, nature of the inquiry, and participant vulnerability in order to make an assessment regarding ethics in these different situations.¹⁰⁷ Obtaining the input of an independent group of scientists and community members as part of the IRB review process can serve as an important check on the process.¹⁰⁸

Observational Methods

As with experiments, observational methods can be used in a range of research contexts from the carefully controlled setting of the laboratory to the field. In evaluating level of intrusion or possible risk, most researchers tend to focus on whether the behavior occurs in a public setting. However, the expectations of people in a particular setting also need to be considered. In using observational methods, researchers must consider (1) whether the setting is public or private and (2) whether the behavior is public or

private. Although these variables can be placed on a continuum, in Table 32.1 we depict them in a 2 × 2 matrix for illustrative purposes.

Table 32.1 shows the interaction of public-private setting and public-private behavior through an example for each cell. Observations of spectators' consumption of alcohol at a baseball game would be considered public behavior in a public setting. Spectators enter this setting assuming that behavior will be observed by others and possibly even recorded (e.g., in photos or videos by other spectators). Observations of public behavior in a public setting are not considered invasive, and risk is generally considered minimal. However, how the behavior is recorded (e.g., field notes or video recording that serves as a permanent record) could potentially increase the invasiveness of the inquiry and the overall risk, and could make data that are otherwise unidentifiable potentially identifiable, thus transforming the observations into human subjects research as defined in the federal regulations at 45 CFR 46.102(f)(2).⁶

Even behavior in a public setting can easily be considered private when people's expectations change. The public setting-private behavior cell is probably the area that causes most concern for investigators. Behavior in a public setting can be considered public by a researcher, but the expectations of the participants in this setting need to be considered in making decisions about responsibilities to human participants in this research. For example, Internet chat rooms may be considered public settings in that any member of the public can access them and become involved in a conversation. However, a number of these chat room discussions involve highly personal and sensitive matters. Although one might argue that participants should consider their behavior public, their expectations may be otherwise. Humphrey's tearroom trade study,³⁷ mentioned earlier, provides another example of the public setting-private behavior overlap. Although the setting was a public restroom, most men probably considered their behavior private.

In an Internet chat room, the use of observational methods may involve no interaction or intervention (i.e., when the researcher's identity is concealed and participation is minimal to nonexistent), but the nature of the inquiry may still be considered invasive from the viewpoint of chat room users' expectations of what might reasonably be expected to occur in this situation. Those who are less aware that the setting is public (e.g., an elderly person with less knowledge of the Internet) are more vulnerable than those who realize its public nature. In addition, risk is increased if the sensitivity of the information can potentially harm research participants. If an investigator is monitoring and recording discussions of alcoholism in an Internet chat room, the information could have economic, social, and legal risks for the participant. Researchers can decrease the vulnerability of participants by recording observations in such a way that identities cannot be traced. In addition, although this setting can allow researchers to remain anonymous and this feature of the design can be important in understanding human behavior in real-life situations, the fact that a researcher's presence is unknown increases the level of invasiveness and risk for those involved because their ability to monitor and control self-presentation to fit the context is reduced.

In the private setting-private behavior cell, both setting and expectations combine to increase the potential risk to participants. First, the home itself is generally considered to be a private place. Second, most private behavior occurs in the home. Participants in

Table 32.1
Illustration of Interaction of Public and Private Dimensions in the Observational Method

		Setting	
		Public	Private
Behavior	Public	Observe alcohol use at baseball game	Observe alcohol use at open-house holiday party
	Private	Observe discussions of alcohol use in Internet chat room	Observe alcohol use in in-home family study

an in-home family study may consider the recording of observations about alcohol use to be intrusive despite their agreement to be involved. Special precautions should be taken to ensure fully informed consent and to plan confidentiality protections in advance. Here, privacy concerns are elevated, but proper informed consent can reduce ethical concerns about overstepping participants' expectations. In addition, taking steps to protect the confidentiality of the data can reduce the risk to participants.

Finally, observations of public behavior in a private setting should also be guided by participants' expectations. Although a home is typically considered private, behavior in the home may be considered "public" if, for example, a homeowner invites residents in the neighborhood into the home. One might reasonably expect that observations of alcohol use by other partygoers at an open-house holiday party could be discussed outside this setting. Still, a researcher's observation and recording of alcohol use at a party may be considered more intrusive than observations by party guests, and how such data are gathered can have different implications for the perceived intrusiveness of the inquiry. Making known a researcher's presence will decrease the perceptions of invasiveness and is more respectful of the autonomy of potential research participants who can decide whether to leave or stay. Acknowledged observation or participant observation in this context gives individuals more control over the situation than if the researcher fully conceals her or his identity. What form the research design should take and what the consent process should be (i.e., how much information should be revealed by the researcher in order to act ethically in obtaining valid data) need careful assessment by the researcher and independent assessment by an IRB, especially if the researcher seeks to waive some or all of the elements of informed consent.

Survey Methods

Survey research methods are widely known in the general public and are used in a range of studies from specific institutional or organizational contexts and small area population studies to major national or international surveys on general adult populations or on specialized populations of adults, children, or youths. Of behavioral and social science methods, survey research may be best known to the public because it is the social science method that has had the widest application outside of the social and behavioral sciences by, for example, commercial, political, and media organizations. The federal government also oversees many large-scale survey research projects. For example, in order to monitor the health and well-being of the population, the government regularly undertakes the National Health Interview Survey.

The level of risk in any survey is affected by several factors that may interact and affect overall risk. Specifically, the factors influencing the risk dimension include questionnaire content (sensitivity), mode of administration, recruitment strategies, mechanisms to increase participation, and the actual survey design (e.g., cross-sectional or longitudinal). Other factors influencing total risk are the population studied, anonymity of the responses, person or entity collecting the data, and data usage and storage. Together, these factors determine the level of risk in a survey. Each is described below.

The factor receiving most attention in survey research is the questionnaire content. Survey methods are used in a variety of substantive areas covering topics ranging from those with little or

no sensitivity to those that may be considered highly sensitive. For example, questions about personal health information are generally considered more private or invasive than those that ask about product preference. Similarly, the mode of administration (e.g., telephone, mail, Internet, in person) affects whether participants think the procedure is more or less invasive. Mail surveys, especially anonymous ones addressed to "resident," are less intrusive than a face-to-face interview in the home. Telephone surveys and Internet surveys fall between these two points. Participants may perceive a certain degree of anonymity when responding to Internet surveys, thereby decreasing the perceived level of invasiveness (even if responses could ultimately be traced). From the human participants' perspective, the type of questions asked and how they are administered affect their view of the level of intrusion and the perceived risk associated with the survey.

Although surveys cover full populations under study, typically they are aimed at a sample of a population selected from a specified frame, however it is identified (often that means use of a list of potential participants who have attributes in common). If researchers access a publicly available list (e.g., a phone book) or obtain or construct a list from public information (e.g., a map of housing units in census tract areas), participants are less likely to consider this an invasion of privacy because they know that the records are publicly available than if the researcher obtains a private list (e.g., a club membership list) that is not generally available. How potential respondents are identified (that is, the sampling frame from which they are drawn) and how they are approached are important in determining participants' perceptions of invasiveness and potential risk. Being asked to participate in a local or national household survey is less invasive and potentially less anxiety-arousing than being approached to participate in a survey as a cancer survivor or because a person is living in a community in which the water has a high lead content.

The quality of survey research is inextricably tied to the representativeness of the sample. Survey researchers employ a number of techniques in order to improve response rate such as callbacks, persuasive introductory or interviewing scripts, or incentives in the form of payments for research participants' time. Properly employed, these techniques can strengthen response rates without being overly intrusive, coercive, or infringing upon an individual's right to privacy. Interestingly, modern technologies such as unlisted cell phone numbers raise problems in sampling designs that can reduce the quality of the survey and thus, the benefits of conducting the research.

The design of the survey can also affect the potential level of risk. In longitudinal versus cross-section designs, there are many more scientific payoffs and potential benefits in terms of causal modeling and identifying patterns of behavior, but longitudinal research can require more from research participants in the amount of cooperation, and repeated follow-up can raise potential risk. Longitudinal designs that seek participation for long spans of time increase the opportunities for participants to be identified in contrast to cross-sectional designs (i.e., one-time-only collections of data), but sensitivity to how subsequent contacts are made and how data linkages are protected can avert increasing disclosure risk.

The level of potential risk is also affected by whether identifying information is obtained or retained. For example, if random-digit dialing is used in a telephone survey, individuals can remain anonymous. In household surveys, individuals are not

anonymous; however, one's responses can be protected by data security and data access plans consonant with the level of sensitivity of the substance of the study. Despite these efforts to protect participants' identity and personal information, other inadvertent disclosures could occur. For example, during a phone or in-home survey, family members may overhear all or part of the conversation and convey that to others. Similarly, research assistants may inadvertently risk identification of participants by sharing examples of interesting cases with others outside the research team. In both instances, the risk level for participants is increased, but the rarity of such events and the nature of the harm or discomfort itself may not generally exceed the everyday standard of minimal risk.

Under federal regulations, surveys of healthy adult populations are exempt from review by IRBs if participation is anonymous and the topic of inquiry presents no more than minimal risk for respondents. Surveys that include identifier information may qualify for expedited review by IRBs if they are on healthy adult populations and if the topic of inquiry and the possibility of information disclosure involve no more than minimal risk. On the other hand, federal rules recognize the inherent vulnerability of children and, as such, require IRB review of surveys involving children. Even with adult populations, however, vulnerability and level of risk may vary. For example, paying low-income persons to participate in a study suggests a different level of potential coercion due to personal characteristics than providing the same payment to a middle-income person, and differential payments can raise questions about just and equitable treatment of human participants. Thus, the vulnerability of the population requires consideration in implementing the survey design and research.

Interview Methods

The level of risk in interviews is affected by many of the same factors as in surveys, such as the content of the questions, the population studied, and how the data are used and stored. There are, however, ethical factors that are more particularistic to the interview method. Surveys that are administered in person raise some of the same concerns. Four issues, in particular, need to be considered: degree of structure in the interview; unanticipated but sensitive responses; disclosure following group interviews; and recruitment through the use of interviews.

In behavioral and social science research, interviews can range from highly structured to unstructured formats. In some research, a list of questions is systematically designed, although not to the level of a survey instrument; in other studies, the interviews may be guided by only a general map. Alternatively, the researcher may prepare a general framework with specific questions that will vary depending on what issues are raised by the respondent in answering earlier questions. Follow-up questions may or may not be specified at the onset, depending upon the research training and tradition in which the investigator is grounded.

As one example, a researcher using a semistructured interview may create an "interview guide" that, for example, lists a range of questions by topic area: introduction (questions about the nature of the study and consent to participate), background (family, friends), and drug use (friends' drug use, personal drug use, multiple drug use), sexual experiences following drug use (who initiated, safe-sex practices). Here, subsequent stages of the interview would be guided by answers earlier in the interview. Questions about multiple drug use would be skipped if respondents

indicate that they use only one drug. Similarly, questions about sexual experiences after drug use would be skipped altogether if respondents indicate that they do not use drugs.

In a structured or even a semistructured interview, the questions can be reviewed to determine the level of invasiveness (e.g., the sensitivity of the questions) as well as participant vulnerability (e.g., the appropriateness of the questions given the study population). In an unstructured interview, consideration must be given to the fact that a more open-ended procedure implies less control about what the interviewer might ask or what might be revealed by the participant, even if the level of invasiveness and the participant vulnerability remain unchanged. Unstructured interviews can also provide an opportunity for the interviewer to build rapport and a trusting relationship with research participants, enhancing the experience of participants and the quality of their responses.

Investigators conducting structured or unstructured interviews may be aware of the questions or type of questions they will ask, but respondents may provide unanticipated answers in an interview session. In surveys, the number of open-ended questions is constrained, and responses are typically selected from among those provided. In interviews, on the other hand, response options may not be given, and the length and type of responses may vary considerably. Generally, the response does not raise ethical issues, but it could if the response (1) indicates activity that a researcher is legally required to report (e.g., child abuse) or (2) reveals other sensitive information that should be protected. Given that the respondent freely communicates the information, the response does not per se affect the invasiveness of the inquiry, nor does the intrinsic vulnerability of the participant change. Nevertheless, the method used (here, open-ended interviews) increases the risk for participants. Investigators can decrease risk by indicating in the informed consent process what information can be protected, how it will be protected, and, depending on the topic, whether the researchers are legally required to disclose to authorities any information revealed by the participants.

An additional consideration when evaluating risk in interviews is whether the information will be collected in a group setting. For example, a group interview of early career faculty about professional transitions, coping strategies, multiple time demands, and mixed messages about performance expectations could enhance the quality of the insights and understandings that come from peer interaction; but a group interview could also make these professionals vulnerable were their views or feelings inadvertently to become known. Highly sensitive questions that could be considered invasive typically are not asked by researchers when interviews are conducted in groups, but respondents may provide answers that increase their risk if they assume the session is confidential. Researchers can protect the information provided, but they cannot ensure that other participants will refrain from intentionally or inadvertently disclosing a respondent's answers. Again, the level of risk is affected by the group interview format.

Researchers can decrease risk by describing the extent of the confidentiality protections during the informed consent process and by training interviewers to "head off" responses that increase risk. Similarly, in a group setting, participants' judgments can be influenced by others, and doing so could increase pressure on them to respond, respond in a particular way, or remain in the interview session when they would not do so were they alone. Researchers should consider the impact of subtle group influence on risk and implement steps to decrease it.

Finally, interviews can be used to screen participants for other research studies or follow-up phases of the current study. How, where, and by whom participants are approached can contribute to the invasiveness of the research and the degree of risk. For example, it is less intrusive to approach people by phone than in a waiting room of a health-related facility. However, if research is conducted on low-income residents, a phone may not be available in the home and approaching potential participants at a clinic may be the best way to obtain a representative sample that does not exclude certain populations from the study.

Under this scenario, who should approach these clinic patients? If a health professional conducts the screening, it will probably be considered less intrusive, but these professionals may not have the time if the research protocol is not a part of their job. Also, depending on how the approach is framed, contact by health professionals either could offer more autonomy for potential research participants to consent or refuse to consent, or could lead to undue influence to consent. Alternatively, assuming approval by the clinic, can the researcher approach potential participants in the clinic waiting room? Although the intrusiveness of the inquiry might be slightly higher, overall risk might be decreased by better protecting the identities of research participants. Discussions with a skilled interviewer may actually be a positive experience for participants, especially for those persons who are lonely or need to be heard on an issue. Of course, the positive aspect of an interview experience may also lead participants to reveal more private information, placing more obligations upon the researcher to ensure that all information is appropriately protected and that participants do not increase the risk of any subsequent harm or discomfort by revealing more than they wish others to know.

Participant vulnerability should also be considered in deciding on the best approach: Are people participating because they are ill and think the information learned in the interview will help them, or are they healthy persons who came to the clinic for an annual checkup? It should not, however, be assumed that vulnerable persons are unwilling or unable to discuss or provide information about certain topics. Investigators or IRBs determining that certain issues are off-limits for certain groups can be disrespectful of individuals, limit their autonomy to be part of studies, and reduce the benefit of having certain forms of knowledge on the most vulnerable populations. Taking care to ensure that research procedures do not add to risk does not mean that research topics should be avoided.

Ethnographic Methods

Ethnography is the in-depth study of individuals and groups in their own environments. The method itself involves the use of multiple methods including unstructured interviews, semistructured interviews, unobtrusive observations, participant observation, and document or audiovisual analysis. Although this method is employed by researchers in many disciplines, anthropologists have typically used it most to provide accounts of particular cultures, societies, or communities. Ethnographers may focus on a particular topic in conducting their research (e.g., child-rearing practices), or they may be interested in more holistic study of the context or setting.

Ethnographic methods typically involve more than one research strategy and more than one type of research participant (e.g., drug users, community leaders, health-care workers). In a

study of domestic violence in a rural African village, for example, an investigator may begin preliminary work by speaking to people in the community over a period of months to learn about the cultural norms and practices that may contribute to the problem. The investigator may follow the informal discussions with a semi-structured interview of couples in the region. Simultaneously, the investigator may observe husband-wife interaction in public places to identify normative practices and the limits of acceptable behavior. Information obtained from ethnographic phases of a study may also suggest culturally sensitive interventions that could be tested in a field experiment.

The ethical issues associated with the use of this method can also be placed within the contours of our model. The invasiveness of the inquiry depends on the subject matter of the research and the vulnerability of the human participants who are the focus of the study. The method itself (or the bundling of methods) may also raise ethical challenges and dilemmas. For example, use of participant observation—especially if the research is conducted over long durations of time—can lead to attachments between the researcher and participants. A researcher studying domestic violence who has created emotional bonds within the community may have access to more and better information from participants. Also, the attachment may increase benefits for participants if they feel more at liberty to share information that previously they have found hard to discuss or disclose (e.g., information regarding abusive experiences, long-held family secrets).

A fundamental feature of the ethnographic method is to build trust between the researcher and the research participants in the study. If rapport is not effectively established, the investigator's presence may lead to perceptions of intrusiveness. Usually, however, the fact that the researcher lives in the community and often does so for a period of time before beginning research—typically in an attempt to identify the research directions, possible participants, and cultural norms—enables the researcher to build trust with community members and may decrease the view that an inquiry, however broad, is invasive.

The degree of risk may also be affected by the level of control inherent in the method itself. For example, the actual beginning and end of the research may not be clear because the researcher may have conversations with community members about their practices and beliefs before deciding where to focus the research. The researcher studying domestic violence may observe and speak to community members regarding views of male and female roles, use of alcohol, and the role of extended family or religion in influencing behavior. At times, conversations may be casual and unrelated to research, may lead to research, or may be a part of the research (in which case the consent of participants should be obtained). In addition, the researcher may come and go from a community over a period of time, at times interviewing people and collecting data and at other times casually observing community members for purposes of deciding the next step in research. Although the nature of the research may signal a need for flexibility with the approach, researchers can decrease risk by ensuring that community members are aware of the research and their roles.

Given the nature of ethnographic research, the pool of human participants is not always identified at the onset. A researcher may begin discussions with community and religious leaders in trying to understand the high incidence of domestic violence in a community, but later move to discussions with employers to determine

the role that job-related stress may play. As the researcher becomes immersed in a community and has a better understanding of it, he or she may choose to focus on certain members of the community. As the research progresses, other participants may also be identified. At these points, the researcher needs to engage potential participants in a conversation about the study and ascertain their interest in participating. If the discussions occur over a period of time, the researcher should continue to check the community members' willingness to participate. Thus, more than with other more targeted and time-bound methodologies, the consent process in ethnographic research is dynamic and ongoing—meeting the changing needs and circumstances of the research itself.

The risk associated with the method can be decreased by the use of a continuous consent process, as well as the flexibility to waive written consent when it would be culturally inappropriate, when participants are illiterate, or when use of consent forms could raise undue anxiety or place participants at risk. Indeed, in some cultures, being asked to sign a consent form may be considered an insult as a verbal agreement is valued. In some instances, it may also be appropriate to seek the consent of community leaders or elders, and community norms will suggest when this approach is congruent with human research protection or when it could elevate risk for research participants. Accounting for community norms, attending to the status of particular individuals in the community, and determining how consent should be obtained and whether it should be documented are elements of ethical decision making that can decrease overall risk.

Finally, as with other methods, the procedures used to collect, preserve, or store the information gathered can place participants at risk. Careful consideration of the protections available as well as individual and cultural expectations for the use and storage of the information can reduce the risk for research participants.

Analysis of Public Use Data Files

A great deal of information collected about individuals can be used in secondary analyses to examine important research questions, test rival hypotheses, verify findings, and so forth. For example, a wealth of information collected in periodic government surveys such as the Census, the National Education Longitudinal Survey, or the National Survey of Family Growth and in major national surveys such as the General Social Survey (GSS), the Panel Study of Income Dynamics (PSID), and the National Election Study (NES) can be accessed and used by other researchers. Some surveys like the GSS, the PSID, and the NES are undertaken to create data resources for multiuser analysis; other studies yield public use files that permit secondary study by other investigators (e.g., the National Longitudinal Study of Adolescent Health, the National Longitudinal Survey of Freshmen). The practice of creating public data files allows for greater use of a vast amount of data that would otherwise go unanalyzed and makes better use of limited resources to examine a range of behavioral and social science issues of scientific significance and societal importance.

By definition, public use data files refer to data that have already been collected and stripped of personal identifiers or altered to eliminate identifiable private information. Once these data files have been created and appropriately reviewed by an IRB or, in the case of a government agency, by a disclosure review board, they are no longer considered human subjects research as defined by 45 CFR 46(f),^{6,109} although institutional IRBs individually act

on their status.¹¹⁰ Because public use data provide essentially anonymous information to the secondary analyst, concerns about invasiveness of this work or risk of harm are not at issue, though the research offers general benefits to those whose information contributed to these data sets.
