ABSTRACT

Objective: To investigate the effect of low doses of subcutaneous testosterone in hypogonadal men since the intramuscular route, which is the most widely used form of testosterone replacement therapy, is inconvenient to many patients.

Methods: All men with primary and secondary hypogonadism attending the reproductive endocrine clinic at Royal Victoria Hospital, Montreal, Quebec, Canada, were invited to participate in the study. Subjects were enrolled from January 2002 till December 2002. Patients were asked to self-administer weekly low doses of testosterone enanthate using 0.5 ml insulin syringe.

Results: A total of 22 patients were enrolled in the study.

The mean trough was 14.48 ± 3.14 nmol/L and peak total testosterone was 21.65 ± 7.32 nmol/L. For the free testosterone the average trough was 59.94 ± 20.60 pmol/L and the peak was 85.17 ± 32.88 pmol/L. All of the patients delivered testosterone with ease and no local reactions were reported.

Conclusion: Therapy with weekly subcutaneous testosterone produced serum levels that were within the normal range in 100% of patients for both peak and trough levels. This is the first report, which demonstrated the efficacy of delivering weekly testosterone using this cheap, safe, and less painful subcutaneous route.

Saudi Med J 2006; Vol. 27 (12): 1843-1846

Androgen replacement therapy has evolved as a result of many years of modifying the testosterone molecule. Changes in the method of testosterone delivery have included implantable pellets, intramuscular injections, and oral formulations. Recently transdermal patches and gels have also been introduced, but these are costly. Choosing between the different testosterone preparations depends upon efficacy, safety, cost, as well as patient acceptability. The most widely used form of testosterone replacement therapy is the intramuscular injection of mixed testosterone esters. This depot formulation relies on

retarded release of the testosterone esters from the oil vehicle injection depot as following release: esters undergo rapid hydrolysis by ubiquitous esterases to liberate free testosterone into the circulation. The pharmacokinetics and pharmacodynamics of androgen esters are therefore primarily determined by ester side chain length, volume of oil vehicle, and site of injection via hydrophobic physicochemical partitioning of the androgen ester between the hydrophobic oil vehicle and the aqueous extracellular fluid.¹ The advantage of testosterone esters over other testosterone preparations is that they are biologically
