Scalp lacerations are the most minor type of head trauma. Because the scalp contains many blood vessels with poor constrictive abilities, most scalp lacerations are associated with profuse bleeding. The major complications associated with scalp laceration are blood loss and infection.

Skull Fractures.

Skull fractures frequently occur with head trauma. There are several ways to describe skull fractures: (1) linear or depressed; (2) simple, comminuted, or compound; and (3) closed or open (Table 59-6). Fractures may be closed or open, depending on the presence of a scalp laceration or extension of the fracture into the air sinuses or the dura. The type and severity of a skull fracture depend on the velocity, the momentum, the direction of the injuring agent, and the site of impact.

TABLE 59-6
TYPES OF SKULL FRACTURES

Description	Cause
Linear	
Break in continuity of bone without alteration of relationship of parts	Low-velocity injuries
Depressed	
Inward indentation of skull	Powerful blow
Simple	
Linear or depressed skull fracture without fragmentation or communicating lacerations	Low-to-moderate impact
Comminuted	
Multiple linear fractures with fragmentation of bone into many pieces	Direct, high-momentum impact
Compound	
Depressed skull fracture and scalp laceration with communicating pathway to intracranial cavity	Severe head injury

The location of the fracture alters the presentation of the manifestations (Table 59-7). For example, a specialized type of linear fracture is seen when the fracture occurs at the base of the skull—a basilar skull fracture. Manifestations include *Battle sign* (postauricular ecchymosis) (Figure 59-13) and *bilateral periorbital ecchymosis* (raccoon eyes). This fracture generally crosses a sinus and tears the dura (e.g., the frontal or temporal dura) and is associated with cranial nerve damage and leakage of CSF. *CSF rhinorrhea* (CSF leakage from the nose) or *CSF otorrhea* (CSF leakage from the ear) generally confirms that the fracture has traversed the dura (Figure 59-14). The CSF leak places these patients at high risk for meningitis.

TABLE 59-7

CLINICAL MANIFESTATIONS OF DIFFERENT TYPES OF SKULL FRACTURES

Location	Clinical Manifestations
Frontal fracture	Exposure of brain to contaminants through frontal air sinus, possible association with air in forehead tissue, CSF rhinorrhea, or pneumocranium (air between the cranium and dura mater)
Orbital fracture	Periorbital ecchymosis (raccoon eyes), optic nerve injury
Temporal fracture	Boggy temporalis muscle because of extravasation of blood, oval bruise behind ear in mastoid region (Battle sign), CSF otorrhea, middle meningeal artery disruption, epidural hematoma
Parietal fracture	Deafness, CSF or brain otorrhea, bulging of tympanic membrane caused by blood or CSF, facial paralysis, Battle sign
Posterior fossa fracture	Occipital bruising resulting in cortical blindness, visual field defects; rare appearance of ataxia or other cerebellar signs
Basilar skull fracture	Otorrhea, bulging of tympanic membrane caused by blood or CSF, Battle sign, tinnitus or hearing difficulty, rhinorrhea, facial paralysis, conjugate deviation of gaze, vertigo, bilateral raccoon eyes

CSF, cerebro-spinal fluid.

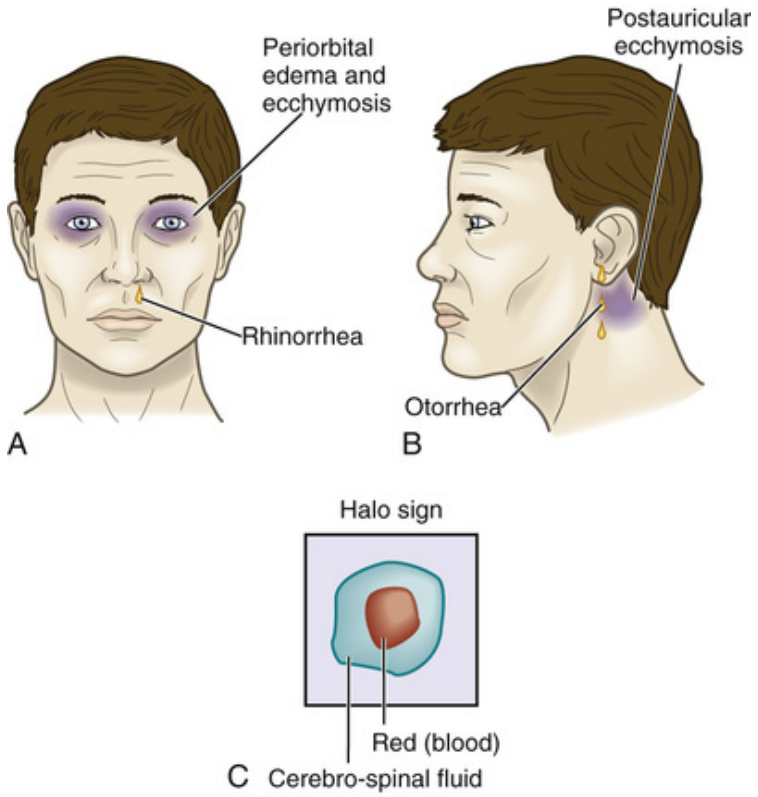

FIGURE 59-14 **A,** Raccoon eyes and rhinorrhea. **B,** Battle sign (postauricular ecchymosis) with otorrhea. **C,** Halo or ring sign (see text).

Two methods of testing can be used to determine whether the fluid leaking from the nose or ear is CSF. The first method is to test the leaking fluid with a Dextrostix or Tes-Tape strip to determine whether glucose is present. CSF gives a positive reading for glucose. If blood is present in the fluid, testing for the presence of glucose is unreliable because blood contains glucose. In this event, the nurse should look for the *halo* or *ring* sign (see Figure 59-14, *C*). To perform this test, the nurse allows the leaking fluid to drip onto a white pad (4 × 4) or towel and observes the drainage. Within a few minutes, the blood coalesces into the centre, and a yellowish ring encircles the blood if CSF is present. The colour, the appearance, and the amount of leaking fluid must be noted because both tests can give false-positive results.

The major potential complications of skull fractures are intracranial infections and hematoma, as well as meningeal and brain tissue damage.

Head Trauma.

Brain injuries are categorized as diffuse (generalized) or focal (localized). In a *diffuse* injury (e.g., concussion, diffuse axonal injury), damage to the

brain cannot be localized to one particular area. In a *focal injury* (e.g., contusion, hematoma), damage can be localized to a specific area of the brain. Brain injury can be classified as *mild* (GCS score of 13 to 15), *moderate* (GCS score of 9 to 12), and *severe* (GCS score of 3 to 8).

Diffuse Injury.

Concussion (a sudden, transient, mechanical head injury with disruption of neural activity and a change in the LOC) is considered a mild brain injury. The patient may or may not lose total consciousness with this injury.

Signs of concussion may include a brief disruption in LOC, amnesia regarding the event (retrograde amnesia), and headache. The manifestations are generally of short duration. If the patient has not lost consciousness, or if the loss of consciousness lasts less than 5 minutes, the patient is usually discharged to the care of a responsible adult with instructions to notify the health care provider if symptoms persist or if behavioural changes are noted. Mild TBI is significantly underdiagnosed, and the societal impact is great.

Postconcussion syndrome is seen anywhere from 2 weeks to 2 months after the concussion. Symptoms include persistent headache, lethargy, personality and behavioural changes, shortened attention span, decreased short-term memory, and changes in intellectual ability. This syndrome can significantly affect the patient's abilities to perform the activities of daily living.

Although concussion is generally considered benign and usually resolves spontaneously, the symptoms may be the beginning of a more serious, progressive problem that can continue for years following the injury. At the time of discharge, it is important to give the patient and the family instructions for observation and accurate reporting of symptoms or changes in neurological status.

Individuals with mild or moderate, sports-related concussions are more likely to have future concussive injuries. Recurrent concussions are also associated with slower recovery and may have long-term effects. Patients should be instructed to avoid contact sports until all symptoms have subsided. In addition, return to play should be gradual.

Chronic traumatic encephalopathy (CTE) is the term used to describe degeneration in the brain from repeated concussions, including those sustained during sports. Research is ongoing to examine the link between repeated concussions and brain degeneration (

Canadian Concussion Centre, 2017).

Diffuse Axonal Injury.

Diffuse axonal injury (DAI) is widespread axonal damage occurring after a mild, moderate, or severe TBI. The damage occurs primarily around axons in subcortical white matter of the cerebral hemispheres, the basal ganglia, the thalamus, and the brain stem. Initially, DAI was believed to occur from the tensile forces of trauma that sheared axons, resulting in axonal disconnection. There is increasing evidence that axonal damage is not preceded by an immediate tearing of the axon from the traumatic impact, but rather that the trauma changes the function of the axon, resulting in axon swelling (axonal ballooning) and disconnection. This process takes approximately 12 to 24 hours to develop and may persist longer. The clinical signs and symptoms include a decreased LOC, increased ICP, decerebration or decortication, and global cerebral edema. Approximately 90% of patients with severe DAI remain in a persistent vegetative state (Wasserman, Koenigsberg, & Feldman, 2014).

Focal Injury.

Focal injury can be mild to severe and is localized to an area of injury. Focal injury consists of lacerations, contusions, hematomas, and cranial nerve injuries.

Lacerations involve actual tearing of the brain tissue and often occur in association with depressed and compound fractures and penetrating injuries. Tissue damage is severe, and surgical repair of the laceration is impossible because of the texture of the brain tissue.

When major head trauma occurs, many delayed responses are seen, including hemorrhage, hematoma formation, seizures, and cerebral edema. Intracerebral hemorrhage is generally associated with cerebral laceration. This hemorrhage manifests as a space-occupying lesion accompanied by unconsciousness, hemiplegia on the contralateral side, and a dilated pupil on the ipsilateral side. As the hematoma expands, symptoms of increased ICP become more severe. Prognosis is generally poor for the patient with a large intracerebral hemorrhage. Subarachnoid hemorrhage and intraventricular hemorrhage can also occur secondary to head trauma. The "Ethical Dilemmas" box considers a case of brain death due to severe brain injury.

A **contusion,** frequently occurring near the site of a skull fracture, is the bruising of the brain tissue within a focal area. A contusion often develops in areas of hemorrhage, infarction, necrosis, and edema. With contusion, the phenomenon of *coup–contrecoup injury* is often noted (Figure 59-15). Damage from coup–contrecoup injury occurs because of mass movement

of the brain inside the skull. Contusions or lacerations occur both at the site of the direct impact of the brain on the skull *(coup)* and at a secondary area of damage on the opposite side away from the injury *(contrecoup),* leading to multiple contused areas. Patient prognosis is dependent upon the amount of bleeding around the contusion sites, which can range from minimal to severe. Contusions may continue to bleed or rebleed and appear to evolve on subsequent CT scans of the brain. Contusions that continue to evolve have a poorer prognosis. Neurological assessment demonstrates focal findings and a generalized disturbance in the LOC. Seizures are a common complication of brain contusion.

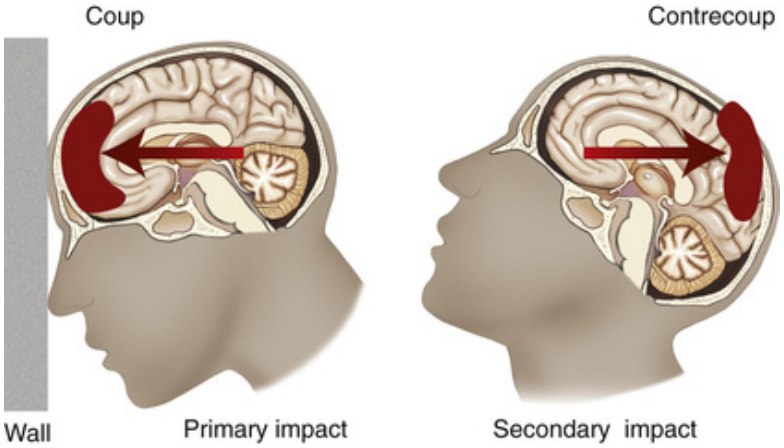

FIGURE 59-15 Coup–contrecoup injury. After the head strikes the wall, a coup injury occurs as the brain strikes the skull (primary impact). The contrecoup injury (the secondary impact) occurs when the brain strikes the skull surface opposite to the site of the original impact.

Ethical Dilemmas

Brain Death

Situation

The emergency nurse receives a radio call from emergency medical services (EMS) personnel about a young man who has been involved in a motorcycle crash. The patient was not wearing a helmet and has a large, open-skull fracture with obvious grey matter oozing from the area.

Transport from the accident scene was delayed by 45 minutes as a result of a severe thunderstorm and traffic congestion. On the way to the hospital, the patient has fixed, dilated pupils and a cardiac arrest. Estimated time of arrival at the hospital is still an additional 45 minutes as a result of the severe weather. EMS personnel request permission to stop cardiopulmonary resuscitation (CPR) efforts.

Important Points for Consideration

- Death by neurological criteria occurs when the cerebral cortex stops functioning or is irreversibly destroyed.
- Because technology has been developed that assists in supporting life, controversies have arisen related to an exact definition of *death*.
- Criteria for brain death include coma or unresponsiveness, absence of brain stem reflexes, and apnea. Specific assessments by a physician are required to validate each of the criteria.
- The patient's clinical manifestations indicate that brain death has occurred.
- Although there is a slight chance that the patient's heart function could be resuscitated and supported with mechanical ventilation, there is no obligation to provide medically futile care for a patient with brain death.
- Brain death criteria do not address patients in a permanent vegetative state because the brain stem activity in these patients is adequate to maintain heart and lung function.

Critical Thinking Questions

1. What are the nurse's feelings about cessation of brain function versus cessation of heart and lung function as the criteria for death of a patient?
2. What legislation or practices are there in the nurse's province or territory about EMS personnel stopping CPR efforts in the field?

Complications

Epidural Hematoma.

An **epidural hematoma** is a collection of blood that results from bleeding between the dura and the inner surface of the skull (Figure 59-16); it produces compression of the dura mater and thus of the brain. Epidural hematomas that are a result of a torn artery and are under the influence of a high-pressure arterial system form rapidly. An arterial epidural hematoma is a neurological emergency (Figure 59-17) and is usually associated with a linear fracture to the thin squamous portion of the temporal bone and laceration of the middle meningeal artery or one of its branches. Venous epidural hematomas are less common, are associated with a tear of the dural venous sinus, and develop slowly. Symptoms typically include unconsciousness at the scene, with a brief lucid interval followed by a decrease in LOC. Other symptoms may be a headache, nausea and vomiting, or focal findings. Rapid surgical intervention to prevent cerebral herniation dramatically improves outcomes.

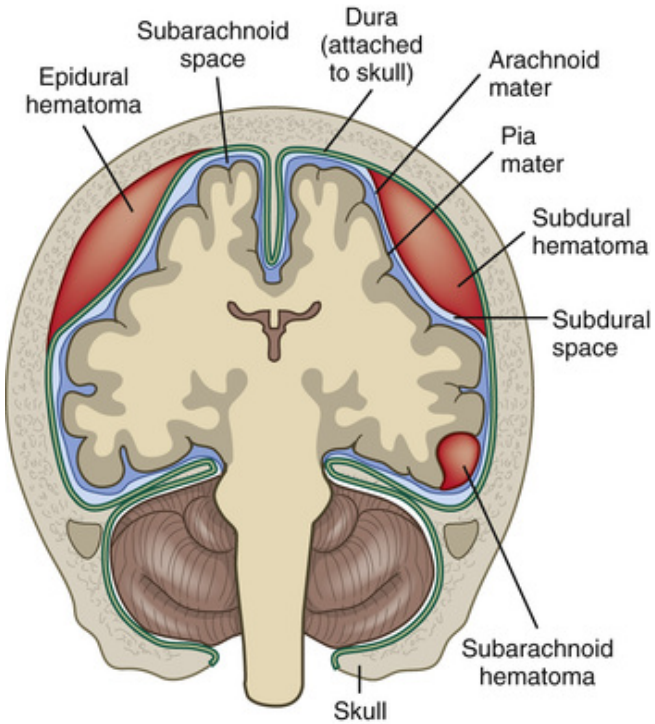

FIGURE 59-16 Locations of epidural, subdural, and subarachnoid hematomas. Source: Copstead, L. C., & Banaski, J. L. (2010). *Pathophysiology* (4th ed., p. 1051, Figure 44-13). Philadelphia: Saunders.

(2010). *Robbins and Cotran: Pathologic basis of disease* (8th ed., p. 1289, Figure 28-11). Philadelphia: Saunders. Courtesy the late Dr. Raymond D. Adams, Massachusetts General Hospital, Boston.

Subdural Hematoma.

A **subdural hematoma** is a collection of blood that results from bleeding between the dura mater and the arachnoid layer of the meningeal covering of the brain. A subdural hematoma usually results from injury to the brain substance and its parenchymal vessels (see Figure 59-16). The bridging veins that drain from the surface of the brain into the sagittal sinus are the source of most subdural hematomas. Because a subdural hematoma is usually venous in origin, the hematoma is much slower to develop into a mass large enough to produce symptoms. However, a subdural hematoma may also be caused by tearing of small cortical arteries, in which case it develops more rapidly. Subdural hematomas may be acute, subacute, or chronic (Table 59-8).

TABLE 59-8
TYPES OF SUBDURAL HEMATOMAS

Occurrence After Injury	Progression of Symptoms	Treatment
Acute		
Up to 48 hr after severe trauma	Immediate deterioration	Craniotomy, evacuation, and decompression
Subacute		
48 hr to 2 wk after severe trauma	Alteration in mental status as hematoma develops; progression dependent on size and location of hematoma	Evacuation and decompression
Chronic		
Weeks, months, usually >20 days after injury; often, injury seemed trivial or is forgotten by patient	Nonspecific, nonlocalizing progression; progressive alteration in LOC	Evacuation and decompression, membranectomy

LOC, level of consciousness.

An *acute subdural hematoma* manifests signs within 48 hours of the injury. The size of the hematoma determines the patient's clinical presentation as well as prognosis. The signs and symptoms are similar to those associated with brain tissue compression in increased ICP and include decreasing LOC and headache. The patient can range from being drowsy and confused to being unconscious. The ipsilateral pupil may dilate and become fixed if ICP is sufficiently increased. Acute subdural hematoma is most often associated with traumatic injury, and underlying brain injury may result in cerebral edema, worsening the neurological assessment. The subsequent cerebral edema contributes to increased morbidity and mortality despite surgical intervention to evacuate the hematoma.

A *subacute subdural hematoma* usually occurs within 2 to 14 days of the injury. Failure to regain consciousness may point to this possibility. After the initial bleeding, a subdural hematoma may appear to enlarge over time as the breakdown products of the blood draw fluid into the subdural space to reach isotonicity.

A *chronic subdural hematoma* develops over weeks or months after a seemingly minor head injury. The peak incidence of chronic subdural hematoma occurs to those in their 50s and 60s, when a potentially larger subdural space is available as a result of brain atrophy. With atrophy, the brain remains attached to the supportive structures, but tension to the bridging veins is increased and the bridging veins are subject to tearing. The larger size of the subdural space also accounts for the presenting complaint being the focal symptoms, rather than the signs of increased ICP. People with chronic alcoholism are also prone to cerebral atrophy and subsequent development of subdural hematoma.

Delay in diagnosis of a subdural hematoma in older adults can be attributed to symptoms that mimic other health problems in people of this age group, such as vascular disease and dementia. Somnolence, confusion, lethargy, and memory loss are also associated with health problems other than subdural hematoma.

Intraparenchymal Hematoma.

Intraparenchymal or intracerebral hematoma is a collection of blood within the parenchyma that results from bleeding within the brain tissue itself and occurs in approximately 16% of head injuries. Usually, it occurs within the frontal and temporal lobes, possibly from the rupture of intracerebral vessels at the time of injury. The size and location of the hematoma are key determinants of patient outcome.

Traumatic Subarachnoid Hemorrhage.

Traumatic subarachnoid hemorrhage is a result of traumatic forces damaging the superficial vascular structures in the subarachnoid space. The presence of a *traumatic subarachnoid hemorrhage* may predispose the patient to cerebral vasospasm and diminished CBF, increasing the risk for ischemic damage following brain injury.

Diagnostic Studies and Collaborative Care

CT scan is considered the best diagnostic test to determine cranio-cerebral trauma because it allows for rapid diagnosis and intervention. An MRI scan is more sensitive in detecting small DAI lesions than a CT scan because of the lack of gross pathological changes in brain tissue. Transcranial Doppler studies allow for the measurement of CBF velocity. A cervical spine radiographic study is indicated because cervical spine trauma often occurs concomitantly with head injury. In general, the diagnostic studies are similar to those used for a patient with increased ICP (see Table 59-3).

Emergency management of the patient with a head injury is presented in Table 59-9. In addition to measures to prevent secondary injury by treating cerebral edema and managing increased ICP, the principal treatment of head injuries is timely diagnosis and surgery if necessary. For the patient with concussion and contusion, observation and management of increased ICP are the primary management strategies.

TABLE 59-9

EMERGENCY MANAGEMENT
Head Injury

Etiology	Assessment Findings	Interventions
Blunt	**Surface Findings**	**Initial**
• Assault • Fall • Motor vehicle accident • Pedestrian event • Sports injury	• Bruises or contusions on face, Battle sign (bruising behind ears) • Fracture or depressions in skull • Raccoon eyes (dependent bruising around eyes) • Scalp lacerations	• Ensure patent airway. • Stabilize cervical spine. • Administer O_2 via nasal cannula or nonrebreather mask. • Establish IV access with two large-bore catheters to infuse normal saline or lactated Ringer's solution. • Control external bleeding with sterile pressure dressing. • Assess for rhinorrhea, otorrhea, scalp wounds. • Remove patient's clothing.
Penetrating	**Respiratory**	**Ongoing Monitoring**
• High-velocity projectile (e.g., gunshot wound) • Low-velocity projectile (e.g., knife, bone fragments from skull fracture)	• Abnormal respiratory patterns (e.g., Cheyne–Stokes respirations) • Central neurogenic hyperventilation • Decreased O_2 saturation • Pulmonary edema	• Administer fluids cautiously to prevent fluid overload and increasing ICP. • Anticipate need for intubation for ineffective breathing patterns or absent gag reflex. • Assume cervical spine injury until proven otherwise. • Maintain patient warmth using blankets; warm IV fluids; overhead warming lights; warm, humidified O_2. • Monitor frequently for signs and symptoms of increased ICP or decreased cerebral perfusion. • Monitor vital signs, level of consciousness, O_2 saturation, cardiac rhythm, Glasgow Coma Scale score, pupil size and reactivity.
	Central Nervous System	
	• Asymmetrical facial movements • Bowel and bladder incontinence • Combativeness • Confusion • CSF leaking from ears or nose • Decerebrate or decorticate posturing • Decreased level of consciousness • Depressed or hyperactive reflexes • Flaccidity • Glasgow Coma Scale score <12 • Incomprehensible speech, abusive speech • Involuntary movements • Seizures • Unequal or dilated pupils	

CSF, cerebro-spinal fluid; *ICP,* intracranial pressure; *IV,* intravenous.

The treatment of skull fractures is usually conservative. For depressed fractures and fractures with loose fragments, a craniotomy is necessary to elevate the depressed bone and remove the free fragments. If large amounts of bone are destroyed, the bone may be removed *(craniectomy)* and a cranioplasty will be needed at a later time (see the Cranial Surgery section later in this chapter).

In cases of clinically large subdural and epidural hematomas, or those associated with significant neurological impairment, the blood must be removed surgically through either a craniotomy or a burr-hole approach.

Nursing Management Head Injury

Nursing Assessment

The patient with a head injury is always considered to have the potential for developing increased ICP. The most important aspects of the objective data are noting the GCS score (see Table 59-5), assessing and monitoring the neurological status (see Figure 59-11), and determining whether a CSF leak has occurred. (See the Nursing Assessment section for Increased Intracranial Pressure earlier in this chapter.)

Nursing Diagnoses

Nursing diagnoses and potential complications for the patient who has sustained a head injury may include, but are not limited to, the following:

- *Risk for ineffective cerebral tissue perfusion* as evidenced by *brain injury, brain neoplasm, cerebral aneurysm*
- *Hyperthermia* related to *increased metabolic rate*
- *Impaired physical mobility* related to *physical deconditioning* (decreased level of consciousness)
- *Anxiety* related to *threat to current status, threat of death* (abrupt change in health status)
- Potential complication: Increased ICP related to cerebral edema and hemorrhage

Planning

The overall goals are that the patient with an acute head injury will (1) maintain adequate cerebral perfusion; (2) remain normothermic; (3) be free from pain, discomfort, and infection; and (4) attain maximal cognitive, motor, and sensory function.

Nursing Implementation

Health Promotion.

One of the best ways to prevent head injuries is to prevent motor vehicle accidents. The nurse can be active in campaigns that promote driving safety and can speak to driver education classes regarding the dangers of unsafe driving and of driving after drinking alcohol or using drugs. The use of seat belts in cars and of helmets for riding on motorcycles are the most effective measures for increasing survival after accidents. It is also recommended that lumberjacks, construction workers, miners, horseback riders, bicycle riders, snowboarders, and skydivers wear protective helmets. The use of helmets when cycling can significantly reduce serious head injury, but not all provinces and territories in Canada have legislation for helmet use (Parachute, n.d.). Nurses can become involved with organizations such as Parachute that attempt to reduce the incidence of injuries among Canadian youth through education, community awareness, and healthy public policy initiatives.

Acute Intervention.

Management at the scene of the accident can have a significant impact on the outcome of a head injury. Emergency management of head injury is discussed in Table 59-9. The general goal of nursing management of the patient with a head injury is to maintain cerebral oxygenation and perfusion and prevent secondary cerebral ischemia. Surveillance or monitoring for changes in neurological status is critically important because the patient's condition may deteriorate rapidly, necessitating emergency surgery. Appropriate preoperative and postoperative nursing interventions are initiated if surgery is anticipated. Because of the close association between hemodynamic status and cerebral perfusion, the nurse must be aware of any coexisting injuries or conditions. In the acute injury period, treating other life-threatening conditions (e.g., hemorrhage, hypoxia) may take initial priority in nursing care.

The nurse should explain the need for frequent neurological assessments to both the patient and the caregivers. Behavioural manifestations associated with head injury can result in patients who may be frightened and disoriented, may be combative, and may resist help. The nurse's approach should be calm and gentle. A family member may be available to stay with the patient and thus prevent increasing anxiety and fear. Nursing research also validates that one of the most pressing needs for family members in the acute injury phase of care is for information about the patient's diagnosis, the treatment plan, and the rationale for the interventions (Coco, Tossavainen, Jaaskelainen, et al., 2011).

The nurse should perform neurological assessments at intervals based on the patient's condition. The GCS is useful in assessing the level of arousal (see Table 59-5). Indications of a deteriorating neurological state, such as a decreasing LOC, increasingly impaired motor strength, or pupillary changes, should be reported to a physician, and the patient's condition should be closely monitored.

The major focus of nursing care for patients with brain injuries relates to increased ICP (see NCP 59-1 on the Evolve website). However, there may be specific problems that require nursing intervention.

Eye problems may include loss of the corneal reflex, periorbital ecchymosis and edema, and diplopia. Loss of the corneal reflex may necessitate administering lubricating eye drops, taping the eyes shut, or suturing the eyelids closed to prevent abrasion. Periorbital ecchymosis and edema disappear spontaneously, but cold and, later, warm compresses provide comfort and hasten the process. Diplopia can be relieved by use of an eye patch.

Hyperthermia may occur in relation to an infectious process or from injury to or inflammation of the hypothalamus. Elevations in body temperature can result in increased cerebral metabolic rate, CBF, cerebral blood volume, and ICP. Pyrexia increases cerebral metabolic rate, which increases CBF, which in turn can further increase ICP. The nurse should attempt to control hyperthermia and maintain normothermia (goal temperature of 36° to 38°C) in patients with head injuries using strategies previously discussed (see section on Supportive Therapy).

If CSF rhinorrhea or otorrhea occurs, the nurse should inform the physician immediately. The head of the bed may be raised to decrease the CSF pressure so that a dural tear can seal. A loose collection pad may be placed under the nose or over the ear. No dressing should be placed into the nasal cavity or ear canal. The patient should be cautioned not to sneeze or blow the nose. Nasogastric tubes should not be used, and nasotracheal suctioning should not be performed on these patients because of the high risk for meningitis.

Nursing measures specific to the care of patients who are immobilized—such as those related to bladder and bowel function, skin care, and infection—are also indicated. Nausea and vomiting may be a problem and can be alleviated by antiemetic drugs. Headache can usually be controlled with acetaminophen or small doses of codeine.

If the patient's condition deteriorates, urgent intracranial surgery may be necessary (see the Cranial Surgery section later in this chapter). A burr-

hole opening or craniotomy may be indicated, depending on the underlying injury causing the symptoms.

The patient is often unconscious before surgery, making it necessary for a family member to sign the consent form for surgery. This is a difficult and frightening time for the patient's family, and the situation requires sensitive nursing management. The suddenness of the situation makes it especially difficult for the family to cope.

Ambulatory and Home Care.

Once the condition has stabilized, the patient is usually transferred for acute rehabilitation management to prepare the patient for re-entry into the community. As with any cranio-cerebral problem, there may be chronic problems related to motor and sensory deficits, communication, memory, and cognitive functioning. Many of the principles of nursing management of patients with a stroke are appropriate (see Chapter 60). Conditions that may require nursing and collaborative management include poor nutritional status, bowel and bladder management, spasticity, dysphagia, deep venous thrombosis, and hydrocephalus. The patient's outward appearance is not a good indicator of how well the patient will ultimately function in the home or work environment given recovery time and rehabilitation.

Post-traumatic seizure (PTS) disorders are seen in approximately 5% of patients with a nonpenetrating head injury. The time when the patient is most vulnerable to the development of PTS is during the first week after the head injury, though some patients may not develop a PTS disorder until years after the initial injury. Anticonvulsant drugs may be used to decrease the risk for early PTS within 7 days of injury (Thompson, Pohlmann-Eden, Campbell, et al., 2015). Phenytoin (Dilantin) is the anticonvulsant drug of choice to use with post-traumatic seizure activity.

The cognitive and emotional sequelae of brain trauma are often the most incapacitating problems. Many patients with head injuries who have been comatose for more than 6 hours undergo some personality change. They may suffer loss of concentration and memory and defective memory processing. Personal drive may decrease; apathy and apparent laziness may increase. Euphoria and mood swings, along with a seeming lack of awareness of the seriousness of the injury, may occur. The patient's behaviour may indicate a loss of social restraint, judgement, tact, and emotional control.

Progressive recovery may continue for 6 months or more before a plateau is reached and a prognosis for recovery can be made. Specific nursing management in the post-traumatic phase depends on specific residual deficits.

In all cases, the family must be given special consideration. They need to be helped to understand what is happening and be taught appropriate interaction patterns. The nurse must give guidance and referrals for financial aid, child care, and other personal needs and must assist the family in involving the patient in family activities whenever possible. Community referrals for support should be offered. Assisting the patient and family in developing and maintaining hope and keeping communication open are strategies perceived as supportive by families (Coco et al., 2011).

The family often has unrealistic expectations of the patient as the coma begins to recede. The family expects full return to pretrauma status. In reality, the patient experiences a reduced awareness and ability to interpret environmental stimuli. The nurse must prepare the family for the emergence of the patient from coma and must explain that the process of awakening often takes several weeks.

When the time for discharge planning arrives, the family and the patient may benefit from very specific posthospital instructions to avoid family–patient friction. Special "no" policies that may be appropriately suggested by the neurosurgeon, neuropsychologist, and nurse include no drinking of alcoholic beverages, no driving, no work with hazardous implements and machinery, and no unsupervised smoking. Family members, particularly spouses, go through role transition as the role changes from spouse to caregiver.

Evaluation

The following are expected outcomes for the patient with a head injury:

- The patient will maintain normal CPP.
- The patient will achieve maximal cognitive, motor, and sensory function.
- The patient will experience no infection or hyperthermia.
- The patient will achieve pain control.

Brain Tumours

It is estimated that 55 000 Canadians are surviving with a brain tumour, and that every day, 27 Canadians are diagnosed with one (Brain Tumour Foundation of Canada [BTFC], 2017a). The brain is a frequent site for metastasis from other sites, as well. The 5-year relative survival rate for brain tumours in Canada is approximately 25% (Canadian Cancer Society, 2017).

Types

Brain tumours can occur in any part of the brain or spinal cord. Tumours of the brain may be *primary,* arising from tissues within the brain, or *secondary,* resulting from a metastasis from a malignant neoplasm elsewhere in the body. Secondary brain tumours are the most common type. Brain tumours are generally classified according to the tissue from which they arise. Meningiomas represent 34% of all primary brain tumours, making them the most common primary brain tumour (BTFC, 2017b). Most meningiomas are benign. Gliomas (a group of tumour types including astrocytoma and glioblastoma multiforme) account for 60% of all primary intracranial brain tumours and are frequently malignant. Glioblastoma multiforme is the most common form of glioma (BTFC, 2017a).

More than half of all brain tumours are malignant; they infiltrate the brain parenchyma and are not amenable to complete surgical removal. Other tumours may be histologically benign, but their location is such that complete removal is not possible. Brain tumours are more commonly seen in middle-aged persons, but they may occur at any age.

Unless treated, all brain tumours eventually cause death from increasing tumour volume leading to increased ICP. Brain tumours rarely metastasize outside the central nervous system (CNS) because they are contained by structural (meninges) and physiological (blood–brain) barriers. Table 59-10 compares the major brain tumours. A glioblastoma and a meningioma are depicted in Figure 59-18.

TABLE 59-10
TYPES OF BRAIN TUMOURS

Type	Tissue of Origin	Characteristics
Gliomas		
• Astrocytoma	Supportive tissue, glial cells and astrocytes	Can range from low-grade to moderate-grade malignancy
• Ependymoma	Ependymal epithelium	Range from benign to highly malignant; most are benign and encapsulated
• Glioblastoma multiforme	Primitive stem cell (glioblast)	Highly malignant and invasive; among the most devastating of primary brain tumours
• Medulloblastoma	Primitive neuroectodermal cell	Highly malignant and invasive; metastatic to spinal cord and remote areas of brain
• Oligodendrogliom a	Oligodendrocytes	Benign (encapsulation and calcification)
Meningioma	Meninges	Can be benign or malignant; most are benign
Acoustic neuroma (Schwannoma)	Cells that form myelin sheath around nerves; commonly affects cranial nerve VIII	Many grow on both sides of the brain; usually benign or low-grade malignancy
Pituitary adenoma	Pituitary gland	Usually benign
Hemangioblastoma	Blood vessels of brain	Rare and benign; surgery is curative
Primary central nervous system lymphoma	Lymphocytes	Increased incidence in transplant recipients and patients with acquired immune deficiency syndrome (AIDS)
Metastatic tumours	Lungs, breast, kidney, thyroid, prostate	Malignant

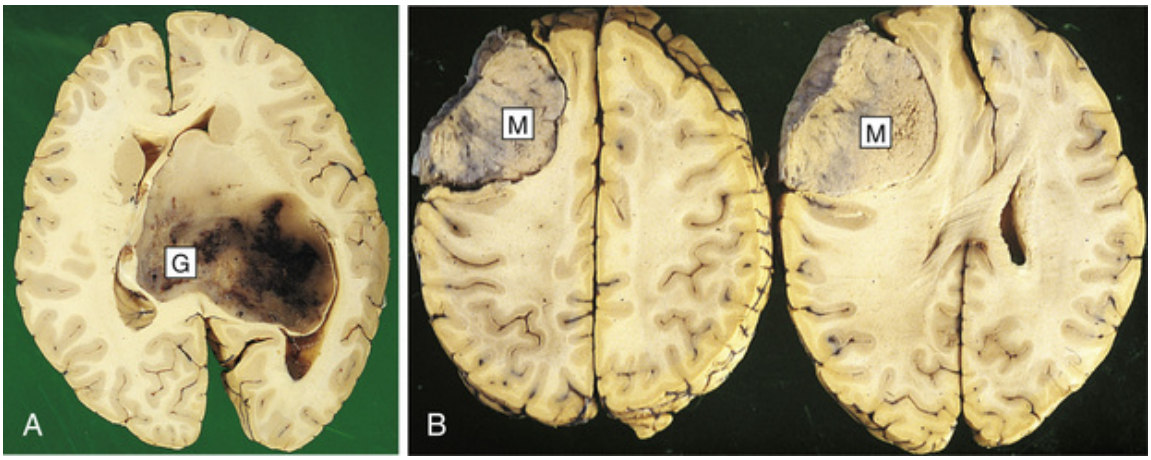

FIGURE 59-18 **A,** Glioblastoma. A large glioblastoma (G) arises from one cerebral hemisphere and has grown to fill the ventricular system. **B,** Meningioma. These two different sections from different levels in the same brain show a meningioma (M) compressing the frontal lobe and distorting the underlying brain. Source: Stevens, A., & Lowe, J. (2000). *Pathology: Illustrated review in colour* (2nd ed.). London: Mosby.

Clinical Manifestations

The clinical manifestations of brain tumours depend mainly on the location, the rate of growth, and the size of the tumour. Figure 59-19 illustrates the functional areas of the cerebral cortex and can be used as a guide to correlate manifestations with the location of the tumour. Some tumours have aggressive mitotic rates and are associated with a rapid onset of symptoms. Tumours such as meningiomas are slow growing and can become quite large before clinical symptoms are noted. The rate of growth depends on the location and size of the tumour and the mitotic rate of the cells of the tissue of origin.

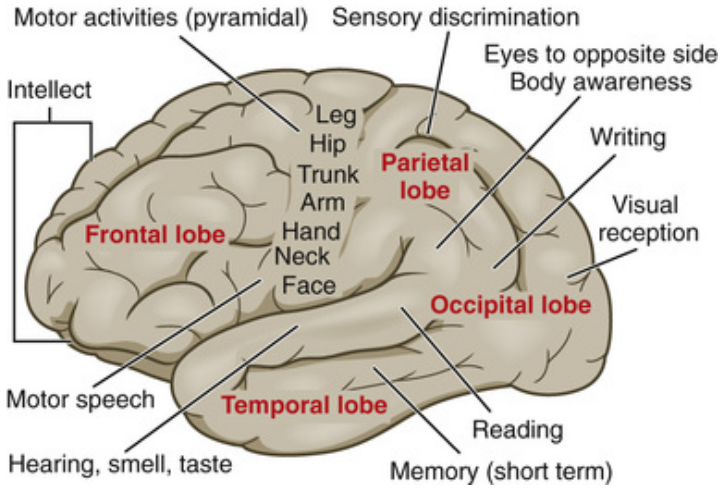

FIGURE 59-19 Each area of the brain controls a particular activity.

Wide ranges of possible clinical manifestations are associated with brain tumours. Headache is a common problem. Tumour-related headaches tend to be worse at night and may awaken the patient. The headaches are usually dull and constant but occasionally throbbing. Seizures are common in gliomas and brain metastases. Brain tumours can cause nausea and vomiting from increased ICP. Cognitive dysfunction, including memory problems and mood or personality changes, is another common manifestation, especially in patients with brain metastases. Muscle weakness, sensory losses, aphasia, and visuospatial dysfunction are further manifestations of brain tumours. As the brain tumour expands, it may also produce global signs of increased ICP, cerebral edema, or obstruction of the CSF pathways. Manifestations may clearly indicate the location of the tumour by an alteration in the function controlled by the affected area (Table 59-11).

TABLE 59-11
BRAIN TUMOUR LOCATIONS AND PRESENTING MANIFESTATIONS

Tumour Location	Clinical Manifestations
Cerebral hemisphere	
• Frontal lobe (unilateral)	Unilateral hemiplegia, seizures, memory deficit, personality and judgement changes, visual disturbances
• Frontal lobe (bilateral)	Symptoms associated with unilateral frontal lobe tumours; ataxic gait
• Occipital lobe	Vision deficits and seizures
• Parietal lobe	Speech disturbance (if tumour is in the dominant hemisphere: inability to write, spatial disorders, and unilateral neglect)
• Temporal lobe	Few symptoms; seizures, impaired speech, and memory difficulty
Subcortical	Hemiplegia; other symptoms may depend on area of infiltration.
Meningeal tumours	Symptoms are associated with compression of the brain and depend on tumour location.
Metastatic tumours	Headache, nausea, or vomiting because of ↑ ICP; other symptoms depend on tumour location
Thalamus and sellar tumours	Headache, nausea, vision disturbances, papilledema, and nystagmus occur from ↑ ICP; diabetes insipidus may occur.
Fourth ventricle and cerebellar tumours	Headache, nausea, and papilledema from ↑ ICP; ataxic gait and changes in coordination
Cerebellopontine tumours	Tinnitus and vertigo, deafness
Brain stem tumours	Headache on awakening, drowsiness, vomiting, ataxic gait, facial muscle weakness, hearing loss, dysphagia, dysarthria, "crossed eyes" or other visual changes, hemiparesis

ICP, intracranial pressure.

Complications

If the tumour mass obstructs the ventricles or occludes the outlet, ventricular enlargement (hydrocephalus) can occur. As a tumour expands, patients may develop manifestations of increased ICP, cerebral edema, or obstruction of the CSF pathways. Unless treated, all brain tumours eventually cause death from increasing tumour volume leading to increased ICP.

Diagnostic Studies

An extensive history and a comprehensive neurological examination must be done in the workup of a patient with a suspected brain tumour. A careful history and physical examination may provide data concerning location. Diagnostic studies are similar to those used for a patient with increased ICP (see Table 59-3). The sensitivity of techniques such as MRI and PET scans allows for detection of very small tumours and may provide more reliable diagnostic information. CT and brain scanning are

used to diagnose the location of the lesion. Other tests include magnetic resonance spectroscopy, functional MRI, and single-photon emission computed tomography (SPECT). The EEG is useful but of less importance. A lumbar puncture is seldom diagnostic and carries with it the risk for cerebral herniation. Angiography can be used to determine blood flow to the tumour and further localize the tumour. Other studies are done to rule out a primary lesion elsewhere in the body. Endocrine studies are helpful when a pituitary adenoma is suspected (see Chapter 51).

The correct diagnosis of a brain tumour can be made by obtaining tissue for histological study. In most patients, tissue is obtained at the time of surgery. Computer-guided stereotactic biopsy is also an option if surgical intervention does not appear to be the most advantageous treatment option. A smear or frozen section can be performed in the operating room for a preliminary interpretation of the histological type. With this information, the neurosurgeon can make a better decision about the extent of surgery. In some cases, immunohistochemical stains or electron microscopy may be necessary to ascertain the correct diagnosis.

Collaborative Care

Treatment goals are aimed at (1) identifying the tumour type and location, (2) removing or decreasing tumour mass, and (3) preventing or managing increased ICP.

Drug Therapy.

Corticosteroids (dexamethasone, prednisone, or methylprednisolone [Solu-Medrol]) are useful in reducing cerebral edema associated with neoplasms. Corticosteroids are often prescribed at diagnosis and continued following surgery, until radiation and chemotherapy have been completed.

Surgical Therapy.

Surgical removal is the preferred treatment for brain tumours (see Cranial Surgery, later in this chapter). Stereotactic surgical techniques are used with increasing frequency to perform a biopsy and remove small brain tumours. The outcome of surgical therapy depends on the type, size, and location of the tumour. Meningiomas and oligodendrogliomas can usually be completely removed, whereas the more invasive gliomas and medulloblastomas can be only partially removed. Computer-guided stereotactic biopsy, ultrasound, functional MRI, and cortical mapping can

be used to localize brain tumours intraoperatively. Complete surgical removal is not always possible because the tumour is not always accessible and sometimes involves vital parts of the brain. Surgery can reduce tumour mass, which decreases ICP and provides relief of symptoms with an extension of survival time.

Ventricular Shunts.

Hydrocephalus can be treated with the placement of a ventricular shunt. A catheter with one-way valves is placed in the lateral ventricle and then tunnelled through the skin to drain CSF into the right atrium or the peritoneum. Rapid decompression of ICP can cause total body collapse and weakness, including a headache that may be prevented by gradually introducing the patient to the upright position.

Manifestations of shunt malfunction, which are related to increased ICP, include decreasing LOC, restlessness, headache, blurred vision, or vomiting. This may necessitate shunt revision or replacement. Infection may also occur, as exhibited by high fever, persistent headache, and stiff neck. Antibiotics are used to treat the infection. In some situations the shunt must be replaced.

Radiation Therapy and Radiosurgery.

Radiation therapy may be used as a follow-up measure after surgery. Radiation seeds can also be implanted into the brain. Cerebral edema and rapidly increasing ICP may be a complication of radiation therapy, but they can be managed with high doses of corticosteroids (dexamethasone, prednisone, or methylprednisolone). (Radiation therapy is discussed in Chapter 18 and in NCP 18-1, available on the Evolve website.)

Stereotactic radiosurgery is a method of delivering a high, concentrated dose of radiation precisely directed at a location within the brain and may be used when conventional surgery has failed or is not an option because of the tumour location. (Radiosurgery is discussed later in this chapter.)

Chemotherapy and Targeted Therapy.

The effectiveness of chemotherapy has been limited by difficulty getting drugs across the blood–brain barrier, tumour cell heterogeneity, and tumour cell drug resistance. A group of chemotherapeutic drugs called the *nitrosoureas* (e.g., carmustine [BiCNU], lomustine [CeeNU]) are particularly effective in treating brain tumours. Normally, the blood–brain barrier prohibits the entry of most drugs into the brain. However, the most malignant tumours cause a breakdown of the blood–brain barrier in the

area of the tumour, allowing chemotherapeutic agents to be used to treat the malignancy. Chemotherapy-laden biodegradable wafers implanted at the time of surgery can deliver chemotherapy directly to the tumour site. Other drugs being used include methotrexate and procarbazine (Matulane). Chemotherapeutic drugs can be administered intrathecally via an Ommaya reservoir (see Chapter 18).

Temozolomide (Temodal) is the first oral chemotherapeutic agent found to cross the blood–brain barrier. In contrast with many traditional chemotherapies, which require metabolic activation to exert their effects, temozolomide has the ability to convert spontaneously to a reactive agent that directly interferes with tumour growth. It does not interact with other drugs commonly taken by patients with brain tumours, such as anticonvulsant drugs, corticosteroids, and antiemetics.

Bevacizumab (Avastin) is used to treat patients with glioblastoma multiforme that continues to progress after standard therapy. Bevacizumab is a targeted therapy that inhibits the action of vascular endothelial growth factor, which helps form new blood vessels. These vessels can feed a tumour, helping it to grow, and can also provide a pathway for cancer cells to circulate in the body. (Targeted therapy is discussed in Chapter 18 and Table 18-16.)

Other Therapies.

A medical device system, NovoTTF-100A System, is used to treat glioblastoma multiforme that recurs or progresses after receiving chemotherapy and radiation therapy. With this system, electrodes are placed on the surface of the patient's scalp to deliver low-intensity, changing electrical fields called *tumour treatment fields* (TTFs) to the tumour site.

Many techniques to control and treat brain tumours are currently under investigation. These include local hyperthermia and biological therapy. Although progress in treatment has increased the length and quality of survival of patients with gliomas, outcomes still remain poor (Preusser, de Ribaupierre, Wohrer, et al., 2011).

Nursing Management Brain Tumours

Nursing Assessment

The initial assessment should be structured to provide baseline data of the neurological status and the information needed to design a realistic, individualized care plan. Areas to be assessed include the LOC and cognitive function, motor abilities, sensory perception, integrated function (including bowel and bladder function), balance and proprioception, and the coping abilities of the patient and family. Watching a patient perform activities of daily living and listening to the patient's conversation are possible ways to perform part of the neurological assessment. Having the patient or the family explain the problem can be helpful in determining the patient's limitations and can also provide the nurse with information about the patient's insight into the problems. All initial data should be accurately recorded to provide a baseline for comparison to determine whether the patient's condition is improving or deteriorating.

Interview data are as important as the actual physical assessment. Questions should be asked concerning medical history, intellectual abilities and educational level, and history of nervous system infections and trauma. Determination of the presence of seizures, syncope, nausea and vomiting, pain, headaches, and physical limitations is important in planning care for the patient.

Nursing Diagnoses

Nursing diagnoses and potential complications for the patient with a brain tumour may include, but are not limited to, the following:

- *Risk for ineffective cerebral tissue perfusion* as evidenced by *brain injury* (cerebral edema)
- *Acute pain* related to *biological injury agent, physical injury agent* (cerebral edema, increased intracranial pressure)
- *Anxiety* related to *threat to current status, threat of death* (diagnosis and treatment)

- Potential complications: seizures related to abnormal electrical activity of the brain and increased ICP related to tumour and failure of normal compensatory mechanisms

Planning

The overall goals are that the patient with a brain tumour will (1) maintain normal ICP, (2) maximize neurological functioning, (3) be free from pain and discomfort, and (4) be aware of the long-term implications with respect to prognosis and cognitive and physical functioning.

Nursing Implementation

A primary or metastatic tumour of the frontal lobe can cause behavioural and personality changes. Loss of emotional control, confusion, disorientation, memory loss, and depression may be signs of a frontal lobe lesion. These behavioural changes are often not perceived by the patient but can be disturbing and even frightening to the family. These changes can also cause a distancing to occur between the family and the patient. The nurse has an important role in assisting the family in understanding what is happening to the patient and emotionally supporting the family.

The patient who is confused and has behavioural instability can be a challenge. Protecting the patient from self-harm is an important part of nursing care. At times when the patient manifests rage and aggression, the nurse must also be concerned about self-protection. Close supervision of activity; use of side rails; use of restraints; padding of the rails and the area around the bed; and a calm, reassuring approach to care are all essential techniques for the care of these patients.

Perceptual problems associated with frontal lobe and parietal lobe tumours contribute to a patient's disorientation and confusion. Minimization of environmental stimuli, creation of a routine, and use of reality orientation can be incorporated into the care plan for the patient experiencing confusion.

Seizures often occur with brain tumours. These are managed with anticonvulsant drugs. Seizure precautions should be instituted for the protection of the patient. Some behavioural changes seen in the patient with a brain tumour are a result of seizure disorders and can improve with control of the seizures by means of drugs (see Chapter 61 for more information regarding seizures and anticonvulsant drug therapy).

Motor and sensory dysfunctions are problems that interfere with the activities of daily living. Alterations in mobility must be managed, and the patient should be encouraged to provide as much self-care as physically possible. Self-image often depends on the patient's ability to participate in care within the limitations of the physical deficits.

Language deficits can also occur in patients with brain tumours. Motor (expressive) or sensory (receptive) aphasia may occur (see Chapter 60). The disturbance in communication can be frustrating for the patient and may interfere with the nurse's ability to meet the patient's needs. Attempts should be made to establish a communication system that can be used by both the patient and the staff.

Nutritional intake may be decreased because of the patient's inability to eat, loss of appetite, or loss of desire to eat. Assessing the patient's nutritional status and ensuring adequate nutritional intake are important aspects of care. The patient may need encouragement to eat or, in some cases, may have to be fed nonorally, by gastrostomy or nasogastric tube, or by parenteral nutrition. The patient with a brain tumour who undergoes cranial surgery requires complex nursing care. This care is discussed in the next section.

Evaluation

The following are expected outcomes for the patient with a brain tumour:

- The patient will achieve control of pain, vomiting, and other discomforts.
- The patient will maintain ICP within normal limits.
- The patient will demonstrate maximal neurological function (cognitive, motor, sensory) in regard to the location and extent of the tumour.
- The patient will maintain optimal nutritional status.
- The patient will accept the long-term consequences of the tumour and its treatment.

Cranial Surgery

The cause or indication for cranial surgery may be related to a brain tumour, CNS infection (e.g., abscess), vascular abnormalities, cranio-

cerebral trauma, seizure, or intractable pain (Table 59-12).

TABLE 59-12
INDICATIONS FOR CRANIAL SURGERY

Cause	Manifestations	Procedure
Brain Abscess		
Bacteria that caused intracranial infection	*Early findings:* stiff neck, headache, fever, weakness, seizures *Later findings:* seizures, hemiplegia, speech disturbances, ocular disturbances, change in LOC	Excision or drainage of abscess
Hydrocephalus		
Overproduction of CSF, obstruction to flow, defective reabsorption	*Early findings:* mental changes, disturbances in gait *Later findings:* memory impairment, urinary incontinence, increased tendon reflexes	Placement of ventriculo-atrial or ventriculo-peritoneal shunt
Brain Tumours		
Benign or malignant cell growth	Change in LOC, pupillary changes, sensory or motor deficit, papilledema, seizures, personality changes	Excision or partial resection of tumour
Intracranial Bleeding		
Rupture of cerebral vessels because of trauma or stroke	*Epidural:* momentary unconsciousness; lucid period, then rapid deterioration *Subdural:* headache, seizures, pupillary changes	Surgical evacuation through burr holes or craniotomy
Skull Fractures		
Trauma to skull	Headache, CSF leakage, cranial nerve deficit	Debridement of fragments and necrotic tissue, elevation and realignment of bone fragments
Arteriovenous Malformation (AVM)		
Congenital tangle of arteries and veins (frequently in middle cerebral artery)	Headache, intracranial hemorrhage, seizures, mental deterioration	Excision of malformation
Aneurysm Repair		
Dilation of weak area in arterial wall (usually near anterior portion of circle of Willis)	*Before rupture:* headache, lethargy, visual disturbance *After rupture*: violent headache, decreased LOC, visual disturbances, motor deficit	Dissection and clipping or coiling of aneurysm

CSF, cerebro-spinal fluid; *LOC*, level of consciousness.

Types

Various types of cranial surgical procedures are presented in Table 59-13.

TABLE 59-13

TYPES OF CRANIAL SURGERY

Type	Description
Burr hole	Opening into the cranium made with a drill; used to remove localized fluid and blood beneath the dura
Craniotomy	Opening into the cranium with removal of a bone flap and opening the dura to remove a lesion, repair a damaged area, drain blood, or relieve increased ICP
Craniectomy	Excision into the cranium to cut away a bone flap
Cranioplasty	Repair of a cranial defect resulting from trauma, malformation, or previous surgical procedure; artificial material used to replace damaged or lost bone
Stereotaxis	Precision localization of a specific area of the brain using a frame or a frameless system based on three-dimensional coordinates; procedure is used for biopsy, radiosurgery, or dissection
Shunt procedures	Alternate pathway created to redirect cerebro-spinal fluid from one area to another using a tube or implanted device; examples include ventriculo-peritoneal shunt and Ommaya reservoir

ICP, intracranial pressure.

Stereotactic Surgery.

Stereotactic surgery is a precision apparatus (often computer-guided) that assists the surgeon to target a very precise area of the brain (Figure 59-20).

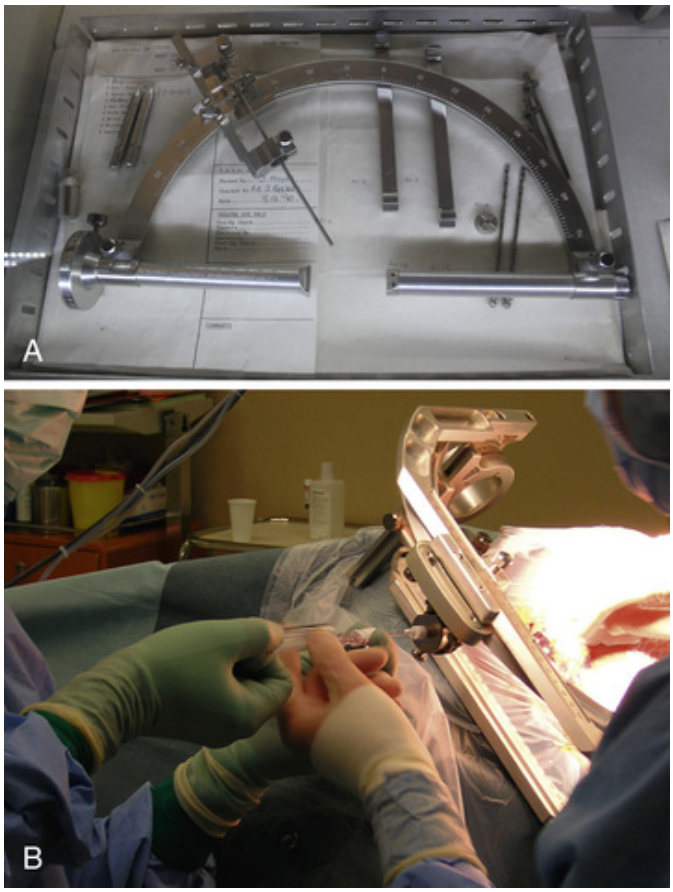

FIGURE 59-20 **A,** Stereotactic frame. **B,** Brain surgery using stereotactic frame. Sources: *A,* Rodw. This file is licensed under the Creative Commons Attribution-Share Alike 4.0 International license, *https://creativecommons.org/licenses/by-sa/4.0/deed.en*. *B,* Dake. This file is licensed under the Creative Commons Attribution-Share Alike 2.5 Generic license, *https://creativecommons.org/licenses/by-sa/2.5/deed.en*.

Stereotactic biopsy can be performed to obtain tissue samples for histological examination. CT scanning and MRI are used to image the targeted tissue. With the patient under general or local anaesthesia, the surgeon drills a burr hole or creates a bone flap for an entry site and then introduces a probe and biopsy needle. Stereotactic procedures are used for removal of small brain tumours and abscesses, drainage of hematomas, ablative procedures for extrapyramidal diseases (e.g., Parkinson's disease), and repair of arteriovenous malformations. A major advantage of the stereotactic approach is a reduction in damage to surrounding tissue.

Stereotactic radiosurgery is a procedure that involves closed-skull destruction of an intracranial target using ionizing radiation, focused with the assistance of an intracranial guiding device. A sophisticated computer program is used while the patient's head is held still in a stereotactic

frame. Radiosurgical techniques can use linear accelerator or a gamma knife. In the gamma-knife procedure, a high dose of cobalt radiation is delivered to precisely targeted tumour tissue. The dose of radiation can be delivered in a few minutes or may take up to an hour or more, depending on the size and shape of the tumour. In some situations, tumours are treated over several weeks.

In combination with stereotactic procedures to identify and localize tumour sites, surgical lasers can be used to destroy tumours. Stereotactic procedures are used to identify the tumour site. Three surgical lasers currently used include the carbon dioxide, argon, and neodymium:yttrium–aluminum–garnet (Nd:YAG) lasers. All three work by creating thermal energy, which destroys the tissue on which it is focused. Laser therapy also provides the benefit of reducing damage to surrounding tissue.

Craniotomy.

Depending on the location of the pathological condition, a craniotomy may be frontal, parietal, occipital, temporal, or a combination of any of these. A set of burr holes is drilled, and a saw is used to connect the holes to remove the bone flap. Sometimes operating microscopes are used to magnify the site. After surgery, the bone flap is wired or sutured. Sometimes drains are placed to remove fluid and blood. Patients are usually cared for in an ICU until stable.

In certain cases, a tumour may be infiltrating brain tissue that is involved in essential functions such as language. In these cases, an *awake craniotomy* may be performed. The patient is fully anaesthetized during the opening of the cranial vault and then brought to consciousness once the brain is exposed. Relevant areas of the brain are stimulated to assess function and determine what tissue can and cannot be safely resected. Although keeping the patient awake adds to the complexity and length of the surgery, it enhances the safety of the procedure.

Nursing Management Cranial Surgery

Nursing Assessment

The nursing assessment of the patient undergoing cranial surgery is similar to that for the patient with increased ICP.

Nursing Diagnoses

Nursing diagnoses for the patient undergoing cranial surgery are similar to those for the patient with increased ICP and may include, but are not limited to, the following:

- *Acute pain* related to *physical injury agent, biological injury agent* (tissue injury, inflammation)
- *Risk for surgical site infection* as evidenced by *invasive procedure*
- *Risk for infection* as evidenced by *invasive procedure* (venous or urinary catheters)

Additional information on nursing diagnoses for the patient undergoing cranial surgery are presented in NCP 59-3, available on the Evolve website.

Planning

The overall goals are that the patient with cranial surgery will (1) return to normal consciousness, (2) be free from pain and discomfort, (3) have maximal neuromuscular functioning, and (4) be rehabilitated to their maximal ability.

Nursing Implementation

Acute Intervention.

Nursing management is presented in NCP 59-1. The patient facing cranial surgery (if conscious and coherent), the caregiver, and the family will be gravely concerned about the potential physical and emotional problems that can result from surgery. The uncertainty regarding prognosis and

outcome necessitates compassionate nursing care in the preoperative period.

Preoperative teaching is important in allaying the fears of the patient and the family and also in preparing them for the postoperative period. The patient and the family should be given information regarding the operative procedure and what can be expected immediately after the surgery. Explaining that some hair may be shaved may help alleviate the patient's concern. The family should also be informed that the patient will be taken to an ICU or to a special care unit after the operation.

The primary goal of care after cranial surgery is prevention of increased ICP. (Nursing management of the patient with increased ICP is presented on pp. 1483–1486.) Frequent assessment of the patient's neurological status is essential during the first 48 hours. In addition to the neurological functions, fluids, electrolyte levels, and osmolality are monitored closely to detect changes in sodium regulation, the onset of diabetes insipidus, or severe hypovolemia. The turning and positioning of the patient sometimes depend on the site of the operation. To lessen postoperative cerebral edema, the patient is cared for with the head of the bed elevated 30 to 45 degrees (see the "Evidence-Informed Practice: Research Highlight" box). Maximum swelling in the operative area usually occurs within 24 to 48 hours after the surgery. If a bone flap has been removed (craniectomy), care should be taken not to have the patient positioned on the operative side.

The surgical dressing should be observed for colour, odour, and amount of drainage. The health care provider should be notified immediately of any excessive bleeding or clear drainage. Checking drains for placement and assessing the area around the dressing are also important. Scalp care should include meticulous care of the incision to prevent wound infection. The area should be cleansed and treated in accordance with hospital protocol. Once the dressing is removed, use of an antiseptic soap for washing the scalp may also be beneficial. Sutures or staples may be removed after 7 days. Incisions to the posterior fossa require sutures or staples to remain in situ for a minimum of 10 days.

Monitor the patient for pain and nausea. Although the brain itself does not possess pain receptors, patients often report headache caused by edema or pain at the incision site. Control pain with short-acting opioids and monitor neurological status. Nausea and vomiting are common after surgery and are usually treated with antiemetics.

The psychological impact of hair removal can be alleviated by the use of a wig, a turban, scarves, or a cap after the incision has completely healed.

For the patient who is receiving radiation, use of a sunblock and head covering should be advocated if any exposure to the sun is anticipated.

Evidence-Informed Practice

Research Highlight

What Is the Optimal Head Elevation to Decrease ICP After Craniotomy?

Clinical Question

In patients who have undergone craniotomy (P), does elevation of the head (I) versus no elevation (C) decrease ICP (O)?

Best Available Evidence

Meta-analysis of interrupted-time-series and randomized crossover experimental designed studies.

Critical Appraisal and Synthesis of Evidence

- 10 (*n* >237) eligible studies were identified that met the following criteria:
    - The study compared different elevations with ICP changes in patients who were postcraniotomy.
    - The study participants had a subarachnoid, subdural, or interventricular monitor.
    - The data included measures of ICP and standard ICP differences (or values could be calculated).
- Interrupted-time-series studies (data are collected at time points before and after an intervention) were used in the analysis as controlled trials were not available.
- Previously published studies demonstrate a decrease in ICP with head elevation; however, most have small sample sizes, and results vary. This is the first published meta-analysis of the optimal degree of head elevation in patients postcraniotomy.

Conclusions

- ICP is significantly decreased when the head is elevated to 45, 30, 15 and 10 degrees when compared with no head elevation (0 degrees).
- 30 and 45 degrees of elevation results in lower ICP than 15 degrees of elevation.
- No significant difference in ICP decrease was noted between elevations of 30 and 45 degrees.
- 30 or 45 degrees is the optimal head elevation to reduce ICP in patients who are postcraniotomy.

Implications for Nursing Practice

- This review provides an evidence base for the standard nursing intervention of patient positioning.
- Nurses can use this information when positioning the head of the bed for patients who are postcraniotomy.

P, patient population of interest; *I,* intervention or area of interest; *C,* comparison of interest or comparison group; *O,* outcome(s) of interest (see Chapter 1).

Jiang Y, Zeng Y, You C, et al. Systematic review of decreased intracranial pressure with optimal head elevation in postcraniotomy patients: A meta-analysis. *Journal of Advanced Nursing*. 2015;71(10):2237–2246; 10.1111/jan.12679.

Ethical Dilemmas

Withholding Treatment

Situation

A 26-year-old patient in a persistent vegetative state is diagnosed with her fifteenth bladder infection. Her home care nurse must determine whether or not to seek antibiotics for this infection. The family members have expressed a concern that no heroic measures be used to extend the biological life of their daughter and sister, but they have been unwilling to withdraw the existing treatment, which is enteral nutrition through a gastrostomy tube. Should antibiotics be withheld?

Important Points for Consideration

- Patients in a persistent vegetative state do not recover.
- Providing nutrition and hydration, even if by artificial means, can have significant cultural, religious, and psychological meaning to patients and families.
- It is imperative to clarify with the family about the goals of treatment and the patient's wishes, when she was competent and if they are known. It is important to know whether treatment for an infection would be considered heroic based on the family's perspective of what the patient would want.
- The family's concerns about pain, suffering, and quality of life for the patient must be explored within the context of the overall plan of care.
- Withholding treatment is morally acceptable when a competent patient consents to it, if there is no medical benefit to the patient, if the

treatment merely prolongs life, or if the burden of treatment outweighs the benefit to the patient.

Clinical Decision-Making Questions

1. How would the nurse approach the patient's family?
2. What might the nurse be feeling about providing nutrition, hydration, and treatments that will prolong life in a patient for whom there is no hope of recovery?
3. What options are available to the family for the care of their daughter once a decision is made about withholding antibiotics?

Ambulatory and Home Care.

The rehabilitative potential for a patient after cranial surgery depends on the reason for the surgery, the postoperative course, and the patient's general state of health. Nursing interventions must be based on a realistic appraisal of these factors. An overall goal for the nurse is to foster independence for as long as possible and to the highest degree possible.

Specific rehabilitation potential cannot be determined until cerebral edema and increased ICP subside postoperatively. Care must be taken to maintain as much function as possible through measures such as careful positioning, meticulous skin and mouth care, regular range of motion exercises, bowel and bladder care, and adequate nutrition.

Referrals may be made to other specialists on the health care team. For example, the speech pathologist may be helpful to the patient who has speech and language or swallowing deficits or the physiotherapist may provide an exercise plan to regain functional deficits. The needs and problems of each patient should be addressed individually because many variables affect the plan. Mental and physical deterioration of the patient, including seizures, personality disorganization, apathy, and wasting, is difficult for both family and health care providers to endure. Cognitive and emotional residual deficits are often more difficult for the patient and the family to accept than are motor and sensory losses. Although progress is continually being made to help the patient with a brain tumour by means of chemotherapy, conventional and interstitial radiation, and biological therapies, prognosis has not changed. The nurse can provide much help and support during the adjustment phase and in long-range planning.

Evaluation

The following are expected outcomes for the patient who has had cranial surgery:

- The patient will regain cognitive, motor, and sensory function to the fullest possible extent.
- The patient will be free of infection.
- The patient's pain and discomfort will be alleviated.
- The patient will be free of seizures.
- The patient will have optimal nutritional intake.

Inflammatory Conditions of the Brain

Meningitis, encephalitis, and brain abscesses are the most common inflammatory conditions of the brain and spinal cord. Inflammation can be caused by bacteria, viruses, fungi, and chemicals (e.g., contrast media used in diagnostic tests or blood in the subarachnoid space) (Table 59-14). CNS infections may occur via the bloodstream (e.g., insect bites), by extension from a primary site (e.g., ear infection, sinusitis, open skull fracture), or along cranial, spinal, and peripheral nerves (e.g., rabies).

TABLE 59-14
COMPARISON OF CEREBRAL INFLAMMATORY CONDITIONS

	Meningitis	Encephalitis	Brain Abscess
Causative organisms	Bacteria (*Streptococcus pneumoniae, Neisseria meningitidis,* group B streptococcus, viruses, fungi)	Bacteria, fungi, parasites, herpes simplex virus (HSV), other viruses (e.g., West Nile virus)	Streptococci, staphylococci through bloodstream
CSF			
• Pressure (normal, <20 cm H_2O, same as SI units)	Increased	Normal to slightly increased	Increased
• WBC count (normal, 0–5 × 10^6/L or 0–5 cells/mcL	*Bacterial:* >1 000/mcL (mainly PMN) *Viral:* 25–500/mcL (mainly lymphocytes)	500/mcL, PMN (early), lymphocytes (later)	25–300/mcL (PMN)
• Protein (normal, 0.15–0.45 g/L)	*Bacterial:* >5 g/L *Viral:* 0.5–5 g/L	Slightly increased	Normal
• Glucose (normal, 2.8–4.2 mmol/L)	*Bacterial:* decreased *Viral:* normal or low	Normal	Low or absent
• Appearance	*Bacterial:* turbid, cloudy *Viral:* clear or cloudy	Clear	Clear
Diagnostic studies	CT scan, Gram stain, smear, culture, PCR*	CT Scan, EEG, MRI, PET, PCR, IgM antibodies to virus in serum or CSF	CT scan, skull radiograph, MRI
Treatment	Antibiotics, dexamethasone, supportive care, prevention of ↑ ICP	Supportive care, prevention of ↑ ICP, acyclovir (Zovirax) for HSV	Antibiotics, incision and drainage, supportive care

*PCR is used to detect viral RNA or DNA.

CSF, cerebro-spinal fluid; *CT,* computed tomography; *EEG,* electroencephalogram; *ICP,* intracranial pressure; *IgM,* immunoglobulin M; *MRI,* magnetic resonance imaging; *PCR,* polymerase chain reaction; *PET,* positron emission tomography; *PMN,* polymorphonuclear cell; *WBC,* white blood cell.

Bacterial Meningitis

Etiology and Pathophysiology

Meningitis is an acute inflammation of meningeal tissues (the pia mater, arachnoid mater, and dura mater) surrounding the brain and the spinal cord. Bacterial meningitis is considered a medical emergency, and untreated meningitis has a mortality rate approaching 100%. The organisms usually gain entry to the CNS through the upper respiratory tract or the bloodstream, but they may enter by direct extension from penetrating wounds of the skull or through fractured sinuses in basal skull fractures. Cases most often occur in infants, older adults, and members of certain high-risk groups.

Meningitis usually occurs in winter or early spring and is often secondary to viral respiratory disease. *Streptococcus pneumoniae* (pneumococcus meningitis) and *Neisseria meningitidis* (meningococcal meningitis) are the leading causes of bacterial meningitis in adults. *Haemophilus influenzae* was once the most common cause. However, the use of *H. influenzae* vaccine has resulted in a significant decrease in meningitis related to this organism.

Other causes of meningitis are *Listeria monocytogenes* (commonly called *Listeria*), a bacteria found in food that can cause a rare and potentially fatal disease called *listeriosis.* In Canada, listeriosis is a relatively rare disease, with only a few cases each year (Meningitis Research Foundation of Canada, n.d.).

The inflammatory response to the infection of the meninges and CSF (whatever the cause) may increase CSF production, while exudate accumulation leads to blockage of the arachnoid villi, causing obstruction of CSF absorption. The resulting hydrocephalus may cause an increase in ICP. The purulent secretions that are produced spread quickly to other areas of the brain through the CSF. If this process extends into the brain parenchyma or if concurrent encephalitis is present, cerebral edema and increased ICP become more of a problem. All patients with meningitis must be observed closely for manifestations of increased ICP, which is thought to be a result of swelling around the dura, and increased CSF volume.

Clinical Manifestations

Fever, severe headache, nausea, vomiting, and **nuchal rigidity** (resistance to flexion of the neck) are key signs of meningitis. A positive Kernig sign

(flexion of the patient's hip 90 degrees and extension of the knee cause pain), a positive Brudzinski sign (flexion of the patient's neck causes flexion of the patient's hips and knees), photophobia, a decreased LOC, and signs of increased ICP may also be present. Coma is associated with a poor prognosis and occurs in 5% to 10% of patients with bacterial meningitis. Seizures occur in one-third of all cases. With meningitis, the headache becomes progressively worse and may be accompanied by vomiting and irritability. If the infecting organism is a meningococcus, early symptoms may include chills, fever, headache, malaise, rash, and petechial hemorrhage on skin and mucous membranes.

Complications

The most common acute complication of bacterial meningitis is increased ICP. Most patients with the infection will have increased ICP, and it is the major cause of altered mental status. Another complication of bacterial meningitis is residual neurological dysfunction. Cranial nerve dysfunction in bacterial meningitis often occurs with cranial nerves III, IV, VI, VII, or VIII. The dysfunction usually disappears within a few weeks. However, hearing loss may be permanent after bacterial meningitis.

Cranial nerve irritation can have serious sequelae. The optic nerve (CN II) is compressed by increased ICP. Papilledema is often present, and blindness may occur. When the oculomotor (CN III), trochlear (CN IV), and abducens (CN VI) nerves are irritated, ocular movements are affected. Ptosis, unequal pupils, and diplopia are common. Irritation of the trigeminal nerve (CN V) is evidenced by sensory losses and loss of the corneal reflex, and irritation of the facial nerve (CN VII) results in facial paresis. Irritation of the vestibulo-cochlear nerve (CN VIII) causes tinnitus, vertigo, and deafness.

Hemiparesis, aphasia, and hemianopia may also occur. These signs usually resolve over time. If resolution does not occur, the presence of a cerebral abscess, subdural empyema, subdural effusion, or persistent meningitis is suggested. Acute cerebral edema may occur with bacterial meningitis, causing seizures, CN III palsy, bradycardia, hypertensive coma, and death.

A noncommunicating hydrocephalus may occur if the exudate causes adhesions that prevent the normal flow of CSF from the ventricles. CSF reabsorption by the arachnoid villi may also be obstructed by the exudate. In these cases, surgical implantation of a shunt may be necessary.

Headaches may occur for months after the diagnosis of meningitis until the irritation and inflammation have completely resolved. It is important to implement pain management for chronic headaches.

Waterhouse–Friderichsen syndrome is a complication of meningococcal meningitis. The syndrome is manifested by petechiae, disseminated intravascular coagulation (DIC), adrenal hemorrhage, and circulatory collapse. DIC and shock, which are some of the most serious complications of meningitis, are associated with meningococcemia. (DIC is discussed in detail in Chapter 33.)

Diagnostic Studies

When a patient is seen with manifestations suggestive of bacterial meningitis, a blood culture and CT scan should be done. Diagnosis is usually verified by doing a lumbar puncture and analysis of the CSF. Variations in the CSF depend on the causative organism. Protein levels in the CSF are usually elevated and are higher in bacterial than in viral meningitis. Decreased CSF glucose concentration is common in bacterial meningitis; the glucose level may be normal in viral meningitis. The CSF is purulent and turbid in bacterial meningitis; it may be the same or clear in viral meningitis. The predominant white blood cell type in the CSF during bacterial meningitis is polymorphonuclear cells (see Table 59-14). Specimens of CSF, sputum, and nasopharyngeal secretions are taken for culture before the start of antibiotic therapy to identify the causative organism. A Gram stain is done to detect bacteria. Variations in the CSF depend on the causative organism (bacterial or viral); see Table 59-14.

Radiographic studies of the skull may demonstrate infected sinuses. CT scans and MRI may be normal in uncomplicated meningitis. In other cases, CT scans may reveal evidence of increased ICP or hydrocephalus.

Collaborative Care

Rapid diagnosis based on history and physical examination is crucial because the patient is usually in a critical state when health care is sought. When meningitis is suspected, antibiotic therapy is instituted after the collection of specimens for cultures, even before the diagnosis is confirmed (Table 59-15).

TABLE 59-15

COLLABORATIVE CARE
Bacterial Meningitis

Diagnostic
• History and physical examination • Analysis of CSF for protein, glucose, WBC; Gram stain; culture • Blood culture • CBC, coagulation profile, electrolyte levels, glucose, platelet count • CT scan, MRI • Skull radiograph studies
Collaborative Therapy

• Acetaminophen (Tylenol) for temperature >38.5°C
• Clear liquids as desired or tolerated
• Codeine for headache
• Dexamethasone
• Hypothermia
• IV antibiotics
  • Ampicillin, penicillin
  • Cephalosporin (e.g., ceftriaxone)
• IV fluids
• IV furosemide (Lasix) or mannitol (Osmitrol) for diuresis
• IV phenytoin (Dilantin)
• Rest

CBC, complete blood cell count; *CSF*, cerebro-spinal fluid; *CT*, computed tomography; *IV*, intravenous; *MRI*, magnetic resonance imaging; *WBC*, white blood cell.

Ampicillin, vancomycin, cefotaxime (Claforan), and ceftriaxone (Moayedi & Gold, 2012) are the drugs of choice for treating meningitis. The corticosteroid dexamethasone may also be prescribed before or with the first dose of antibiotics. Although data are limited, administration of dexamethasone appears to be associated with a reduced incidence of hearing loss in patients with bacterial meningitis (Brouwer, McIntyre, Prasad, et al., 2015).

Nursing Management Bacterial Meningitis

Nursing Assessment

Initial assessment should include vital signs, neurological evaluation, assessment of fluid intake and output, and evaluation of the lungs and skin (see Figure 59-10).

Nursing Diagnoses

Nursing diagnoses for the patient with bacterial meningitis may include, but are not limited to, the following:

- *Decreased intracranial adaptive capacity* (related to decreased cerebral perfusion or increased ICP)
- *Risk for ineffective cerebral tissue perfusion* as evidenced by *brain injury* (reduction of blood flow, cerebral edema)
- *Hyperthermia* related to *increase in metabolic rate* (infection)
- *Acute pain* related to *biological injury agent* (headache, muscle aches)

Additional information on nursing diagnoses for the patient with bacterial meningitis is presented in NCP 59-2, available on the Evolve website.

Planning

The overall goals are that the patient with bacterial meningitis will have (1) return to maximal neurological functioning, (2) resolution of infection, and (3) control of pain and discomfort.

Nursing Implementation

Health Promotion.

Prevention of respiratory infections through vaccination programs for pneumococcal pneumonia and influenza should be supported by nurses. Several meningococcal vaccine preparations are available in Canada and are recommended to protect against developing bacterial meningitis. The schedule varies by province and territory. In addition, early and vigorous treatment of respiratory and ear infections is important. People who have close contact with anyone who has bacterial meningitis should be given prophylactic antibiotics. In Canada, cases of pneumococcal meningitis must be reported to the Public Health Agency of Canada.

Acute Intervention.

The patient with bacterial meningitis is usually acutely ill. The fever is high, and headache is severe. Irritation of the cerebral cortex may result in seizures. The changes in mental status and LOC depend on the degree of increased ICP. Assessment of vital signs, neurological evaluation, monitoring of fluid intake and output, and evaluation of lung fields and skin should be performed at regular intervals, based on the patient's condition, and recorded carefully.

Head pain and neck pain secondary to movement require attention. Codeine provides some pain relief without undue sedation for most patients. The patient should be assisted to a position of comfort, often curled up with the head slightly extended. The head of the bed should be slightly elevated, when permitted after lumbar puncture. A darkened room and a cool cloth over the eyes may relieve the discomfort of photophobia.

For the patient who is delirious, additional low lighting may be necessary to decrease hallucinations. All patients with bacterial meningitis suffer some degree of mental distortion and hypersensitivity and may be frightened and misinterpret the environment. Every attempt should be made to minimize environmental stimuli and prevent injury. The presence of a familiar person at the bedside often has a calming effect. The nurse must be efficient with care but also should project an attitude of caring and of unhurried gentleness. The use of touch and a soothing voice to give simple explanations of activities is helpful. If seizures occur, appropriate observations should be made and protective measures should be taken. Anticonvulsant drugs such as phenytoin (Dilantin) are administered as ordered. Problems associated with increased ICP are also managed (see the “Increased Intracranial Pressure” section, earlier in this chapter).

Fever must be vigorously managed because it increases cerebral edema and the frequency of seizures. In addition, neurological damage may result from an extremely high temperature over a prolonged time. If the fever is resistant to antipyretics, more vigorous means may be necessary, such as an automatic cooling blanket. Care should be taken not to reduce the temperature too rapidly because shivering may result, causing a rebound effect and increasing the temperature. The extremities should be wrapped in soft towels or covered with a thin blanket to protect them from "frostbite." Skin assessment and care should be meticulous. If a cooling blanket is not available or desirable, tepid sponge baths with water may be effective in lowering the temperature. The skin must be protected from excessive drying and injury.

Because high fever greatly increases the metabolic rate and thus insensible fluid loss, the patient should be assessed for dehydration and adequacy of fluid intake. Diaphoresis further increases fluid losses, which should be estimated and included in an intake and output record. Replacement fluids should be calculated as 800 mL/day for respiratory losses plus 100 mL for each degree of temperature above 38°C. Supplemental feeding to maintain adequate nutritional intake via tube or oral feedings may be necessary. The designated antibiotic schedule must be followed to maintain therapeutic blood levels. Observations should be made for adverse effects of the drugs used.

In most cases, patients with meningitis are placed in respiratory isolation for up to 48 hours of appropriate antibiotic therapy. Meningococcal meningitis is highly contagious, whereas other causes of meningitis may pose minimal to no infection risk with patient contact. Routine practices (also called *Standard Precautions*) are essential to protect the patient and the nurse.

Ambulatory and Home Care.

After the acute period has passed, the patient requires several weeks of convalescence before normal activities can be resumed. In this period, good nutrition should be stressed, with an emphasis on a high-protein, high-calorie diet in small, frequent feedings.

Muscle rigidity may persist in the neck and the backs of the legs. Progressive range of motion exercises and warm baths are useful. Activity should be gradually increased as tolerated, but adequate bed rest and sleep should be encouraged.

Residual effects are uncommon in meningococcal meningitis, but pneumococcal meningitis can result in sequelae such as dementia, seizures, deafness, hemiplegia, and hydrocephalus. Vision, hearing, cognitive skills, and motor and sensory abilities should be assessed after recovery, with appropriate referrals as indicated. Throughout the acute and convalescent periods, the nurse should be aware of the anxiety and stress experienced by individuals close to the patient.

Evaluation

The expected outcomes for the patient with bacterial meningitis are addressed in NCP 59-2, available on the Evolve website.

Viral Meningitis

The most common causes of viral meningitis are enteroviruses, arboviruses, human immunodeficiency virus (HIV), and herpes simplex virus (HSV). Viral meningitis usually presents as a headache, fever, photophobia, and nuchal rigidity. The fever may be moderate or high. There are usually no symptoms of brain involvement.

The most important diagnostic test is examination of the CSF obtained via a lumbar puncture. The CSF can be clear or cloudy, and the typical finding is lymphocytosis (see Table 59-14). Organisms are not seen on Gram stain or acid-fast smears. Polymerase chain reaction used to detect viral-specific deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) is a highly sensitive method for diagnosing CNS viral infections. Viral meningitis is managed symptomatically because the disease is self-limiting. Antiviral therapy is not used. Full recovery from viral meningitis is expected. Rare sequelae include persistent headaches, mild mental impairment, and incoordination.

Encephalitis

Etiology and Pathophysiology

Encephalitis, an acute inflammation of the brain, is a serious and sometimes fatal disease. Encephalitis is usually caused by a virus. Many different viruses have been implicated in encephalitis, some associated with seasons of the year or endemic to certain geographic areas. Ticks and mosquitoes transmit epidemic encephalitis. Examples include La Crosse encephalitis, St. Louis encephalitis, West Nile virus, and Western equine

encephalitis. Nonepidemic encephalitis may occur as a complication of measles, chicken pox, or mumps. HSV encephalitis is the most common form of acute, nonepidemic, viral encephalitis. Cytomegalovirus encephalitis is one of the common complications in patients with acquired immune deficiency syndrome (AIDS).

West Nile virus was first identified in Uganda in 1937. The first human case of West Nile virus in Canada occurred in summer–fall 2001. Since that time, the number of cases annually has fluctuated. In 2014, only 21 cases were reported in Canada. (Public Health Agency of Canada [PHAC], 2015a). Advanced age is the primary risk factor for encephalitis and mortality associated with this virus. The incubation period is from 3 to 14 days. Most cases involve mild, flulike symptoms, but about 1 in 150 will result in severe neurological disease, with encephalitis more commonly seen than meningitis.

Clinical Manifestations and Diagnostic Studies

The onset of infection is typically nonspecific, with fever, headache, nausea, and vomiting. It can be acute or subacute. Signs of encephalitis appear on day 2 or 3 and may vary from minimal alterations in mental status to coma. Virtually any CNS abnormality can occur, including hemiparesis, tremors, seizures, cranial nerve palsies, personality changes, memory impairment, amnesia, and aphasia.

Early diagnosis and treatment of viral encephalitis are essential for favourable outcomes. Diagnostic findings related to viral encephalitis are shown in Table 59-14. Brain imaging techniques include CT, MRI, and PET. Polymerase chain reaction tests for HSV DNA and RNA levels in CSF allow for early detection of HSV viral encephalitis. West Nile virus should be strongly considered in adults older than 50 years who develop encephalitis or meningitis in summer or early fall. The best diagnostic test for West Nile virus is a blood test that detects viral RNA. This test is also used in screening blood, organs, cells, and tissues that have been donated.

Nursing and Collaborative Management Viral Encephalitis

To prevent encephalitis, mosquito control should be practised, including cleaning rain gutters, removing old tires, draining bird baths, and removing water where mosquitoes can breed. In addition, insect repellent should be used during mosquito season.

Collaborative and nursing management of encephalitis, including West Nile virus infection, is symptomatic and supportive. Treatment for mild cases consists mainly of rest, adequate nutrition and fluids, acetaminophen for fever and headaches, and anticonvulsant drugs for seizures, if necessary. Generally, encephalitis does not respond to antiviral medications; however, the HSV and varicella-zoster virus respond to antiviral drugs such as acyclovir (Zovirax) or ganciclovir (Cytovene), and these have been shown to reduce mortality rates. For maximal benefit, antiviral agents should be started before the onset of coma. Current research is investigating the use of interferon therapy as a treatment for encephalitis caused by West Nile and St. Louis viruses; however, more studies are needed. In the initial stages, many patients require intensive care.

Seizure disorders should be treated with anticonvulsant drugs (see Chapter 61, Table 61-10). Prophylactic treatment with anticonvulsant drugs may be used in severe cases of encephalitis. Treatment of cytomegalovirus encephalitis in patients with AIDS is discussed in Chapter 17.

Rabies

Rabies has been a threat to humans since ancient times. Between 30 000 and 70 000 people die each year from rabies worldwide; however, only 24 people have died in Canada from rabies since reporting started in 1924 (PHAC, 2015b). Louis Pasteur developed the first rabies vaccine in 1885, which drastically reduced the risk for disease transmission from domestic animals to humans, particularly in developed countries where vaccine programs were effectively implemented. The threat is much greater in developing countries. Rabies vaccine is encouraged for individuals who travel globally, since it remains a serious public health concern.

The etiology of rabies is an RNA virus that produces an acute, progressive viral encephalitis. Although rabies is generally transmitted via saliva from the bite of an infected animal, it can also be spread by scratches, mucous membrane contact with infected secretions, and inhalation of aerosolized virus into the respiratory tract. Any warm-blooded mammal can carry rabies, including livestock. Throughout the world, rabid dogs are the most common disease vector. In developed countries, raccoons, skunks, bats, and foxes are the primary animal carriers.

The rabies virus spreads from the contact site through the CNS via peripheral nerves and possibly muscle fibres. During this time (2 to 14 days after exposure), patients experience flulike symptoms, and pain, paresthesias, or numbness at the bite site. An acute neurological syndrome then occurs 2 to 7 days later and is manifested by agitation, hypersalivation, hydrophobia, dysarthria, vertigo, diplopia, hallucinations, and other neurological sequelae (e.g., hyperactive reflexes, nuchal rigidity, and a positive Babinski sign). Coma develops within 7 to 10 days of the neurological syndrome. Death ensues as a result of respiratory and cardiovascular collapse within a few days after the onset of coma. Treatment is a vaccine series to induce active immunity. Because rabies is nearly always fatal, management efforts are directed at preventing the transmission and onset of the disease.

Brain Abscess

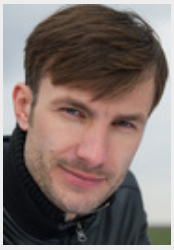
Brain abscess is an accumulation of pus within the brain tissue that can result from a local or systemic infection. Direct extension from ear, tooth, mastoid, or sinus infection is the primary cause. Other causes for brain abscess formation include spread from a distant site (e.g., pulmonary infection, bacterial endocarditis), skull fracture, and a prior brain trauma or surgery. *Streptococci* and *Staphylococcus aureus* are the primary infective organisms.

Manifestations are similar to those of meningitis and encephalitis and include headache, fever, and nausea and vomiting. Signs of increased ICP may include drowsiness, confusion, and seizures. Focal symptoms may be present and reflect the local area of the abscess. For example, visual field defects or psychomotor seizures are common with a temporal lobe abscess, whereas an occipital abscess may be accompanied by visual impairment and hallucinations. CT and MRI are used to diagnose a brain abscess.

Antimicrobial therapy is the primary treatment for brain abscess. Depending on the size and response of the abscess to antimicrobial treatment, the patient may require surgery to drain or remove the abscess if it is encapsulated. Other manifestations are treated symptomatically. In untreated cases, the mortality rate approaches 100%. Nursing measures are similar to those for management of meningitis or increased ICP. However, the distinct difference is the requirement of longer term (6 weeks or possibly longer) antibiotic therapy (either IV or oral) (Brouwer, Tunkel, McKhann, et al., 2014). If surgical drainage or removal is the treatment of choice, nursing care is similar to that described under cranial surgery. Some patients may be clinically well enough after the acute surgical phase to be discharged home. The nurse must be aware of the additional discharge planning requirements of a patient going home with IV antibiotic therapy, if indicated.

Case Study

Head Injury



Source: Andriy Solovyov/Shutterstock.com.

Patient Profile

George Roustas is a 33-year-old driver of a motorcycle that ran into an automobile broadside at a high rate of speed. He was sedated, paralyzed, and intubated by emergency medical personnel (EMS) at the scene before transport by helicopter. He was brought to the emergency department with a prehospital report of multiple trauma and an open skull fracture. Paramedics also reported that he was not wearing a helmet.

Subjective Data

He was reportedly unresponsive at the scene, with a Glasgow Coma Scale (GCS) score of 3, hypotension, tachycardia, and shallow, irregular respirations.

Objective Data

At the Scene

- Was unresponsive, with obvious deformity to the left side of the skull
- Respirations were shallow and irregular
- O_2 saturations ranged from 88% to 90%
- Systolic BP ranged from 50 to 80 mm Hg
- Heart rate ranged from 100 to 130 beats/min

In the Emergency Department

- Right pupil, 4 mm nonreactive; left pupil, 3 mm nonreactive
- GCS score = 3
- Hypotension and tachycardia continued in spite of fluid resuscitation

Diagnostic Studies

- Computed tomography (CT) of the head showed left skull fracture, left subdural hematoma, bilateral intraventricular and subarachnoid hemorrhage, and cerebral edema.
- CT of the abdomen and pelvis showed a lacerated liver, multiple infarcts to the right kidney, fluid around the duodenum and pancreas, and multiple left pelvic fractures.
- C-spine radiograph series was negative.
- Chest radiograph showed a right lung contusion and pneumomediastinum and subcutaneous emphysema.

Discussion Questions

1. What could be the cause of Mr. Roustas's hypoxia, hypotension, and tachycardia?
2. How could the injuries affect his neurological condition?

3. What area of the brain do Mr. Roustas's clinical manifestations suggest may be injured?
4. ***Priority decision:*** What are the priority nursing interventions that should be implemented?
5. ***Priority decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Vasogenic cerebral edema increases intracranial pressure by which of the following effects?
   a. Shifting fluid in the grey matter
   b. Altering the endothelial lining of cerebral capillaries
   c. Leaking molecules from the intracellular fluid to the capillaries
   d. Altering the osmotic gradient flow into the intravascular component
2. A client with ICP monitoring has pressure of 12 mm Hg. The nurse understands that this pressure reflects which of the following?
   a. A severe decrease in cerebral perfusion pressure
   b. An alteration in the production of cerebro-spinal fluid (CSF)
   c. The loss of autoregulatory control of intracranial pressure
   d. A normal balance between brain tissue, blood, and cerebro-spinal fluid
3. A nurse caring for a client with increased intracranial pressure knows that the best way to position the client is which of the following?
   a. Keep the head of the bed flat.
   b. Elevate the head of the bed to 30 degrees.
   c. Maintain the client on the left side with head supported on a pillow.
   d. Use a continuous-rotation bed to continuously change the client's position.
4. The nurse is alerted to a possible acute subdural hematoma in the client who has which of the following symptoms?
   a. A linear skull fracture crossing a major artery
   b. Focal symptoms of brain damage with no recollection of a head injury
   c. Decreased level of consciousness and a headache within 48 hours of a head injury
   d. An immediate loss of consciousness with a brief lucid interval followed by decreasing level of consciousness
5. During admission of a client with a severe head injury to the emergency department, the nurse places the highest priority on assessment for which of the following?

a. Patency of the airway
b. Presence of a neck injury
c. Neurological status according to the Glasgow Coma Scale
d. Cerebro-spinal fluid leakage from the ears or nose

6. A client is suspected of having an intracranial tumour. The signs and symptoms include memory deficits, visual disturbances, weakness of right upper and lower extremities, and personality changes. The nurse recognizes that the tumour is most likely located in which of the following areas?
   a. The frontal lobe
   b. The parietal lobe
   c. The occipital lobe
   d. The temporal lobe
7. Nursing management of a client with a brain tumour includes which of the following? *(Select all that apply)*
   a. Discussing with the client methods to control inappropriate behaviour
   b. Using diversion techniques to keep the client stimulated and motivated
   c. Assisting and supporting the family in understanding any changes in behaviour
   d. Limiting self-care activities until the client has regained maximum physical functioning
   e. Planning for seizure precautions and teaching the patient and the caregiver about anticonvulsant drugs
8. The nurse on the clinical unit is assigned to four clients. Which client should the nurse assess first?
   a. The client with a skull fracture whose nose is bleeding
   b. The older adult client with a stroke who is confused and whose daughter is present
   c. The client with meningitis who is suddenly agitated and reporting a headache of 10 on a 0–10 scale
   d. The client who had a craniotomy for a brain tumour who is now 3 days postoperative and has had continued emesis
9. Which of the following nursing measures is indicated to reduce the potential for seizures and increased intracranial pressure in the client

with bacterial meningitis?

a. Administering codeine for relief of head and neck pain

b. Controlling fever with prescribed drugs and cooling techniques

c. Keeping the room darkened and quiet to minimize environmental stimulation

d. Maintaining the client on strict bed rest with the head of the bed slightly elevated

1. b; 2. d; 3. b; 4. c; 5. a; 6. a; 7. c, e; 8. c; 9. b.

CHAPTER 60

Nursing Management

Stroke

Written by, Meg Zomorodi

Adapted by, Denise Elliott

LEARNING OBJECTIVES

1. Describe the incidence of and risk factors for stroke.
2. Explain mechanisms that affect cerebral blood flow.
3. Differentiate the etiology and pathophysiology of ischemic and hemorrhagic strokes.
4. Correlate the clinical manifestations of stroke with the underlying pathophysiology.
5. Identify diagnostic studies performed for a patient with a stroke.
6. Describe the collaborative care, drug therapy, and nutritional therapy for a patient with a stroke.
7. Describe the acute nursing management of a patient with a stroke.
8. Discuss the rehabilitative nursing management of a patient with a stroke.
9. Explain the psychosocial impact of a stroke on the patient, caregiver, and family.

thrombotic stroke, p. 1511

transient ischemic attack (TIA), p. 1510

Stroke, or **cerebro-vascular accident** (the medical term for *stroke*), occurs when there is *ischemia* (inadequate blood flow) to a part of the brain or hemorrhage into the brain that results in death of brain cells. Functions such as movement, sensation, or emotions that were controlled by the affected area of the brain are lost or impaired. The severity of the loss of function varies according to the location and extent of the brain involved. Early recognition of the clinical manifestations associated with the onset of a stroke is vital to ensure that immediate medical attention is sought, which is crucial in reducing disability and preventing death.

Stroke is a major public health concern. Each year 62 000 persons in Canada experience a stroke (Heart and Stroke Foundation of Canada, 2016). Over 13 000 Canadians die from stroke annually, making it the third most common cause of death in Canada, behind cancer and heart disease (Statistics Canada, 2017). More than 400 000 Canadians are currently living with the effects of stroke, and it is the leading cause of adult disability (Ontario Stroke Network, 2016; Heart and Stroke Foundation of Canada, 2017a). Common long-term disabilities include *hemiparesis* (paralysis of one side of the body), inability to walk, complete or partial dependence in activities of daily living (ADLs), **aphasia** (total loss of comprehension and use of language or total inability to communicate), and depression. In addition to the physical, cognitive, and emotional impact of a stroke on stroke survivors and their families, stroke also has an enormous financial impact. The direct and indirect costs of strokes are estimated to be greater than $3.6 billion per year in Canada (Public Health Agency of Canada, 2011).

Pathophysiology of a Stroke

Anatomy of Cerebral Circulation

Blood is supplied to the brain by two major pairs of arteries: the internal carotid arteries (anterior circulation) and the vertebral arteries (posterior circulation). The carotid arteries branch to supply most of the frontal, parietal, and temporal lobes; the basal ganglia; and part of the diencephalon (thalamus and hypothalamus). The major branches of the carotid arteries are the middle cerebral and anterior cerebral arteries. The vertebral arteries join to form the basilar artery, which branches to supply the middle and lower part of the temporal lobes, the occipital lobes, the cerebellum, the brain stem, and part of the diencephalon. The main branch of the basilar artery is the posterior cerebral artery. The anterior and posterior cerebral circulation is connected at the circle of Willis by the anterior and posterior communicating arteries (Figure 60-1). (See Chapter 58, Figure 58-14, for an illustration of the arteries at the base of the brain.) Genetic variations in this area are common, and some connecting vessels may not be present.

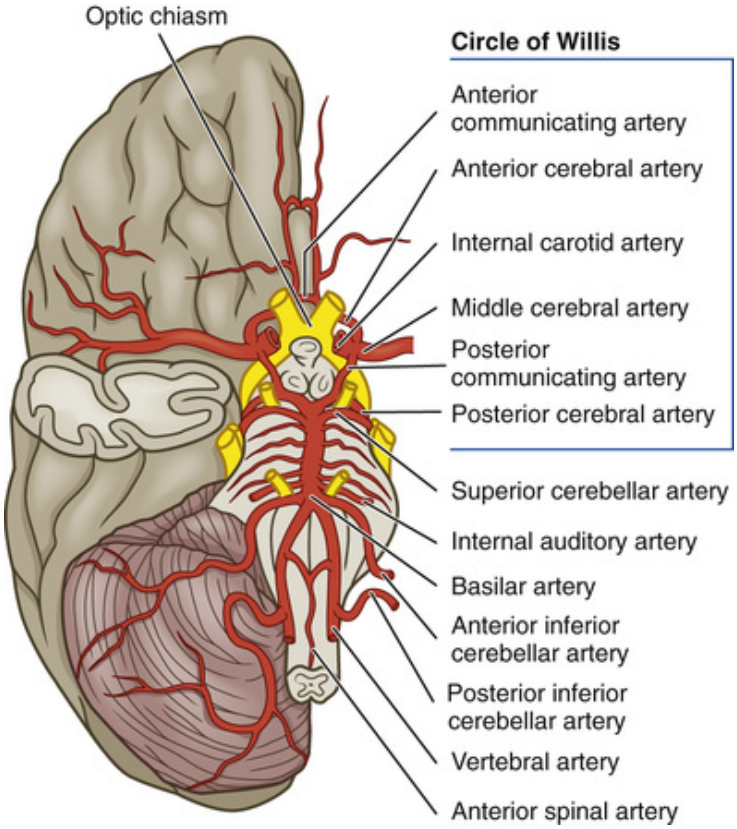

FIGURE 60-1 Cerebral arteries and the circle of Willis. The tip of the temporal lobe has been removed to show the course of the middle cerebral artery.

Regulation of Cerebral Blood Flow

The brain requires a continuous supply of blood to provide the oxygen and glucose that neurons need to function. Blood flow must be maintained at 750 to 1 000 mL/min (55 mL/100 g of brain tissue), or 20% of the cardiac output, for optimal brain functioning. If blood flow to the brain is totally interrupted (e.g., cardiac arrest), neurological metabolism is altered in 30 seconds, metabolism stops in 2 minutes, and cellular death occurs in 5 minutes.

The brain is normally well protected from changes in blood pressure (BP) by a mechanism known as *cerebral autoregulation* (see Chapter 59). Factors that affect blood flow to the brain include systemic BP, cardiac output, and blood viscosity. During normal activity, oxygen requirements vary considerably, but changes in cardiac output, vasomotor tone, and distribution of blood flow normally maintain adequate blood flow to the head. Cardiac output has to be reduced by one-third before cerebral blood

flow is reduced. Changes in blood viscosity affect cerebral blood flow, with decreased viscosity increasing flow.

Collateral circulation may develop to compensate for a decrease in cerebral blood flow. Because of the connections between arteries at the circle of Willis, an area of the brain can potentially receive blood supply from another blood vessel if its original blood supply is cut off (e.g., because of thrombosis). Individual differences in collateral circulation partly determine the degree of brain damage and functional loss when a stroke occurs.

Intracranial pressure (ICP) also influences cerebral blood flow (see Chapter 58). Increased ICP within the fixed space of the skull may cause reduced cerebral blood flow as a compensatory mechanism.

Atherosclerosis

Atherosclerosis (hardening and thickening of arteries) is a major cause of stroke. It can lead to thrombus formation and contribute to emboli. (The role of atherosclerosis in thrombosis and emboli development is discussed in Chapter 36.) Initially, there is abnormal infiltration of lipids in the intimal layer of the artery. This fatty streak further develops into a plaque. Plaques often develop in areas of increased turbulence of the blood, such as at the bifurcation of an artery or a tortuous area (Figure 60-2). Calcified, brittle plaques may rupture or fissure, leading to an inflammatory response. Platelet and fibrin are released and stick to the roughened plaque surface. Plaque may narrow or occlude the artery. Also, parts of the plaque or thrombus can break off and travel to a narrower distal artery. Cerebral infarction occurs when a cerebral artery becomes blocked and blood supply to the brain beyond the blockage is occluded.

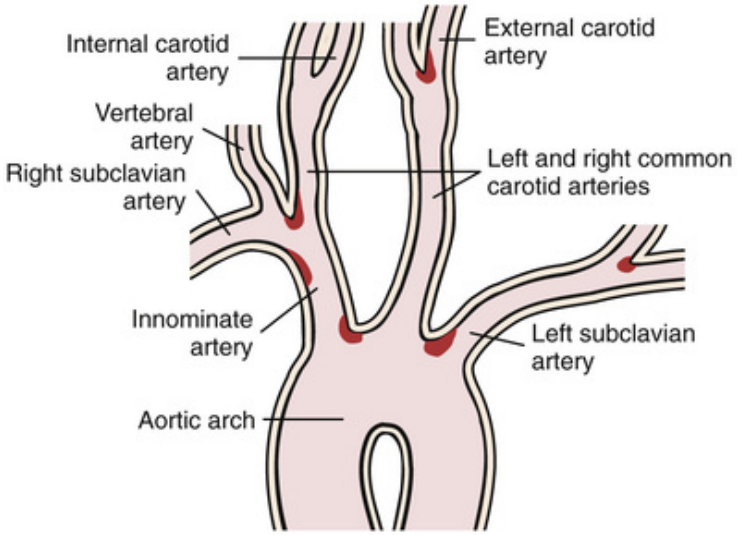

FIGURE 60-2 Common sites for the development of atherosclerosis in extracranial and intracranial arteries. The main locations are just above the common carotid bifurcation (most common site) and the start of the branches from the aorta and the innominate and subclavian arteries.

In response to ischemia, a series of metabolic events, termed the *ischemic cascade,* occur, including inadequate adenosine triphosphate production, loss of ion homeostasis, release of excitatory amino acids (e.g., glutamate), free radical formation, and cell death. Around the core area of ischemia is a border zone of reduced blood flow called the *penumbra,* where ischemia is potentially reversible. If adequate blood flow can be restored early (i.e., within 3 hours) and the ischemic cascade can be interrupted, brain damage may be minimized and less neurological function lost. Research is ongoing to identify thrombolytic and neuroprotective therapies to re-establish blood flow and protect neurons from further ischemic damage.

Risk Factors for Stroke

The most effective way to decrease the burden of and reduce the incidence of stroke is prevention through awareness and control of modifiable risk factors. Stroke risk increases considerably in the presence of multiple risk factors. The "Determinants of Health" box offers more specific information on nonmodifiable and modifiable risk factors within the Canadian population.

Nonmodifiable Risk Factors

Nonmodifiable risk factors include age, gender, ethnicity and race, family history and heredity, and low birth weight (Meschia, Bushnell, Boden-Albala, et al., 2014; Heart and Stroke Foundation, 2016). Stroke risk increases with age, doubling each decade after age 55. Two-thirds of all strokes occur in individuals older than 65 years, but a stroke can occur at any age. Strokes are more common in men, but more women than men die from them (Ontario Stroke Network, 2016). Because women tend to live longer than men, they have more opportunity to suffer a stroke. A family history of stroke, a prior TIA, or a prior stroke also increases the risk for stroke.

Determinants of Health

Stroke

Gender

- Men have a slightly higher risk for stroke than women, although the mortality rates are higher for women than for men.

Biology and Genetic Endowment

- Individuals from African, Latin American, or South Asian descent and Indigenous people are at increased risk for stroke due to underlying risk factors (e.g., hypertension, diabetes).

- Risk for stroke increases with a family history (first-generation) prior to age 65.

Personal Health Practices and Coping Skills

- Illicit drug use (e.g., cocaine, crack cocaine) can lead to stroke.
- Central obesity (waist circumference >84 cm) is linked to a higher risk for stroke.
- Physical inability, excessive alcohol consumption, smoking, and unhealthy diet increase stroke risk.
- Heart-healthy diets can reduce stroke risk by up to 80%.
- Stress is associated with increased risk for stroke.

Modifiable Risk Factors

Modifiable risk factors are those that can potentially be altered through lifestyle changes and medical treatment, thus reducing the risk for stroke (Table 60-1).

TABLE 60-1

MODIFIABLE RISK FACTORS FOR STROKE

- Asymptomatic carotid stenosis
- Arteriovenous malformation (in brain)
- Diabetes mellitus
- Heart disease; atrial fibrillation
- Alcohol use
- Hypercoagulability
- Illicit drugs
- Dyslipidemia
- Hypertension
- Obesity and body fat distribution
- Oral contraceptive use
- Physical inactivity
- Sleep apnea
- Smoking

Hypertension is the single most important, well-documented modifiable risk factor for stroke. Five million Canadian adults, approximately 22.6% of the population, have diagnosed hypertension (Padwal, Bienek, McAlister, et al., 2015). Increases in systolic and diastolic BP independently increase the risk for stroke. Stroke risk can be significantly reduced through the adequate treatment and early diagnosis of hypertension (Coutts, Wein, Lindsay, et al., 2014).

Heart disease, including atrial fibrillation (AF), myocardial infarction (MI), cardiomyopathy, cardiac valve abnormalities, and congenital defects, is also a risk factor for stroke. Of these, AF is the most important modifiable cardiac-related risk factor, controlled through the use of anticoagulants. The incidence of AF increases with age. Approximately 15% of all strokes are caused by AF, and this risk is greater after the age of

60, when 33% of strokes are caused by atrial fibrillation (Heart and Stroke Foundation of Canada, 2017b).

Diabetes mellitus is a significant risk factor for ischemic stroke. The risk for stroke in people with diabetes mellitus is four to five times higher than in the general population. Although tight control of hypertension in diabetics significantly decreases stroke risk, achieving a hemoglobin A_{1c} less than or equal to 7% and treatment with a "statin" and, if appropriate, a low dose of acetylsalicylic acid (ASA; Aspirin), have been proved to be beneficial (Coutts, Wein, Lindsay, et al., 2014).

Increased serum cholesterol and carotid stenosis are both other risk factors for ischemic stroke. Smoking increases the risk for ischemic stroke two to four times. Fortunately, the risk associated with smoking decreases over time after quitting smoking and, in 5 to 10 years, is reduced to that of nonsmokers (Centers for Disease Control and Prevention, 2017).

The effect of alcohol on stroke risk appears to depend on the amount consumed. Light to moderate use of alcohol, in particular wine, has been linked to reduced risk for ischemic stroke. Heavier use of alcohol does increase risk for stroke. Heavy drinking is defined as >4 drinks per day or 14 drinks a week in men; and >3 drinks per day or 7 drinks per week in women (Meschia, Bushnell, Boden-Albala, et al., 2014).

About 54% of adults ages 18 and older, or 14.2 million Canadians, self-reported being overweight or obese in 2014 (Statistics Canada, 2016). An association between physical inactivity and increased ischemic stroke risk is present in both men and women, regardless of ethnicity. Benefits of physical activity can occur with even light to moderate regular activity and may be in part related to the beneficial effect of exercise on other risk factors. Nutrition teaching is important for individuals at risk for stroke, since a diet high in fat and low in fruits and vegetables may increase stroke risk (Coutts, Wein, Lindsay, et al., 2014). Use of illicit drugs, notably the herbal stimulant khat, cocaine, methamphetamine, and heroin, has been associated with increased stroke risk (Meschia, Bushnell, Boden-Albala, et al., 2014).

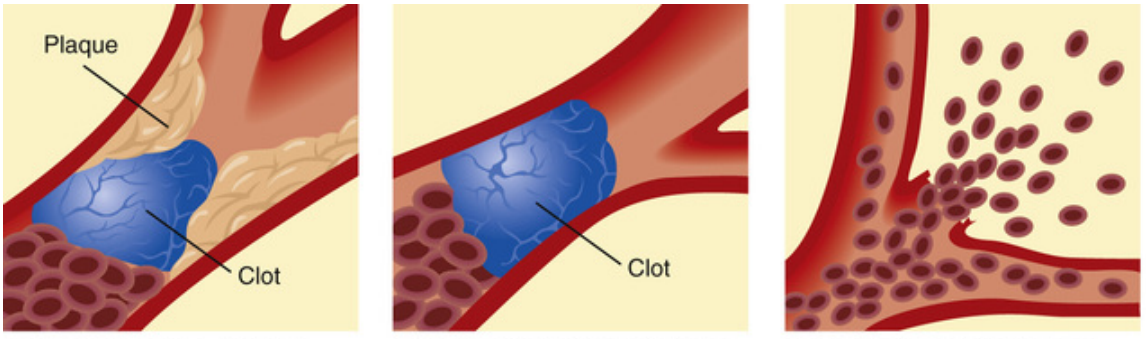
An *arteriovenous malformation* (AVM) is an abnormal group of tangled arteries and veins. AVMs can occur anywhere in the body; however, they pose the greatest risk in the brain as these vessels are more likely than others to bleed. Based on the location and size of the AVM, treatment options can include embolization, radiation, or surgery (Toronto Brain Vascular Malformation Study Group, 2012).

The early forms of birth control pills that contained high levels of progestin and estrogen increased a woman's chance of experiencing a

stroke, especially if the woman also smoked heavily. Newer, low-dose oral contraceptives have lower risks for stroke except in those individuals who are hypertensive and smoke. Women also face higher risk for stroke during pregnancy and when taking hormone therapy, so their other risk factors should be assessed by a health care provider (Rantanen & Tatlisumak, 2013). Other conditions that may increase stroke risk include migraines, metabolic syndrome, sleep-disordered breathing, inflammation and infection, hypercoagulability, and hyperhomocysteinemia.

Types of Stroke

Strokes are classified as ischemic or hemorrhagic based on the underlying pathophysiological findings (Figure 60-3 and Table 60-2).



Thrombotic stroke. Cerebral thrombosis is a narrowing of the artery by fatty deposits called *plaque*. Plaque can cause a clot to form, which blocks the passage of blood through the artery.

A

Embolic stroke. An embolus is a blood clot or other debris circulating in the blood. When it reaches an artery in the brain that is too narrow to pass through, it lodges there and blocks the flow of blood.

B

Hemorrhagic stroke. A burst blood vessel may allow blood to seep into and damage brain tissues until clotting shuts off the leak.

C

FIGURE 60-3 **A** to **C,** Major types of stroke.

TABLE 60-2
TYPES OF STROKE

Gender/Age	Warning/Onset	Course
Ischemic		
Thrombotic Men more than women Oldest median age	*Warning:* TIA (30%–50% of cases) *Onset:* Often during or after sleep	Stepwise progression, signs and symptoms develop slowly, usually some improvement, recurrence in 20%–25% of survivors
Embolic Men more than women	*Warning:* TIA uncommon *Onset:* Lack of relationship to activity, sudden onset	Single event, signs and symptoms develop quickly, usually some improvement, recurrence common without aggressive treatment of underlying disease
Hemorrhagic		
Intracerebral Slightly higher in women	*Warning:* Headache (25% of cases) *Onset:* Activity (often)	Progression over 24 hours; fatality more likely with presence of coma
Subarachnoid Higher in women Youngest median age	*Warning:* Headache (common) *Onset:* Activity (often), sudden onset	Acute onset, usually single sudden event described as the "worst headache of the patient's life," fatality more likely with presence of coma

TIA, transient ischemic attack.

Ischemic Stroke

Ischemic strokes result from inadequate blood flow to the brain from partial or complete occlusion of an artery; these account for approximately 87% of all strokes (American Heart Association, 2017). Ischemic strokes are further divided by their causality into *thrombotic* and *embolic*. A TIA is usually a precursor to ischemic stroke.

Transient Ischemic Attack.

A **transient ischemic attack (TIA)** is a temporary episode of neurological dysfunction caused by focal brain, spinal cord, or retinal ischemia but without acute infarction of the brain. Clinical symptoms typically last less than 1 hour. In the past, TIAs were operationally defined as any focal cerebral ischemic event with symptoms lasting less than 24 hours. However, it has been demonstrated that this arbitrary time threshold was too broad because over 30% of classically defined TIAs show brain infarction on magnetic resonance imaging (MRI) (Souillard-Scemama, Tisserand, Calvet, et al., 2015). Patients experiencing TIAs with imaging

that demonstrates tissue damage can have a 20 times higher risk for stroke than patients experiencing TIA without brain injury on MRI (Sorenson & Ay, 2011).

Most TIAs resolve. However, once a TIA starts, it is not possible to know whether it will persist and become a true stroke or resolve. Stroke risk following TIA is greatest immediately after the event; therefore, it is urgent that individuals seek medical attention immediately upon symptom onset (Sorenson & Ay, 2011).

TIAs may be caused by microemboli or plaque that temporarily block the blood flow. TIAs are a warning sign of progressive cerebro-vascular disease (Heart and Stroke Foundation of Canada, 2017c). The signs and symptoms of a TIA depend on the blood vessel that is involved and the area of the brain that is ischemic. If the carotid system is involved, patients may have a temporary loss of vision in one eye *(amaurosis fugax),* a transient hemiparesis, numbness or loss of sensation, or a sudden inability to speak. Signs of a TIA involving the vertebrobasilar system may include tinnitus, vertigo, darkened or blurred vision, *diplopia* (double vision), *ptosis* (drooping eyelid), **dysarthria** (a disturbance in the muscular control of speech), *dysphagia* (difficulty swallowing), *ataxia* (loss of muscle control), and unilateral or bilateral numbness or weakness.

Thrombotic Stroke.

A **thrombotic stroke** occurs when a blood clot forms in a diseased and narrowed blood vessel in the brain (see Figure 60-3, *A*). If the narrowed lumen of the blood vessel becomes occluded, infarction occurs. Thrombosis develops readily where atherosclerotic plaques have already narrowed blood vessels. Thrombotic stroke is the most common type of ischemic stroke. Two-thirds of thrombotic strokes are associated with hypertension or diabetes mellitus, both of which accelerate atherosclerosis. Patients experiencing a TIA have symptoms that resolve without interventions, whereas patients suffering a thrombotic stroke have symptoms that will continue to evolve if treatment is not received quickly. In 30% to 50% of individuals, TIAs have preceded thrombotic strokes.

The extent of the stroke depends on the rapidity of onset, the size of the lesion, and the presence of collateral circulation. Most patients with ischemic stroke do not have a decreased level of consciousness (LOC) in the first 24 hours, unless it is owing to a brain stem stroke or other conditions such as seizures, increased ICP, or hemorrhage. Ischemic stroke

symptoms may progress in the first 72 hours as infarction and cerebral edema increase.

A *lacunar stroke* refers to a stroke from occlusion of a small penetrating artery that supplies blood to tissues deep within the brain. This most commonly occurs in the basal ganglia, thalamus, internal capsule, or pons. Although many lacunar strokes are asymptomatic, when present, symptoms can cause considerable deficits. These include pure motor *hemiplegia* (paralysis of one side of the body), pure sensory stroke (contralateral loss of all sensory modalities), contralateral leg and face weakness with arm and leg ataxia, and isolated motor or sensory stroke. Multiple small vessel infarcts may also result in a decrease in vascular function (e.g., vascular dementia) (see Chapter 62).

Embolic Stroke.

Embolic stroke occurs when an embolus lodges in and occludes a cerebral artery, resulting in infarction and edema of the area supplied by the involved vessel (see Figure 60-3, *B*). Embolism is the second most common cause of stroke, accounting for about 24% of strokes. The majority of emboli originate in the endocardial (inside) layer of the heart, with plaque breaking off from the endocardium and entering the circulation. The embolus travels upward to the cerebral circulation and lodges where a vessel narrows or bifurcates. Heart conditions associated with emboli include valvular heart disease and valvular prosthesis MI, infective endocarditis, rheumatic heart disease, and intracardiac congenital defects such as atrial septal defects and patent foramen ovale. In addition, AF is associated with a four- to five-fold increased risk for ischemic stroke owing to embolism of stasis-induced thrombi in the left atrium (Meschia, Bushnell, Boden-Albala, et al., 2014). Less common triggers of emboli include air and fat from long bone (femur) fractures.

The patient with an embolic stroke commonly has a rapid occurrence of severe clinical symptoms, but warning signs are less common than with thrombotic stroke. The onset of an embolic stroke is usually sudden and may or may not be related to activity. The patient usually remains conscious and may or may not experience a headache. Prognosis is related to the amount and location of brain tissue deprived of its blood supply. The effects of the emboli are initially characterized by severe neurological deficits, which can be temporary if the clot breaks up and allows blood to flow. Smaller emboli then continue to obstruct smaller vessels, which in turn involve smaller portions of the brain with fewer deficits noted. The

embolic stroke often occurs rapidly, and the body does not have time to accommodate by developing collateral circulation. Recurrence of embolic stroke is common unless the underlying cause is aggressively treated.

Hemorrhagic Stroke

Hemorrhagic strokes account for approximately 15% of all strokes; they result from bleeding into the brain tissue itself (intracerebral or intraparenchymal hemorrhage) or into the subarachnoid space or the ventricles (subarachnoid hemorrhage [SAH] or intraventricular hemorrhage).

Intracerebral Hemorrhage.

Intracerebral hemorrhage is bleeding within the brain caused by a rupture of a vessel; it accounts for about 10% of all strokes (see Figure 60-3, *C*). Hypertension is the most important risk factor for intracerebral hemorrhage (Figure 60-4). Other causes include cerebral amyloid angiopathy, vascular malformations, coagulation disorders, anticoagulant and thrombolytic drugs, trauma, brain tumours, and ruptured aneurysms. Hemorrhage commonly occurs during periods of activity. There is most often a sudden onset of symptoms, with progression over minutes to hours because of ongoing bleeding. Symptoms include neurological deficits, headache, nausea, vomiting, decreased LOC (in about 50% of patients), and hypertension. The extent of the symptoms varies depending on the amount, location, and duration of the bleeding. A blood clot within the closed skull can result in a mass that causes pressure on brain tissue, displaces brain tissue, and decreases cerebral blood flow, leading to ischemia and infarction.

FIGURE 60-4 Massive hypertensive hemorrhage rupturing into a lateral ventricle of the brain. Source: Kumar, V., Abbas, A. K., Fausto, N., et al. (2010). *Robbins and Cotran pathologic basis of disease* (8th ed., p. 1296, Figure 28-18). Philadelphia: Saunders.

Approximately 50% of intracerebral hemorrhages occur in the putamen and the internal capsule, central white matter, thalamus, cerebellar hemispheres, and pons. Initially, patients experience a severe headache with nausea and vomiting. Clinical manifestations of bleeding within the putamen and internal capsule include weakness of one side (including face, arm, and leg), slurred speech, and deviation of the eyes. Progression of symptoms related to a severe hemorrhage includes hemiplegia, fixed and dilated pupils, abnormal body posturing, and coma. Thalamic hemorrhage results in hemiplegia with more sensory than motor loss. Bleeding into the subthalamic areas of the brain leads to problems with vision and eye movement. Cerebellar hemorrhages are characterized by severe headache, vomiting, loss of ability to walk, dysphagia, dysarthria, and eye movement disturbances. Hemorrhage in the pons is the most

serious because basic life functions (e.g., respiration) are rapidly affected. Hemorrhage in the pons can be characterized by hemiplegia leading to complete paralysis, coma, abnormal body posturing, fixed pupils (small in size), hyperthermia, and death. It is difficult to predict the prognosis of patients with intracerebral hemorrhage. Early recognition and aggressive medical management are associated with improved outcomes. Factors such as the patient's age, initial Glasgow Coma Scale (GCS) score, and location and volume of hemorrhage play a role in decision making and prognostication (Hemphill, Greenberg, Anderson, et al., 2015).

Subarachnoid Hemorrhage.

Subarachnoid hemorrhage (SAH) occurs when there is intracranial bleeding into the cerebro-spinal fluid (CSF)–filled space between the arachnoid and the pia mater membranes on the surface of the brain. SAH is commonly caused by rupture of a cerebral **aneurysm** (congenital or acquired permanent, localized outpouching or dilation of the blood vessel wall). Aneurysms may vary in shape and can be described as saccular or berry aneurysms, ranging from a few millimetres to 20 to 30 mm in size, or fusiform atherosclerotic aneurysms. The majority of aneurysms are in the circle of Willis. Other causes of SAH include AVMs, trauma, and illicit drug (cocaine) use. About 25% of people who have a hemorrhagic stroke owing to a ruptured aneurysm die, and 50% of survivors have persistent neurological deficits. The incidence of SAH caused by a ruptured aneurysm increases with age and is higher in women than in men (Connolly, Rabinstein, Carhuapoma, et al., 2012).

The patient may have warning symptoms if the ballooning artery applies pressure to brain tissue or if an aneurysm leaks before major rupture. Overall, cerebral aneurysms are viewed as a “silent killer” because individuals usually do not have warning signs of an aneurysm until rupture has occurred.

Safety Alert

Sudden onset of a severe headache that is different from a previous headache and typically the “worst headache of one's life” is characteristic of a ruptured aneurysm, and individuals experiencing it should seek medical attention immediately.

Loss of consciousness may or may not occur. The patient's LOC may range from alert to comatose, depending on the severity of the bleed. Other symptoms include focal neurological deficits (including cranial nerve deficits), nausea, vomiting, seizures, and stiff neck. Improvements in surgical techniques and aggressive medical management of complications have led to better outcomes; however, many patients are left with significant morbidity, including cognitive difficulties.

Complications of aneurysmal SAH include rebleeding before surgery or other therapy is initiated and cerebral vasospasm (narrowing of the large blood vessels at the base of the brain), which can result in cerebral infarction. Cerebral vasospasm is most likely owing to an interaction between the metabolites of blood and the vascular smooth muscle. During the lysis of subarachnoid blood clots, metabolites are released. These metabolites can cause endothelial damage and vasoconstriction. In addition, release of endothelin (a potent vasoconstrictor) may play a major role in the induction of cerebral vasospasm after SAH. Peak time for vasospasm to occur is 7 to 10 days after the initial bleed.

Clinical Manifestations of Stroke

The neurological manifestations do not significantly differ between ischemic and hemorrhagic stroke. The reason for this is that destruction of neural tissue is the basis for neurological dysfunction caused by both types of stroke. The clinical manifestations are related to location of the stroke. Specific manifestations related to the type of stroke are discussed in the previous section on types of stroke.

The general clinical manifestations of ischemic and hemorrhagic stroke are discussed together in this section. A stroke can have an effect on many body functions, including motor activity, bladder and bowel elimination, intellectual function, spatial–perceptual alterations, personality, affect, sensation, and communication. The functions affected are directly related to the artery involved and the area of the brain it supplies (Table 60-3). Manifestations related to right- and left-brain damage differ somewhat and are shown in Figure 60-5.

TABLE 60-3

STROKE MANIFESTATIONS RELATED TO ARTERY INVOLVEMENT

Artery	Deficit or Syndrome
Anterior cerebral	Motor or sensory deficit (contralateral) or both, sucking or rooting reflex, rigidity, gait problems, loss of proprioception, fine touch
Middle cerebral	*Dominant side:* Aphasia, motor and sensory deficit, *hemianopia* (blindness over half the field of vision) *Nondominant side:* Neglect, motor and sensory deficit, hemianopia
Posterior cerebral	Hemianopia, visual hallucination, spontaneous pain, motor deficit
Vertebral	Cranial nerve deficits, diplopia, dizziness, nausea, vomiting, dysarthria, dysphagia, coma

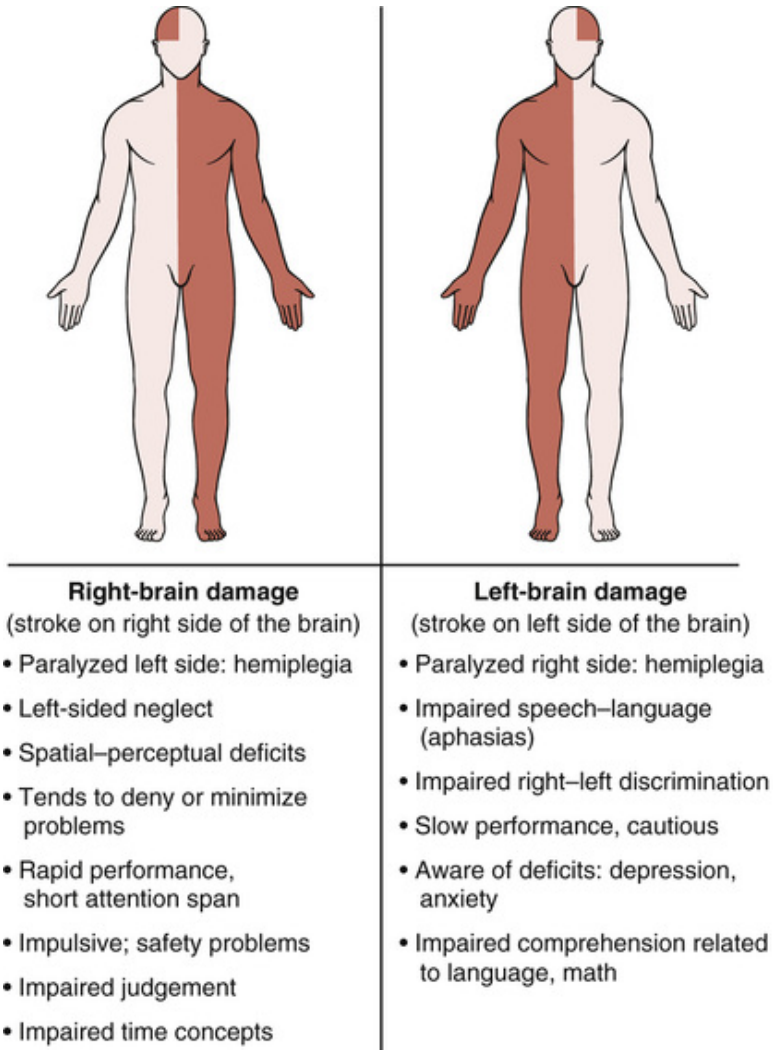


FIGURE 60-5 Manifestations of right-brain and left-brain stroke.

Motor Function.

Motor deficits are the most obvious effect of stroke. Motor deficits include impairment of (a) mobility, (b) respiratory function, (c) swallowing and speech, (d) gag reflex, and (e) self-care abilities. Symptoms are caused by the destruction of motor neurons in the pyramidal pathway (nerve fibres from the brain and passing through the spinal cord to the motor cells). The characteristic motor deficits include loss of skilled voluntary movement *(akinesia)*, impairment of integration of movements, alterations in muscle tone, and alterations in reflexes. The initial *hyporeflexia* (depressed reflexes) progresses to *hyperreflexia* (hyperactive reflexes) for most patients.

Motor deficits after a stroke follow certain specific patterns. A lesion on one side of the brain affects facial features on the same side as the lesion *(ipsilateral);* however, because the pyramidal pathway crosses at the level of the medulla, motor function on the opposite side of the brain lesion becomes impaired *(contralateral).* The arms and legs of the affected side may be weakened or paralyzed to different degrees depending on which part of and to what extent the cerebral circulation was compromised. A stroke affecting the middle cerebral artery leads to a greater weakness in the upper extremity than the lower extremity. The affected shoulder tends to rotate internally and the hip rotates externally. The affected foot is plantar flexed and inverted. An initial period of flaccidity may last from days to several weeks and is related to nerve damage. Spasticity of the muscles follows the flaccid stage and is related to interruption of upper motor neuron influence.

Communication.

The left hemisphere is dominant for language skills in right-handed persons and in most left-handed persons. Language disorders involve expression and comprehension of written and spoken words. The patient may experience aphasia affecting the comprehension of language, the ability to speak, or both. It occurs when a stroke damages the dominant hemisphere of the brain. **Dysphasia** refers to impaired ability to communicate. However, in most settings, the terms *aphasia* and *dysphasia* are used interchangeably to mean the same thing, with *aphasia* often being the more common term used.

According to the National Institute of Neurological Disorders and Stroke (NINDS, 2017), there are four categories of aphasia: (a) *Expressive aphasia* (also called *Broca's aphasia*) is difficulty in expressing thoughts through speech or writing. The patient cannot find the words needed but

does know what he or she wants to say. The stroke survivor's speech is reduced often to fewer than four words. (b) *Receptive aphasia* (also called *Wernicke's aphasia*) is difficulty understanding spoken or written language. These patients are difficult to understand. They speak without hesitation, but words may be used incorrectly and sentences may be ungrammatical. (c) *Anomic* or *amnesic aphasia* is the least severe form of aphasia and involves problems finding the correct names for specific objects, people, places, or events. (d) *Global aphasia* results in loss of all expressive and receptive function. It is usually caused by a massive stroke. Some aphasia is mixed, with impairment in both expression and understanding.

Many stroke patients also experience dysarthria, a disturbance in the muscular control of speech. Impairments may involve pronunciation, articulation, and phonation (use of the voice). Dysarthria does not affect the meaning of communication or the comprehension of language, but it does affect the mechanics of speech. Some patients experience a combination of aphasia and dysarthria.

Affect.

Patients who have had a stroke may have difficulty controlling their emotions, and so emotional responses may be exaggerated or unpredictable. Depression, common in the first year following a stroke (National Stroke Association, 2017), and feelings associated with changes in body image and loss of function can make this worse. Patients may also be frustrated by mobility and communication problems.

Intellectual Function.

Both memory and judgement may be impaired as a result of stroke. These impairments can occur with strokes affecting either side of the brain. A left-brain stroke is more likely to result in memory problems related to language. Patients with a left-brain stroke often are very cautious in making judgements. The patient with a right-brain stroke tends to be impulsive and to move quickly. An example of behaviour with right-brain stroke is the patient who tries to rise quickly from the wheelchair without locking the wheels or raising the foot rests. The patient with a left-brain stroke would move slowly and cautiously from the wheelchair. Patients with either type of stroke may have difficulty making generalizations, which interferes with their ability to learn.

Spatial–Perceptual Alterations.

A stroke on the right side of the brain is more likely to cause problems in spatial–perceptual orientation, although these issues can also occur with left-brain stroke. Spatial–perceptual problems may be divided into four categories:

1. The patient's incorrect perception of self and illness. This deficit follows damage to the parietal lobe. Patients may deny their illnesses or their own body parts *(anosognosia).*
2. The patient's erroneous perception of self in space. The patient may neglect all input from the affected side. This may be worsened by *homonymous hemianopia,* in which blindness occurs in the same half of the visual fields of both eyes. The patient also has difficulty with spatial orientation, such as judging distances.
3. *Agnosia,* the inability to recognize an object by sight, touch, or hearing.
4. *Apraxia,* the inability to carry out learned sequential movements on command.

Patients may or may not be aware of their spatial–perceptual alterations.

Elimination.

Fortunately, most problems with urinary and bowel elimination that occur initially are temporary. When a stroke affects one hemisphere of the brain, the prognosis for normal bladder function is excellent. At least partial sensation for bladder filling remains, and voluntary urination is present. Initially, the patient may experience frequency, urgency, and incontinence. Although motor control of the bowel is usually not a problem, patients frequently become constipated. Constipation is associated with immobility, weak abdominal muscles, dehydration, and diminished response to the defecation reflex. Urinary and bowel elimination problems may also be related to inability to express needs and to manage clothing.

Diagnostic Studies

When manifestations of a stroke occur, diagnostic studies are done to (a) confirm that it is a stroke and not another brain lesion, such as a subdural hematoma, and (b) identify the likely cause of the stroke (Table 60-4). Tests also guide decisions about therapy to prevent a secondary stroke. The

single most important timely primary assessment tool for a stroke patient is brain imaging—either MRI or noncontrast computed tomographic (CT) scan (Casaubon, Boulanger, Blacquiere, et al., 2015). The CT scan is quick and easy to access in most facilities. It should optimally be obtained within 25 minutes and read within 45 minutes of arrival at the emergency department. The CT scan indicates the size and location of the lesion and helps to differentiate between ischemic and hemorrhagic stroke. Serial CT scans may be used to assess the effectiveness of treatment and to evaluate recovery.

TABLE 60-4

DIAGNOSTIC STUDIES
Stroke

Diagnosis of Stroke (Including Extent of Involvement)
• Computed tomographic (CT) scan • CT angiography (CTA) • Magnetic resonance angiography (MRA) • Magnetic resonance imaging (MRI)
Cerebral Blood Flow
• Carotid angiography • Carotid duplex scanning • Cerebral angiography • Digital subtraction angiography • Transcranial Doppler ultrasonography
Cardiac Assessment
• Cardiac markers (troponin, creatine kinase–MB) • Chest radiograph • Echocardiography (transthoracic, transesophageal) • Electrocardiogram
Additional Studies
• Cerebro-spinal fluid (CSF) analysis* • Coagulation studies: prothrombin time/international normalized ratio (INR), activated partial thromboplastin time (aPTT) • Complete blood cell count (CBC) including platelets • Electrolytes, blood glucose; hemoglobin A_{1c} (Hb A_{1c}) • Lipid profile • Renal and hepatic studies

*A lumbar puncture to obtain CSF is avoided if increased intracranial pressure is suspected because this procedure can cause a low-pressure shunt, drawing the CSF fluid down the spinal column. As the CSF pressure decreases, CSF and brain mass may shift toward the lower pressure area, causing herniation of the brain (see Chapter 58).

Computed tomographic angiography (CTA) provides visualization of cerebral vasculature and can be performed after or at the same time as the noncontrast CT scan. CTA can provide an estimate of perfusion and detect defects in the cerebral arteries.

MRI is used to determine the extent of brain injury and has greater specificity than CT in determining the location of vascular lesions and blockages. Patient preparation and access to an MRI scanner can be delayed for many reasons but should not delay the patient having alternative diagnostic studies performed. Magnetic resonance angiography can detect vascular lesions and blockages, similar to CTA.

Angiography can identify cervical and cerebro-vascular occlusion, atherosclerotic plaques, and malformation of vessels. Cerebral angiography is a definitive study to identify the source of SAH. Risks of angiography include dislodging an embolus, vasospasm, inducing further hemorrhage, and allergic reaction to contrast media.

Intra-arterial digital subtraction angiography uses a smaller dose of contrast material, uses smaller catheters, and is a shorter procedure compared with conventional angiography. Digital subtraction angiography involves the injection of a contrast agent to visualize blood vessels in the neck and the large vessels of the circle of Willis. It is considered safer than cerebral angiography because less vascular manipulation is required.

Transcranial Doppler ultrasonography is a noninvasive study that measures the velocity of blood flow in the major cerebral arteries. Transcranial Doppler has been shown to be effective in detecting microemboli and vasospasm and is ideal for patients confirmed to have SAH. Carotid duplex scanning is used not only to detect the cause of the stroke but also to stratify patients for either medical management or carotid intervention if they have carotid stenosis.

If the suspected cause of the stroke includes emboli from the heart, diagnostic cardiac tests should be done (see Table 60-4). Blood tests are also done to help identify conditions contributing to stroke and to guide treatment (see Table 60-4).

Collaborative Care

Prevention Therapy.

Primary prevention is a priority for decreasing morbidity and mortality from stroke (Table 60-5). The goals of stroke prevention include health management for the well individual and education and management of modifiable risk factors to prevent a primary or secondary stroke. Health management focuses on (a) BP control, (b) blood glucose control, (c) diet and exercise, (d) smoking cessation, (e) limiting alcohol consumption, and (f) routine health assessments. Patients with known risk factors such as

diabetes mellitus, hypertension, smoking, high serum lipids, or cardiovascular dysfunction require close management.

TABLE 60-5
COLLABORATIVE CARE
Stroke

Diagnostic
• History and physical examination • See Table 60-4
Collaborative Therapy
Prevention
• Control of hypertension • Control of diabetes mellitus • Treatment of underlying cardiac problem
Lifestyle Modifications
• Limiting of alcohol intake • Increase in exercise • Weight loss to normalize BMI • Reduction of sodium intake • Smoking cessation
Drug Therapy
• Anticoagulation therapy for patients with atrial fibrillation (if indicated by use of the CHADS2 classification) • Platelet inhibitors (e.g., acetylsalicylic acid [ASA; Aspirin])
Surgical Therapy
• Carotid endarterectomy (see Figure 60-6) • Extracranial–intracranial bypass • Stenting of carotid artery • Surgical interventions for aneurysms at risk of bleeding • Transluminal angioplasty
Acute Care
• DVT prevention with LMWH • Fluid therapy • Maintenance of airway • Prevention of secondary injury • Treatment of cerebral edema
Ischemic Stroke
• Endovascular treatment • Tissue plasminogen activator (tPA)
Hemorrhagic Stroke
• Clipping or coiling of aneurysm • Surgical decompression if indicated
Embolic Stroke
• Treatment of underlying cause (usually cardiac related)

BMI, body mass index; *CHADS2,* clinical prediction rule used to estimate the risk for stroke in patients with atrial fibrillation and to determine the degree of anticoagulation required; *DVT,* deep-vein thrombosis; *LMWH,* low-molecular-weight heparin.

Drug Therapy.

Measures to prevent the development of a thrombus or embolus are used in patients with TIAs because they are at risk for stroke. Antiplatelet drugs

are usually the chosen treatment to prevent stroke in patients who have had a TIA. ASA (Aspirin) is the most frequently used antiplatelet agent, commonly at a dose of 81 to 325 mg/day. Drug therapy may also include clopidogrel (Plavix). Oral anticoagulation using apixaban (Eliquis), dabigatran (Pradaxa), or rivaroxaban (Xarelto) is the treatment of choice for individuals with AF who have had a TIA. Patients using these anticoagulation drugs need to have their renal function regularly monitored and doses adjusted accordingly. Statins (simvastatin [Zocor], lovastatin) have also been shown to be effective in the prevention of stroke for individuals who have experienced a TIA (Coutts, Wein, Lindsay, et al., 2014).

Drug Alert

Clopidogrel (Plavix)

- All health care providers and dentists must be informed that this medication is being taken, especially before scheduling surgery or major dental procedures.
- Medication may need to be discontinued 10 to 14 days before surgery if antiplatelet effect is not desired.

Surgical Therapy.

Surgical interventions for the patient with TIAs from carotid disease are outlined in Table 60-5. Figure 60-6 demonstrates one intervention, carotid endarterectomy.

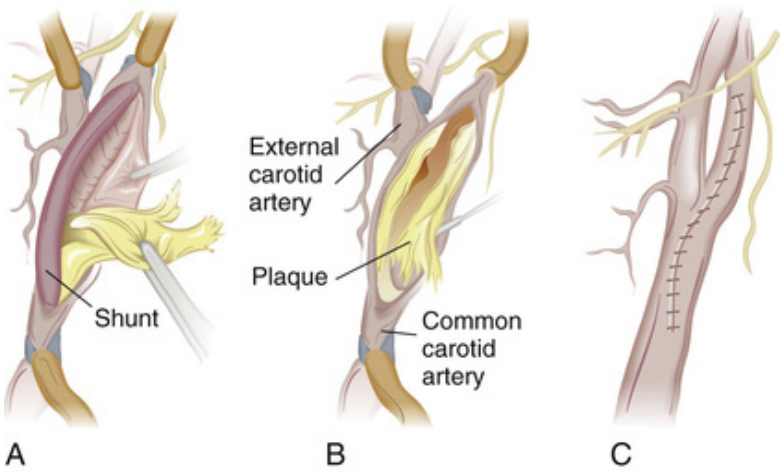

FIGURE 60-6 Carotid endarterectomy is performed to prevent impending cerebral infarct. **A,** A tube is inserted above and below the blockage to reroute the blood flow. **B,** Atherosclerotic plaque in the common carotid artery is removed. **C,** Once the artery is stitched closed, the tube can be removed. A surgeon may also perform the technique without rerouting the blood flow.

Transluminal angioplasty is the insertion of a balloon to open a stenosed artery and improve blood flow. The balloon is threaded up to the carotid artery via a catheter inserted in the femoral artery. Stenting involves intravascular placement of a stent in an attempt to maintain patency of the artery (Figure 60-7). The stent can be inserted during an angioplasty. Once in place, the system can be used with a tiny filter that opens like an umbrella. The filter catches and removes the debris that is stirred up during the stenting procedure so that it does not float to the brain, where it can trigger a stroke. Patients' comorbidities should be carefully considered as carotid stenting is associated with a higher risk for stroke, whereas carotid endarterectomy has an increased risk for MI (Liu, Fu, Guo, et al., 2012).

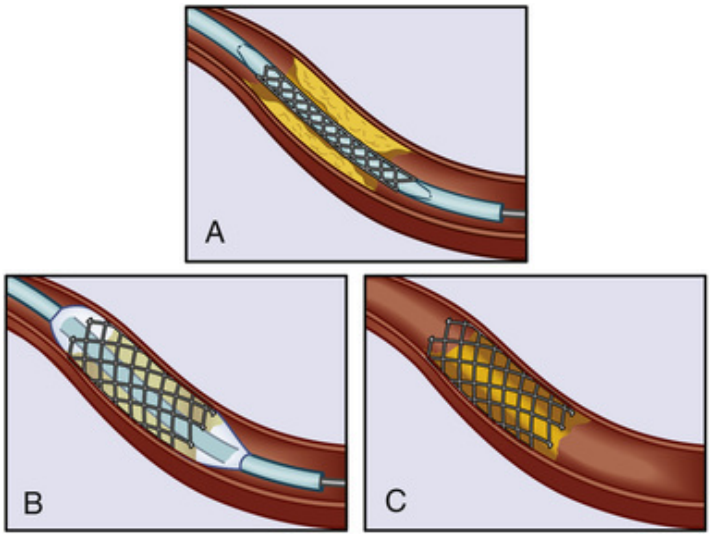

FIGURE 60-7 Brain stent used to treat blockages in cerebral blood flow. **A,** A balloon catheter is used to implant the stent into an artery of the brain. **B,** The balloon catheter is moved to the blocked area of the artery and then inflated. The stent expands due to inflation of the balloon. **C,** The balloon is deflated and withdrawn, leaving the stent permanently in place holding the artery open and improving the flow of blood.

Extracranial-to-intracranial artery bypass involves anastomosing (surgically connecting) a branch of an extracranial artery to an intracranial artery (most commonly, superficial temporal to middle cerebral artery) beyond an area of obstruction with the goal of increasing cerebral perfusion. This procedure is generally reserved for those patients who do not benefit from other forms of therapy.

Collaborative Acute Care for Ischemic Stroke.

The goals for collaborative care during the acute phase are preserving life, preventing further brain damage, and reducing disability. During initial evaluation, the single most important point in the patient's history is the time of onset. Fifty-four percent of patients who seek acute care for stroke present at the emergency department, and the rest seek out their primary health care physicians. The current standard for acute care treatment of stroke is that all patients with possible stroke will be assessed, have their acute health needs addressed, undergo diagnostic studies, and receive thrombolytic therapy within 4.5 hours from the onset of their symptoms. Best practice includes attempting to transfer patients presenting at primary care clinics or basic stroke care hospitals to a facility with advanced and comprehensive stroke services so the patient can receive tissue

plasminogen activator (tPA) within the allotted time if necessary (Canadian Stroke Network & Heart and Stroke Foundation of Canada, 2013).

Table 60-6 outlines the emergency management of patients with a stroke. Acute care begins with managing circulation, airway, and breathing. Patients may have difficulty keeping an open and clear airway because of a decreased LOC or decreased or absent gag and swallowing reflexes. Maintaining adequate oxygenation is important. Both hypoxia and hypercarbia are to be prevented because they can contribute to secondary neuronal injury. Oxygen administration, artificial airway insertion, intubation, and mechanical ventilation may be required. Baseline neurological assessment is carried out, and patients are monitored closely for signs of increasing neurological deficit. About 25% of patients will worsen in the first 24 to 48 hours. It is recommended that acute care facilities have designated protocols in place to ensure stroke patients receive timely access to care and have interprofessional stroke teams in place in a geographically dedicated unit to improve outcomes (Canadian Stroke Network & Heart and Stroke Foundation of Canada, 2013).

TABLE 60-6

EMERGENCY MANAGEMENT
Stroke

Etiology	Assessment Findings	Interventions
• Aneurysm • Arteriovenous malformation • Embolism • Hemorrhage • Sudden vascular compromise causing disruption of blood flow to the brain • Thrombosis • Trauma	• Altered level of consciousness • Bladder or bowel incontinence • Difficulty swallowing • Facial drooping on affected side • Hypertension • Increased or decreased heart rate • Nausea and vomiting • Respiratory distress • Seizures • Severe headache • Speech or visual disturbances • Unequal pupils • Vertigo • Weakness, numbness, or paralysis of portion of body	**Initial Care** • Ensure patent airway. • Call a stroke code or the stroke team. • Remove dentures. • Perform pulse oximetry. • Maintain adequate oxygenation (SaO_2 >95%) with supplemental O_2, if necessary. • Establish IV access with normal saline. • Maintain BP according to guidelines (e.g., advanced cardiac life support). • Remove clothing. • Insert Foley catheter. • Obtain CT scan immediately. • Perform baseline laboratory tests (including blood glucose) immediately, and treat if hypoglycemic. • Position head midline. • Elevate head of bed 30 degrees if no symptoms of shock or suspicion of spinal cord injury. • Institute seizure precautions. • Anticipate thrombolytic therapy for ischemic stroke. • Keep patient NPO until swallow reflex evaluated. **Ongoing Monitoring** • Monitor vital signs and neurological status, including level of consciousness (e.g., Glasgow Coma Scale or Canadian Neurological Scale or NIH Stroke Scale), motor and sensory function, pupil size and reactivity, SaO_2, and cardiac rhythm. • Educate and update patient and family/caregiver.

BP, blood pressure; *CT,* computed tomography; *IV,* intravenous; *NIH,* National Institutes of Health; *NPO,* nothing by mouth; O_2, oxygen; SaO_2, arterial oxygen saturation.

Elevated BP is common immediately after a stroke and may be a protective response to maintain cerebral perfusion. Immediately following ischemic stroke, use of drugs to lower BP is recommended only if BP is markedly increased (mean arterial pressure >130 mm Hg or systolic BP >220 mm Hg). Intravenous (IV) antihypertensive drugs such as labetalol are used in the acute phase. Although low BP immediately following stroke is uncommon, hypotension and hypovolemia should be corrected if present.

Fluid and electrolyte balance must be controlled carefully. The goal generally is to keep the patient adequately hydrated to promote perfusion

and decrease further brain injury. Overhydration may compromise perfusion by increasing cerebral edema. Adequate fluid intake during acute care via oral, IV, or tube feedings should be 1 500 to 2 000 mL/day. Urine output should be closely monitored. If secretion of antidiuretic hormone increases in response to the stroke, urine output decreases and fluid is retained. Low serum sodium (hyponatremia) may occur. IV solutions with glucose and water are avoided because they are hypotonic and may further increase cerebral edema and ICP. In addition, hyperglycemia may be associated with further brain damage and should be treated. In general, decisions regarding individualized fluid and electrolyte replacement therapy are based on the extent of intracranial edema, symptoms of increased ICP, central venous pressure levels, laboratory values for electrolytes, and intake and output.

Increased ICP is more likely to occur with hemorrhagic strokes but can occur with ischemic strokes. Increased ICP from cerebral edema usually peaks in 72 hours and may cause brain herniation. Management of increased ICP includes practices that improve venous drainage, such as elevating the head of the bed, maintaining head and neck in alignment, and avoiding hip flexion. Hyperthermia, which is seen commonly following stroke, is associated with poorer outcome, and should be prevented if possible (Campos, Sobrino, Vieites-Prado, et al., 2013). Increased temperature contributes to increased cerebral metabolism. Drug therapies to treat hyperthermia include acetaminophen (Tylenol) or indomethacin. A temperature elevation of even 1°C can increase brain metabolism by 10% and contribute to further brain damage. Cooling blankets or intravenous cooling methods may be used to lower temperature. The nurse must closely monitor the patient's temperature. Aggressive management of temperature during the first 24 hours after a stroke is most effective in preventing detrimental outcomes.

Seizures occur in 5% to 7% of stroke patients in the first 24 hours. Anticonvulsant drugs, such as phenytoin (Dilantin) or levetiracetam (Keppra), are given if a seizure occurs. There is varying research that supports and opposes the prophylactic use of anticonvulsant drugs in patients who have not had a seizure (Sykes, Wood, & Kwan, 2014).

Other measures include pain management, avoidance of hypervolemia, and management of constipation. CSF drainage may be used in some patients to reduce ICP or manage hydrocephalus. Osmotic agents, such as mannitol (Osmitrol) or hypertonic saline (3% saline), may be used to decrease cerebral edema. Current research shows that both agents are successful in lowering ICP (Rickard, Smith, Newell, et al., 2014).

As a last resort in the management of increased ICP, a bone flap may be removed to allow for cerebral edema without increases in ICP. Additional strategies for managing ICP are found in Chapter 59.

Drug Therapy for Ischemic Stroke.

Recombinant tPA is administered intravenously to re-establish blood flow through a blocked artery to prevent cell death in patients with the acute onset of ischemic stroke symptoms. Patients are screened carefully before tPA can be given. Screening includes a noncontrast CT or MRI to rule out hemorrhagic stroke; blood tests for coagulation disorders; and screening for recent history (past 3 months) of gastro-intestinal bleeding, stroke, or head trauma or major surgery within previous 14 days. Intra-arterial infusion of tPA remains an option for a subgroup of patients with large vessel occlusions primarily in the middle cerebral artery. Thrombolytic drugs, such as tPA, produce localized fibrinolysis by binding to the fibrin in the thrombi. The fibrinolytic action of tPA occurs as the plasminogen is converted to plasmin, whose enzymatic action digests fibrin and fibrinogen and thus lyses the clot. Because it is clot specific in its activation of the fibrinolytic system, tPA is the only treatment indicated for acute ischemic stroke. tPA must be administered within 3 to 4.5 hours of the onset of clinical signs of ischemic stroke. The door-to-needle time for tPA remains less than 60 minutes whether the patient arrives at the hospital at 3 hours or 1 hour after the onset of clinical signs. Thrombolytics given in this time frame reduce disability, but at the expense of an increase in deaths within the first 7 to 10 days and an increase in the incidence of intracranial hemorrhage (Heart and Stroke Foundation of Canada, 2015; Grotta, 2014). (Thrombolytic therapy is further discussed in Chapter 36.)

During infusion of the drug, the patient's vital signs and neurological status are monitored closely to assess for improvement or for potential deterioration related to intracerebral hemorrhage. Control of BP is critical during treatment and for 24 hours afterward. No anticoagulant or antiplatelet drugs are given for 24 hours after tPA treatment because of the risk for intracranial hemorrhage.

Surgical Therapy for Ischemic Stroke.

Endovascular treatment (Figure 60-8) during cerebral ischemia allows physicians to go inside the blocked artery of patients who are experiencing ischemic strokes. The retriever goes to the artery that is blocked, directly to the site of the problem, and pulls the clot out. The retriever is a tiny

corkscrew device that uses a microcatheter inserted through a femoral artery balloon catheter. Once the corkscrew device reaches the clot in the brain, the device penetrates the clot, allowing it to be removed. Under radiographic guidance, the balloon catheter is manoeuvred up to the carotid artery in the neck; a guide wire and the microcatheter are deployed through the balloon catheter and then placed just beyond the clot. The physician then deploys the retriever device to engage and ensnare the clot. Once the clot is captured, the balloon catheter is inflated to temporarily arrest forward flow while the clot is being withdrawn. The clot is pulled into the balloon catheter and completely out of the body. The balloon is then deflated, and blood flow is restored. Research has shown that endovascular treatment reduces mortality and increases functional outcomes (Goyal, Demchuk, Menon, et al., 2015).

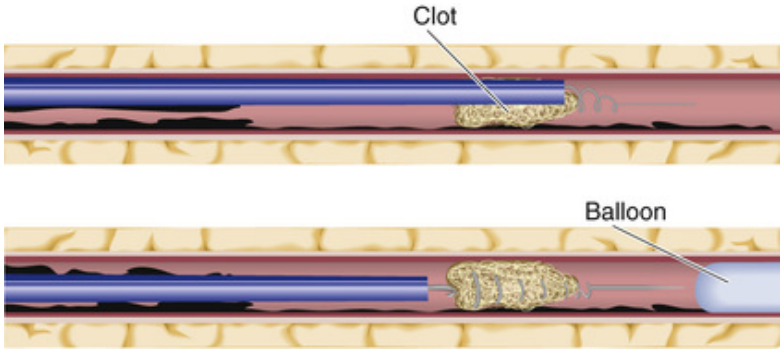

FIGURE 60-8 Endovascular treatment removes blood clots in patients who are experiencing ischemic strokes. The retriever is a long, thin wire that is threaded through a catheter into the femoral artery. The wire is pushed through the end of the catheter up to the carotid artery. The wire reshapes itself into tiny loops that latch onto the clot, and the clot can then be pulled out. To prevent the clot from breaking off, a balloon at the end of the catheter inflates to stop blood flow through the artery.

Collaborative Acute Care for Hemorrhagic Stroke

Drug Therapy.

Anticoagulants and platelet inhibitors are contraindicated in patients with acute hemorrhagic strokes. The main drug therapy for patients with hemorrhagic stroke is the management of hypertension. Oral and IV agents may be used to maintain BP within a normal to high-normal range

(systolic BP <160 mm Hg). Once BP is stabilized, low-dose anticoagulation can be initiated for DVT prophylaxis (Hemphill, Greenberg, Anderson, et al., 2015). Patients who are on blood thinners and experience a hemorrhagic stroke should be given reversal agents (if available) as soon as possible to reduce the risk for further bleeding.

Seizure prophylaxis in the acute period after intracerebral hemorrhages and SAHs may be used. Limited research has been conducted to strongly support or oppose the use of antiepileptic drugs in this patient population (Connolly, Rabinstein, Carhuapoma, et al., 2012).

Surgical Therapy.

Surgical interventions for hemorrhagic stroke include immediate evacuation of aneurysm-induced hematomas or cerebellar hematomas larger than 3 cm. Individuals who have an AVM may experience a hemorrhagic stroke if the AVM ruptures. The treatment of AVM is surgical resection, radiosurgery (e.g., Gamma Knife), or both. Either may be preceded by interventional neuroradiology to embolize the blood vessels that supply the AVM.

SAH is usually caused by a ruptured aneurysm. Approximately 20% of patients will have multiple aneurysms. Treatment of an aneurysm involves coiling or clipping the aneurysm to prevent rebleeding (Figures 60-9 and 60-10). In the endovascular procedure known as *coiling*, a metal coil is inserted into the lumen of the aneurysm via interventional neuroradiology (see Figure 60-9). Guglielmi detachable coils provide immediate protection against hemorrhage by reducing the blood pulsations within the aneurysm. Eventually, a thrombus forms within the aneurysm and the aneurysm becomes sealed off from the parent vessel by the formation of an endothelialized layer of connective tissue. Guglielmi detachable coils provide a less invasive therapy than the traditional surgical clipping of aneurysms (see Figure 60-10).

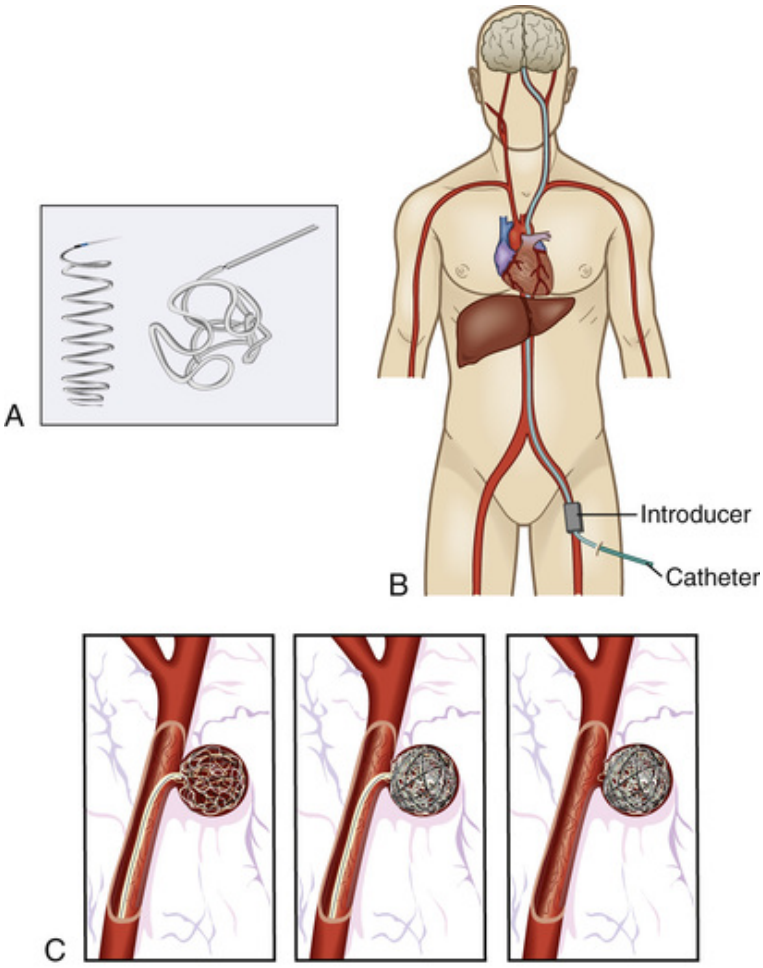

FIGURE 60-9 Guglielmi detachable coil. **A,** A coil is used to occlude an aneurysm. Coils are made of soft, springlike platinum. The softness of the platinum allows the coil to assume the shape of irregularly shaped aneurysms while posing little threat of rupture of the aneurysm. **B,** A catheter is inserted through an introducer (small tube) in an artery in the leg. The catheter is threaded up to the cerebral blood vessels. **C,** Platinum coils attached to a thin wire are inserted into the catheter and then placed in the aneurysm until the aneurysm is filled with coils. Packing the aneurysm with coils prevents the blood from circulating through the aneurysm, reducing the risk for rupture.

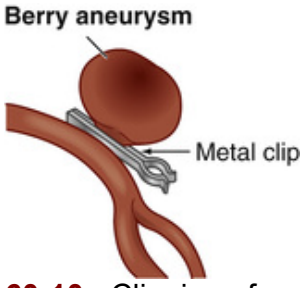

FIGURE 60-10 Clipping of aneurysms.

The calcium channel blocker nimodipine (Nimotop) is given every 2 or 4 hours from the time of aneurysmal rupture (SAH) for 21 days to decrease the effects of vasospasm and minimize cerebral damage. Nimodipine restricts the influx of calcium ions into cells by reducing the number of open calcium channels. Although nimodipine is a calcium channel blocker, its exact mechanism of action in reducing vasospasm is not well understood.

Slight neurological decline or pronator drift is an indicator of vasospasm. Assessment for these complications is important. Once vasospasm is confirmed by a CTA, the goals of therapy are to use IV milrinone to promote cerebral vasodilation and to maintain homeostasis by replacing fluid losses, targeting normal parameters for glucose, electrolytes, and temperature (Lannes, Teitelbaum, del Pilar Cortés, et al., 2012).

Drug Alert

Nimodipine (Nimotop)

- Assessment of BP and apical pulses before administration.
- If pulse ≤60 beats/min or systolic BP <90 mm Hg, medication should be held and the physician contacted.

SAH and intracerebral hemorrhage can involve bleeding into the ventricles of the brain. This situation produces hydrocephalus (enlarged ventricles), which further damages brain tissue from increased ICP. Insertion of an external ventricular drain (EVD) for CSF drainage in patients with hydrocephalus can drain excess CSF that is not draining due

to lack of absorption or obstruction. CSF drainage can reduce ICP, and the patient may have an improved neurological examination.

Rehabilitation Care.

After the acute stroke patient has stabilized for 12 to 72 hours, collaborative care shifts from preserving life to lessening disability and attaining optimal function. The patient may be evaluated by a physiatrist (a physician who specializes in physical medicine and rehabilitation). It is important to remember that some aspects of rehabilitation actually begin in the acute care phase as soon as the patient is stabilized. Depending on the patient's status, other medical conditions, rehabilitation potential, and available resources, the patient may be transferred to a rehabilitation unit. Other options for rehabilitation include outpatient therapy and home care–based rehabilitation (Canadian Stroke Network & Heart and Stroke Foundation of Canada, 2013).

As part of the long-term collaborative care after a stroke, various members of the health care team may be involved in the effort to promote optimal function of the patient and family. The composition of the interdisciplinary team depends on patient and family or caregiver needs and rehabilitation facility resources. The "Evidence-Informed Practice" box discusses how health care providers can assist family caregivers. It highlights family caregivers' changes in support needs as the patient transitions through the health care system.

Evidence-Informed Practice

Research Highlight

How Can Nurses Support Stroke Patients and Their Caregivers?

Clinical Question

What kinds of support do family caregivers of stroke survivors (P) need from health care providers (E) across the continuum from acute care to the community (O)?

Best Available Evidence

Qualitative study within a large Canadian city

Critical Appraisal and Synthesis of Evidence

- 38 interviews conducted (24 caregivers and 14 health care providers).
- Three themes emerged: (a) the type and intensity of support, (b) who provides the support and how it is provided, and (c) the primary focus of care.
- Caregivers and health care providers have similar outlooks regarding caregivers' need for support during the acute phase and in preparing for transition into the community. Caregivers of stroke survivors with communication difficulties or high cognitive or physical disability or both require long-term support.
- The patient was the primary focus of the support; however, caregivers had more needs than were being addressed. Since caregivers often come to facilities after hours and on weekends, they have limited time to receive education and support from rehabilitation therapists in order to prepare them for the patient's transition into the community.

Conclusion

- Be aware of caregivers' needs for education.

Implications for Nursing Practice

- Caregivers should be offered frequent opportunities to ask questions in an unhurried atmosphere. This is most effectively done well in advance of discharge.
- Active patient involvement has greater impact on improving mood than passive receipt of information.

P, population and their problem; *E*, exposure; *O*, outcomes/themes of interest (see Chapter 1).

Nursing Management Stroke

Nursing Assessment

Subjective and objective data that should be obtained from a person who has had a stroke are presented in Table 60-7. Primary assessment focuses on cardiac status and respiratory and neurological assessment. If the patient's condition is stable, the nursing history is obtained as follows: (a) description of the current illness with attention to initial symptoms, including onset and duration, nature (intermittent or continuous), and changes; (b) history of similar symptoms previously experienced; (c) current medications; (d) history of risk factors and other illnesses such as hypertension; and (e) family history of stroke or cardiovascular diseases. This information is gained through an interview of the patient, family members, significant others, or caregiver.

TABLE 60-7

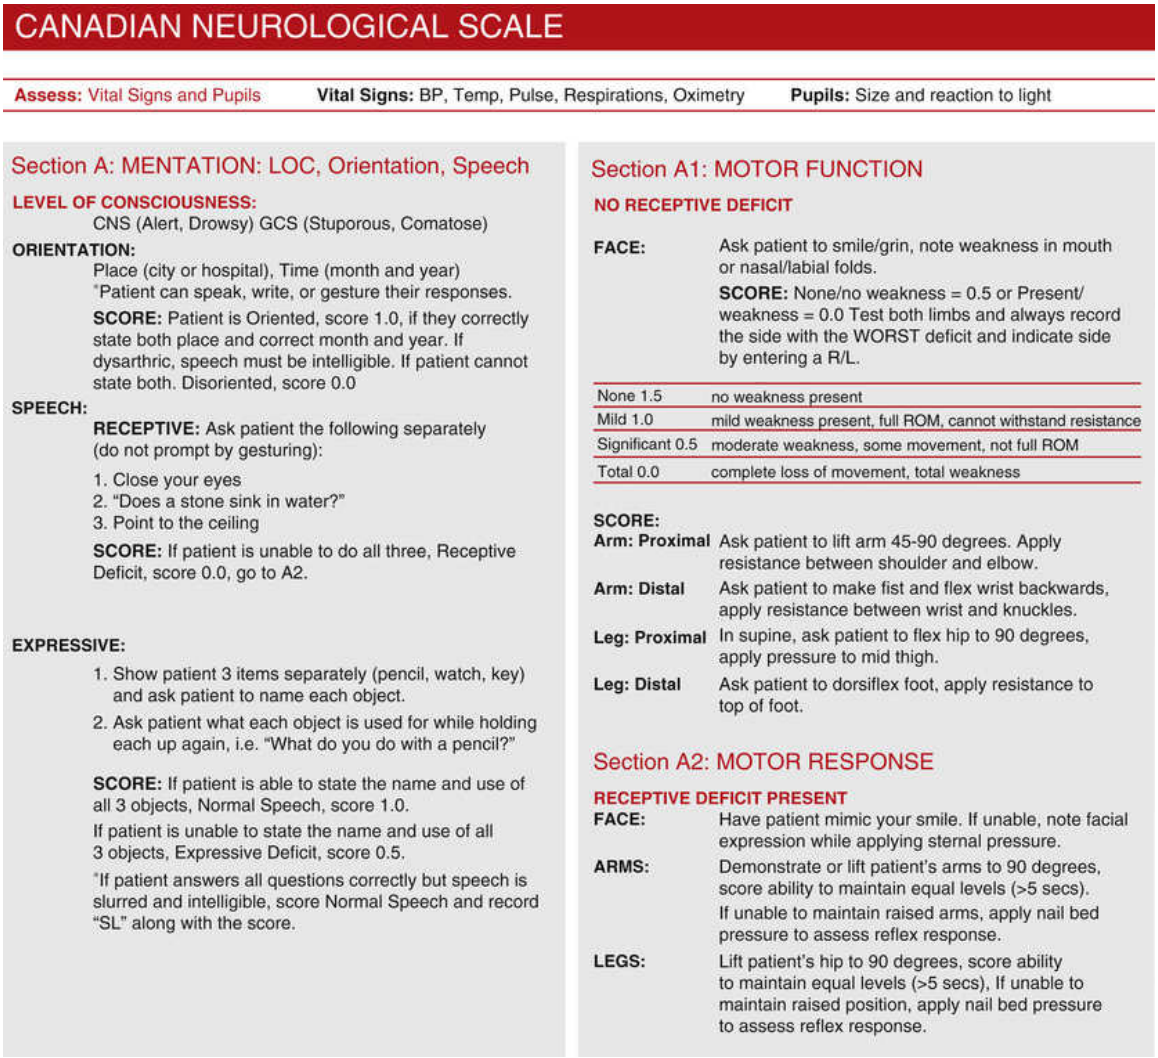
NURSING ASSESSMENT
Stroke

Subjective Data
Important Health Information
Past health history: Hypertension; previous stroke, TIA, aneurysm, trauma, cardiac disease (including recent MI), dysrhythmias, heart failure, valvular disease, infective endocarditis, polycythemia, dyslipidemia, smoking, kidney disease, diabetes, gout, family history of hypertension, diabetes, deep-vein thrombosis, stroke, or coronary artery disease *Medications:* Use of hormone therapy or oral contraceptives; use of and compliance with antihypertensive and diabetes regimen, antiplatelet therapy, and anticoagulant drugs; use of illegal substances (e.g., cocaine)
Symptoms
• Anorexia, nausea, vomiting; dysphagia, altered sensation of taste and smell • Change in bowel and bladder patterns • Loss of movement and sensation; syncope; weakness on one side; mouth droop, half smile; generalized weakness, easy fatigability • Numbness, tingling of one side of the body; loss of memory; alteration in speech, language, problem-solving ability • Pain; headache, possibly sudden and severe (hemorrhage); visual disturbances; denial of illness
Objective Data
General
Emotional lability, lethargy, apathy or combativeness, fever
Respiratory
Loss of cough reflex, laboured or irregular respirations, tachypnea, wheezing (aspiration), airway occlusion (tongue), apnea, coughing when eating or delayed coughing
Cardiovascular
Hypertension, tachycardia, carotid bruit
Gastro-Intestinal
Loss of gag reflex, bowel incontinence, decreased or absent bowel sounds, constipation
Urinary
Frequency, urgency, incontinence
Neurological
Contralateral motor and sensory deficits, including weakness, paresis, paralysis, anaesthesia; unequal pupils, hand grasps; akinesia, aphasia (expressive, receptive, global), dysarthria (slurred speech), agnosias, apraxia, visual deficits, perceptual or spatial disturbances, altered level of consciousness (drowsiness to deep coma) and Babinski reflex, ↓followed by ↑deep tendon reflexes, flaccidity followed by spasticity, amnesia, ataxia, personality change, nuchal rigidity, seizures
Possible Findings
Positive CT, CTA, MRI, MRA, or other neuroimaging scans showing size, location, and type of lesion; positive Doppler ultrasonography and angiography indicating stenosis

CT, computed tomography; *CTA*, computed tomographic angiography; *MI*, myocardial infarction; *MRA*, magnetic resonance angiography; *MRI*, magnetic resonance imaging; *TIA*, transient ischemic attack.

Secondary assessment should include a comprehensive neurological examination of the patient. This includes (a) LOC, using the Canadian Neurological Scale (Figure 60-11) (or a similar tool), (b) cognition, (c) motor abilities, (d) cranial nerve function, (e) sensation, (f) proprioception, (g) cerebellar function, and (h) deep tendon reflexes. Clear documentation of initial and ongoing neurological examinations is essential to note changes in patient status. The Registered Nurses' Association of Ontario

(2005) and the Canadian Stroke Strategy (Heart and Stroke Foundation of Canada, 2017d) have also developed best-practice guidelines and recommendations for stroke care across the continuum.



CANADIAN NEUROLOGICAL SCALE

Assess: Vital Signs and Pupils **Vital Signs:** BP, Temp, Pulse, Respirations, Oximetry **Pupils:** Size and reaction to light

Section A: MENTATION: LOC, Orientation, Speech

LEVEL OF CONSCIOUSNESS:
CNS (Alert, Drowsy) GCS (Stuporous, Comatose)

ORIENTATION:
Place (city or hospital), Time (month and year)
*Patient can speak, write, or gesture their responses.
SCORE: Patient is Oriented, score 1.0, if they correctly state both place and correct month and year. If dysarthric, speech must be intelligible. If patient cannot state both. Disoriented, score 0.0

SPEECH:
RECEPTIVE: Ask patient the following separately (do not prompt by gesturing):
1. Close your eyes
2. "Does a stone sink in water?"
3. Point to the ceiling

SCORE: If patient is unable to do all three, Receptive Deficit, score 0.0, go to A2.

EXPRESSIVE:
1. Show patient 3 items separately (pencil, watch, key) and ask patient to name each object.
2. Ask patient what each object is used for while holding each up again, i.e. "What do you do with a pencil?"

SCORE: If patient is able to state the name and use of all 3 objects, Normal Speech, score 1.0.
If patient is unable to state the name and use of all 3 objects, Expressive Deficit, score 0.5.
*If patient answers all questions correctly but speech is slurred and intelligible, score Normal Speech and record "SL" along with the score.

Section A1: MOTOR FUNCTION

NO RECEPTIVE DEFICIT

FACE: Ask patient to smile/grin, note weakness in mouth or nasal/labial folds.
SCORE: None/no weakness = 0.5 or Present/ weakness = 0.0 Test both limbs and always record the side with the WORST deficit and indicate side by entering a R/L.

None 1.5	no weakness present
Mild 1.0	mild weakness present, full ROM, cannot withstand resistance
Significant 0.5	moderate weakness, some movement, not full ROM
Total 0.0	complete loss of movement, total weakness

SCORE:
Arm: Proximal Ask patient to lift arm 45-90 degrees. Apply resistance between shoulder and elbow.
Arm: Distal Ask patient to make fist and flex wrist backwards, apply resistance between wrist and knuckles.
Leg: Proximal In supine, ask patient to flex hip to 90 degrees, apply pressure to mid thigh.
Leg: Distal Ask patient to dorsiflex foot, apply resistance to top of foot.

Section A2: MOTOR RESPONSE

RECEPTIVE DEFICIT PRESENT
FACE: Have patient mimic your smile. If unable, note facial expression while applying sternal pressure.
ARMS: Demonstrate or lift patient's arms to 90 degrees, score ability to maintain equal levels (>5 secs).
If unable to maintain raised arms, apply nail bed pressure to assess reflex response.
LEGS: Lift patient's hip to 90 degrees, score ability to maintain equal levels (>5 secs), If unable to maintain raised position, apply nail bed pressure to assess reflex response.

Nursing Diagnoses

Nursing diagnoses for a person with a stroke may include but are not limited to the following:

- *Decreased intracranial adaptive capacity* (related to decreased cerebral perfusion pressure of ≤50 to 60 mm Hg, baseline ICP ≥15 mm Hg, elevated systolic BP, bradycardia, widened pulse pressure, and decreasing Canadian Neurological Scale score)
- *Risk for aspiration* related to as evidenced by *barrier to elevating upper body, decrease in level of consciousness, depressed gag reflex*
- *Impaired physical mobility* related to *decrease in muscle control, decrease in muscle strength, physical deconditioning*
- *Unilateral neglect* (related to visual field cut and sensory loss on one side of body and brain injury from cerebro-vascular problems)
- *Impaired urinary elimination* related to *multiple causality* (impaired impulse to void, inability to reach toilet, manage tasks of voiding)
- *Impaired swallowing* related to *behavioural feeding problem* (weakness, paralysis of affected muscles)
- *Situational low self-esteem* related to *alteration in body image, decreased control over environment*

Additional information on nursing diagnoses for the patient with stroke is presented in Nursing Care Plan (NCP) 60-1.

Nursing Care Plan 60-1

Stroke

NURSING DIAGNOSIS	***Decreased intracranial adaptive capacity*** (related to decreased cerebral perfusion pressure of ≤50–60 mm Hg, baseline ICP ≥15 mm Hg, elevated systolic BP, bradycardia, widened pulse pressure, and decreasing Canadian Neurological Scale score)
Expected Patient Outcome	**Nursing Interventions and *Rationales***
• Demonstrates signs of stable or improved cerebral perfusion	*Cerebral Perfusion Promotion* • Consult with physician *to determine hemodynamic parameters, and maintain hemodynamic parameters within this range*. • Monitor neurological status *to detect changes indicative of worsening or improving condition.* • Calculate and monitor CPP *to detect change in condition.* • Monitor respiratory status (e.g., rate, rhythm, and depth of respirations; PaO_2, $PaCO_2$, pH, and bicarbonate levels) *because high $PaCO_2$ and a high hydrogen ion concentration (acidosis) are potent vasodilators that increase cerebral blood flow.* • Monitor patient's ICP and neurological responses to care activities *because changes in positioning and movement can increase ICP.* • Monitor determinants of tissue oxygen delivery (e.g., $PaCO_2$, SaO_2, hemoglobin levels, and cardiac output) *to ensure adequate cerebral oxygenation*. • Administer and titrate vasoactive drugs, as ordered, *to maintain hemodynamic parameters.* • Avoid neck flexion or extreme hip or knee flexion *to avoid obstruction of arterial and venous blood flow.*
NURSING DIAGNOSIS	***Risk for aspiration*** as evidenced by *decreased level of consciousness, depressed gag reflex, impaired ability to swallow*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Demonstrates ability to swallow oral foods without aspiration • Maintains a clear airway	*Aspiration Precautions* • Monitor level of consciousness, cough reflex, gag reflex, and swallowing ability *to determine patient's ability to swallow food without aspiration*. • Avoid liquids or use thickening agent *to facilitate swallowing*. • Feed in small amounts *to reduce risk for aspiration.* • Offer foods or liquids that can be formed into a bolus before swallowing. *Airway Management* • Auscultate breath sounds, noting areas of decreased or absent ventilation and presence of adventitious sounds *to identify airway obstruction and accumulation of secretions*. • Remove secretions by encouraging coughing or by suctioning *to clear airway.* • Encourage slow, deep breathing; turning; and coughing *to increase airway clearance without increasing ICP.* • Assist with incentive spirometer *to open collapsed alveoli, promote deep breathing, and prevent atelectasis.*
NURSING DIAGNOSIS	***Impaired physical mobility*** related to *decrease in muscle control, decrease in muscle strength, physical deconditioning* as evidenced by *neuro-muscular impairment, sensory-perceptual impairment*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Demonstrates increased muscle strength and ability to move • Uses adaptive equipment to increase mobility	*Exercise Therapy: Muscle Control* • Collaborate with physical, occupational, and recreational therapists in developing and executing exercise program *to determine extent of problem and plan appropriate interventions.* • Determine patient's readiness to engage in activity or exercise protocol *to assess expected level of participation.* • Apply splints to achieve stability of proximal joints involved with fine motor skill activities *to prevent contractures.* • Encourage patient to practise exercises independently *to promote patient's sense of control.* • Reinforce instructions provided to patient about the proper way to perform exercises *to minimize injury and maximize effectiveness.* • Provide restful environment for patient after periods of exercise *to facilitate recuperation.*
NURSING DIAGNOSIS	***Impaired verbal communication*** related to *central nervous system impairment* as evidenced by *difficulty speaking*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Uses effective oral and written	*Communication Enhancement: Speech Deficit*

communication techniques • Demonstrates congruency of verbal and nonverbal communication	• Provide alternative methods of speech communication (e.g., writing tablet, flash cards, eye blinking, communication board with pictures and letters, hand signals or other gestures, and computer) *to aid and promote patient communication.* • Provide positive reinforcement *to build self-esteem and confidence.* • Adjust communication style (e.g., stand in front of patient when speaking, listen attentively, present one idea or thought at a time, speak slowly while avoiding shouting, use written communication, or solicit caregiver's or family's assistance in understanding patient's speech) *to meet patient's needs.* • Maintain structured environment and routines (e.g., ensure consistent daily schedules, provide frequent reminders, and provide calendars and other environmental cues) *to promote patient's independence and self-care.* • Collaborate with caregiver, family, or both and speech–language pathologist or therapist *to develop a plan for effective communication.*
NURSING DIAGNOSIS	***Unilateral neglect*** (related to visual field cut and sensory loss on one side of body and brain injury from cerebro-vascular problems as evidenced by consistent inattention to stimuli on affected side)
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Cares for both sides of the body appropriately • Uses strategies to minimize unilateral neglect	*Unilateral Neglect Management* • Monitor for abnormal responses to three types of stimuli—sensory, visual, and auditory—*to determine the presence of and degree to which unilateral neglect exists* (e.g., inability to see objects on affected side, leaving food on a plate that corresponds to affected side, lack of sensation on affected side). • Instruct patient to scan from left to right *to visualize the entire environment.* • Position bed in room so that individuals approach and care for patient on unaffected side. • Rearrange the environment to use the right or left visual field; position personal items, television, or reading materials within view on unaffected side *to compensate for visual field deficits.* • Touch unaffected shoulder when initiating conversation *to attract patient's attention.* • Gradually move personal items and activity to affected side as patient demonstrates an ability to compensate for neglect. • Include caregiver(s), family member(s), or both in rehabilitation process *to support the patient's efforts and assist with care to promote reintegration with the whole body.*
NURSING DIAGNOSIS	***Impaired urinary elimination*** related to *multiple causality* (impaired impulse to void, inability to reach toilet or manage tasks of voiding) as evidenced by *sensory motor impairment*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Perceives impulse to void, removes clothing for toileting, and uses toilet • Demonstrates ability to urinate when the urge arises or with a timed schedule	*Urinary Habit Training* • Keep a continence specification record for 3 days *to establish voiding pattern and plan appropriate interventions.* • Establish interval of initial toileting schedule (based on voiding pattern and usual routine) *to initiate process of improving bladder functioning and increased muscle tone.* • Assist patient to toilet and prompt to void at prescribed intervals *to assist patient in adapting to new toileting schedule.* • Discuss daily record of continence with staff *to provide reinforcement and encourage compliance with toileting schedule.* • Give positive feedback or positive reinforcement to patient when he or she voids at scheduled toileting times, and make no comment when patient is incontinent, *to reinforce desired behaviour.*
NURSING DIAGNOSIS	***Impaired swallowing*** related to *behavioural feeding problem* (weakness, paralysis of affected muscles) as evidenced by *brain injury* (difficulty swallowing, choking).
Expected Patient Outcome	**Nursing Interventions and *Rationales***
• Demonstrates effective swallowing without choking, coughing, or aspiration	*Swallowing Therapy* • Collaborate with other members of health care team (e.g., occupational therapist, speech–language pathologist, dietitian) *to provide continuity in patient's rehabilitative plan.* • Assist patient to sit in an erect position (as close to 90 degrees as possible) for feeding and exercise *to provide optimal position for chewing and swallowing without aspirating.*

	• Assist patient to position head in forward flexion in preparation for swallowing ("chin tuck"). • Assist patient to maintain sitting position for 30 minutes after completing meal *to prevent regurgitation of food.* • Instruct patient or caregiver on emergency measures for choking *to prevent complications in the home setting.* • Check mouth for pocketing of food after eating *to prevent collection and putrefaction of food or aspiration.* • Provide mouth care as needed *to promote comfort and oral health.* • Monitor body weight *to determine adequacy of nutritional intake.*
NURSING DIAGNOSIS	***Situational low self-esteem*** related to *decreased control over environment, alteration in body image* as evidenced by *helplessness, purposelessness, indecisive behaviour, self-negating verbalizations.*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Expresses positive feelings of self-worth • Participates in self-care of affected body parts	*Self-Esteem Enhancement* • Monitor patient's statements of self-worth *to determine effect of stroke on self-esteem.* • Encourage patient to identify strengths *to facilitate patient's recognition of intrinsic value.* • Assist in setting realistic goals *to achieve higher self-esteem.* • Reward or praise patient's progress toward reaching goals. • Encourage increased responsibility for self *to promote sense of satisfaction, independence, and control and to reduce frustrations.* • Monitor levels of self-esteem over time *to determine stressors or situations that trigger low self-esteem and to teach coping mechanisms.*

BP, blood pressure; *CPP*, cerebral perfusion pressure; *ICP*, intracranial pressure; $PaCO_2$, partial pressure of carbon dioxide in arterial blood; PaO_2, partial pressure of oxygen in arterial blood; SaO_2, saturation of oxygen in arterial blood.

Planning

The patient, the family, and the nurse establish the goals of nursing care in a cooperative manner. Typical goals are that the patient will (a) maintain a stable or improved LOC, (b) attain maximum physical functioning, (c) attain maximum self-care abilities and skills, (d) maintain stable body functions (e.g., bladder control), (e) maximize communication abilities, (f) maintain adequate nutrition, (g) avoid complications of stroke, and (h) maintain effective personal and family coping.

Nursing Implementation

Health Promotion.

In any health care setting and for the population as a whole, nurses can play a major role in the promotion of a healthy lifestyle. To reduce the incidence of stroke, the nurse should focus teaching efforts toward stroke prevention, particularly for persons with known risk factors (see Table 60-1). Measures to reduce risk factors for stroke are similar to those for coronary artery disease (see Table 36-2 and surrounding discussion of health promotion in Chapter 36).

One of the nurse's major roles is education about hypertension control and maintaining adherence with antihypertensive medications. Uncontrolled hypertension is the primary cause of stroke.

The nurse needs to be an advocate for the monitoring and management of hypertension, including assessing financial need and prescription coverage. For patients with diabetes, it is very important that the blood glucose level be well controlled. For patients with AF, an anticoagulant such as apixaban (Eliquis), dabigatran (Pradaxa), or rivaroxaban (Xarelto) may be used to treat the problem to prevent the risk for stroke. Because smoking is a major risk factor for stroke, the nurse needs to be actively involved in helping patients to stop smoking (see Chapter 11).

Another very important aspect of health promotion is teaching patients and families about early symptoms associated with stroke or TIA. Table 60-8 presents information on when to seek health care for these symptoms.

Acute Intervention for All Stroke Patients.

Acute intervention for the stroke patient includes care of the respiratory, neurological, cardiovascular, musculo-skeletal, integumentary, gastro-intestinal, and urinary systems, as well as attention to the patient's nutrition.

Respiratory System.

During the acute phase following a stroke, management of the respiratory system is a nursing priority. Stroke patients are particularly vulnerable to respiratory problems as it has been shown that respiratory muscle strength decreases following stroke. Advancing age and immobility increase the risk for atelectasis and pneumonia (Pollock, Rafferty, Moxham, et al., 2013).

Risk for aspiration pneumonia may be high because of impaired consciousness or dysphagia. Dysphagia after stroke is common. Airway obstruction can occur because of problems with chewing and swallowing, food pocketing (food remaining in the buccal cavity of the mouth), and the tongue falling back. Some patients with stroke, especially those with brain stem or hemorrhagic stroke, may require endotracheal intubation and mechanical ventilation initially or with increasing cerebral edema or ICP. Enteral tube feedings also place the patient at risk for aspiration pneumonia. All patients should be screened for their ability to swallow and kept on nothing-by-mouth status until dysphagia has been ruled out (Daniels, Anderson, & Willson, 2012).

Nursing interventions to support adequate respiratory function are individualized to meet the needs of the patient. An oropharyngeal airway may be used in comatose patients to prevent the tongue from falling back and obstructing the airway and to provide access for suctioning. Alternatively, a nasopharyngeal airway may be used to provide airway protection and access. When an artificial airway will be required for a prolonged time, a tracheostomy may be performed. Nursing interventions include frequent assessment of airway patency and function, oxygenation, suctioning, patient mobility, positioning of the patient to prevent aspiration, and encouraging deep breathing. Patients who have an unclipped or uncoiled aneurysm may experience rebleeding and the possibility of further ICP increases with coughing exercises.

Interventions related to maintenance of airway function are described in NCP 60-1.

Neurological System.

The patient's neurological status must be monitored closely to detect slight changes suggesting extension of the stroke, increased ICP, vasospasm, or recovery from stroke symptoms. There are many neurological assessment tools, such as the Glasgow Coma Scale (GCS), National Institutes of Health Stroke Scale, and the Canadian Neurological Scale, that can be used to assist in the monitoring of a patient's neurological status. The GCS measures LOC, mental status, pupillary responses, and extremity

movement and strength. (The GCS is shown in Chapter 59, Table 59-5.) The GCS might not be sensitive enough for use with stroke patients who have cognitive and communication deficits (rather than impaired LOC), which would not be detected using this scale. The Canadian Neurological Scale was designed specifically for evaluating and monitoring the neurological status of patients with acute stroke (see Figure 60-11). It is an assessment tool that measures LOC, orientation, speech, and motor responses of the face, arms, and legs and takes into account if the patient has a receptive deficit.

Additional neurological assessment includes mental status, pupillary responses, checking for pronator drift, and extremity movement and strength. Also, vital signs need to be monitored closely. A decreasing LOC may indicate increasing ICP. ICP and cerebral perfusion pressure may be monitored as well if the patient is in an intensive care environment. Data from the nursing assessment are recorded on flow sheets to compare the trends over time and to communicate the evaluation of neurological status to the interdisciplinary team.

Cardiovascular System.

Nursing goals for the cardiovascular system are aimed at maintaining homeostasis. Many patients with stroke have decreased cardiac reserves from the secondary diagnoses of cardiac diseases. Cardiac efficiency may be further compromised by fluid retention, overhydration, dehydration, BP variations, or a combination of these. Fluids are retained if there is increased production of antidiuretic hormone and aldosterone secondary to stress. Fluid retention plus overhydration can result in fluid overload. It can also increase cerebral edema and ICP. At the same time, dehydration can add to the morbidity and mortality associated with stroke, especially in patients with vasospasm. IV therapy should be carefully regulated. The nurse should closely monitor intake and output. Central venous pressure, pulmonary artery pressure, or hemodynamic monitoring may be used as indicators of fluid balance or cardiac function in the intensive care unit.

Nursing interventions include (a) monitoring vital signs frequently; (b) monitoring cardiac rhythms; (c) calculating intake and output, noting imbalances; (d) regulating IV infusions; (e) adjusting fluid intake to the individual needs of the patient; (f) monitoring lung sounds for indications of pulmonary congestion; and (g) monitoring heart sounds for murmurs or for third (S_3) or fourth (S_4) heart sounds. Bedside monitors or telemetry may record cardiac rhythms. Hypertension is sometimes seen following a stroke as the body attempts to increase cerebral blood flow. It is important

to monitor for orthostatic hypertension before ambulating the patient for the first time. Neurological changes can occur with a sudden decrease in BP.

After a stroke, the patient is at risk for deep-vein thrombosis (DVT), especially in the weak or paralyzed lower extremity. This complication is related to immobility, loss of venous tone, and decreased muscle pumping activity in the leg. The most effective prevention is to keep the patient moving. Active range-of-motion exercises should be taught if the patient has voluntary movement in the affected extremity. For the patient with hemiplegia, passive range-of-motion exercises should be done several times a day. Additional measures to prevent DVT include positioning to minimize the effects of dependent edema and the use of elastic gradient compression stockings or support hose. Sequential compression devices may be ordered for bedridden patients. DVT prophylaxis may include low-molecular-weight heparin (e.g., dalteparin [Fragmin]). The nursing assessment for DVT includes measuring the calf and the thigh daily, observing for swelling or colour changes of the extremities, noting unusual warmth of the leg, and asking the patient about pain in the limbs.

Musculo-Skeletal System.

The nursing goal for the musculo-skeletal system is to maintain optimal function. This is accomplished by preventing joint contractures and muscular atrophy. In the acute phase, range-of-motion exercises and positioning are important nursing interventions. Passive range-of-motion exercise is begun on the first day of hospitalization. If the stroke is caused by SAH, the movement is limited to the extremities. The patient is taught to actively exercise as soon as possible. Muscle atrophy secondary to lack of innervation and activity can develop within 1 month following stroke.

The paralyzed or weak side needs special attention when the patient is positioned. Each joint should be positioned higher than the joint proximal to it to prevent dependent edema. Specific deformities on the weak or paralyzed side that may be present in patients with stroke include internal rotation of the shoulder; flexion contractures of the hand, wrist, and elbow; external rotation of the hip; and plantar flexion of the foot. Subluxation of the shoulder on the affected side is common. Careful positioning and moving of the affected arm may prevent the development of a painful shoulder condition; immobilization of the affected upper extremity may precipitate a painful shoulder–hand syndrome.

Nursing interventions to optimize musculo-skeletal function include (a) placing a trochanter roll at the hip to prevent external rotation; (b) using

hand splints (not rolled washcloths) to prevent hand contractures; (c) providing arm supports with slings and lap boards to prevent shoulder displacement; (d) avoiding pulling the patient by the arm to prevent shoulder displacement; (e) using posterior leg splints, footboards, or high-topped tennis shoes to prevent foot drop; and (f) using hand splints to reduce spasticity. The early use of splints in hemiplegic patients has been associated with improved mobility and strength in the extremities following rehabilitation (Chang & Lai, 2015; Tyson, Sadeghi-Demneh, & Nestor, 2013).

Integumentary System.

The skin of the patient with stroke is particularly susceptible to breakdown related to loss of sensation, decreased circulation, and immobility. This complication is compounded by patient age, poor nutrition, dehydration, edema, and incontinence. The nursing plan for prevention of skin breakdown includes (a) relieving pressure through position changes, special mattresses, or wheelchair cushions; (b) providing good skin hygiene; (c) applying emollients to dry skin; and (d) promoting early mobility. The ideal position change schedule is side–back–side with a maximum duration of 2 hours for any position. Nurses should position the patient on the weak or paralyzed side for only 30 minutes. If an area of redness develops and does not return to normal colour within 15 minutes of pressure relief, the epidermis and dermis are damaged. The damaged area should not be massaged because massage may cause additional damage. Pressure relief is the single most important factor in both the prevention and the treatment of skin breakdown. Pillows can be used under lower extremities to reduce pressure on the heels. Vigilance and good nursing care are required to prevent pressure injuries.

Gastro-Intestinal System.

The most common bowel problem for patients who have experienced a stroke is constipation. Patients may be prophylactically placed on stool softeners or fibre (psyllium [Metamucil]) or both. The patient who has liquid stools should also be checked for stool impaction. Depending on the patient's fluid balance status and swallowing ability, fluid intake should be 1 800 to 2 000 mL/day, and fibre intake up to 25 g/day. Physical activity also promotes bowel function. Laxatives, suppositories, or additional stool softeners may be ordered if the patient does not respond to increased fluid and fibre. Similarly, enemas are used only if suppositories and digital

stimulation are ineffective because they cause vagal stimulation and increase ICP.

Urinary System.

In the acute stage of stroke, the primary urinary problem is poor bladder control, resulting in incontinence. Efforts should be made to promote normal bladder function and avoid the use of in-dwelling catheters. If an in-dwelling catheter must be used initially, it should be removed as soon as the patient is medically and neurologically stable. Long-term use of an in-dwelling catheter is associated with urinary tract infections and delayed bladder retraining. An alternative to intermittent catheterizations is offering the opportunity for frequent toileting to patients with urinary incontinence. Male patients with urinary incontinence also have the alternative of using an external catheter.

A bladder retraining program consists of (a) adequate fluid intake with the majority given between 0800 and 1900 hours; (b) scheduled toileting every 2 hours using bedpan, urinal, commode, or bathroom; and (c) noting signs of restlessness, which may indicate the need for urination.

Nutrition.

The nutritional needs of patients require quick assessment and treatment. Patients may initially receive IV infusions to maintain fluid and electrolyte balance as well as for administration of drugs. Patients with severe impairment may require enteral or parenteral nutrition support. Individual assessment and planning for nutrition are necessary, and patients' needs will depend on the severity of the stroke.

Safety Alert

The first oral feeding should be approached carefully because dysphagia may be present following a stroke. A swallowing screen should be performed prior to administering any food or drink.

Speech–language pathologists (SLPs) (if available) can perform a swallowing evaluation before patients are started on oral intake. The first oral feeding should be approached carefully because dysphagia may be present. The majority of patients will experience dysphagia after a stroke (Daniels, Anderson, & Willson, 2012). Before initiation of feeding, the gag reflex may be assessed by gently stimulating the back of the throat with a

tongue blade. If a gag reflex is present, the patient will gag spontaneously. If it is absent, feeding should be deferred, and exercises to stimulate swallowing should be started. The SLP or occupational therapist is usually responsible for designing this program. However, in some clinical settings, the nurse may be called on to develop the program.

To screen for swallowing ability, the nurse should elevate the head of the bed to an upright position (unless contraindicated) and do a bedside trial of fluid (e.g., Toronto Bedside Swallowing Screening Test [TOR-BSST] or Burke test), giving the patient at least 3 tsp of water before proceeding to 50 mL of water by cup. Because of the dangers of silent aspiration, the nurse should not use any other liquid but water for this screening. If problems are experienced, the patient is not allowed anything orally and is referred to an SLP. If no problems are experienced, the patient should be placed on a modified diet and monitored during meals (Daniels, Anderson, & Willson, 2012).

After careful assessment of swallowing, chewing, gag reflex, and pocketing, oral feedings can be initiated. Mouth care before feeding helps stimulate sensory awareness and salivation and can facilitate swallowing. The patient should remain in a high Fowler's position, preferably in a chair with the head flexed forward for the feeding and for 30 minutes afterward. Various dietary items may be recommended by the SLP. Foods should be easy to swallow and provide enough texture, temperature (warm or cold), and flavour to stimulate a swallow reflex. Crushed ice can be used as a stimulant. The patient should be instructed to swallow and then swallow again. Puréed foods are not usually the best choice because they are often bland and too smooth. Thin liquids are often difficult to swallow and may promote coughing. Thin fluids can be thickened through the use of a commercially available thickening agent (e.g., Thick-It). Milk products should be avoided because they tend to increase the viscosity of mucus and increase salivation.

Food should be placed on the unaffected side of the mouth. The nurse should ensure an unrushed, nonstressful atmosphere. Feedings must be followed by scrupulous oral hygiene because food may collect on the affected side of the mouth.

Communication.

During the acute stage of stroke, the nurse's role in meeting the psychological needs of the patient is primarily supportive. An alert patient is usually anxious because of lack of understanding about what has happened and because communication is difficult. The patient is assessed

for the ability to both speak and understand. The patient's response to simple questions can give the nurse a guideline for structuring explanations and instructions. If the patient cannot understand words, gestures may be used to support verbal cues. It is helpful to speak slowly and calmly, using simple words or sentences to enhance communication. The nurse must give the patient extra time to comprehend and respond to communication. The stroke patient with aphasia may be easily overwhelmed by verbal stimuli. (Guidelines for communicating with a patient who has aphasia are presented in Table 60-9.) Evaluation and treatment of language and communication deficits are often done by the SLP once the patient has stabilized.

TABLE 60-9
COMMUNICATION WITH A PATIENT EXPERIENCING APHASIA

1. Environmental stimuli that may distract and disrupt communication efforts should be avoided.
2. When speaking, the nurse should look in the patient's direction because observance of facial expression may help the patient with aphasia to understand what the nurse is saying.
3. The nurse should speak with normal volume and in a tone of voice suitable for communicating with an adult rather than a child.
4. The nurse should present one thought or idea at a time.
5. Writing out key words or drawing instructions using a thick black marker and large printed letters can help the patient to follow along.
6. Questions should be kept simple and preferably be able to be answered with “yes” or “no.”
7. The nurse should let the patient speak and not interrupt, allowing the patient time to complete thoughts.
8. Mimicking or making use of gestures or demonstration is an acceptable alternative form of communication. The nurse can encourage this by saying, “Show me …” or “Point to what you want.”
9. If the nurse does not understand the patient, the nurse should calmly express the lack of understanding and encourage the use of nonverbal communication or ask the person to write out what he or she wants.
10. The patient should be given time to process information and generate a response before a question or statement is repeated.
11. The nurse should allow body contact (e.g., the clasp of a hand, touching) as much as possible. Touching may be the only way the patient can express feelings.
12. The more familiar a routine, the easier it will be, so the nurse should organize the patient's day by preparing and following a schedule.
13. The nurse should not push communication if the patient is tired or upset. Aphasia worsens with fatigue.

Sensory–Perceptual Alterations.

Homonymous hemianopia (blindness in the same half of each visual field) is a common problem after a stroke (Figure 60-12, *B*). Persistent disregard of objects in part of the visual field should alert the nurse to this possibility. Initially, the nurse helps the patient to compensate by arranging the environment within the patient's perceptual field, such as arranging the food tray so that all foods are on the right side or the left side to accommodate for field of vision (see Figure 60-12, *B*). Later, the patient learns to compensate for the visual defect by consciously attending or

scanning the neglected side (see Figure 60-12, *A*). The weak or paralyzed extremities are carefully checked for adequacy of dressing, for hygiene, and for trauma.

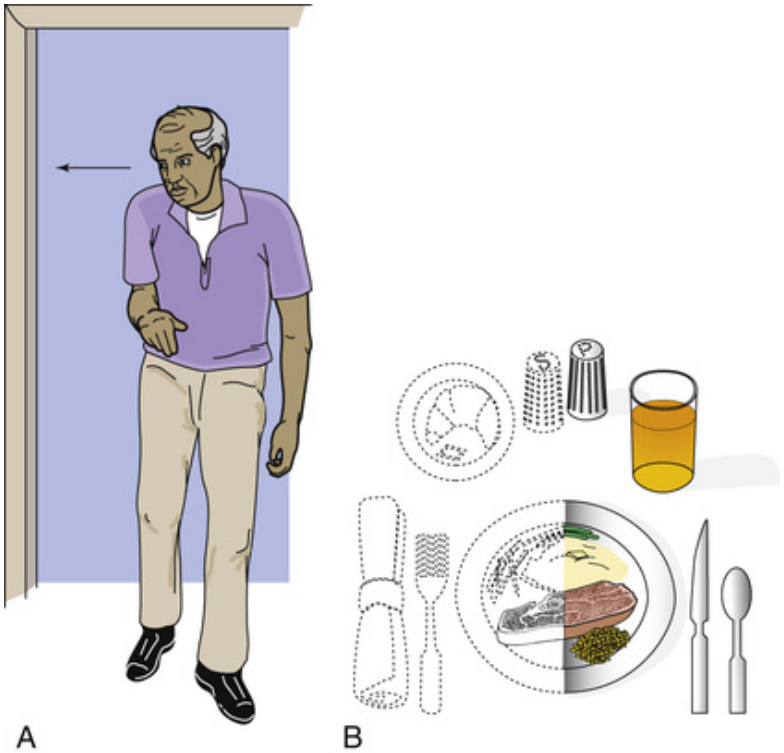

FIGURE 60-12 Spatial and perceptual deficits in stroke. **A,** The patient is instructed to look toward the affected side when walking to avoid bumping into things. **B,** With homonymous hemianopia, the patient is unable to see the left side of the tray and may ignore items on that side. Source: Monahan, F. D., Neighbors, M., Sands, J. K., et al. (2007). *Phipps' medical-surgical nursing: Health and illness perspectives* (8th ed., p. 1437, Figure 49-10). St. Louis: Mosby.

In the clinical situation, it is often difficult to distinguish between a visual field cut and a neglect syndrome. Both problems may occur with strokes affecting either the right or the left side of the brain. A person may be unfortunate enough to have both homonymous hemianopia and a neglect syndrome, a combination that increases the inattention to the weak or paralyzed side. A neglect syndrome results in decreased safety awareness and thereby places the patient at high risk for injury. Immediately after the stroke, the nurse must anticipate potential safety hazards and provide protection from injury. Safety measures can include close observation of the patient, use of a sitter or family member, a lower

bed height, and video monitors. The use of restraints and soft vests is avoided as they may agitate the patient.

Other visual problems may include diplopia, loss of the corneal reflex, and ptosis, especially if the area of stroke is in the vertebrobasilar distribution. Diplopia is often treated with an eye patch. If the corneal reflex is absent, the patient is at risk for corneal abrasion and should be observed closely and protected against eye injuries. Corneal abrasion can be prevented with artificial tears or gel to keep the eyes moist and an eye shield (especially at night). Ptosis is generally not treated because it usually does not inhibit vision.

Coping.

A stroke is usually a sudden, extremely stressful event for the patient, family members, and significant others. A stroke is often a family disease, affecting the family emotionally, socially, and financially as well as changing roles and responsibilities within the family. An older couple may perceive the stroke as a very real threat to life and to accustomed lifestyle. Reactions to this threat vary considerably but may involve fear, apprehension, denial of the severity of stroke, depression, anger, and sorrow. During the acute phase of caring for the stroke patient and the family, nursing interventions designed to facilitate coping involve providing information and emotional support.

Explanations to the patient and family about what has happened and about diagnostic and therapeutic procedures should be clear, detailed, and understandable. However, if the family is extremely anxious and upset during the acute phase, explanations may need to be repeated at a later time. Because family members usually have not had time to prepare for the illness, they may need assistance in arranging care for family members or pets and for transportation and finances. A social services referral is often helpful.

The patient's decision making and health care providers' commitment to uphold the patient's wishes during this challenging time are of utmost importance. Advance directives should be honoured and family meetings or updates should be held regularly in regard to feeding tube placement or tracheotomy.

It is particularly challenging to keep the aphasic patient adequately informed. Tone, demeanour, and touch may help to convey support. When communicating with a patient who has a communication deficit, the nurse should speak with normal volume and tone, keep questions simple, and present one thought or idea at a time. To decrease the patient's

frustration, the nurse should always let the patient speak without interruption and use gestures. It is important, too, to make use of writing and communication boards (Burns, Baylor, Dudgeon, et al., 2015).

Ambulatory and Home Care: Stroke Recovery.

The patient is usually discharged from the acute care setting to home, an intermediate- or long-term care facility, or a rehabilitation facility. Ideally, discharge planning with the patient and family or caregiver starts early in the hospitalization and promotes a smooth transition from one care setting to another. The interdisciplinary team provides the guidance for the appropriate care required after discharge. If the patient requires a short- or long-term health care facility, the team can make appropriate referrals that allow time for the family to select and arrange care. A critical factor in discharge planning is the patient's level of independence in performing ADLs. If the patient is returning home, the team can make referrals for needed equipment and services in preparation for discharge.

Nurses have an excellent opportunity to prepare the patient and family or caregiver for discharge through education, demonstration and return demonstration, practice, and evaluation of self-care skills before discharge. Total care is considered in discharge planning: medications, nutrition, mobility, exercises, hygiene, and toileting. Follow-up care is carefully planned to permit continuing nursing care, physiotherapy, occupational therapy, and speech therapy, as well as medical care. Community resources should be identified to provide recreational activities, group support, spiritual assistance, respite care, adult day care, and home assistance based on the individual patient's needs.

Rehabilitation is the process of maximizing the patient's capabilities and resources to promote optimal functioning related to physical, mental, and social well-being. The goals of rehabilitation are to prevent deformity and maintain and improve function. Regardless of the care setting, ongoing rehabilitation is essential to maximize the patient's abilities. Most patients will see the maximum benefit in the first year of recovery following a stroke (Pollock, Baer, Campbell, et al., 2014).

Rehabilitation requires a team approach so the patient and family can benefit from the combined, expert care of an interdisciplinary team. The team must communicate and coordinate care to achieve the patient's and family's goals. There is strong evidence that organized post-acute inpatient stroke care delivered within the first 4 weeks by an interdisciplinary team of health care providers can result in a reduction in the number of deaths

related to stroke. The stroke rehabilitation team generally consists of a rehabilitation nurse, neuropsychologist, occupational therapist, certified rehabilitation counsellor, physiotherapist, physician, recreational therapist, social worker, and SLP. The nurse is in a good position to facilitate rehabilitation and is often key to successful rehabilitation efforts. Physiotherapy focuses on mobility, progressive ambulation, transfer techniques, and equipment needed for mobility (Pollock, Baer, Campbell, et al., 2014). Occupational therapy emphasizes retraining for ADLs such as eating, dressing, hygiene, and cooking. Occupational therapists are also skilled in cognitive and perceptual evaluation and training. Speech–language pathology focuses on speech, communication, cognition, and swallowing abilities.

Many of the nursing interventions outlined in NCP 60-1 for the patient with a stroke are initiated in the acute phase of care and continue throughout rehabilitation. Some of the interventions are independent nursing actions, whereas others involve the entire rehabilitation team.

The rehabilitation nurse assesses the patient, caregiver, and family with attention to the (a) rehabilitation potential of the patient, (b) physical status of all body systems, (c) presence of complications caused by the stroke or other chronic conditions, (d) cognitive status of the patient, (e) family resources and support, and (f) expectations of the patient and family related to the rehabilitation program.

Musculo-Skeletal Function.

The nurse initially emphasizes the musculo-skeletal functions of eating, toileting, and walking for the rehabilitation of the patient. Initial assessment consists of determining the stage of recovery of muscle function. If the muscles are still flaccid several weeks after the stroke, the prognosis for regaining function is poor, and the focus of care is on preventing additional loss. Most patients begin to show signs of spasticity with exaggerated reflexes within 48 hours following the stroke. Spasticity at this phase of the stroke denotes progress toward recovery. As improvement continues, small voluntary movements of the hip or the shoulder may be accompanied by involuntary movements in the rest of the extremity *(synergy)*. The final stage of recovery occurs when the patient has voluntary control of isolated muscle groups.

Interventions for the musculo-skeletal system advance in a manner of progressive activity. Balance training is the initial step and begins with the patient sitting up in bed or dangling the legs from the edge of the bed. The nurse evaluates tolerance by noting dizziness or syncope caused by

vasomotor instability. Loss of postural stability is common after a stroke. When the nondominant hemisphere is involved, walking apraxia and loss of postural control are usually apparent. Assess whether patients autocorrect their posture when sitting on the edge of the bed. If the patient can straighten her or his posture instead of leaning to the weaker side, the patient may be ready for the next step of transferring from the bed to a chair. The chair is placed beside the bed so that the patient can lead with the stronger arm and leg. The patient sits on the side of the bed, stands, places the strong hand on the far wheelchair arm, and sits down. The nurse may either supervise the transfer or provide minimal assistance by guiding the patient's strong hand to the wheelchair arm, standing in front of the patient and blocking the patient's knees with his or her own knees to prevent knee buckling, and guiding the patient into a sitting position.

A more recent approach to stroke rehabilitation is constraint-induced movement therapy. Constraint-induced movement therapy encourages the patient to use the weakened extremity by restricting movement of the unaffected extremity. This approach has demonstrated improved mobility in patients following stroke; however, research is still being conducted to determine the best protocol. Movement training, skill acquisition, splinting, and exercise are additional therapies offered for the rehabilitation of stroke patients (Peurala, Kantanen, Sjögren, et al., 2011). Supportive or assistive equipment, such as canes, walkers, and leg braces, may be needed on a short- or long-term basis for mobility. The physiotherapist usually selects the most appropriate supportive device(s) to meet individual needs and instructs the patient regarding use. The nurse should incorporate physiotherapy activities into the patient's daily routine for additional practice and repetition of rehabilitation efforts.

Informatics in Practice

Video Games for Stroke Recovery

Patients dealing with the effects of a stroke often have difficulty performing ADLs. Playing active video games, like Nintendo Wii or Xbox Kinect, brings some fun into stroke recovery and may get patients to spend more time in therapy.

Gaming helps patients regain lost strength, improve motor skills, and improve problem solving and short- and long-term memory.

Patients can play with their families, including children, making gaming a way to involve others in rehabilitation.

Nutritional Therapy.

After the acute phase, a dietitian can assist in determining the appropriate daily caloric intake based on the patient's size, weight, and activity level. If the patient is unable to take in an adequate oral diet, a percutaneous endoscopic gastrostomy (see Chapter 42, Figure 42-8) may be used for nutritional support if dysphagia persists. Most commercially prepared formulas provide about 1 cal/mL. (Enteral feedings are described in Chapter 42.)

The nurse and the SLP must assess the ability of the patient to swallow solids and fluids and adjust the diet appropriately. The dietitian plans the diet type, texture, calorie count, and fluids to meet the patient's nutritional needs. The occupational therapist and the nurse must evaluate the patient's ability to feed himself or herself and recommend assistive devices to allow for independent eating.

The inability to feed oneself can be frustrating and may result in malnutrition and dehydration. Interventions to promote self-feeding include using the unaffected upper extremity to eat; employing assistive devices such as rocker knives, plate guards, and nonslip pads for dishes (Figure 60-13); removing unnecessary items from the tray or table, which can reduce spills; and providing a nondistracting environment to decrease sensory overload and distraction. The effectiveness of the dietary program is evaluated in terms of maintenance of weight, adequate hydration, and patient satisfaction.

FIGURE 60-13 Assistive devices for eating. **A,** The curved fork fits over the hand. The rounded plate helps keep food on the plate. Special grips and swivel handles are helpful for some persons. **B,** Knives with rounded blades are rocked back and forth to cut food. The person does not need a fork in one hand and a knife in the other. **C,** Plate guards help keep food on the plate. **D,** Cup with special handle. Source: Courtesy Sammons Preston, Bolingbrook, Illinois.

Bowel Function.

A bowel management program is implemented for problems with bowel control, constipation, or incontinence. A high-fibre diet (see Chapter 45, Table 45-9) and adequate fluid intake (2 500–3 000 mL) are usually recommended. Patients with stroke frequently have constipation, which responds to the following dietary management:

- Fluid intake of 2 500 to 3 000 mL daily unless contraindicated
- Prune juice (120 mL) or stewed prunes daily
- Cooked vegetables or fruit three times daily

- Whole-grain cereal or bread three to five times daily

The bowel management program for incontinence consists of placing the patient on the bedpan or bedside commode or taking the patient to the bathroom at a regular time daily to re-establish bowel regularity. A good time for the bowel program is 30 minutes after breakfast because eating stimulates the gastrocolic reflex and peristalsis. The time can be adjusted for individual bowel habits and preferred timing. Sitting on the commode or toilet promotes bowel elimination through both gravity and increased abdominal pressure. Stool softeners or suppositories may be ordered if the bowel program is ineffective in re-establishing bowel regularity. A glycerin suppository can be inserted 15 to 30 minutes before evacuation time to stimulate the anorectal reflex. A bisacodyl (Dulcolax) suppository is a chemical stimulant to the bowel and is used when other measures are ineffective. Ideally, suppository use is for short-term management.

Bladder Function.

The nurse assists the patient with urinary difficulties or incontinence that may follow a stroke. Often the patient with stroke has functional incontinence, which is associated with communication difficulties, mobility problems, and dressing or undressing difficulties. Nursing interventions focused on urinary continence include (a) assessing for bladder distension by palpation; (b) offering the bedpan, urinal, commode, or toilet every 2 hours during waking hours and every 3 to 4 hours at night; (c) focusing the patient on the need to urinate with direct command; (d) assisting with clothing and mobility; (e) scheduling the majority of fluid intake between 0700 and 1900 hours; and (f) encouraging the usual position for urinating (standing for men and sitting for women).

Short-term interventions for urinary incontinence may include in-dwelling catheters, intermittent catheterization, frequent toileting, or incontinence briefs. These are not long-term solutions for urinary incontinence because complications such as urinary infections or skin irritation may occur.

Nurses often assess postvoid residual volume using bladder ultrasonography. The ultrasonogram measures how much urine is in the bladder after voiding. If urine remains in the bladder, incomplete emptying is a problem and may cause urinary tract infections. A coordinated program by the entire nursing staff is needed to achieve urinary continence.

Sensory–Perceptual Function.

Patients who have had a stroke frequently have perceptual deficits. Patients with a stroke on the right side of the brain usually have difficulty in judging position, distance, and rate of movement. These patients are often impulsive and impatient and tend to deny problems related to strokes. They may fail to correlate spatial–perceptual problems with the inability to perform activities, such as guiding a wheelchair through the doorway. The patient with a right-brain stroke (left hemiplegia) is at higher risk for injury because of mobility difficulties. Directions for activities are best given verbally for comprehension. The task should be broken down into simple steps for ease of understanding. Environmental control, such as removing clutter and obstacles and providing good lighting, aids in concentration and helps provide safer mobility. The patient should wear nonslip socks at all times. One-sided neglect is common for people with right-brain stroke, so the nurse may assist or remind the patient to dress the weak or paralyzed side or shave the forgotten side of the face.

Patients with a left-brain stroke (right hemiplegia) commonly are slower in organization and performance of tasks. They tend to have impaired spatial discrimination. These patients usually admit to deficits and have a fearful, anxious response to a stroke. Their behaviours are slow and cautious. Nonverbal cues and instructions are helpful for comprehension with patients who have had a left-brain stroke.

Affect.

Patients who have had strokes often exhibit emotional responses that are not appropriate or typical for the situation. Patients may appear apathetic, depressed, fearful, anxious, weepy, frustrated, or angry. Some patients, especially those with a stroke on the left side of the brain, exhibit exaggerated mood swings. The patient may be unable to control emotions and may suddenly burst into tears or laughter. This behaviour is out of context and often is unrelated to the underlying emotional state of the patient. Nursing interventions for atypical emotional response are to (a) distract the patient who suddenly becomes emotional, (b) explain to the patient and family that emotional outbursts may occur after a stroke, (c) maintain a calm environment, and (d) avoid shaming or scolding the patient during emotional outbursts.

Coping.

The patient with a stroke may experience many losses, including those that are sensory, intellectual, communicative, functional, role behaviour, emotional, social, and vocational. The patient, caregiver, and family often go through the process of grief and mourning associated with the losses. Some patients experience long-term depression, exhibiting symptoms such as anxiety, weight loss, loss of energy, poor appetite, and sleep disturbances. In addition, the time and energy required to perform previously simple tasks can arouse anger and frustration.

The patient, caregiver, and family need help with coping with the losses associated with stroke. The nurse may assist the coping by (a) supporting communication between the patient and the family; (b) discussing lifestyle changes resulting from stroke deficits; (c) discussing changing roles and responsibilities within the family; (d) being an active listener to allow the expression of fear, frustration, and anxiety; (e) including the family and patient in short- and long-term goal planning and patient care; and (f) supporting family conferences. Maladjusted dependence with inadequate coping occurs when the patient does not maintain optimal functioning for self-care, family responsibilities, decision making, or socialization. This situation can cause resentment from both the patient and the family with a negative cycle of interpersonal dependency and control. *Maladjusted independence* occurs when the patient overestimates personal cognitive or physical capabilities and energy levels. These patients are at risk for injury.

Family members must cope with three aspects of the patient's behaviour: (a) recognition of behavioural changes resulting from neurological deficits that are not changeable, (b) responses to multiple losses by both the patient and the family, and (c) behaviours that may have been reinforced during the early stages of stroke as continued dependency. The patient, caregiver, and family may express feelings of guilt over not living healthy lifestyles or not seeking professional help sooner. Family therapy is a helpful adjunct to rehabilitation. Open communication, information regarding the total effects of stroke, education regarding stroke treatment, and therapy are helpful. Stroke support groups within rehabilitation facilities and in the community are helpful in terms of mutual sharing, education, coping, and understanding.

Sexual Function.

A patient who has had a stroke may be concerned about the loss of sexual function. Many patients are comfortable talking about their anxieties and fears regarding sexual function if the nurse is comfortable and open to the topic. The nurse may initiate the topic with the patient and spouse or

significant other. Common concerns about sexual activity among patients with stroke are impotence and the occurrence of another stroke during sex. Nursing interventions for sexual activity include education on (a) optimal positioning of partners, (b) timing for peak energy times, and (c) patient and partner counselling.

Community Reintegration.

Traditionally, successful community integration following stroke has been difficult for the patient because of persistent problems with cognition, coping, physical deficits, and emotional lability that interfere with functioning. Older patients who have had a stroke often have more severe deficits and frequently experience multiple health problems. Failure to continue the rehabilitation regimen at home may result in deterioration and further complications.

Improved outcomes have been noted in patients suffering from severe stroke who have received inpatient rehabilitation. Results showed these patients had lower mortality rates, stayed in hospital for shorter lengths, and were more likely to return home than those receiving rehab in other facilities. Best results were seen in patients treated in units that were designated as specialized stroke units (Pereira, Graham, Shahabaz, et al., 2012).

Community resources can be an asset to patients and their families. The Heart and Stroke Foundation of Canada is a great resource for anyone who has been affected by or had a family member affected by a stroke. The Canadian Stroke Network provides newsletters on stroke, and Stroke Recovery Canada offers support to stroke survivors. Other local groups can offer more daily assistance, such as provision of meals and transportation. These resources can be identified by nurse case managers, advanced-practice nurses, community health nurses, discharge planners, and social workers. (Resources are listed at the end of the chapter.)

Age-Related Considerations

Stroke

Stroke is a significant cause of death and disability. The highest incidence of stroke occurs among older adults. Stroke can result in a profound disruption in the life of an older person. The magnitude of disability and changes in total function can leave patients wondering if they can ever return to their prestroke life, and loss of independence may be a major concern. Performing ADLs may require many adaptive changes because of physical, emotional, perceptual, and cognitive deficits. Home management may be a particular challenge if the patient has an elderly spouse caretaker who also has health problems. There may be limited family members (including adult children) living nearby to provide help.

Assisting the older patient through the rehabilitative phase and to deal with the residual deficits of stroke, as well as aging, can provide a challenging nursing experience. Patients may become fearful and depressed because of the possibility of another attack or death. The fear can become immobilizing and interfere with effective rehabilitation.

Changes may occur in the patient–spouse relationship. The dependency resulting from a stroke can be threatening to the relationship. Some spouses may also have chronic medical problems that affect their ability to take care of the stroke survivor. The patient may not want anyone other than the spouse to provide care, putting a significant burden on the spouse.

The nurse has the opportunity to assist the patient and family in the transition through acute hospitalization, rehabilitation, long-term care, and home care. The needs of the patient and the family require ongoing nursing assessment, and interventions must be adapted in response to changing needs to optimize quality of life for both the patient and the family.

Case Study

Stroke

Source: Jeanette Dietl/Shutterstock.com.

Patient Profile

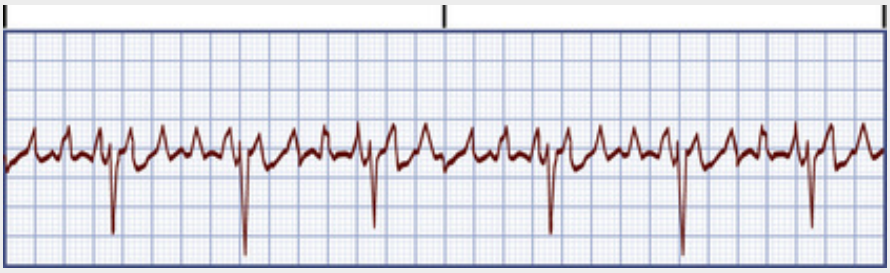
Ms. Evelyn Jones, a 66-year-old woman, awoke in the middle of the night and fell when she tried to get up to go to the bathroom (see the Chapter 58 case study). She fell because she was not able to control her left leg. Her husband took her to the hospital, where she was diagnosed with an acute right-sided ischemic stroke (right middle cerebral artery stroke). Because she had awakened with symptoms, the actual time of onset was unknown, and she was not a candidate for tissue plasminogen activator (tPA).

Subjective Data

- Left arm, leg, and face are weak and feel numb
- Feeling depressed and fearful
- Requires help with activities of daily living
- Is concerned about having another stroke
- Says she has not taken her drugs for high cholesterol for many weeks
- Has history of a brief episode of left-sided weakness and tingling of face, arm, and hand 3 months earlier, which totally resolved and for which she did not seek treatment

Objective Data

- BP: 180/110 mm Hg
- ECG is as follows:



- Left-sided arm weakness (3/5) and leg weakness (4/5)
- Decreased sensation on the left side, particularly the hand
- Left homonymous hemianopsia
- 160 cm tall and weighs 73 kg; body mass index = 28.5
- Alert, oriented, and able to answer questions appropriately but has mild slowness in responding

Past Medical History

- Migraines
- Hyperlipidemia
- Hypertension
- Smoking

Discussion Questions

1. How does Ms. Jones's health history and current findings put her at risk for a stroke?
2. How can the nurse address Ms. Jones's concerns regarding having another stroke?
3. Why would Ms. Jones's ability to drive be affected after the stroke?
4. What strategies might the nurse use to help Ms. Jones and her family cope with her feeling depressed?
5. ***Priority decision:*** What priority lifestyle changes should Ms. Jones make to reduce the likelihood of another stroke?
6. How will homonymous hemianopia affect Ms. Jones's hygiene, eating, driving, and community activities?
7. What factors should the nurse assess for related to outpatient rehabilitation for Ms. Jones?

8. ***Priority decision:*** What are the priority nursing interventions for Ms. Jones?
9. ***Priority decision:*** Based on the assessment data provided, what are the priority nursing diagnoses? Are there any collaborative problems?
10. ***Evidence-informed practice:*** Ms. Jones's family wants to know if her atrial flutter caused her stroke and, if so, what she can do to prevent additional problems with her atrial flutter.

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Which health condition(s) can increase an individual's risk for stroke? *(Select all that apply)*
   a. Pneumonia
   b. Atrial fibrillation
   c. Previous TIA
   d. Hypertension
   e. Migraines
2. Which of the following factors related to cerebral blood flow most often determines the extent of cerebral damage from a stroke?
   a. Amount of cardiac output
   b. Oxygen content of the blood
   c. Degree of collateral circulation
   d. Level of carbon dioxide in the blood
3. Which of the following pieces of information provided by the client would help differentiate a hemorrhagic stroke from an ischemic stroke?
   a. Sensory disturbance
   b. A history of hypertension
   c. Presence of motor weakness
   d. Sudden onset of severe headache
4. A client with right-sided hemiplegia and aphasia resulting from a stroke most likely has involvement of which of the following?
   a. Brain stem
   b. Vertebral artery
   c. Left middle cerebral artery
   d. Right middle cerebral artery
5. A client with a stroke is scheduled for angiography. Which of the following can this test detect?
   a. Presence of increased intracranial pressure
   b. Site and size of the infarction
   c. Patency of the cerebral blood vessels

d. Presence of blood in the cerebro-spinal fluid

6. A client experiencing transient ischemic attacks is scheduled for a carotid endarterectomy. What does the nurse explain to the client about the purpose of this procedure?
   a. To decrease cerebral edema
   b. To reduce the brain damage that occurs during a stroke in evolution
   c. To prevent a stroke by removing atherosclerotic plaques blocking cerebral blood flow
   d. To provide a circulatory bypass around thrombotic plaques obstructing cranial circulation
7. For a client who is suspected to have had a stroke, what is one of the most important pieces of information that the nurse can obtain?
   a. Time of the client's last meal
   b. Time at which stroke symptoms first appeared
   c. Client's hypertension history and management
   d. Family history of stroke and other cardiovascular diseases
8. What does bladder training in a male client who has urinary incontinence after a stroke include?
   a. Limiting fluid intake
   b. Keeping a urinal in place at all times
   c. Assisting the client to stand to void
   d. Catheterizing the client every 4 hours
9. What is the most common response of a client who sustained a stroke regarding the change in body image?
   a. Denial
   b. Depression
   c. Dissociation
   d. Intellectualization

1. b, c, d; 2. c; 3. d; 4. c; 5. c; 6. c; 7. b; 8. c; 9. b.

CHAPTER 61

Nursing Management

Chronic Neurological Problems

Written by, Dottie Roberts, Madona Plueger

Adapted by, Denise Ouellette

LEARNING OBJECTIVES

1. Compare and contrast the etiology, clinical manifestations, collaborative care, and nursing management of tension-type, migraine, and cluster headaches.
2. Differentiate the etiology, clinical manifestations, diagnostic studies, collaborative care, and nursing management of seizure disorders, multiple sclerosis, Parkinson's disease, myasthenia gravis, and normal pressure hydrocephalus.
3. Describe the clinical manifestations and the nursing and collaborative management of restless legs syndrome, amyotrophic lateral sclerosis, and Huntington's disease.
4. Explain the potential impact of chronic neurological disease on physical, emotional, and psychological well-being.
5. Outline the major goals of treatment for the patient with a chronic, progressive neurological disease.

KEY TERMS

absence seizure, p. 1540

amyotrophic lateral sclerosis (ALS), p. 1560
aura, p. 1535
cluster headaches, p. 1536
epilepsy, p. 1539
focal seizures, p. 1541
generalized seizures, p. 1540
headache, p. 1534
Huntington's disease (HD), p. 1560
migraine headache, p. 1534
multiple sclerosis (MS), p. 1546
myasthenia gravis (MG), p. 1557
myasthenic crisis, p. 1558
normal pressure hydrocephalus (NPH), p. 1561
Parkinson's disease (PD), p. 1552

restless legs syndrome (RLS), p. 1559
seizure, p. 1539
status epilepticus, p. 1541
tension-type headache, p. 1535
tonic–clonic seizure, p. 1540

Headache

Headache is probably the most common type of pain that humans experience. The majority of people have functional headaches, such as migraine or tension-type headaches. Others have organic headaches caused by intracranial or extracranial disease.

Not all tissues of the head are sensitive to pain. Pain-sensitive cranial structures include the venous sinuses, the dura, cranial blood vessels, the three divisions of the trigeminal nerve, the facial nerve, the glossopharyngeal nerve, the vagus nerve, and the first three cervical spinal nerves.

Headaches are classified as either primary or secondary. Primary headaches have no organic cause and include tension-type, migraine, and cluster headaches. The type of primary headache is determined using the International Headache Society (IHS) guidelines, based on characteristics of the headache (Table 61-1). Secondary headaches are caused by another condition or disorder, such as sinus infection or stroke. A patient may have more than one type of headache. The history and neurological examination are keys to determining the type of headache.

TABLE 61-1

COMPARISON OF MIGRAINE, TENSION-TYPE, AND CLUSTER HEADACHES

	Migraine Headache	Tension-Type Headache	Cluster Headache
Site (see Figure 61-1)	Unilateral (in 60%), may switch sides, commonly anterior	Bilateral, bandlike pressure at base of skull	Unilateral, radiating up or down from one eye
Quality	Throbbing, synchronous with pulse	Constant, squeezing tightness	Severe, "bone-crushing"
Frequency	Periodic, cycles of several months to years	Cycles for many years	May have months or years between attacks Attacks occur in clusters: once every second day to eight times a day over a period of 4 to 8 weeks
Duration	4–72 hours	30 minutes–7 days	15–180 minutes
Time and mode of onset	May be preceded by prodrome Onset after awakening Gets better with sleep	Not related to time	Nocturnal, commonly awakens patient from sleep
Associated symptoms	Nausea; vomiting; edema; irritability; sweating; photophobia; phonophobia; prodrome of sensory, motor, or psychic phenomena	Palpable neck and shoulder muscle tension, stiff neck, tenderness	Facial flushing or pallor, unilateral lacrimation, ptosis, and rhinitis

Migraine Headache

Migraine headache (MH) is characterized by unilateral throbbing pain, a triggering event or factor, and manifestations associated with neurological and autonomic nervous system dysfunction. The effects of MH pain are dramatic, often causing both physical and emotional disability. In Canada, the lifetime prevalence of MH is 24% of females and 9% of males (Pringsheim, Davenport, Mackie, et al., 2012).

Etiology and Pathophysiology

Although many theories have addressed the cause of MHs, the exact etiology is unknown. The current theory is that a complex series of neuro-vascular events initiates an MH (Cecil, Goldman, & Schafer, 2012). People with migraines have a state of neuronal hyper-excitability in the cerebral cortex, especially in the occipital cortex. Approximately 70% of those with migraine have a first-degree relative who also had MHs. Migraine is associated with seizure disorders, ischemic stroke, asthma, depression, anxiety, myocardial infarction, Raynaud's syndrome, and irritable bowel syndrome (Cecil et al., 2012). In many cases, MHs have no known

precipitating events; however, for some patients, specific factors may trigger a headache. These may include dietary factors, menstruation, head trauma, physical exertion, fatigue, stress, weather, and drugs. Food triggers include chocolate, cheese, oranges, tomatoes, onions, monosodium glutamate, aspartame, and alcohol (particularly red wine).

Clinical Manifestations

MHs are subdivided by the IHS into categories, including those without **aura** and those with aura (Headache Classification Committee of the International Headache Society [HCCIHS], 2013). Auras are the neurological symptoms such as visual field defects, tingling or burning sensations, paresthesias, motor dysfunction (e.g., weakness, paralysis), dizziness, confusion, and even loss of consciousness that usually precede the onset of migraine pain (HCCIHS, 2013). Clinical manifestations that might occur in MH without and with aura are generalized edema, irritability, pallor, nausea and vomiting, and sweating. In MH without and with aura, the **prodrome** is not sharply defined. Prodrome signs or symptoms are those that may precede a MH, including psychic disturbances, gastro-intestinal upset, and changes in fluid balance.

During the headache phase, some patients with MH may seek shelter from noise, light, odours, people, and problems. The headache is described as a steady, throbbing pain that is synchronous with the pulse. However, the presentation of MH is varied in its severity. Although the headache is usually unilateral, it may switch to the opposite side in another episode. Not all MHs are disabling, and many patients do not seek health care treatment for them. In some patients, the symptoms of MHs may become worse over time.

Diagnostic Studies

Usually, the diagnosis of MH is made based on patient history. Neurological and other diagnostic examinations are often normal. There are no specific laboratory or radiological tests used to diagnose MHs. Neuroimaging techniques (e.g. computed tomographic [CT] scan or magnetic resonance imaging [MRI]) of the head are not recommended for routine evaluation of headache unless there are abnormal findings on the neurological examination. If atypical features are present, secondary headaches must be ruled out.

Tension-Type Headache

Tension-type headache (TTH), also called *stress headache*, is the most common type of primary headache. These headaches are characterized by their bilateral location and pressing or tightening quality. TTHs are usually of mild or moderate intensity and can last from minutes to days. TTHs are divided by frequency into episodic and chronic types (HCCIHS, 2013).

Etiology and Pathophysiology

It was originally thought that TTHs were the result of sustained and painful contraction of the muscles of the scalp and the neck. However, research has shown it is likely that neuro-vascular factors similar to those involved in MH play a role in the development of TTH, including central neurological disturbances (Tfelt-Hansen & Koehler, 2011; HCCIHS, 2013).

Clinical Manifestations

Patients usually present with a bilateral frontal–occipital headache described as a constant, dull pressure, or bandlike headache associated with neck pain and increased muscle tension. The headache may involve sensitivity to light or sound but does not involve nausea or vomiting. There is no prodrome, and physical activity does not aggravate symptoms. The headaches may occur intermittently for weeks, months, or even years. Many patients can have a combination of migraine and TTHs, with features of both occurring simultaneously. Patients with MHs may experience TTHs between migraine attacks. Figure 61-1 shows the location of pain for common headache syndromes.

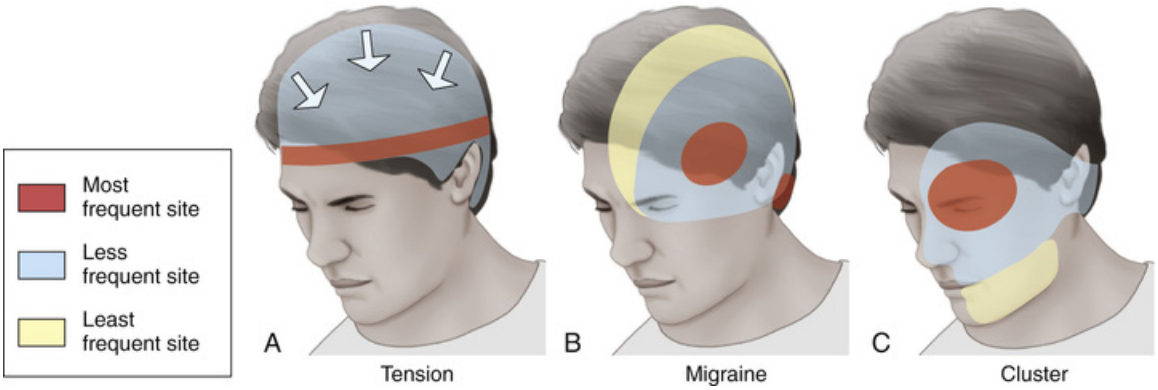

FIGURE 61-1 Location of pain for common headache syndromes. **A,** Tension headache is often described as the feeling of a weight in or on the head or a band squeezing the head (or both). **B,** Migraine headache is described as an intense, throbbing, or pounding pain that involves one temple. The pain is usually unilateral, although it can be bilateral. **C,** Cluster headache pain is focused in and around one eye and is often described as sharp, penetrating, or burning.

Diagnostic Studies

If a patient meets TTH criteria, further diagnostic tests are not always conclusive, but they may be done to rule out secondary headache disorders. If TTH is present during physical examination, increased resistance to passive movement of the head, and tenderness of the head and neck may be present.

Cluster Headache

Cluster headaches (CHs) are a rare form of headache, affecting less than 0.1% of the population (Costa, Antonaci, Ramusino, et al., 2015). CHs involve repeated headaches that can occur for weeks to months at a time, followed by periods of remission.

Etiology and Pathophysiology

Neither the cause nor the pathophysiological mechanism of CH is fully known. The trigeminal nerve is implicated in the production of pain, but CHs also involve dysfunction of intracranial blood vessels, the sympathetic nervous system, and pain modulation systems. Imaging studies show hypothalamic activation at the onset of CH (Goldman & Schafer, 2012). Common triggers include beer, caffeine, histamines, nicotine, and bright lights (Rozen & Fishman, 2012).

Clinical Manifestations

The CH is one of the most severe forms of headache and is characterized by intense, stabbing pain that is ipsilateral in nature and lasts an average of 97 minutes per attack (Gaul, Diener, & Müller, 2011). Other manifestations may include swelling around the eye, lacrimation (tearing), facial flushing or pallor, rhinitis, and constriction of the pupil (Gaul et al., 2011). During the headache, the patient is often agitated and restless, unable to sit still or relax. The headaches occur with regularity, usually occurring at the same time each day, during the same seasons of the year. Clusters typically last 2 weeks to 3 months and then go into remission for months to years (HCCIHS, 2013).

Diagnostic Studies

The diagnosis of CH is based primarily on the patient history. Asking patients to keep a headache diary can be useful. CT scan, MRI, or magnetic resonance angiography (MRA) may rule out an aneurysm, a tumour, or an infection. A lumbar puncture may rule out other disorders that may cause similar symptoms.

Other Types of Headaches

The inability to diagnose a headache as MH, TTH, or CH may indicate that the pain is a symptom of a more serious illness. Headache can accompany subarachnoid hemorrhage; brain tumours; other intracranial masses; arteritis; vascular abnormalities; trigeminal neuralgia (tic douloureux); diseases of the eyes, nose, and teeth; and systemic illness (e.g., bacteremia, carbon monoxide poisoning, mountain sickness, polycythemia vera). The symptoms vary greatly. Because of the variety of causes of headache, clinical evaluation must be thorough. It should include an evaluation of personality, life adjustment, environment, and family situation as well as a comprehensive evaluation of neurological and physical status.

Collaborative Care for Headaches

If no systemic underlying disease is the cause, the type of headache guides therapy. Table 61-2 outlines the general workup for a patient with headache to rule out any intracranial or extracranial disease. Table 61-3 summarizes the current therapies for prophylaxis and symptom relief of

common headaches. These therapies include drugs, meditation, yoga, biofeedback, cognitive behavioural therapy, and relaxation training.

TABLE 61-2

DIAGNOSTIC STUDIES
Headaches

- History and physical examination
  - Neurological examination (often negative)
  - Inspection for local infections
  - Palpation for tenderness, bony swellings
  - Auscultation for bruits over major arteries
- Routine laboratory studies
  - CBC
  - Electrolytes
  - Urinalysis
- CT scan of sinuses
- Special studies (e.g., CT scan of brain, angiography, EEG, EMG, MRA, MRI, lumbar puncture)

CBC, complete blood cell count; *CT,* computed tomographic (scan); *EEG,* electroencephalography; *EMG,* electromyography; *MRA,* magnetic resonance angiography; *MRI,* magnetic resonance imaging.

TABLE 61-3
COLLABORATIVE CARE
Headaches

	Migraine Headache	Tension-Type Headache	Cluster Headache
Diagnostic	• History*	• History*	• History*
Collaborative Therapy			
Symptomatic	• Anti-emetic: metoclopramide Prokinetics: domperidone • Nonopioid analgesics: acetylsalicylic acid (ASA; Aspirin), acetaminophen (Tylenol), ibuprofen (Advil), naproxen (Naprosyn) • Sympatholytic (adrenergic blocking) agent: dihydroergotamine (DHE) via inhalation or intravenous • Triptans: sumatriptan (Imitrex), zolmitriptan (Zomig)	• Analgesic combinations: acetaminophen with caffeine, ibuprofen with caffeine • Nonopioid analgesics: acetylsalicylic acid (ASA; Aspirin), ibuprofen (Advil), acetaminophen (Tylenol), nonsteroidal anti-inflammatory drug: naproxen (Naprosyn)	• Oxygen • Sympatholytic (adrenergic blocking) agent: dihydroergotamine (DHE) via inhalation or intravenous • Triptans: sumatriptan (Imitrex), zolmitriptan (Zomig)
Prophylactic	• β-Adrenergic blockers: propranolol (Inderal), metoprolol (Lopresor), nadolol • Acupuncture • Anticonvulsant: valproic acid (Depakene), divalproex sodium (Epival), gabapentin (Neurontin), topiramate (Topamax) • Antidepressants: amitriptyline (Elavil), nortriptyline (Aventyl), venlafaxine (Effexor) • Biofeedback • Cognitive behavioural therapy • Relaxation therapy	• Acupuncture • Antidepressants: amitriptyline (Elavil), mirtazapine (Remeron), venlafaxine (Effexor) • Biofeedback • Cognitive behavioural therapy • Muscle relaxation training • Physiotherapy • Psychotherapy • Relaxation therapy	• Anticonvulsant: topiramate (Topamax) • Antimanic agent: lithium • Biofeedback • Calcium channel blocker: verapamil (Isoptin) • Corticosteroid: prednisone (Apo-prednisone) • Melatonin • Physiotherapy

*Magnetic resonance imaging (MRI) should be considered in patients with nonacute headache who have an unexplained abnormal neurological examination, an atypical headache or headache features, or an additional risk factor, such as immune deficiency.

Drug Therapy

Migraine Headache.

Drug treatment of the acute MH attack is aimed at terminating or decreasing the symptoms of the attack. Many people with mild or moderate MH can obtain relief with nonsteroidal anti-inflammatory drugs (NSAIDs), acetylsalicylic acid (ASA: Aspirin), or caffeine-containing

combination analgesics. For moderate to severe headaches, the triptans have become the first line of therapy. Triptans are drugs that affect selected serotonin receptors and treat the primary cause of MH. These drugs reduce neurogenic inflammation of the cerebral blood vessels and produce vasoconstriction. Because these drugs cause constriction of coronary arteries, they must be avoided in patients with heart disease. Triptans should be taken at the first symptom of MH.

Drug Alert

Sumatriptan (Imitrex)

- Should not be given to patients with the following:
    - History or manifestations of ischemic cardiac, cerebro-vascular, or peripheral vascular problems
    - Uncontrolled hypertension since it may increase blood pressure
- Excess dosage may produce tremor and decrease respirations.

Tension-type Headache.

Drug treatment for TTH usually involves ASA (Aspirin), acetaminophen (Tylenol), or NSAIDs used alone or in combination with a sedative, caffeine, or antidepressants; however, many of these drugs have serious adverse effects. Caution the patient about the long-term use of ASA (Aspirin) and ASA (Aspirin)-containing drugs because they can cause gastric bleeding and coagulation abnormalities in susceptible patients. Drugs containing acetaminophen (Tylenol) can cause kidney damage with chronic use and liver damage when taking large doses or when combined with alcohol. To decrease the recurrence of TTH, the patient may receive preventive therapy with amitriptyline (Elavil), venlafaxine (Effexor), or mirtazapine (Remeron).

Drug Alert

Topiramate (Topamax)

Instruct patient to do the following:

- Not abruptly discontinue drug since this may cause seizures
- Avoid tasks that require alertness until response to drug is established
- Take adequate fluids to decrease risk for development of renal stones

Cluster Headache.

Because CHs occur suddenly, often at night, and are not long-lasting, they are extremely hard to treat. Acute treatment of CH is inhalation of 100% oxygen delivered at a rate of 8 to 12 L/minute for 15 minutes (Gaul et al., 2011), which may relieve headache by causing vasoconstriction and increasing synthesis of serotonin in the central nervous system. Prophylactic drugs may include calcium channel blockers, steroids, topiramate (Topamax), melatonin, NSAIDs, and inhaled dihydroergotamine (DHE).

Other Headaches.

Patients with frequent headaches may overuse analgesic drugs. Such overuse can lead to chronic daily headache, also called *analgesic rebound headache* or *drug-induced headache*. Drugs known to cause this problem are acetaminophen (Tylenol), ASA (Aspirin), NSAIDs (e.g., ibuprofen [Advil]), triptans, and opioids. Treatment can be difficult and involves gradual withdrawal, possible hospitalization, and initiation of prophylactic drugs such as amitriptyline (Elavil).

Nursing Management Headaches

Nursing Assessment

Data that should be obtained from a patient with headache are presented in Table 61-4. Because the history provides the key to assessment of headache, it should include specific details of the headache itself, such as the location and type of pain, onset, frequency, duration, relation to events (emotional, psychological, physical), and time of day of the occurrence. Information should also be obtained about previous illnesses, surgery, trauma, allergies, family history, and response to medication. The nurse should suggest that the patient keep a diary of headache episodes with specific details. This type of record can be of great help in determining the type of headache and the precipitating events. If the patient has a history of MH, TTH, or CH, it is important to determine if the character, intensity, or location of the headache has changed. This may be an important clue about the cause of the headache (Table 61-5).

TABLE 61-4

NURSING ASSESSMENT
Headaches

Subjective Data
Important Health Information
Current health history: Pain assessment including location, characteristics, onset and duration, frequency, quality, intensity or severity of pain, and precipitating factors (nurse should use a pain scale and observation of actions for cognitively impaired individual); positive family history of headaches; history of recent ingestion of alcohol, caffeine, cheese, chocolate, monosodium glutamate, aspartame, lunch meats (nitrites in cured meats), sausage, hot dog, onion, avocado; level of hydration *Past health history:* Seizures, cancer, recent fall or trauma, cranial infection, stroke; asthma or allergies; mental health disorder; relationship of headache to overwork, stress, menstruation, sexual activity, travel, bright lights, disruptions in sleep, or noxious environmental stimuli *Medications:* Use of hydralazine, bromides, nitroglycerin, ergotamine (withdrawal), nonsteroidal anti-inflammatory drugs, estrogen preparations, oral contraceptives, over-the-counter or prescription remedies *Surgery or other treatments:* Craniotomy, sinus surgery, facial surgery, dental surgery
Symptoms
• Anorexia, nausea, vomiting (migraine prodrome) • Vertigo, fatigue, weakness, paralysis, fainting, malaise • *Migraine:* aura; unilateral, severe, throbbing (possible switching of side) headache; visual disturbances; photophobia; phonophobia; dizziness; tingling or burning sensations • *Tension-type:* bilateral, bandlike, dull and persistent, base-of-skull headache, neck tenderness • *Cluster:* unilateral and severe, nocturnal headaches; nasal stuffiness, unilateral lacrimation
Objective Data
General
Anxiety, apprehension
Integumentary
Cluster: Forehead diaphoresis, pallor, unilateral facial flushing with cheek edema, conjunctivitis *Migraine:* Generalized edema (prodrome), pallor, diaphoresis
Neurological
Horner syndrome (results from damage to sympathetic nerves, and is signified by the following ipsilateral signs: pupillary contraction, ptosis, and a lack of facial sweating), restlessness *(cluster)*, hemiparesis *(migraine)*
Musculo-Skeletal
Neck stiffness (or nuchal rigidity) resulting from impaired neck flexion secondary to muscle spasms of the neck *(meningeal, tension-type)*, palpable neck and shoulder muscles *(tension-type)*
Possible Findings
Possible evidence of disease, deformity, or infection on brain imaging, cerebral angiogram, lumbar puncture, EEG, EMG; nonspecific brain imaging or laboratory tests

CT, computed tomographic (scan); *EEG*, electroencephalography; *EMG*, electromyography; *MRA*, magnetic resonance angiography; *MRI*, magnetic resonance imaging.

TABLE 61-5

COMMON SCREENING ASSESSMENT QUESTIONS TO DETERMINE TYPE OF HEADACHE

- When do the headaches occur?
- How frequent are the headaches?
- What is the duration of the headache(s)?
- Are there any known triggers for the headaches, such as environmental, food, or alcohol?
- Where do you feel the headache pain? Does the pain radiate?
- Do you experience any visual changes such as blurring or double vision?
- Do you experience any other symptoms, such as nausea, vomiting, dizziness, weakness, changes in speech, swallowing difficulty?
- What relieves the headache pain?

Nursing Diagnoses

Nursing diagnoses for the patient with headache may include, but are not limited to, the following:

- *Acute pain* related to *biological injury agent* (headache)
- *Ineffective health management* related to *difficulty managing complex treatment regimen* (drug therapy, lifestyle adjustment)

Additional information on nursing diagnoses for the patient with headache is presented in NCP 61-1, Patient With Headache, available on the Evolve website.

Planning

The overall goals are that the patient with a headache will (1) have reduced or no pain, (2) experience increased comfort and decreased anxiety, (3) demonstrate understanding of triggering events and treatment strategies, (4) use positive coping strategies to deal with chronic pain, and (5) experience increased quality of life and decreased disability.

Nursing Implementation

Patients with chronic headache present a challenge to nurses. Headaches may be related to an inability to cope with daily stresses. The most

effective therapy may be to help patients examine their lifestyle, recognize stressful situations, and learn to cope with them more appropriately. Encouraging the patient to keep a journal may aid in identifying precipitating factors and developing ways of avoiding them. Daily exercise, relaxation periods, and socializing can be encouraged because each can help decrease the recurrence of headache. The nurse can suggest alternative ways of handling the pain of headache.

In addition to using analgesics for the symptomatic relief of headache, patients should be encouraged to use relaxation techniques because they are effective in relieving TTH and MH. People with MHs often need a quiet, dimly lit environment. Massage and moist hot packs to the neck and head can help a patient with TTH. Patients should learn about the drugs prescribed for prophylactic and symptomatic treatment of headache and should be able to describe the purpose, action, dosage, and adverse effects of the drug. To prevent accidental overdose, patients should make a written note of each dose of drug taken.

For patients whose headaches are triggered by food, dietary counselling may be provided. Patients are encouraged to eliminate foods that may provoke headaches. Active challenge and provocative testing with specific foods may be necessary to determine the specific causative agents. However, food triggers may change over time. Patients should avoid smoking and exposure to triggers such as strong perfumes, volatile solvents, and gasoline fumes. CH attacks may occur at high altitudes with low oxygen levels, such as during air travel. Inhaled DHE may decrease the likelihood of these attacks. A teaching guide for patients with headaches is presented in Table 61-6. The “Evidence-Informed Practice” box looks at evidence related to the efficacy of botulinum toxin A (Botox) in headache prevention.

TABLE 61-6

PATIENT & CAREGIVER TEACHING GUIDE
Headaches

The following information should be included when teaching the caregiver about headaches.

1. Keep a diary or calendar of headaches and possible precipitating events.
2. Avoid factors that can trigger a headache:
    - Foods containing amines (cheese, chocolate), nitrites (meats such as hot dogs), vinegar, onions, or monosodium glutamate
    - Fermented or marinated foods
    - Caffeine
    - Nicotine
    - Ice cream
    - Alcohol (particularly red wine)
    - Emotional stress
    - Fatigue
    - Drugs such as those containing ergot and monoamine oxidase inhibitors
3. Describe the purpose, action, dosage, and adverse effects of drugs taken.
4. Be able to self-administer sumatriptan (Imitrex) subcutaneously if prescribed.
5. Use stress-reduction techniques such as relaxation.
6. Participate in regular exercise.
7. Contact the health care provider if any of the following occur:
    - Symptoms become more severe, last longer than usual, or are resistant to medication.
    - Nausea and vomiting (if severe or not typical), change in vision, or fever occurs with the headache.

Evidence-Informed Practice

Research Highlight

Can Botulinum Toxin A Prevent Headaches?

Clinical Question

For adults with chronic headaches (P), does prophylactic botulinum toxin A (I) versus placebo versus medication (C) decrease headache frequency or severity (O)?

Best Available Evidence

Meta-analysis of randomized controlled trials (RCTs) and comparative effectiveness trials

Critical Appraisal and Synthesis of Evidence

- Twenty-seven RCTs (n = 5 313) comparing botulinum toxin A (Botox) with placebo, and four trials comparing botulinum toxin A (Botox)

with medication (amitriptyline [Elavil], topiramate [Topamax], valproic acid (Depakene).
- Headaches assessed were migraine or tension, episodic (<15 headaches per month) or chronic (>15 headaches per month), or a chronic daily headache.
- Botulinum toxin A (Botox) resulted in decreased frequency of chronic daily and chronic migraine headaches. It had no effect on episodic migraine or chronic tension-type headaches.
- Botulinum toxin A (Botox) was not related to fewer migraine headaches when compared with valproic acid (Depakene), topiramate (Topamax), or amitriptyline (Elavil).

Conclusion

Botulinum toxin A (Botox) is beneficial for chronic daily headaches and chronic migraine headaches.

Implications for Nursing Practice

- Inform patients that botulinum toxin A (Botox) can prevent some types of headaches.
- Advise patients of botulinum toxin A (Botox) adverse effects, including blepharoptosis (drooping upper eyelid), paresthesia, neck stiffness and pain, and muscle weakness.

P, Patient population of interest; *I*, intervention or area of interest; *O*, outcomes of interest (see Chapter 1).

Reference for Evidence

Jackson JL, Kuriyama A, Hayashino Y. Botulinum toxin A for prophylactic treatment of migraine and tension headaches in adults: A meta-analysis. *JAMA: The Journal of the American Medical Association*. 2012;307(16):1736–1745.

Evaluation

Expected outcomes for the patient with headache are addressed in the Nursing Care Plan (NCP) 61-1, available on the Evolve website.

Chronic Neurological Disorders

Seizure Disorders and Epilepsy

Seizure is transient, uncontrolled electrical discharge of neurons in the brain that interrupts normal function. Often, seizures are symptoms of an underlying illness. They may accompany a variety of disorders, or they may occur spontaneously without apparent cause. Seizures resulting from systemic and metabolic disturbances are not considered epilepsy if the seizures cease when the underlying problem is corrected. In adults, metabolic disturbances that cause seizures include acidosis, electrolyte imbalances, hypoglycemia, hypoxia, alcohol and barbiturate withdrawal, dehydration, and water intoxication. Extracranial disorders that can cause seizures are heart, lung, liver, or kidney diseases; systemic lupus erythematosus; diabetes mellitus; hypertension; and septicemia.

Epilepsy is a condition in which at least two spontaneous seizures occur more than 24 hours apart and is caused by a chronic underlying pathology (Cavazos, 2012). Epilepsy affects approximately 0.6% of Canadians, with 75% to 85% of people with epilepsy receiving a diagnosis before age 18. Epilepsy is more prevalent in developing countries. The incidence rates are high during the first year of life, decline through childhood and adolescence, plateau in middle age, and rise sharply again among older adults.

Etiology and Pathophysiology

The most common causes of seizures during the first 6 months of life are severe birth injury, central nervous system (CNS) congenital defects, infections, and inborn errors of metabolism. In patients between 2 and 20 years of age, the primary causative factors are birth injury, infection, trauma, and genetic factors. In individuals between 20 and 30 years of age, seizure disorder usually occurs as the result of structural lesions, such as trauma, brain tumours, or vascular disease. After 50 years of age, primary causes of seizure disorders are cerebro-vascular lesions and metastatic brain tumours. Although many causes of seizure disorders have been identified, 50% to 60% of all people with seizure disorders cannot be attributed to a specific cause (Epilepsy Canada, 2016). The role of heredity in seizure disorders has been difficult to determine because of the problem of separating hereditary from environmental or acquired influences.

Furthermore, some families carry a predisposition to seizure disorders in the form of an inherently low threshold to seizure-producing stimuli, such as trauma, disease, and high fever. The etiology of recurring seizures (epilepsy) has long been attributed to a group of abnormal neurons (seizure focus) that seem to undergo spontaneous firing. This firing spreads by physiological pathways to involve adjacent or distant areas of the brain. If this activity spreads to involve the whole brain, a generalized seizure occurs. The factor responsible for this abnormal firing is not clear. Any stimulus that causes the cell membrane of the neuron to depolarize induces a tendency to spontaneous firing. Scar tissue (gliosis) is often found in the area of the brain from which the epileptic activity arises. Scarring is believed to interfere with the normal chemical and structural environment of neurons, making them more likely to fire abnormally. In addition to neuronal alterations, changes in the function of astrocytes may play several key roles in recurring seizures. Activation of astrocytes by hyperactive neurons is one of the crucial factors that predispose neurons nearby to the generation of an epileptic discharge. Previously, epilepsy research focused on neuronal causes. However, there is now evidence that dysfunctional astrocytes may play a key role in recurring seizures; therefore, therapies targeting astrocytic dysfunction could prove promising (Seifert & Steinhäuser, 2013).

Clinical Manifestations

The specific clinical manifestations of a seizure are determined by the site of the electrical disturbance. The preferred method of classifying recurring seizures is the International League Against Epilepsy (ILAE) Classification System (Fisher, Cross, French, et al., 2017) (Table 61-7). Revised in 2017, this system is based on the clinical and electroencephalographic manifestations of seizures. In this system, seizures are divided into three major classes: generalized onset, focal onset, and unknown onset, with each of these classes further subdivided according to motor or non-motor presentation (Fisher et al., 2017). Depending on the type, a seizure may progress through several phases, which include (1) the prodrome phase, with signs or activities that precede a seizure; (2) the aural phase, with a sensory warning; (3) the ictal phase, with full seizure; and (4) the postictal phase, which is the period of recovery after the seizure.

TABLE 61-7
INTERNATIONAL CLASSIFICATION OF SEIZURE TYPES

Focal Onset	Generalized Onset	Unknown Onset
Aware or impaired awareness Motor or non-motor onset	Motor or non-motor onset	Motor or non-motor onset
Motor onset type examples: • Automatisms • Atonic • Clonic • Epileptic spasms • Hyperkinetic • Myoclonic • Tonic	Motor onset type examples: • Atonic • Epileptic spasms • Clonic • Myoclonic • Tonic • Tonic–clonic	Motor onset type examples: • Epileptic spasms • Tonic–clonic
Non-motor onset type examples: • Autonomic • Behaviour arrest • Cognitive • Emotional • Sensory	Non-motor (absence) onset type examples: • Atypical • Eyelid myoclonia • Myoclonic • Typical	Non-motor onset type examples: • Behaviour arrest

Source: Adapted from Fisher, R. S., Cross, J. H., French, J. A., et al. (2017). Operational classification of seizure types by the International League Against Epilepsy: Position Paper of the ILAE Commission for Classification and Terminology. *Epilepsia*, *58*(4), 522–530.

Generalized Seizures.

Generalized seizures are characterized by bilateral synchronous epileptic discharges in the brain from the onset of the seizure. Because the entire brain is affected at the onset of the seizures, there is no warning or aura. In most cases, the patient loses consciousness for a few seconds to several minutes. There are a number of generalized seizure types. Some of the more common ones are discussed below.

Tonic–Clonic Seizures.

The most common generalized seizure is the generalized tonic–clonic seizure. **Tonic–clonic seizure** is characterized by loss of consciousness and falling to the ground if the patient is upright, followed by stiffening of the body (tonic phase) for 10 to 20 seconds and subsequent jerking of the extremities (clonic phase) for another 30 to 40 seconds. Cyanosis, excessive salivation, tongue or cheek biting, and incontinence may accompany the seizure.

In the postictal phase, the patient usually has muscle soreness, is very tired, and may sleep for several hours. Some patients may not feel normal

for several hours or days after a seizure. The patient has no memory of the seizure.

Typical Absence Seizures.

Usually, the **absence seizure** occurs only in children and rarely continues beyond adolescence. This type of seizure may cease altogether as the child matures, or it may evolve into another type of seizure. The typical clinical manifestation is a brief staring spell that lasts only a few seconds, so it often occurs unnoticed. There may be an extremely brief loss of consciousness. When untreated, the seizures may occur up to 100 times a day.

The electroencephalogram (EEG) demonstrates a 3-Hz (cycles/sec) spike-and-wave pattern that is unique to this type of seizure. Absence seizures can often be precipitated by hyperventilation and flashing lights.

Atypical Absence Seizures.

Another type of generalized seizure is atypical absence seizure, which is characterized by a staring spell accompanied by other signs and symptoms, including brief warnings, peculiar behaviour during the seizure, or confusion after the seizure. The EEG demonstrates atypical spike-and-wave patterns.

Other Types of Generalized Seizures.

Other types of generalized seizures are myoclonic, atonic, tonic, and clonic seizures. A myoclonic seizure is characterized by a sudden, excessive jerk of the body or the extremities. The jerk may be forceful enough to hurl the person to the ground. These seizures are very brief and may occur in clusters.

An atonic (“drop attack”) seizure involves either a tonic episode or a paroxysmal loss of muscle tone and begins suddenly with the person falling to the ground. Usually, consciousness returns by the time the person hits the ground, and normal activity can be resumed immediately. Patients with this type of seizure are at a great risk for head injury and often have to wear protective helmets. A tonic seizure involves a sudden onset of sustained increased tone in the extensor muscles. These patients often fall. Clonic seizures begin with loss of consciousness and sudden loss of muscle tone, followed by limb jerking that may or may not be symmetrical.

Focal Seizures.

Focal seizures (previously known as *partial seizures*) are one of the other major classes of seizures in the ILAE classification system. They are caused by electrical activity that is focal to a particular area of the brain, resulting in unilateral manifestations. Focal seizures begin in a specific region of the cortex, as indicated by the EEG and the clinical manifestations. For example, if the discharging focus is located in the medial aspect of the postcentral gyrus, the patient may experience numbness and tingling in the leg on the side opposite the focus. If the discharging focus is located in the part of the brain that governs a particular function, manifestations of those functions—for example, sensory, motor, cognitive, or emotional—may occur.

Focal seizures may be confined to one side of the brain and remain partial, or focal, in nature, or they may spread to involve the entire brain, culminating in a generalized tonic–clonic seizure. Any tonic–clonic seizure that is preceded by an aura is a focal seizure that generalizes secondarily. Many tonic–clonic seizures that appear to be generalized from the outset may actually be secondary generalized seizures, but the preceding partial component may be so brief that it is undetected by the patient, by an observer, or even on the EEG. Unlike the primary generalized tonic–clonic seizure, the secondary generalized seizure may result in a transient residual neurological deficit postictally. This phenomenon is called *Todd paralysis* (focal weakness), which resolves after varying lengths of time.

As per the ILAE's updated classification system, focal seizures are further divided into (1) focal aware seizures (those with simple motor or sensory phenomena) and (2) focal impaired awareness seizures (those with complex symptoms).

Focal Aware Seizures.

Focal aware seizures (formerly known as *simple partial seizures*) with elementary symptoms do not involve loss of consciousness and rarely last longer than one minute. They may involve motor, sensory, or autonomic phenomena, or a combination of these. The terms *focal motor*, *focal sensory*, and *jacksonian* have been used to describe seizures of the focal aware type.

Focal Impaired Awareness Seizures.

Focal impaired awareness (FIA) seizures (formerly called *complex partial seizures*) can involve behavioural, emotional, affective, sensory, and cognitive functions. The location of the discharging focus is usually in the temporal lobe; hence the seizure is often termed a *temporal lobe seizure*. Usually, these seizures last longer than one minute, and they are

frequently followed by a period of postictal confusion. FIA seizures are distinct from focal aware seizures in that they involve alterations in consciousness. The sole manifestation of FIA seizures may be a confused state without any motor or sensory components. This type of attack is sometimes termed *temporal lobe absence*. There is rarely the complete loss of consciousness that is typical of the generalized absence attack, and the patient does not snap back to the preseizure state as occurs in the patient who has had a generalized absence attack.

Most commonly, FIA seizures involve lip smacking and automatisms (repetitive movements that may not be appropriate). These are often called *psychomotor seizures*. The patient may continue an activity that was initiated before the seizure, such as counting out change or picking items from a grocery shelf but after the seizure does not remember the activity performed during the seizure. Other automatisms are less organized, such as picking at clothing, fumbling with objects (real or imaginary), or simply walking away.

A variety of psychosensory symptoms may occur during a FIA seizure, including distortions of visual or auditory sensations and vertigo. There may be alterations in memory, such as a feeling of having experienced an event before (déjà vu) or alterations in thought processes. Alterations in sexual functioning can vary from hyposexuality to hypersexuality. Many patients with temporal lobe seizures have decreased sexual drive or erectile dysfunction. However, some may experience sexual sensations during their seizures. This is because the abnormal electrical activity arises from the brain centres responsible for these sensations. Some experience increased sexual drive just after a seizure. In addition, some anticonvulsant drugs can cause a decrease in sexual drive because of sedation. Others can cause erectile dysfunction.

Complications

Physical.

Status epilepticus is a state of continuous seizure activity in which seizures recur in rapid succession without return to consciousness between seizures. Status epilepticus is a neurological emergency and can involve any type of seizure. During repeated seizures, the brain uses more energy than can be supplied. Permanent brain damage may result. Tonic–clonic status epilepticus is the most dangerous type because it can cause ventilatory insufficiency, hypoxemia, cardiac dysrhythmias, hyperthermia, and systemic acidosis, all of which can be fatal. Airway securement via

medical intervention using sedation and endotracheal intubation may be necessary to avoid life-threatening complications. Patients who lose consciousness during a seizure are at greatest risk. Death can result from head injury incurred during a fall, from drowning, or from severe burns. Perinatal seizures are associated with acute and long-term adverse outcomes to pregnant women and their babies (Hart & Sibai, 2013).

Psychosocial.

Seizure disorders place many limitations on a patient's lifestyle. Epilepsy generally carries a social stigma, and patients diagnosed with seizure disorders may experience depression, anxiety, or anger, and relationships are often affected. The patient with epilepsy may experience discrimination in employment and educational opportunities. Obtaining a driver's license may be difficult because of legal sanctions against driving (Epilepsy Canada, 2016).

Depression is common among people with epilepsy (Zamani, Mehdizadeh, & Sadeghi, 2012). Not only can depression impair daily functioning, but it can also lead to increased seizure frequency through sleep deprivation and its role as an emotional stressor. Treatment for depression among patients with epilepsy should focus first on seizure control, and if depression persists in spite of the latter, antidepressant medication and psychological therapy may be necessary (McLaughlin & McFarland, 2011).

Diagnostic Studies

The most useful diagnostic tools are accurate and comprehensive description of the seizures and the patient's health history (Table 61-8). The EEG is a useful diagnostic adjuvant to the history but only if it shows abnormalities. Abnormal findings help determine the type of seizure and help pinpoint the seizure focus. Unfortunately, only a small percentage of patients with seizure disorders have abnormal findings on the EEG the first time the test is done. EEGs may need to be repeated often, or continuous EEG monitoring may be needed to detect abnormalities. Abnormal discharges may not occur during the 30 to 40 minutes of sampling during EEG, and the test may be negative. It is not a definitive test because some patients who do not have seizure disorders have abnormal patterns on their EEGs, whereas many patients with seizure disorders have normal EEGs between seizures. Magnetoencephalography may be done in conjunction with the EEG. This test has greater sensitivity

in detecting small magnetic fields generated by neuronal activity. Video-EEG can give definitive diagnosis of seizures with impairment of consciousness.

TABLE 61-8
COLLABORATIVE CARE
Diagnosis of Seizure Disorders and Epilepsy

Diagnostic
• History and physical examination
  • Birth and development history
  • Comprehensive neurological assessment
  • Family history
  • Febrile seizures
  • Significant illnesses and injuries
• Seizure history
  • Antecedent events
  • Precipitating factors
  • Seizure description (including onset, duration, frequency, postictal state)
	• Diagnostic studies
	  • CBC, urinalysis, electrolytes, creatinine, fasting blood glucose
	  • CT, MRI, MRA, MRS, PET scan
	  • EEG
	  • Lumbar puncture
	Collaborative Therapy
	• Anticonvulsant drugs (see Table 61-10)
	• Psychosocial counselling
	• Surgery (see Table 61-11)
	• Vagal nerve stimulation

CBC, complete blood cell count; *CT*, computed tomographic (scan); *EEG*, electroencephalography; *MRA*, magnetic resonance angiography; *MRI*, magnetic resonance imaging; *MRS*, magnetic resonance spectroscopy; *PET*, positron emission tomography.

A complete blood cell count, serum chemistries, studies of liver and kidney function, and urinalysis should be done to rule out metabolic disorders. A CT or MRI scan should be done with any new-onset seizure to rule out structural abnormalities (Cavazos, 2012). Cerebral angiography, single-photon emission computed tomography, magnetic resonance spectroscopy, magnetic resonance angiography, and positron emission tomography may be used in selected situations.

Collaborative Care

Most seizures do not require professional emergency medical care because they are self-limiting and rarely cause bodily injury. However, if status epilepticus occurs, if significant bodily harm occurs, or if the event is a first-time seizure, medical care should be sought immediately. Table 61-9 summarizes emergency care of the patient with a generalized tonic–clonic seizure, the seizure most likely to warrant professional emergency medical care. The diagnostic studies and collaborative care of seizure disorders are summarized in Table 61-8.

TABLE 61-9

EMERGENCY MANAGEMENT
Tonic–Clonic Seizures

Etiology	Assessment Findings	Interventions

Etiology	Assessment Findings	Interventions
Head Trauma • Epidural hematoma • Subdural hematoma • Intracranial hematoma • Cerebral contusion • Traumatic birth injury **Drug-Related Processes** • Overdose • Withdrawal of alcohol, opioids, anticonvulsant drugs • Ingestion, inhalation **Infectious Processes** • Meningitis • Septicemia • Encephalitis **Intracranial Events** • Brain tumour • Subarachnoid hemorrhage • Stroke • Neurodegenerative diseases • Hypertensive crisis • Increased ICP secondary to clogged shunt **Metabolic Imbalances** • Fluid and electrolyte imbalance • Hypoglycemia **Medical Disorders** • Heart, liver, lung, or kidney disease • Systemic lupus erythematosus **Other** • Cardiac arrest • Idiopathic • Psychiatric disorders • High fever • Autoimmune disease • Genetic diseases	• Aura—peculiar sensations that precede seizure • Loss of consciousness • Bowel and bladder incontinence • Tachycardia • Diaphoresis • Warm skin • Pallor, flushing, or cyanosis • *Tonic phase:* continuous muscle contractions • *Hypertonic phase:* extreme muscular rigidity lasting 5–15 sec • *Clonic phase:* rigidity and relaxation alternate in rapid succession • *Postictal phase:* lethargy, altered level of consciousness • Confusion and headache • Repeated tonic–clonic seizures for several minutes	**Initial** • Ensure patent airway (sedation may be required if teeth are clenched). • Apply oxygen as needed. • Assist ventilations if patient does not breathe spontaneously after seizure. Anticipate need for intubation if gag reflex absent. • Suction as needed. • Stay with patient until seizure has passed. • Ensure safety at all times and protect patient from injury during seizure. *Do not restrain.* Pad side rails. • Establish IV access. • Anticipate administration of phenobarbital, phenytoin (Dilantin), or benzodiazepines (diazepam [Valium], midazolam, lorazepam [Ativan]) to control seizures. • Reposition to side lying position when possible to avoid aspiration if patient vomits. • Remove or loosen tight clothing. **Ongoing Monitoring** • Monitor vital signs, level of consciousness, oxygen saturation, Glasgow Coma Scale score, pupil size and reactivity. • Reassure and orient the patient after seizure. • Never force an airway between a patient's clenched teeth. • Give IV dextrose for hypoglycemia.

ICP, intracranial pressure; *IV,* intravenous.

Drug Therapy.

Seizure disorders are treated primarily with anticonvulsant drugs (Table 61-10). Therapy is aimed at preventing seizures because a cure is not possible. Drugs generally act by stabilizing nerve cell membranes and preventing spread of the epileptic discharge. Anticonvulsant drugs offer seizure control in approximately 50% of patients; 30% have a reduction in both the intensity and frequency of seizures; and 20% of patients have seizures that are resistant to medication (Epilepsy Ontario, 2016).

TABLE 61-10

DRUG THERAPY
Epilepsy

Drug	Average Adult Daily Dosage	Possible Adverse Effects
carbamazepine (Tegretol)	800–1 200 mg	Dizziness, drowsiness, blurred or double vision, nausea, skin rashes, blood abnormalities
clobazam (Frisium)	30–40 mg	Drowsiness, dizziness, fatigue
clonazepam (Rivotril)	8–10 mg	Drowsiness, clumsiness, behaviour changes, tremor, appetite loss
divalproex sodium (Epival)	1 750–3 000 mg	Upset stomach, altered bleeding time, liver toxicity (rare), hair loss, weight gain, tremor
ethosuximide (Zarontin)	500 mg	Appetite loss, nausea, drowsiness, headache, dizziness, fatigue
gabapentin (Neurontin)	900–2 400 mg	Somnolence, fatigue, dizziness
lamotrigine (Lamictal)	100–500 mg	Headache, fatigue, nausea, dizziness, clumsiness, serious and life-threatening rash (rare), double or blurred vision
levetiracetam (Keppra)	1 000–3 000 mg	Dizziness, somnolence, asthenia (weakness), low hematocrit and leukocyte count (rare), depression and mood swings
oxcarbazepine (Trileptal)	1 200–2 400 mg	Somnolence, diplopia, rash, hyponatremia, ataxia and staggering gait
phenobarbital	30–600 mg	Drowsiness, irritability, hyperactivity, somnolence
phenytoin (Dilantin)	300 mg	Clumsiness, drowsiness, nausea, rash, gum overgrowth, hairiness, thickening of features
primidone	250–1 000 mg	Clumsiness, dizziness, appetite loss, fatigue, drowsiness, hyperirritability
topiramate (Topamax)	200–600 mg	Drowsiness, dizziness, weight loss, tingling, decreased alertness, kidney stones (rare)
vigabatrin (Sabril)	1 000–4 000 mg	Drowsiness, weight gain, headache, dizziness, decreased peripheral vision, depression
valproic acid (Depakene)	1 750–3 000 mg	Upset stomach, altered bleeding time, liver toxicity

Source: Adapted from Epilepsy Canada. (1987 [revised 2009]). *Your medication for epilepsy*. (pp. 12–13). Toronto: Author. Retrieved from http://www.epilepsy.ca/uploads/7/0/8/6/70868839/medication-new.pdf.

The primary goal of anticonvulsant drug therapy is to obtain maximum seizure control with minimal toxic adverse effects. The principle of drug therapy is to begin with a single drug and increase the dosage until

seizures are controlled or toxic adverse effects occur (Epilepsy Foundation, 2013a). Serum levels of the drug should be monitored if seizures continue to occur, if seizure frequency increases, or if drug compliance is questioned. The therapeutic range for each drug indicates the serum level above which most patients experience toxic adverse effects and below which most continue to have seizures. Therapeutic ranges are only guides for therapy. If the patient's seizures are well controlled with a subtherapeutic level, the drug dose need not be increased. Likewise, if a drug level is above the therapeutic range and the patient has good seizure control without toxic adverse effects, the drug dose need not be decreased. Many of the newer drugs do not require drug-level monitoring because the therapeutic range is very large. If seizure control is not achieved with a single drug, the drug dosage or the timing of administration may be changed, or a second drug may be added.

Drug Alert

Carbamazepine (Tegretol)

Patients taking carbamazepine should be instructed as follows:

- Do not take with grapefruit juice.
- Report visual abnormalities.
- Be aware that abrupt withdrawal after long-term use may precipitate seizures.

For many years, the primary drugs for treatment of generalized tonic–clonic and focal seizures were sodium channel blockers. Barbiturates, such as phenobarbital, also have a long history of use. Both sodium channel blockers and benzodiazepines are effective in the treatment of absence, akinetic, and myoclonic seizures.

Treatment of status epilepticus requires immediate initiation of a rapid-acting anticonvulsant drug that can be given intravenously. The drugs most commonly used are lorazepam (Ativan) and diazepam (Valium). Because these are short-acting drugs, they must be followed by administration of long-acting drugs such as phenytoin (Dilantin) or phenobarbital (Epilepsy Ontario, 2011).

Current drugs used in seizure management are shown in Table 61-10. Because many of these drugs (e.g., phenytoin [Dilantin], phenobarbital, ethosuximide [Zarontin], lamotrigine [Lamictal], topiramate [Topamax]) have a long half-life, they can be given in once- or twice-daily doses. This increases the patient's compliance with taking the drug by simplifying the drug regimen and avoiding the need to take it at work or school.

Drug Alert

Phenytoin (Dilantin)

- IV phenytoin (Dilantin) should be administered slowly to prevent acute hypotension.
- Serum albumin levels should be considered along with serum phenytoin levels during therapeutic monitoring.
- Phenytoin (Dilantin) should be discontinued at the first sign of rash and anticonvulsive treatment therefore re-assessed.
- Alcoholic intake (acute and chronic) may affect phenytoin serum levels

Adverse effects of anticonvulsant drugs primarily involve the CNS and include diplopia, drowsiness, ataxia, and mental slowing. Neurological assessment for dose-related toxicity involves testing the eyes for nystagmus, hand and gait coordination, cognitive functioning, and general alertness. Anticonvulsant drugs should not be discontinued abruptly because this can precipitate seizures or status epilepticus and can be life-threatening (Epilepsy Canada, 2009).

Drug Alert

Anticonvulsant Drugs

- Abrupt withdrawal after long-term use may precipitate seizures.
- If weaning is to occur, the patient must be seizure free for a prolonged period (e.g., 2 to 5 years) and have a normal neurological examination

and EEG.

Idiosyncratic adverse effects involve organs outside the CNS, including skin (rashes), gingiva (hyperplasia), bone marrow (blood dyscrasias), liver, and kidneys. Nurses should teach patients about these adverse effects. A common adverse effect of phenytoin is gingival hyperplasia (excessive growth of gingival tissue), especially in children and young adults. This can be limited by good dental hygiene. If gingival hyperplasia is extensive, the hyperplastic tissue may have to be surgically removed (gingivectomy), and phenytoin may have to be replaced by another drug. Because phenytoin can also cause hirsutism in young people, other drugs are often used first.

Medication nonadherence can be a problem in people with epilepsy, owing to the aforementioned adverse effects. Therefore, measures should be taken to increase adherence to the prescribed drug regimens. If made aware of the issue, health care providers can work with the patient to find an acceptable drug regimen to prevent many of these undesirable adverse effects.

Surgical Therapy.

A significant number of patients whose epilepsy cannot be controlled with drug therapy are candidates for surgical intervention to remove the epileptic focus or prevent spread of epileptic activity in the brain (Table 61-11). Surgical interventions include resections or lobectomies, and disconnection procedures such as corpus callosotomies (Epilepsy Foundation, 2013b).

TABLE 61-11

SURGICAL PROCEDURES FOR SEIZURE DISORDERS AND EPILEPSY

Type of Seizure	Surgical Procedure	Results
Focal impaired awareness seizures of temporal lobe origin	Resectioning of epileptogenic tissue	Absence of seizures 5 yr postoperatively in 55%–70% of patients
Focal seizures of frontal lobe origin	Resectioning of epileptogenic tissue (if in resectable area)	Absence of seizures 5 yr postoperatively in 30%–50% of patients
Generalized seizures (Lennox–Gastaut syndrome or drop attacks)	Sectioning of corpus callosum	Persistence of seizures; less violent, less frequent, less disabling events
Intractable, unilateral multifocal epilepsy associated with infantile hemiplegia	Hemispherectomy or callosotomy	Reduction in seizure frequency and type, improvement in behaviour

The benefits of surgery include cessation or reduction in frequency of the seizures, but not all types of epilepsy benefit from surgery. An extensive preoperative evaluation is important, including continuous EEG monitoring and other specific tests to ensure precise localization of the focal point. Before surgery is performed, three requirements must be met: (1) the diagnosis of epilepsy must be confirmed, (2) there must have been an adequate trial with drug therapy without satisfactory results, and (3) the electroclinical syndrome (type of seizure disorder) must be defined.

Alternate Therapies.

Vagal nerve stimulation is used as an adjunct to medications when surgery is not feasible. The exact mechanism of action is unknown, but it is thought to interrupt the synchronization of epileptic brain wave activity and stop excessive discharge of neurons. A surgically implanted electrode in the neck is programmed to deliver the electrical impulse to the vagus nerve. The patient can activate it with a magnet when he or she senses a seizure is imminent. Vagal nerve stimulation can cause adverse effects such as coughing, hoarseness, dyspnea, and tingling in the neck. Battery replacement is required via surgery about every 5 years.

The ketogenic diet is a special high-fat, low-carbohydrate diet that has been used to control seizures in some people with epilepsy. When a person is on this diet, ketones are produced and pass into the brain and replace glucose as an energy source. The diet may be effective for some patients with drug-resistant epilepsy, but the long-term effects of the diet are not clear. Current literature suggests that this diet is not without adverse effects and that there may be risks with long-term adherence to it (Southern, Fitzsimmons, & Cross, 2015). Patients on this diet who use anticoagulants need close monitoring for bleeding (Payne, Cross, Sander, et al., 2011).

Biofeedback to control seizures is aimed at teaching the patient to maintain a certain brain wave frequency that is refractory to seizure activity. Further trials are needed to assess the effectiveness of biofeedback for seizure control.

Nursing Management Seizure Disorders and Epilepsy

Nursing Assessment

Data that should be obtained from a patient with a seizure disorder are presented in Table 61-12. Data related to a specific seizure episode can be obtained from a witness.

TABLE 61-12

NURSING ASSESSMENT
Seizure Disorders and Epilepsy

Subjective Data
Important Health Information
Past health history: Previous seizures, birth defects, or injuries; anoxic episodes; CNS trauma, tumours, or infections; stroke; metabolic disorders; alcoholism; exposure to metals and carbon monoxide; hepatic or renal failure; fever; pregnancy; systemic lupus erythematosus; positive family history of seizure disorders or epilepsy *Medications:* Compliance with anticonvulsant drugs; barbiturate or alcohol withdrawal; use of cocaine, amphetamines, lidocaine, theophylline (Theo-Dur, Uniphyl), penicillins, lithium, phenothiazines, tricyclic antidepressants, benzodiazepines
Symptoms
• Headaches, aura, mood or behavioural changes before seizure; mentation changes; abdominal pain, muscle pain (postictal) • Anxiety, depression; loss of self-esteem, social isolation • Decreased sexual drive, erectile dysfunction; increased sexual drive (postictal)
Objective Data
General
Precipitating factors, including severe metabolic acidosis or alkalosis, hyperkalemia, hypoglycemia, dehydration, or water intoxication
Integumentary
Bitten tongue, soft tissue damage, cyanosis, diaphoresis (postictal)
Respiratory
Abnormal respiratory rate, rhythm, or depth; apnea (ictal); absent or abnormal breath sounds, possible airway occlusion
Cardiovascular
Hypertension, tachycardia, or bradycardia (ictal)
Gastro-Intestinal
Bowel incontinence; excessive salivation
Urinary
Incontinence
Neurological
Generalized
Tonic–clonic: Loss of consciousness, muscle tightening, then jerking; dilated pupils; hyperventilation, then apnea; postictal somnolence *Absence:* Altered consciousness (5–30 sec), minor facial motor activity
Focal
Simple: Aura; consciousness; focal sensory, motor, cognitive, or emotional phenomena (focal motor); unilateral "marching" motor seizure (jacksonian) *Complex:* Altered consciousness with inappropriate behaviours, automatisms, amnesia of event
Musculo-Skeletal
Weakness, paralysis, ataxia (postictal)
Possible Findings
Positive toxicology screen or alcohol level; altered serum electrolytes, acidosis or alkalosis, very low blood glucose level, ↑ blood urea nitrogen or creatinine, liver function tests, ammonia; abnormal CT scan or MRI of head, abnormal findings from lumbar puncture; abnormal discharges on EEG

CNS, central nervous system; *CT*, computed tomographic (scan); *EEG*, electroencephalography; *MRI*, magnetic resonance imaging.

Nursing Diagnoses

Nursing diagnoses for the patient with seizure disorders and epilepsy may include, but are not limited to, the following:

- *Ineffective breathing pattern* related to *body position that inhibits lung expansion* (neuro-muscular impairment)
- *Ineffective health management* related to *difficulty managing complex treatment regimen* (drug therapy and lifestyle adjustment)
- *Risk for injury* as evidenced by *alteration in cognitive functioning, alteration in psychomotor functioning* (seizure)

Additional information on nursing diagnoses for the patient with a seizure disorder is presented in Nursing Care Plan (NCP) 61-2, available on the Evolve website.

Planning

The overall goals are that the patient with seizures will (1) be free from injury during a seizure, (2) have optimal mental and physical functioning while taking anticonvulsant drugs, and (3) have satisfactory psychosocial functioning.

Nursing Implementation

Health Promotion.

Complications such as head injury related to seizure disorders can be prevented through general safety measures such as the wearing of helmets. Optimal perinatal care facilitates reduced fetal trauma and hypoxia, and therefore, reduced brain damage leading to seizure disorders.

The patient with a seizure disorder should practise good general health habits (e.g., maintaining a proper diet, getting adequate rest, exercising). The nurse should help the patient identify events or situations that precipitate the seizures and provide suggestions for avoiding them or handling them better. The patient should be taught to avoid excessive

alcohol intake, fatigue, and loss of sleep and be helped to handle stress constructively.

Acute Intervention.

The nurse caring for a patient who is hospitalized with seizures involves several responsibilities, including observation and treatment of the seizure, education, and psychosocial intervention.

When a seizure occurs, the nurse should carefully observe and record details of the event because the diagnosis and subsequent treatment often rest solely on the seizure description. All aspects of the seizure should be noted. What events preceded the seizure? When did the seizure occur? How long did each phase last? What occurred during each phase?

Both subjective and objective data are important. Objective data should include the exact time of seizure onset; the course and nature of the seizure activity (loss of consciousness, tongue biting, automatisms, stiffening, jerking, total lack of muscle tone); the body parts involved and their sequence of involvement; and the presence of autonomic signs, such as dilated pupils, excessive salivation, altered breathing, cyanosis, flushing, diaphoresis, or incontinence. Assessment of the postictal period should include a detailed description of level of consciousness, vital signs, memory loss, muscle soreness, speech disorders (aphasia, dysarthria), weakness or paralysis, sleep period, and the duration of each sign or symptom.

Safety Alert

During a seizure, the nurse should do the following:

- Maintain a patent airway for the patient. This may be facilitated by turning the patient to the side and ensuring the tongue falls forward so as not to block the patient's airway.
- Protect the patient's head, turn the patient to the side, loosen constrictive clothing, ease patient to the floor (if seated).
- Do not restrain the patient.
- Do not place any objects in the patient's mouth.

After the seizure, the patient may require suctioning, and oxygen may be needed; therefore, the nurse should ensure that oxygen and suction

equipment are available and in working order for patients with a history of seizures. A seizure can be a frightening experience for the patient and for others who may witness it. The nurse should assess their level of understanding and provide information about how and why the event occurred. This is an excellent opportunity for the nurse to dispel many common misconceptions about seizures.

Ambulatory and Home Care.

Prevention of recurring seizures is the major goal in the treatment of epilepsy. Because many seizure disorders cannot be cured, drugs must be taken regularly, often for life. The nurse should ensure that the patient knows this, as well as the specifics of the drug regimen and what to do if a dose is missed. Usually, the dose should be made up if the omission is remembered within 24 hours. The patient should be cautioned not to adjust drug doses without professional guidance because this can increase seizure frequency and even cause status epilepticus. The patient should be encouraged to report any adverse effects and to keep regular appointments with a health care provider.

Nurses play an important role in teaching the patient and caregivers. Guidelines for teaching are shown in Table 61-13. Nurses should teach family members and significant others the emergency management of tonic–clonic seizures (see Table 61-9). They should be reminded that it is not necessary to call an ambulance or send a person to the hospital after a single seizure unless it is the first seizure, it is prolonged, it is immediately followed by another seizure, or extensive injury has occurred.

TABLE 61-13

PATIENT & CAREGIVER TEACHING GUIDE
Seizure Disorders and Epilepsy

The following information should be included when teaching the patient and caregiver about seizure disorders and epilepsy.

1. Drugs must be taken as prescribed. Adverse effects of drugs should be reported to the health care provider. When necessary, blood work may be drawn to ensure that therapeutic drug levels are maintained.
2. Use of nonpharmacological techniques, such as diet and biofeedback training, to potentially reduce the number of seizures.
3. Availability of community resources.
4. Need to wear a medical alert bracelet or necklace and carry an identification card.
5. Avoidance of excessive alcohol intake, fatigue, and loss of sleep.
6. Regular meals and snacks in between if feeling shaky, faint, or hungry.

Caregivers should be taught the following:

1. For first aid treatment of tonic–clonic seizure, it is not necessary to call an ambulance or send the patient to the hospital after a single seizure unless the seizure is prolonged, another seizure immediately follows, or extensive injury has occurred.
2. During an acute seizure, it is important to protect the patient from injury. This may involve supporting and protecting the head, turning the patient to the side, loosening constrictive clothing, and easing the patient to a lying position on the floor, if seated.

Patients with a seizure disorder also experience concerns or fears related to recurrent seizures, incontinence, and loss of self-control. The nurse provides support for the patient through education and by helping to identify coping mechanisms.

Perhaps the greatest challenge that a seizure disorder presents to the patient is adjusting to the personal limitations imposed by the illness. Discrimination in employment is the most serious problem facing the person with a seizure disorder. For issues relating to job discrimination, patients can be referred to the Canadian Human Rights Commission through its national or regional offices.

A variety of other resources can be offered to the patient with a seizure disorder. Patients should be informed that medical alert bracelets, necklaces, and identification cards are available through a number of North American companies specializing in identification devices (e.g., MedicAlert; see Figure 52-11). If the nurse believes that associating with others who have a seizure disorder would be beneficial, the patient can be referred to Epilepsy Canada, a voluntary agency with local members' associations across the country that offer a variety of services to patients with epilepsy. Patients who are eligible veterans can be referred to Veterans Affairs Canada to explore services for which they may qualify.

Social workers and welfare agencies can help with financial problems and living arrangements. Provincial and territorial services for individuals with developmental disabilities include assistance with vocational assessment and training, sheltered housing, funding for special needs, and

placement for patients whose seizures are not well controlled. They can also offer financial assistance for transportation and medical costs that are necessary for vocational rehabilitation or job maintenance. If intensive psychological counselling is needed, the nurse can refer the patient to a community mental health centre.

Patients should be encouraged to learn more about epilepsy through self-education materials. Epilepsy Canada provides information pamphlets and may facilitate support groups. Many agencies that offer services to people with epilepsy, as well as many locally based epilepsy associations, have these services available.

Evaluation

Expected outcomes for patients with seizures are addressed in NCP 61-2.

Multiple Sclerosis

Multiple sclerosis (MS) is a chronic, progressive, degenerative, autoimmune disorder of the CNS characterized by disseminated demyelination of nerve fibres of the brain, the spinal cord, and the optic nerves. Canadians have one of the highest rates of MS in the world, and an estimated 55 000 to 75 000 Canadians have MS (Government of Canada, 2016). Across the country, prevalence rates range from 1 case per 500 to 1 000 people. More than three Canadians a day are diagnosed with MS (Multiple Sclerosis Society of Canada, 2014). On a global scale (Figure 61-2), MS has relatively high prevalence rates (>33 cases per 100 000 people) in areas with temperate climates (like those found in large areas of Europe [including Russia], Canada, northern United States, southeastern Australia, and New Zealand), and relatively low prevalence rates (<5 cases per 100 000 people) in warmer climates (like those found in large areas of Asia, Africa, and northern South America) (Multiple Sclerosis International Federation, 2013). MS is considered a disease of young to middle-aged adults, with an average age of onset of 30 years (Multiple Sclerosis International Federation, 2013). Women are affected more often than men, with a ratio of 3 : 1 (Multiple Sclerosis Society of Canada, 2016a). Chao, Ramagopalan, Herrera, and colleagues (2011) suggest that MS may be triggered by environmental factors in individuals, with genetic susceptibility seen more commonly in females.

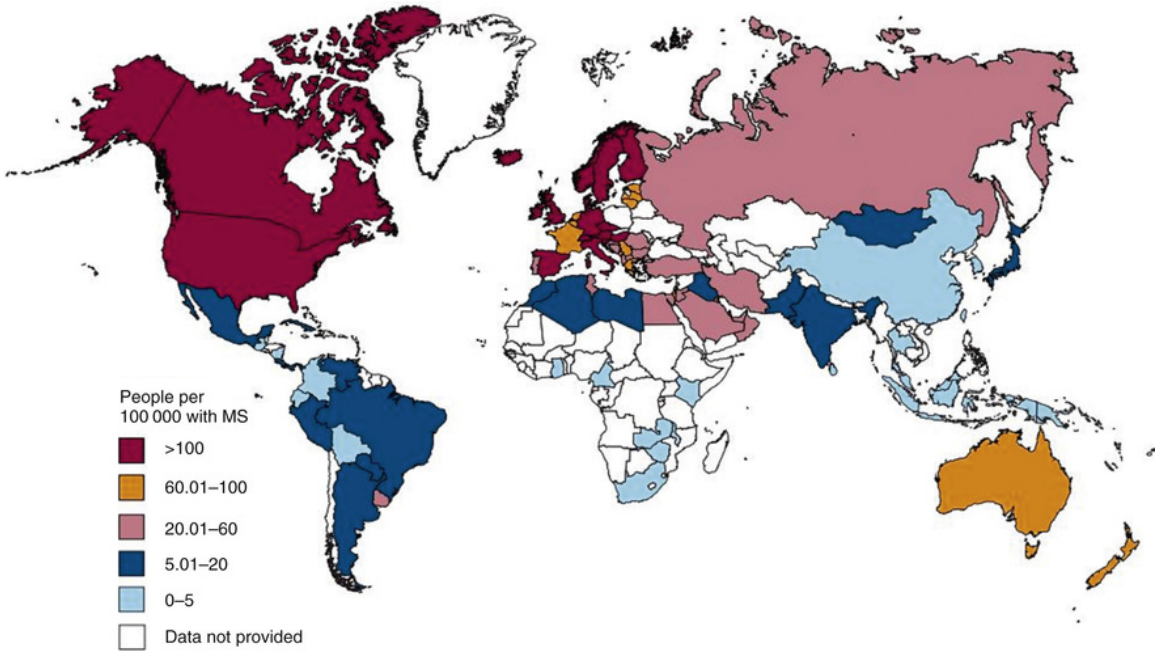

FIGURE 61-2 Prevalence of MS. Source: Multiple Sclerosis International Federation. (2013). Atlas of MS 2013. p. 8. Retrieved from http://www.msif.org/about-us/advocacy/atlas/. Reprinted with permission.

Etiology and Pathophysiology

The cause of MS is unknown, although research findings suggest that MS may be related to environmental, infectious (viral), and vascular factors, and to a vitamin D deficiency (Bernstein, 2012; Mokry, Ross, Ahmad, et al., 2015; Guo, He, Zhang, et al., 2012). The susceptibility to MS appears to be inherited. First-, second-, and third-degree relatives of patients with MS are at a slightly increased risk.

The role of precipitating factors, such as exposure to pathogenic agents, in the etiology of MS is controversial. It is possible that their association with MS is random and that there is no cause-and-effect relationship. Possible precipitating factors include infection, trauma, emotional stress, excessive fatigue, pregnancy, and a state of poor health.

MS is characterized by chronic inflammation, demyelination, and gliosis (scarring) in the CNS. The primary neuropathological condition is an autoimmune disease orchestrated by autoreactive T cells (lymphocytes). This process may be initially triggered by a virus in genetically susceptible individuals. The activated T cells in the systemic circulation migrate to the CNS, causing blood–brain barrier disruption. This is likely the initial event in the development of MS. Subsequent antigen–antibody reaction within

the CNS results in activation of the inflammatory response and, through multiple effector mechanisms, leads to demyelination of axons. The disease process consists of loss of myelin, disappearance of oligodendrocytes, and proliferation of astrocytes. These changes result in characteristic plaque formation, or sclerosis, with plaques scattered throughout multiple regions of the CNS.

Initially, the myelin sheaths of the neurons in the brain and spinal cord are attacked (Figure 61-3, *A* and *B*). Early in the disease, the myelin sheath is damaged, but the nerve fibre is not affected and nerve impulses are still transmitted (see Figure 61-3, *C*). At this point, the patient may complain of a noticeable impairment of function (e.g., weakness). However, the myelin can regenerate, and the symptoms disappear, resulting in a remission.

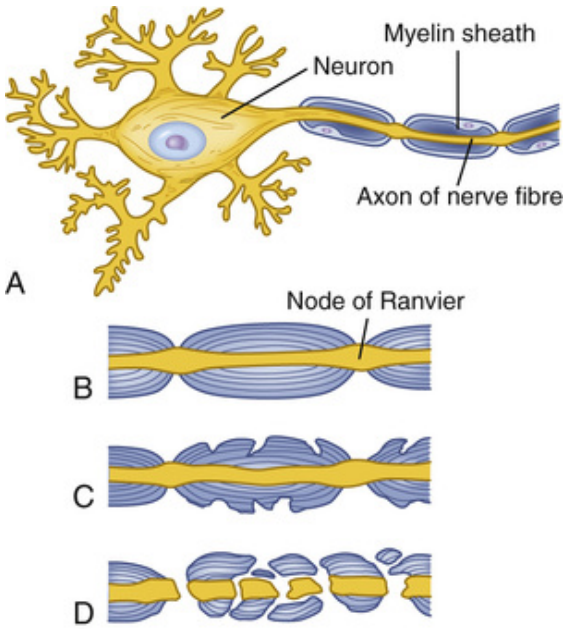

FIGURE 61-3 Pathogenesis of multiple sclerosis. **A,** Normal nerve cell with myelin sheath. **B,** Normal axon. **C,** Myelin breakdown. **D,** Myelin totally disrupted; axon not functioning.

In addition to myelin disruption, the axon also becomes involved (see Figure 61-3, *D*). Myelin is replaced by glial scar tissue, which forms hard, sclerotic plaques in multiple regions of the CNS (Figure 61-4). Without myelin, nerve impulses slow down, and with destruction of nerve axons, impulses are totally blocked, resulting in permanent loss of function. In many chronic lesions, demyelination continues with progressive loss of nerve function.

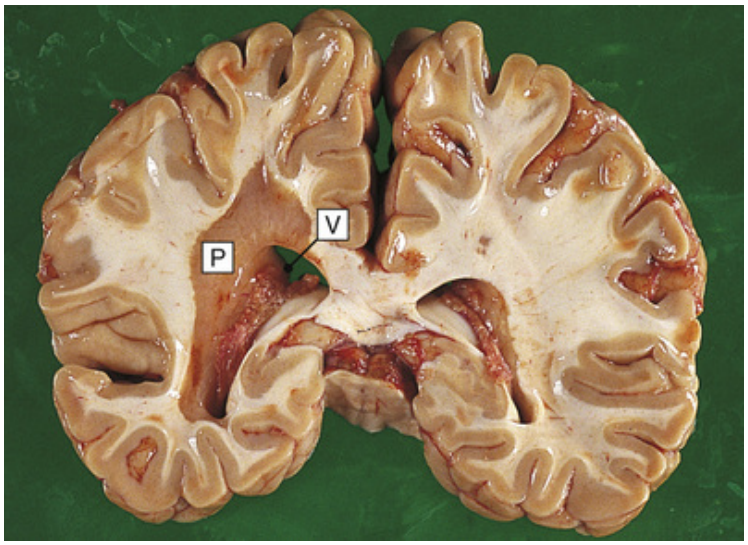

FIGURE 61-4 Chronic multiple sclerosis. Demyelination plaque (P) at grey-white junction and adjacent partially remyelinated shadow plaque (V). Source: Stevens, A., & Lowe, J. (2000). *Pathology: Illustrated review in colour* (2nd ed.). London: Mosby.

Clinical Manifestations

The onset of MS is often insidious, with vague symptoms that occur intermittently over months or years. As a result, the disease may not be diagnosed until long after the onset of the first symptom. The disease process has a spotty distribution in the CNS, so the signs and symptoms vary over time. MS is characterized by chronic, progressive deterioration in some people and by remissions and exacerbations in others. With repeated exacerbations, the overall trend is progressive deterioration in neurological function resulting in disability (Shirani, Zhao, Karim, et al., 2012).

The clinical manifestations vary according to the areas of the CNS involved. Some patients have severe, long-lasting symptoms early in the course of the disease. Others may experience only occasional and mild symptoms for several years after onset. A classification scheme that identifies the various courses of MS has been developed (Multiple Sclerosis Society of Canada, 2016b) (Table 61-14 and Figure 61-5).

TABLE 61-14

CLINICAL COURSES OF MULTIPLE SCLEROSIS (MS)

Category	Characteristics
Clinically isolated syndrome (CIS)	CIS is defined by a single episode of neurological symptoms reminiscent of MS.
Relapsing–remitting MS (RRMS)	Clearly defined relapses with full recovery or sequelae and residual deficit on recovery. This is the most common form of MS.
Primary-progressive MS (PPMS)	Slow and steady disease progression from onset with occasional plateaus and temporary minor improvements; no clear relapses or remissions
Secondary-progressive MS (SPMS)	A relapsing–remitting initial course, followed by progression with or without occasional relapses, minor remissions, and plateaus; disability generally accumulates over time.
Progressive–relapsing MS (PRMS)	Progressive disease from onset, with clear acute relapses, with or without full recovery; periods between relapses are characterized by continuing progression, occurring in approximately 5% of cases of MS.

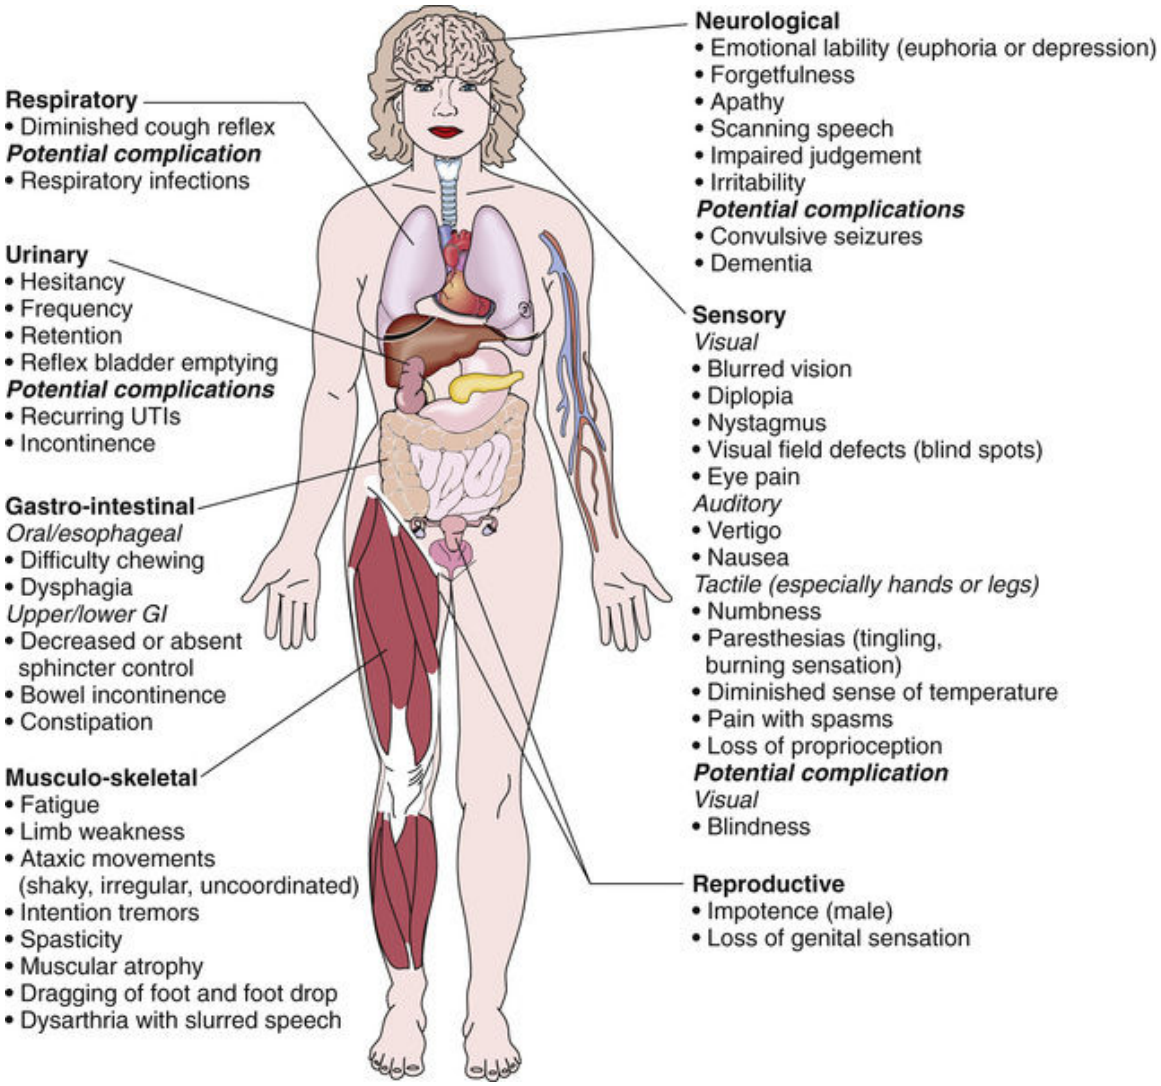

FIGURE 61-5 Multisystem effects of multiple sclerosis. UTIs, urinary tract infections. Source: *LEMONE, PRISCILLA T; BURKE, KAREN M.; BAULDOFF, GERENE, MEDICAL-SURGICAL NURSING: CRITICAL THINKING IN PATIENT CARE, 5th Ed., ©2011*. Reprinted by permission of Pearson Education, Inc., New York, New York.

Common signs and symptoms of MS include motor, sensory, cerebellar, and emotional problems. Motor symptoms include weakness or paralysis of the limbs, the trunk, or the head; diplopia; scanning speech (spoken words are unintentionally slowed or injected with pauses between syllables and may be accompanied by involuntary variations in vocal tone); and spasticity of the muscles that are chronically affected. Patients with MS experience a variety of sensory abnormalities, including numbness, tingling and other paresthesias, patchy blindness (scotomas), blurred vision, vertigo, tinnitus, decreased hearing, and chronic

neuropathic pain. Radicular (nerve root) pains may be present, particularly in the low thoracic and abdominal regions. Lhermitte sign is a transient sensory symptom described as an electric shock radiating down the spine or into the limbs with flexion of the neck. Cerebellar signs include nystagmus, ataxia, dysarthria, and dysphagia. Severe fatigue is present in many patients with MS, and it causes significant disability for some patients. The fatigue is usually associated with increased energy needs, deconditioning, depression, and medication adverse effects (Multiple Sclerosis International Federation, 2011).

Bowel and bladder function can be affected if the sclerotic plaque is located in areas of the CNS that control elimination. Problems with defecation usually involve constipation rather than fecal incontinence. Urinary problems are variable. A common problem in patients with MS is a spastic (uninhibited) bladder. This indicates a lesion above the second sacral nerve, which cuts off suprasegmental inhibiting influences on bladder contractility. As a result, the bladder has a small capacity for urine, and its contractions are unchecked. This problem is accompanied by urinary urgency and frequency and results in dribbling or incontinence. A flaccid (hypotonic) bladder indicates a lesion in the reflex arc governing bladder function. The bladder has a large capacity for urine because there is no sensation or desire to void, no pressure, and no pain. Generally, there is urinary retention, but urgency and frequency may also occur with this type of lesion. Another urinary problem is a combination of the previous two problems. Urinary problems cannot be adequately diagnosed and treated unless urodynamic studies are done.

Sexual dysfunction occurs in many people with MS and may stem from anatomical, physiological, psychological, and medical factors (Guo et al., 2012). Physiological erectile dysfunction may result from spinal cord involvement in men. Women may experience decreased libido, difficulty with orgasmic response, painful intercourse, and decreased vaginal lubrication. Diminished sensation can prevent a normal sexual response in both sexes.

MS has no apparent effect on the course of pregnancy, labour, delivery, or lactation. Some women with MS who become pregnant experience remission or an improvement in their symptoms during the gestation period. The hormonal changes associated with pregnancy appear to affect the immune system. However, during the postpartum period, women are at greater risk for remission relapses (Houtchens & Kolb, 2013).

Although intellectual functioning generally remains intact, emotional stability may be affected. Cognitive sequelae can produce significant

disability for some patients with MS. They may experience anger, depression, or euphoria. Signs and symptoms of MS are aggravated or triggered by physical and emotional trauma, fatigue, and infection.

The average life expectancy after the onset of symptoms is more than 25 years. Usually, death occurs because of infective complications (e.g., pneumonia) of immobility or because of an unrelated disease.

Diagnostic Studies

Because there is no definitive diagnostic test for MS, diagnosis is based primarily on history, clinical manifestations, and the presence of multiple lesions over time as measured by MRI (Table 61-15). Certain laboratory tests are currently used as adjuncts to clinical examination. In some patients, cerebro-spinal fluid (CSF) analysis may show an increase in oligoclonal immunoglobulin G. The CSF also contains a high number of lymphocytes, monocytes, and protein. Evoked responses are often delayed in people with MS because of decreased nerve conduction from the eye and the ear to the brain. MRI scan may be helpful because sclerotic plaques as small as 3 to 4 mm in diameter can be detected. Characteristic white-matter lesions scattered through the brain or spinal cord (or both) are evident on such a scan. Magnetic resonance spectroscopy may also be used to evaluate patients with MS.

Collaborative Care

Drug Therapy.

Because there is no cure for MS, collaborative care is aimed at treating the disease process and providing symptomatic relief (see Table 61-15). The goal of drug therapy is to decrease the progression of the disease process and control symptoms with a variety of drugs and other forms of therapy. Adrenocorticotrophic hormone, methylprednisolone (Solu-Medrol), and prednisone are helpful in treating acute exacerbations of the disease, probably by reducing edema and acute inflammation at the site of demyelination (Table 61-16). These drugs are used in patients with all types of MS; however, they do not affect the ultimate outcome or the degree of residual neurological impairment from the exacerbation (See Chapter 51 for effects of long-term corticosteroid therapy).

TABLE 61-16

DRUG THERAPY
Multiple Sclerosis

Drug	Patient Teaching
Corticosteroids ACTH, prednisone, methylprednisolone (Solu-Medrol)	• Restrict salt intake. • Do not abruptly stop therapy. • Know drug interactions.
Immuno-modulators Interferon beta (Betaseron, Avonex, Rebif) glatiramer acetate (Copaxone)	• Perform self-injection techniques. • Report adverse effects.
Cholinergics bethanechol (Duvoid) neostigmine	• Consult with health care provider before using other drugs, including over-the-counter drugs.
Anticholinergics oxybutynin (Ditropan)	• Consult health care provider before using other drugs, especially sleeping aids, antihistamines (possibly leading to potentiated effect).
Muscle Relaxants diazepam (Valium) baclofen (Lioresal) dantrolene (Dantrium) tizanidine	• Avoid driving and similar activities because of sedative effects. • Do not abruptly stop therapy. • Avoid use with tranquilizers and alcohol.
Acetylcholinesterase Inhibitor donepezil (Aricept)	• Maintain adequate hydration of 2–3 L of fluid per day. • Rise slowly when getting up from a sitting or lying position. • Report persistent abdominal discomfort, increased salivation, unresolved diarrhea, increased muscle pain, visual changes, or shortness of breath.
Nerve Conduction Enhancer fampridine (Fampyra)	• Be aware that drug may cause seizures, especially at higher doses.
Sphingosine-1-Phosphate Receptor Modulator fingolimod (Gilenya)	• May increase risk for infections and reduce effectiveness of influenza and tetanus boosters (Absher, 2015)

ACTH, adrenocorticotrophic hormone.

Immuno-suppressive drugs, such as azathioprine (Imuran), methotrexate, and cyclophosphamide (Procytox), have been shown to produce some beneficial effects in patients with progressive–relapsing, secondary-progressive, and primary-progressive MS. However, the potential benefits of these drugs in patients with MS must be weighed against the potential risks.

Immuno-modulator drugs modify the disease process. Interferon beta-1b (Betaseron) is used for patients with relapsing–remitting MS who are ambulatory. Interferon beta-1a (Avonex) is similar to interferon beta-1b in efficacy and is used in similar patient groups with MS. These drugs have antiviral effects. Glatiramer acetate (Copaxone), formerly known as copolymer-1, is unrelated to interferon.

Drug Alert

Interferon Beta Drugs (Avonex, Betaseron, Rebif)

- Rotate injection sites with each dose.
- Assess for depression, suicidal ideation.
- Wear sunscreen and protective clothing while exposed to sun.
- Know that flulike symptoms are common after initiation of therapy.

Teriflunomide (Aubagio) is an emerging immuno-modulatory drug that is a promising new therapy for the treatment of relapsing–remitting multiple sclerosis (RRMS). It has been shown to decrease the number of MS relapses and to reduce the progression toward disability in patients with MS (Oh & O'Connor, 2014).

Mitoxantrone is an antineoplastic drug used for the treatment of primary-progressive and progressive–relapsing MS. It is an immuno-suppressant drug that reduces both B and T lymphocytes and impairs antigen presentation. Unlike the other disease-modifying drugs, it has a lifetime dose limit because of cardiac toxicity. Therefore, it cannot be used for more than 2 to 3 years.

Many other drugs are used to treat the symptoms of MS. Antispasmodics are used for spasticity. Amantadine and CNS stimulants such as methylphenidate (Ritalin) and modafinil (Alertec) are used for fatigue. Anticholinergics are used to treat bladder symptoms. Tricyclic antidepressants and anticonvulsant drugs are used for chronic pain. Dopamine (DA) agonists may be effective in the treatment of erectile dysfunction, while hormone therapy has shown efficacy in increasing libido (Guo et al., 2012). Cannabinoids have also been used to treat both pain and spasticity, with mild adverse effects (Corey-Bloom, Wolfson, Gamst, et al., 2012).

Alternate Therapies.

A variety of alternate therapies have been utilized, aiming to minimize MS symptoms and decrease exacerbations. Surgical intervention may include neurectomy, rhizotomy, cordotomy, dorsal-column electrical stimulation, or use of an intrathecal baclofen (Lioresal) pump may be required to manage spasticity. Tremors that become unmanageable with drugs are sometimes treated by thalamotomy or deep brain stimulation.

Neurological dysfunction may improve with physiotherapy and speech therapy. Exercise improves the daily functioning for patients with MS not experiencing an exacerbation. Exercise decreases spasticity, increases coordination and muscle strength, and improves mobilization, gait, fatigue, and quality of life for patients with MS (Motl & Pilutti, 2012). The Canadian Physical Activity Guidelines for Adults With MS (Multiple Sclerosis Society of Canada, 2016c) is a useful document that outlines recommendations for adults with mild to moderate disability related to MS. An especially beneficial type of physical therapy is water exercise. Water gives buoyancy to the body and allows the patient to perform activities that would normally be too difficult because the patient has more control over the body. Other therapies may include the use of heat therapy, massage, acupuncture, bee stings, and aromatherapy. The effectiveness of these therapies requires more research.

In recent years, media attention has emerged surrounding the controversial MS treatment of chronic cerebro-spinal venous insufficiency (CCSVI). Zamboni, Galeotti, Menegatti, and associates (2008) first proposed the theory that CCSVI may be a contributing factor in the pathology of MS. These researchers suggest that MS may be related to an immune or inflammatory reaction to iron accumulation in the CNS relating to drainage impairment of the cerebro-spinal vessels. This accumulation was detected via the use of cranial ultrasound. Patients with MS have undergone endovascular CCSVI procedures such as angioplasty or stent placement in jugular and azygos veins to improve venous drainage (Figure 61-6). The safety and efficacy of these procedures is unknown and they are not without risk (Awad, Marder, Milo, et al., 2011; Burton, Alikhani, Goyal, et al., 2011; Lazzaro, Zaidat, Mueller-Kronast, et al., 2011). In 2010, the American and Canadian Multiple Sclerosis Societies contributed to the funding of seven studies to investigate the link between CCSVI and MS (Multiple Sclerosis Society of Canada, 2017). At the time of writing, four of the seven studies presented no relationship between CCSVI and MS, and CCSVI surgery for patients with MS remained unavailable in Canada (Multiple Sclerosis Society of Canada, 2017).

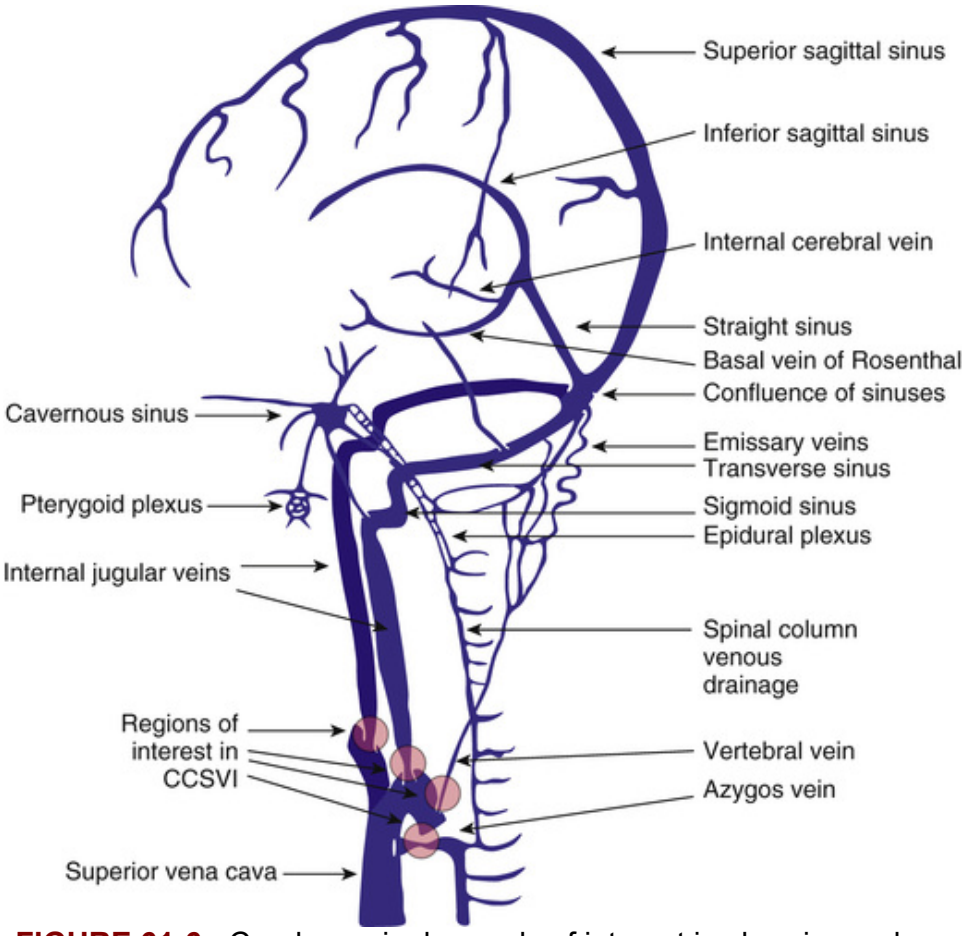

FIGURE 61-6 Cerebro-spinal vessels of interest in chronic cerebro-spinal venous insufficiency (CCSVI). Source: Lazzaro, M. A., Zaidat, O. O., Mueller-Kronast, N., et al. (2011). Endovascular therapy for chronic cerebrospinal venous insufficiency in multiple sclerosis. *Frontiers in Neurology, 2*(44), 1–7. doi:10.3389/fneur.2011.00044

Nutritional Therapy.

Various nutritional measures have been used in the management of MS, including megavitamin therapy (cobalamin [vitamin B_{12}], vitamin C), supplemental vitamin D, and diets consisting of low-fat, gluten-free food and raw vegetables. Particular dietary measures are not widely recommended, owing to insufficient evidence supporting their effectiveness.

A nutritious, well-balanced diet is essential. Although there is no standard prescribed diet, a high-protein, high roughage diet with supplementary vitamins is often advocated. Vitamins are merely supplemental and not curative. Nutrition therapy must be adapted, depending on the patient's ability to chew and swallow.

Nursing Management Multiple Sclerosis

Nursing Assessment

Subjective and objective data that should be obtained from a patient with MS are presented in Table 61-17.

TABLE 61-17

NURSING ASSESSMENT
Multiple Sclerosis

Subjective Data
Important Health Information
Past health history: Recent or past viral infections or vaccinations, other recent infections, residence in cold or temperate climates, recent physical or emotional stress, pregnancy, exposure to extremes of heat and cold; positive family history *Medications:* Use of and compliance in taking corticosteroids, immuno-modulators, immuno-suppressants, selective adhesion molecule inhibitor cholinergics, anticholinergics, antispasmodics, antivirals
Symptoms
• Weight loss; difficulty chewing, dysphagia • Urinary frequency, urgency, dribbling or incontinence, retention; constipation • Generalized muscle weakness, muscle fatigue; tingling and numbness, ataxia (clumsiness), malaise • Eye, back, leg, joint pain; painful muscle spasms; vertigo; blurred or lost vision; diplopia; tinnitus • Erectile and sexual dysfunction; decreased libido • Anger, depression, euphoria, social isolation, cognitive changes, memory loss
Objective Data
General
Apathy, inattentiveness
Neurological
Scanning speech, nystagmus, ataxia, tremor, spasticity, hyper-reflexia, decreased hearing
Musculo-Skeletal
Muscular weakness, paresis, paralysis, spasms, foot dragging, dysarthria (may be unilateral or bilateral changes)
Possible Findings
↓ T suppressor cells, demyelinating lesions on MRI or MRS scans, increased IgG or oligoclonal banding in cerebro-spinal fluid, delayed evoked potential

IgG, immunoglobulin G; *MRI*, magnetic resonance imaging; *MRS*, magnetic resonance spectroscopy.

Nursing Diagnoses

Nursing diagnoses for patients with MS may include, but are not limited to, the following:

- *Impaired physical mobility* related to *decrease in muscle strength, decrease in muscle control, physical*

deconditioning
- *Overflow urinary incontinence* related to *detrusor hypocontractility*
- *Ineffective health management* related to *difficulty managing complex treatment regimen* (knowledge deficit regarding management of MS)

Additional information on nursing diagnoses for the patient with MS is presented in NCP 61-3, available on the Evolve website.

Planning

The overall goals are that the patient with MS will (1) maximize neuromuscular function, (2) maintain independence in activities of daily living for as long as possible, (3) manage disabling fatigue, (4) optimize psychosocial well-being, (5) adjust to the illness, and (6) reduce factors that precipitate exacerbations.

Informatics in Practice

Phone Applications in Multiple Sclerosis

- Patients with multiple sclerosis (MS), especially those who are newly diagnosed, might feel overwhelmed at the thought of living with a chronic disease and managing multiple medications.
- Smartphone applications can improve the lives of patients with MS by helping them manage their health care.
- Applications are available that send medication reminders by text message or email, track injection site rotation, and email medication reports to the health care provider. Patients can keep track of their medication inventory and be reminded to order refills.

Nursing Implementation

Patients with MS should be aware of triggers that may cause exacerbations or worsening of the disease. Exacerbations of MS may be triggered by

infection (especially upper respiratory and urinary tract infections), trauma, immunization, childbirth, stress, and change in climate. Each person responds differently to these triggers. The nurse should help the patient identify particular triggers and develop ways to avoid them or minimize their effects.

The most common reasons for hospitalization of the patient with MS are for a diagnostic workup and for treatment of an acute exacerbation. During the diagnostic phase, the patient needs reassurance that, even though there is a tentative diagnosis of MS, certain diagnostic studies must be done to rule out other neurological disorders. The nurse should assist the patient in dealing with the anxiety caused by a diagnosis of a disabling illness. Patients with recently diagnosed MS may need assistance with the grieving process.

During an acute exacerbation, the patient may be immobile and bedridden. The focus of nursing intervention at this phase is to prevent major complications of immobility, such as respiratory and urinary tract infections and pressure injuries.

Patient teaching should focus on building general resistance to illness, including avoiding fatigue, extremes of heat and cold, and exposure to infection. It is also important to teach the patient to achieve a good balance of exercise and rest, eat nutritious and well-balanced meals, and avoid the hazards of immobility (e.g., contractures, pressure injuries). Patients should know their treatment regimens, the adverse effects of drugs and how to watch for them, and drug interactions with over-the-counter medications. The patient should consult a health care provider before taking nonprescription drugs.

Bladder control is a major problem for many patients with MS. Although anticholinergics may be beneficial for some patients to decrease spasticity, other patients may need to be taught self-catheterization (see Chapter 48). Bowel problems, particularly constipation, occur frequently in patients with MS. Increasing dietary fibre intake may help some patients achieve regularity in bowel habits.

Patients with MS and their families must make many emotional adjustments because of the unpredictability of the disease, the need to change lifestyles, and the challenge of avoiding or decreasing precipitating factors. The Multiple Sclerosis Society of Canada and its local chapters can offer a variety of services to meet the needs of patients with MS and their families.

Evaluation

Expected outcomes for patients with MS are addressed in NCP 61-3, available on the Evolve website.

Parkinson's Disease

Parkinson's disease (PD) is a progressive, neurodegenerative disease of the CNS (basal ganglia) characterized by a slowing down in the initiation and the execution of movement (bradykinesia), increased muscle tone (rigidity), tremor at rest, and impaired postural reflexes. It is the most common form of parkinsonism (a syndrome characterized by similar symptoms). PD is named after James Parkinson, who in 1817 wrote a classic essay on "shaking palsy," a disease whose cause is still unknown and for which no cure exists.

Etiology and Pathophysiology

PD is the second most common neurodegenerative disease. As of 2011, approximately 55 000 living adults have been diagnosed with PD, a movement disorder (Statistics Canada, 2015). This number is expected to rise dramatically as the population ages because the average age of diagnosis is 60 years (Parkinson Society Canada, 2015). Research has shown that many forms of PD have a genetic component, and the field continues to grow and evolve as new genes are identified and mutations in known genes are discovered (Singleton, Farrer, & Bonifati, 2013). PD is more common in men than in women, by a ratio of 3 : 2.

There are many forms of parkinsonism other than PD. Parkinsonism-like symptoms have occurred after intoxication with a variety of chemicals, including carbon monoxide and manganese (among copper miners) and the product of meperidine-analogue synthesis, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). Drug-induced parkinsonism can sometimes follow the use of medications within the antipsychotic, other neuroleptic, and calcium-channel entry-blocking classes (Bohlega & Al-Foghom, 2013). Parkinsonism can also be seen following the use of illicit drugs, including amphetamine and methamphetamine. Other causes of parkinsonism include encephalitis, vascular parkinsonism, normal pressure hydrocephalus, progressive supranuclear palsy, multiple system atrophy, and dementia with Lewy bodies (National Institute for Neurological Disorders and Stroke, 2016).

The pathological process of PD involves degeneration of the DA-producing neurons in the substantia nigra of the midbrain (Figures 61-7 and 61-8), which in turn disrupts the normal balance between DA and

acetylcholine (ACh) in the basal ganglia. DA is a neurotransmitter that is essential for normal functioning of the extrapyramidal motor system, including control of posture, support, and voluntary motion. Manifestations of PD do not occur until 80% of neurons in the substantia nigra are lost.

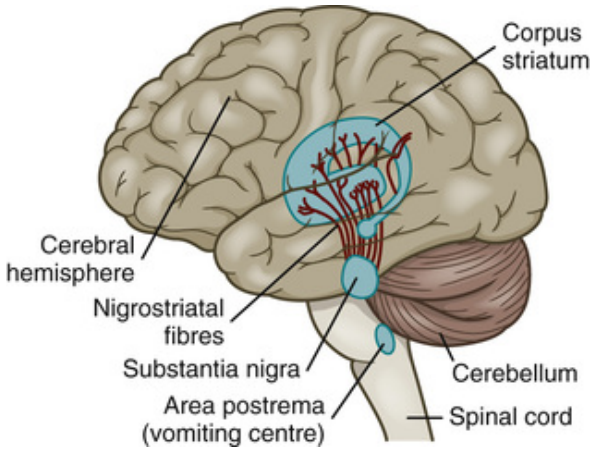

FIGURE 61-7 Nigrostriatal disorders produce parkinsonism. Left-sided view of the human brain shows the substantia nigra and the corpus striatum (shaded area) lying deep within the cerebral hemisphere. Nerve fibres extend upward from the substantia nigra, divide into many branches, and carry dopamine to all regions of the corpus striatum.

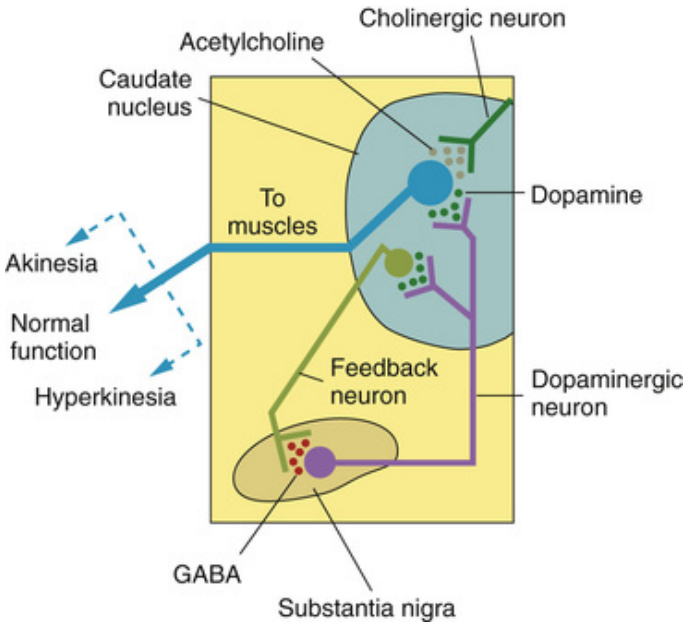

FIGURE 61-8 Dopaminergic synaptic activity is mediated by dopamine. Cholinergic synaptic activity is mediated by acetylcholine. A balance between the two kinds of activity produces normal motor function. A relative excess of cholinergic activity produces akinesia and rigidity. A relative excess of dopaminergic activity produces involuntary movements. Neurons in the caudate nucleus contain γ-aminobutyric acid (GABA) and possibly control dopaminergic neurons in the substantia nigra through a feedback pathway. Source: McCance, K. L., & Huether, S. E. (2006). *Pathophysiology: The biologic basis for disease in adults and children* (5th ed., p. 537, Figure 16-23, B). St. Louis: Mosby.

Clinical Manifestations

The onset of PD is gradual and insidious, with an ongoing progression. It may involve only one side of the body, initially. The classic manifestations of PD are a triad of tremor, rigidity, and bradykinesia (Figure 61-9). In the beginning stages, only a mild tremor, a slight limp, or a decreased arm swing may be evident. Later in the disease, the patient may have a shuffling, propulsive gait with arms flexed and loss of postural reflexes. Some patients have a slight change in speech patterns. None of these manifestations alone is sufficient evidence for a diagnosis of the disease.

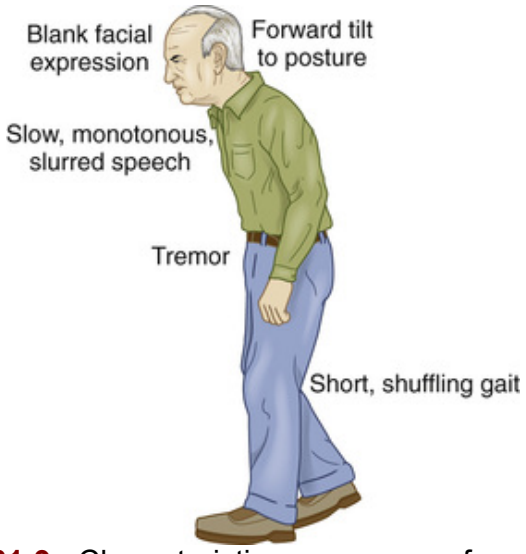

FIGURE 61-9 Characteristic appearance of a patient with Parkinson's disease.

Tremor.

Tremor, often the first sign, may be minimal initially, so the patient is the only one who notices it. This tremor can affect handwriting, causing it to trail off, particularly toward the ends of words. Parkinsonian tremor is more prominent at rest and is aggravated by emotional stress or increased concentration. The hand tremor is described as "pill rolling" because the thumb and forefinger appear to move in a rotary fashion, as if rolling a pill, coin, or other small object. Tremor can also involve the diaphragm, tongue, lips, and jaw but rarely causes shaking of the head.

Unfortunately, in many people, a benign essential tremor is mistakenly diagnosed as PD. Essential tremor occurs during voluntary movement, has a more rapid frequency than parkinsonian tremor, and is often familial.

Rigidity.

Rigidity, the second sign of the triad, is the increased resistance to passive motion when the limbs are moved through their range of motion. Parkinsonian rigidity is typified by cogwheel rigidity, or a jerky quality, as if there were intermittent catches in the movement of a cogwheel, when the joint is moved passively. Sustained muscle contraction causes the rigidity and consequently elicits complaints of muscle soreness; feeling tired and achy; or pain in the head, the upper body, the spine, or the legs. Another consequence of rigidity is slowness of movement because it

inhibits the alternating of contraction and relaxation in opposing muscle groups (e.g., biceps and triceps).

Bradykinesia.

Bradykinesia is particularly evident in the loss of automatic movements, which is secondary to the physical and chemical alteration of the basal ganglia and related structures in the extrapyramidal portion of the CNS. In the unaffected patient, automatic movements are involuntary and occur subconsciously. They include blinking of the eyelids, swinging of the arms while walking, swallowing of saliva, self-expression with facial and hand movements, and minor movements of postural adjustment. Patients with PD do not execute these movements and lack spontaneous activity. These factors account for the stooped posture, masked face (deadpan expression), drooling of saliva, and shuffling gait (festination) that are characteristic of a person with this disease. The posture is that of a slowed "old man" image, with the head and trunk bent forward and the legs constantly flexed (Figure 61-9). Postural instability is common. Patients may complain of being unable to stop themselves from going forward or backward. Assessment of postural instability includes the "pull test," in which the examiner stands behind the patient and gives a tug backward on the shoulder, causing the patient to lose his or her balance and fall backward. In addition to the motor signs of PD, many non-motor symptoms are common. They include depression, anxiety, apathy, fatigue, pain, constipation, impotence, and short-term memory impairment. Sleep problems are common in patients with PD and include difficulty staying asleep, restless sleep, nightmares, and drowsiness or sudden sleep onset during the day (National Institute of Neurological Disorders and Stroke, 2016).

Complications

As the disease progresses, complications increase. These include motor symptoms (e.g., dyskinesias [spontaneous, involuntary movements], weakness, akinesia [total immobility]), neurological problems (e.g., dementia), and neuropsychiatric problems (e.g., depression, hallucinations, psychosis). As PD progresses, it often results in severe dementia, which is associated with an increase in mortality. As swallowing becomes more difficult (dysphagia), malnutrition or aspiration may result. General debilitation may lead to pneumonia, urinary tract infections, and skin breakdown. Orthostatic hypotension may occur in

some patients and, along with loss of postural reflexes, may result in falls or other injuries.

Diagnostic Studies

Because there is no specific diagnostic test for PD, the diagnosis is based on the history and clinical features. A firm diagnosis can be made only when at least two of the three signs of the classic triad are present: tremor, rigidity, and bradykinesia. The ultimate confirmation of PD is a positive response to antiparkinsonian drugs. Research is ongoing regarding the role of genetic testing and MRI in diagnosing patients with PD (Chahine & Stern, 2011).

Collaborative Care

Because there is no cure for PD, collaborative management (Table 61-18) is focused on symptom management.

TABLE 61-18

COLLABORATIVE CARE
Parkinson's Disease

Diagnostic
• History and physical examination • Bradykinesia • MRI • Positive response to antiparkinsonian drugs* • Rigidity • Rule out adverse effects of phenothiazines, benzodiazepines, haloperidol • Tremor
Collaborative Therapy
• Antiparkinsonian drugs* • Ablation surgery • Deep brain stimulation

*See Table 61-19.

MRI, magnetic resonance imaging.

Drug Therapy.

Drug therapy for PD is aimed at correcting an imbalance of neurotransmitters within the CNS. Antiparkinsonian drugs either enhance the release or supply of DA (dopaminergic) or antagonize or block the effects of the overactive cholinergic neurons in the striatum (anticholinergic). Levodopa (L-dopa) with carbidopa (Sinemet) is often the

first drug used. L-Dopa is a precursor of DA and can cross the blood–brain barrier. It is converted to DA in the basal ganglia. Sinemet is the preferred drug because it also contains carbidopa, an agent that inhibits the enzyme dopa decarboxylase in the peripheral tissues. This enzyme breaks down L-dopa before it reaches the brain. The net result of the combination of L-dopa and carbidopa is that more L-dopa reaches the brain, and therefore less drug is needed.

Drug Alert

Carbidopa–Levodopa (Sinemet)

- The patient should be monitored for signs of dyskinesia.
- Effects may be delayed for several weeks to months.
- The patient or caregiver should be instructed to report any uncontrolled movement of the face, eyelids, mouth, tongue, arms, hands, or legs; mental changes; palpitations; severe nausea and vomiting; and difficulty urinating.

Many patients are given Sinemet early in the disease course. However, some health care providers believe that after a few years of therapy, the effectiveness of Sinemet wears off. Instead, these providers may prefer to initiate therapy with a dopaminergic drug that directly stimulates DA receptors. When more moderate-to-severe symptoms become present, L-dopa with carbidopa (Sinemet) is added to the drug regimen.

Anticholinergic drugs are also used to manage PD. These drugs act by decreasing the activity of ACh, thus providing balance between cholinergic and dopaminergic actions. Antihistamines (e.g., diphenhydramine [Benadryl]) with anticholinergic properties or a β-adrenergic blocker (e.g., propranolol [Inderal]) is used to manage tremors. The antiviral agent amantadine is also an effective antiparkinsonian drug. Although its exact mechanism of action is not known, amantadine promotes the release of DA from neurons.

Selegiline is a monoamine oxidase inhibitor that is sometimes used in combination with Sinemet. By inhibiting monoamine oxidase, the degradative enzyme for DA, levels of DA are increased. Rasagiline (Azilect), a type B monoamine oxidase inhibitor, is used as an initial drug

therapy in early PD and as an addition to L-dopa in patients with more advanced disease.

Entacapone (Comtan) blocks the enzyme catechol-O-methyltransferase, which breaks down L-dopa in the peripheral circulation, thus prolonging the effect of Sinemet. These drugs are used only as adjuncts to L-dopa (Lindahl & MacMahon, 2011).

Table 61-19 summarizes the drugs commonly used in PD. The use of only one drug is preferred because there are fewer adverse effects and the drug dosage is easier to adjust than when several drugs are used. However, as the disease progresses, combination therapy is often required. Excessive amounts of dopaminergic drugs can lead to paradoxical intoxication (aggravation rather than relief of symptoms).

TABLE 61-19

DRUG THERAPY
Parkinson's Disease

Drug	Symptoms Relieved	Adverse Effects and Precautions
Dopaminergic		
levodopa (L-dopa)	Bradykinesia, tremor, rigidity	Nausea, dyskinesia, hypotension, palpitations, dysrhythmias; agitation, hallucinations, confusion (in older-adult patient) Avoidance of multivitamin pills and diet high in vitamin B_6 (reversal of effect of levodopa); contraindicated in narrow-angle glaucoma
levodopa–carbidopa (Sinemet)	Same as above	Less nausea but greater chance of dyskinesia, confusion, hallucinations Periodic check of BUN, AST, WBCs, Hct Contraindicated in melanoma; narrow-angle glaucoma; combination with MAO inhibitors, methyldopa, antipsychotics
bromocriptine mesylate	Same as above	Orthostatic hypotension, nausea, vomiting, toxic psychosis, limb edema, phlebitis, dizziness, headache, insomnia
pramipexole (Mirapex)	Same as above	
ropinirole (Requip)	Same as above	
amantadine	Rigidity, akinesia	Nervousness, insomnia, confusion, hallucinations, dry mouth, nausea, edema, orthostatic hypotension
Anticholinergic		
benztropine procyclidine trihexyphenidyl	Tremor	Dry mouth, blurred vision, constipation, delirium, anxiety, agitation, hallucinations Avoidance of drugs with similar actions, including over-the-counter drugs containing scopolamine or antihistamines, antispasmodics (e.g., Bellergal), tricyclic antidepressants (e.g., amitriptyline [Elavil])
Antihistamine		
diphenhydramine (Benadryl) orphenadrine	Tremor, rigidity	Sedation, same precautions as for anticholinergic drugs
Monoamine Oxidase Inhibitor		
selegiline	Bradykinesia, rigidity, tremor	Similar to dopaminergic drugs
Catechol-*O*-Methyltransferase (COMT) Inhibitor		
entacapone (Comtan)	By blocking COMT, this drug slows down the breakdown of levodopa, thus prolonging the action of levodopa	Similar to dopaminergic drugs; works only when used in combination with Sinemet

AST, aspartate aminotransferase; *BUN,* blood urea nitrogen; *Hct,* hematocrit; *MAO,* monoamine oxidase; *WBCs,* white blood cells.

Surgical Therapy.

Surgical procedures are aimed at relieving symptoms of PD and are usually used in patients who are unresponsive to drug therapy or who have developed severe motor complications. Surgical procedures fall into

three categories: ablation (destruction), deep brain stimulation (DBS), and transplantation.

Ablation surgery involves stereotactic ablation of areas in the thalamus (thalamotomy), globus pallidus (pallidotomy), and subthalamic nucleus (subthalamic nucleotomy). Ablative procedures have been used for PD for over 50 years, but they have been replaced recently by DBS. DBS involves placing an electrode in the thalamus, the globus pallidus, or the subthalamic nucleus and connecting it to a generator placed in the upper chest (like a pacemaker). The device is programmed to deliver a specific current to the targeted brain location. Unlike ablation procedures, DBS can be adjusted to control symptoms better and is reversible (the device is removable). These ablative and DBS procedures work by blocking the neuronal impulses that lead to the motor symptoms seen in PD (National Institute of Neurological Disorders and Stroke, 2016).

Transplantation of fetal neural tissue into the basal ganglia is designed to provide DA-producing cells in the brains of patients with PD. Currently, it is the only therapy that allows patients full functional restoration. Aside from the ethical dilemma of using fetal tissue as a treatment, this therapy has many limitations and is still in experimental stages. Stem cell transplantation is an alternative therapy showing some promise. Both epithelial and bone marrow cells are currently being studied. Clinical trial outcomes related to stem cell transplantation have been inconsistent (Politis & Lindvall, 2012).

Nutritional Therapy.

Diet is important for patients with PD because malnutrition and constipation can be serious consequences of inadequate nutrition. Patients who have dysphagia and bradykinesia need appetizing foods that are easily chewed and swallowed. The diet should contain adequate roughage and fruit to avoid constipation. Food should be cut into bite-sized pieces before it is served, and hot food should be served on a warmed plate to preserve its appeal. Eating six small meals a day may be less exhausting than eating three large meals a day. Ample time should be planned for eating to avoid frustration and encourage independence. In addition, absorption of L-dopa can be impaired by ingestion of protein and of vitamin B_6. Some patients are advised to limit their protein intake to the evening meal to decrease this problem and to consult with their health care provider regarding vitamin B_6 in their multivitamins and fortified cereals.

Nursing Management Parkinson's Disease

Nursing Assessment

Subjective and objective data that should be obtained from a patient with PD are presented in Table 61-20.

TABLE 61-20

NURSING ASSESSMENT
Parkinson's Disease

Subjective Data
Important Health Information
Past health history: CNS trauma, cerebro-vascular disorders, exposure to metals or carbon monoxide, encephalitis; positive family history *Medications:* Use of major tranquilizers, especially haloperidol and phenothiazines, methyldopa, amphetamines
Symptoms
• Excessive salivation, dysphagia; weight loss • Constipation, incontinence; excessive sweating • Fatigue, sleep disturbance, difficulty initiating movements; postural instability; frequent falls; loss of dexterity; micrographia (handwriting deterioration) • Diffuse headache; pain in shoulders, neck, back, legs, and hips; muscle soreness and cramping; difficulty concentrating • Depression, mood swings, hallucinations
Objective Data
General
Blank (masked) facies, slow and monotonous speech, infrequent blinking
Integumentary
Seborrhea, dandruff; ankle edema
Cardiovascular
Postural hypotension
Gastro-Intestinal
Drooling
Neurological
Tremor at rest, first in hands (pill rolling), later in legs, arms, face, and tongue; aggravation of tremor with anxiety, absence in sleep; poor coordination; subtle dementia, impaired postural reflexes
Musculo-Skeletal
Cogwheel rigidity, dysarthria, bradykinesia, contractures, stooped posture, shuffling gait
Possible Findings
Lack of specific tests; diagnosis on basis of history and physical findings and ruling out of other diseases

CNS, central nervous system.

Nursing Diagnoses

Nursing diagnoses for patients with PD may include, but are not limited to, the following:

- *Impaired physical mobility* related to *decrease in muscle control, decrease in muscle strength, physical deconditioning*
- *Imbalanced nutrition: less than body requirements* related to *insufficient dietary intake* (difficulty ingesting food)
- *Impaired swallowing* related to *behavioural feeding problem* (neuro-muscular impairment)

Additional information on nursing diagnoses for the patient with PD is presented in NCP 61-4, available on the Evolve website.

Planning

The overall goals are that the patient with PD will (1) experience a lower intensity and frequency of distressing symptoms, (2) maximize neurological function, (3) maintain independence in activities of daily living for as long as possible, and (4) optimize psychosocial well-being.

Nursing Implementation

Because PD is a chronic, degenerative disorder with no acute exacerbations, patient teaching and nursing care should include the assessment and management of medications (Magennis, Lynch, & Corry, 2014), maintenance of good health, encouragement of independence, and avoidance of complications such as contractures. Problems secondary to bradykinesia can be alleviated by relatively simple measures.

Promotion of physical exercise and a well-balanced diet are major concerns for nursing care. Exercise can limit the consequences of decreased mobility, such as muscle atrophy, contractures, and constipation. Parkinson Canada (see Resources section at the end of this chapter) publishes a series of booklets and videos with helpful exercises that can be used by family members and health care professionals.

A physiotherapist may be consulted to design an exercise program aimed at strengthening, muscle tone, and stretching specific muscles. A speech–language pathologist may be consulted to strengthen the muscles involved with speaking and swallowing. Although exercise will not halt the progress of the disease, it will enhance the patient's functional ability.

An occupational therapist can also assist the patient with strategies to increase self-care abilities, including eating and dressing.

Safety Alert

Have patients who are at risk for falling and tend to "freeze" while walking do the following:

- Consciously think about stepping over imaginary or real lines on the floor.
- Drop grains of rice and step over them.
- Rock from side to side.
- Lift the toes when stepping.
- Take one step backward and two steps forward.

The nurse should work closely with the patient's caregiver and family in exploring creative adaptations that allow maximal independence and self-care. The patient can facilitate getting out of a chair by using an upright chair with arms and placing the back legs of the chair on small (2-inch) blocks. Encourage environmental alterations, such as removing rugs and excess furniture to avoid stumbling, using an elevated toilet seat to facilitate getting on and off the toilet, and elevating the legs on an ottoman to decrease dependent ankle edema. Clothing can be simplified by the use of slip-on shoes and Velcro hook-and-loop fasteners or zippers on clothing, instead of buttons and hooks.

Effective management of sleep problems can greatly improve the quality of life for patients with PD. Some patients with PD find the use of satin nightwear or satin sheets beneficial. Information on teaching regarding sleep hygiene practices is presented in Chapter 9.

In the early stages of PD, many patients experience depression and anxiety. Patients need to adjust their lifestyle, including work and home responsibilities. As the disease progresses, the impact on the patient's psychological well-being also increases. The nurse can assist the patient by listening, providing teaching, challenging distorted thoughts, and encouraging social interactions. Psychotherapy and counselling can also be helpful.

In the early stage of the disease, the patient has subtle changes in cognitive function, which may progress to dementia. This progression

results in increased caregiver burden and the potential for long-term care placement. Information on care of the patient with dementia is provided in Chapter 62.

The majority of patients with PD are cared for by family caregivers. As the disease progresses, the caregiver burden increases, often while the caregiver's physical and mental health decline. Strategies to reduce caregiver stress are described in Chapter 62, Table 62-15. Other interventions for the patient with PD are presented in NCP 61-4 (available on the Evolve website).

Evaluation

The expected outcomes are that the patient with PD will:

- Perform physical exercise to deter muscle atrophy and joint contractures.
- Use assistive devices appropriately for ambulation and mobility.
- Maintain nutritional intake adequate for metabolic needs.
- Experience safe passage of fluids and solids from the mouth to the stomach.
- Use methods of communication that meet needs for interaction with others.

Additional information on expected outcomes for the patient with PD is presented in NCP 61-4 (available on the Evolve website).

Myasthenia Gravis

Myasthenia gravis (MG) is an autoimmune disease of the neuro-muscular junction characterized by fluctuating weakness of certain skeletal muscle groups. MG can occur at any age. The mean age at time of diagnosis is 60.2 years plus or minus 17.1 years, with the incidence of MG reportedly higher in younger women and older men (Breiner et al., 2015). In 2013, there were approximately 32 cases of MG per 100 000 population in Ontario (Breiner,

Widdifield, Katzberg, et al., 2015); however, MG is thought to be underdiagnosed and the prevalence is likely higher.

Etiology and Pathophysiology

MG is caused by an autoimmune process in which antibodies attack ACh receptors, resulting in a decreased number of ACh receptor (AChR) sites at the neuro-muscular junction (Figure 61-10). This prevents ACh molecules from attaching and stimulating muscle contraction. Anti-AChR antibodies are detectable in the serum of patients with generalized MG. In patients who lack autoantibodies to AChR, their muscular weakness may be related to autoantibodies to the muscle-specific receptor tyrosine kinase, although other autoantibodies may also be involved (Guptill, Soni, & Meriggioli, 2016). Thymic tumours are found in about 15% of patients, and abnormal thymus tissue is found in most others.

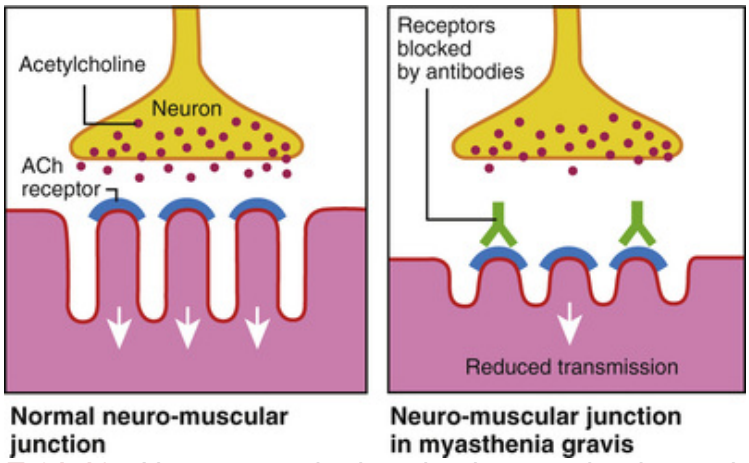

FIGURE 61-10 Neuromuscular junction in myasthenia gravis. *ACh*, acetylcholine. Source: Myasthenia Gravis Coalition of Canada. (2017). *What is MG?* Retrieved from http://www.mgcc-ccmg.org/about.asp.

Clinical Manifestations and Complications

The primary feature of MG is fluctuating weakness of skeletal muscle. Strength is usually restored after a period of rest. The muscles most often involved are those used for moving the eyes and eyelids, chewing, swallowing, speaking, and breathing. The muscles are generally the strongest in the morning and become exhausted with continued activity.

Consequently, by the end of the day, muscle weakness is prominent (Myasthenia Gravis Coalition of Canada, 2017) (Table 61-21).

TABLE 61-21
CLINICAL MANIFESTATIONS OF MYASTHENIA GRAVIS

• A change in facial expression • Chronic muscle fatigue • Difficulty breathing • Difficulty chewing or swallowing • Drooping eyelid(s) (ptosis) • Impaired or slurred speech • Unstable or unusual gait • Vision changes (blurred or double) • Weakness in arms, hands, fingers, legs, and neck

Source: National Institute of Neurological Disorders and Stroke. (2015). *Myasthenia fact sheet.* Retrieved from http://www.ninds.nih.gov/disorders/myasthenia_gravis/detail_myasthenia_gravis.htm?css=print#3153_4.

The course of this disease is variable. Some patients may have short-term remissions, others may stabilize, and others may have severe, progressive involvement. Restricted ocular myasthenia, usually seen only in men, has a good prognosis. Exacerbations of MG can be precipitated by stress, pregnancy, menses, secondary illness, trauma, temperature extremes, and hypokalemia. Ingestion of drugs including chlorpromazine, haloperidol, amitriptyline (Elavil), lithium, carbamazepine (Tegretol), and quetiapine have also been associated with worsening of MG (Wilson & Ferguson, 2013).

Myasthenic crisis is an acute exacerbation of muscle weakness triggered by infection, surgery, emotional distress, or overdose of or inadequate drugs in a person with MG. Generally, it occurs in the first 2 years after diagnosis. The major complications of MG result from muscle weakness in areas that affect swallowing and breathing. This weakness results in aspiration, respiratory insufficiency, and respiratory infection.

Diagnostic Studies

The diagnosis of MG can be made on the basis of history, physical examination, and diagnostic testing. Diagnostic testing would include a routine electromyography (EMG) (to rule out other possible causes of the symptoms) as well as repetitive nerve stimulation. In addition, single-fibre EMG is done to show the muscles' response to electrical shocks, and antibody testing is done to detect acetylcholine receptor antibodies.

Collaborative Care

Drug Therapy.

Drug therapy for MG includes anticholinesterase drugs, alternate-day corticosteroids, and immuno-suppressants (Table 61-22). Anticholinesterase drugs are aimed at enhancing function of the neuro-muscular junction. Acetylcholinesterase is the enzyme that breaks down ACh in the synaptic cleft. Thus, inhibition of this enzyme by an anticholinesterase inhibitor will prolong the action of ACh and facilitate transmission of impulses at the neuro-muscular junction. Pyridostigmine (Mestinon) is the most successful drug of this group in the long-term treatment of MG.

TABLE 61-22

COLLABORATIVE CARE
Myasthenia Gravis

Diagnostic
• History and physical examination • Acetylcholine receptor antibodies • EMG • Fatigability when upward gaze is prolonged (2–3 min) • Muscle weakness
Collaborative Therapy

• Drugs
  • Anticholinesterase agents
  • Corticosteroids
  • Immuno-suppressive agents
• Plasmapheresis
• Surgery (thymectomy)

EMG, electromyography.

Tailoring the dose to avoid a myasthenic or cholinergic crisis often presents a clinical challenge. Corticosteroids (specifically prednisone) are used to suppress the immune response. Drugs such as azathioprine (Imuran), mycophenolate (CellCept), and cyclosporin (Sandimmune) may also be used for immuno-suppression.

Many drugs are contraindicated for use or must be used with caution in patients with MG. Classes of drug that should be cautiously evaluated before use include anaesthetics, antidysrhythmics, antibiotics, quinine, antipsychotics, barbiturates and sedative–hypnotics, cathartics, diuretics, opioids, muscle relaxants, thyroid preparations, and tranquilizers.

Surgical Therapy.

Because the presence of the thymus gland in patients with MG appears to enhance the production of ACh receptor antibodies, removal of the thymus gland results in improvement in most patients. Thymectomy is indicated for all patients with thymoma, for patients with generalized MG between puberty and about age 65 years, and for patients with purely ocular MG.

Other Therapies.

Plasmapheresis and IV immunoglobulin G (IVIG) can yield a short-term improvement in symptoms and are indicated for patients in myasthenic crisis or in preparation for surgery when corticosteroids must be avoided. Plasmapheresis directly removes circulating AChR antibodies, leading to a decrease in symptoms. (Plasmapheresis is discussed in Chapter 16.) Some evidence has shown that IVIG is just as effective as plasmapheresis in the treatment of MG (Dhawan, Goodman, Harper, et al., 2015). Treatment decisions should be based on the patient's unique clinical presentation.

Nursing Management Myasthenia Gravis

Nursing Assessment

The nurse can assess the severity of MG by asking the patient about fatigability, what body parts are affected, and how severely he or she is affected. The patient's coping abilities and understanding of the disorder should also be assessed. Some patients become so fatigued that they are no longer able to ambulate.

Objective data should include respiratory rate and depth, oxygen saturation, arterial blood gas analyses, pulmonary function tests, and evidence of respiratory distress in patients with acute myasthenic crisis. Muscle strength of all face and limb muscles should be assessed, as should swallowing, speech (dysarthria) and voice (volume and clarity), cough and gag reflexes, and bladder function.

Nursing Diagnoses

Nursing diagnoses for patients with MG may include, but are not limited to, the following:

- *Ineffective airway clearance* related to *excessive mucus, retained secretions* (intercostal muscle weakness, impaired cough and gag reflexes)
- *Activity intolerance* related to *immobility, physical deconditioning* (muscle weakness, fatigue)
- *Disturbed body image* related to *alteration in self-perception* (inability to maintain usual lifestyle and role responsibility)

Planning

The overall goals are that the patient with MG will have a return of normal muscle endurance, avoid complications, and maintain a quality of life appropriate to disease course.

Nursing Implementation

The patient with MG who is admitted to the hospital usually has a respiratory tract infection or is in an acute myasthenic crisis. Nursing care is aimed at maintaining adequate ventilation, continuing drug therapy, and watching for adverse effects of therapy. The nurse must be able to distinguish cholinergic from myasthenic crisis (Table 61-23) because the causes and treatment of the two conditions differ greatly.

TABLE 61-23

COMPARISON OF MYASTHENIC CRISIS AND CHOLINERGIC CRISIS

Myasthenic Crisis	Cholinergic Crisis
Causes	
Exacerbation of myasthenia following precipitating factors or failure to take drug as prescribed or drug dose too low	Overdose of anticholinesterase drugs resulting in increased ACh at the receptor sites, remission (spontaneous or after thymectomy)
Differential Diagnosis	
Improved strength after IV administration of anticholinesterase drugs Increased weakness of skeletal muscles manifesting as ptosis, bulbar signs (e.g., difficulty in swallowing, difficulty in articulating words), or dyspnea	Weakness within 1 hour after ingestion of anticholinesterase Increased weakness of skeletal muscles manifesting as ptosis, bulbar signs, dyspnea Effects on smooth muscle, include papillary miosis, salivation, diarrhea, nausea or vomiting, abdominal cramps, increased bronchial secretions, sweating, or lacrimation

ACh, acetylcholine; *IV*, intravenous.

As with other chronic illnesses, care focuses on the neurological deficits and their impact on daily living. A balanced diet, with food that can be chewed and swallowed easily, should be prescribed. Semisolid foods may be easier to eat than solids or liquids. Scheduling doses of drugs so that peak action is reached at mealtime may make eating less difficult. Teaching should focus on the importance of following the medical regimen, potential adverse reactions to specific drugs, planning activities of daily living to avoid fatigue, the availability of community resources, and the complications of the disease and therapy (crisis conditions) and what to do about them. Contact with the Myasthenia Gravis Coalition of Canada or an MG support group may be helpful.

Evaluation

The following are overall expected outcomes for the patient with MG:

- The patient will maintain optimal muscle function.

- The patient will be free from adverse effects of drugs.
- The patient will not experience complications from the disease, in particular, myasthenic or cholinergic crisis.
- The patient will maintain a quality of life appropriate to the disease course.

Restless Legs Syndrome

Etiology and Pathophysiology

Restless legs syndrome (RLS) (also known as Willis–Ekbom disease) is characterized by unpleasant sensory (paresthesias) and motor abnormalities of one or both legs. RLS is more common in older adults, and prevalence rates range from 5% to 15% (Yeh, Walters, & Tsuang, 2012); however, the numbers may be higher because the condition is often underdiagnosed. There are two distinct types of RLS: primary (idiopathic) and secondary. The majority of cases are primary, and many patients with this type of RLS report a positive family history. Secondary RLS can occur with metabolic abnormalities associated with iron deficiency, renal failure, hypertension, diabetes mellitus, or rheumatoid arthritis. Conditions such as anemia, pregnancy, and certain medications can cause or worsen symptoms. Although the exact pathophysiology of primary RLS is unknown, it is believed that RLS is related to a dysfunction in the brain's basal ganglia circuits that use the neurotransmitter DA, which controls movement. In RLS, this dysfunction causes the urge to move the legs. Abnormal iron metabolism or brain iron deficiencies may result in abnormalities of the DA system, thus leading to RLS (National Institute for Disorders and Stroke, 2015c).

Clinical Manifestations

The severity of RLS sensory symptoms ranges from infrequent minor discomfort (paresthesias, including numbness and tingling) to severe pain. Sensory symptoms often appear first. Patients describe annoying and uncomfortable (but usually not painful) sensations in the legs. Some describe the sensations like bugs crawling on the legs. The leg pain is localized within the calf muscles. Patients can also experience pain in the

upper extremities and the trunk. The discomfort occurs when the patient is sedentary and is most common in the evening or at night, resulting in sleep disruption. In severe cases, patients sleep only a few hours at night, resulting in daytime fatigue and disruption of the daily routine. Physical activity, such as walking or stretching, often relieves the pain. The motor abnormalities associated with RLS consist of voluntary restlessness and stereotyped, periodic, involuntary movements (National Institute for Neurological Disorders and Stroke, 2015c). Fatigue further aggravates symptoms. Over time, RLS advances to more frequent and severe episodes.

Diagnostic Studies

RLS is a clinical diagnosis and is based in large part on the patient's history or the report of the bed partner related to nighttime activities. The International Restless Legs Study Group proposed five minimum diagnostic criteria. They are (1) desire to move the limbs, not necessarily in relation to, or accompanied by, pain or discomfort, (2) desire to move limbs, and any accompanying discomfort begins or worsens at rest, (3) desire to move limbs, and any accompanying discomfort is relieved with continuous activity, (4) desire to move limbs, and any accompanying discomfort begins or worsens at night, and (5) the presence of any of the above criteria are not uniquely attributable to a medical or psychological condition (International Restless Legs Syndrome Study Group, 2015). Generally, the patient history clearly suggests a diagnosis of RLS (Restless Legs Syndrome Foundation, 2015a). If the patient has a history of diabetes mellitus, its management may provide information to determine whether paresthesias are caused by peripheral neuropathy or RLS.

Nursing and Collaborative Management Restless Legs Syndrome

The goal of collaborative management is to reduce patient discomfort and distress and to improve sleep quality. When RLS is secondary to uremia or iron deficiency, correction of these conditions will decrease symptoms. Nonpharmacological approaches to RLS management include establishing regular sleep habits, encouraging exercise, and eliminating aggravating factors such as certain activities, alcohol, caffeine, and certain drugs (i.e., neuroleptics, lithium, antihistamines, and antidepressants) (Restless Legs Syndrome Foundation, 2015b).

If nonpharmacological measures fail to provide symptom relief, drug therapy may be started. The main drugs used in RLS are dopaminergic agents, opioids, and benzodiazepines. Dopaminergic agents such as carbidopa–levodopa (Sinemet) and DA agonists (bromocriptine, pramipexole [Mirapex]) are preferred for treating RLS. These agents are effective in managing sensory and motor symptoms.

Other agents that may be used include anticonvulsant drugs such as gabapentin (Neurontin), divalproex (Epival), lamotrigine (Lamictal), and carbamazepine (Tegretol). Clonidine and propranolol (Inderal) are also effective in some patients. While quinine sulphate has been used prophylactically and as a treatment for RLS, its use is not recommended as it has been linked with serious adverse reactions such as life-threatening hematological reactions and chronic renal failure. Opioids are usually reserved for those patients with severe symptoms who fail to respond to other drugs. When used, opioids given in low doses have also been found to be effective in reducing the symptoms associated with RLS.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) is a rare progressive neurological disorder that is characterized by loss of motor neurons and by weakness and atrophy of the muscles of the hands, the forearms, and the legs, spreading to involve most of the body and the face. ALS became known as Lou Gehrig's disease when the famous baseball player was stricken with it in the 1940s.

The Canadian incidence of ALS is about 2 of every 100 000 per year, and approximately 2 500 to 3 000 Canadians are currently living with it

(Amyotrophic Lateral Sclerosis [ALS] Society of Canada, 2015). The mortality rate of ALS is approximately 2 per 100 000 per year (ALS Society of Canada, 2015). ALS usually leads to death within 2 to 6 years after diagnosis.

For unknown reasons, motor neurons in the brain stem and spinal cord gradually degenerate in ALS. Dead motor neurons cannot produce or transport vital signals to muscles. Consequently, electrical and chemical messages originating in the brain do not reach the muscles to activate them.

The typical symptoms of ALS are limb weakness, dysarthria, and dysphagia. Muscle wasting and fasciculations result from the denervation of the muscles and lack of stimulation and use. Other symptoms include pain, sleep disorders, spasticity, drooling, emotional lability, depression, constipation, and esophageal reflux. Death usually results from respiratory tract infection secondary to compromised respiratory function. Unfortunately, there is no cure for ALS. Riluzole (Rilutek) slows the progression of ALS. This drug works to decrease the amount of glutamate (an excitatory neurotransmitter) in the brain.

The illness trajectory for ALS is devastating because the patient remains cognitively intact while wasting away. The nurse guides the patient in the use of moderate-intensity, endurance-type exercises for the trunk and limbs since this may help reduce ALS spasticity. Nursing interventions include facilitating communication, reducing risk for aspiration, facilitating early identification of respiratory insufficiency, decreasing pain secondary to muscle weakness, decreasing risk for injury related to falls, and providing diversional activities such as reading and companionship.

The patient's cognitive and emotional functions are supported, and the patient and family are helped to manage the disease process, including grieving related to the loss of motor function and ultimately death. The nurse discusses with the patient and caregiver issues such as artificial methods of ventilation and advance directives.

Huntington's Disease

Huntington's disease (HD) is a genetically transmitted, autosomal dominant disorder that affects both men and women of all races. It is characterized by chronic, devastating loss of all neurological function, resulting in a movement disorder and dementia. The offspring of a person with this disease have a 50% risk of inheriting it (see the "Genetics in Clinical Practice" box). The onset of HD is usually between 30 and 50 years

of age. Often, the diagnosis is made after the affected individual has had children. The estimated prevalence rate of HD is at 13.7 per 100 000 in the general population (Fisher & Hayden, 2013).

The diagnostic process for HD begins with a review of the family history and clinical symptoms. Genetic testing confirms the disease in a person with symptoms. People who are asymptomatic but who have a positive family history of HD face the dilemma of whether to be genetically tested. If the test is positive, the person will develop HD, but when and to what extent the disease develops cannot be determined.

Genetics in Clinical Practice

Huntington's Disease

Genetic Basis

- Autosomal dominant disorder
- Caused by HTT gene, located on chromosome 4

Incidence

- 1 in 10 000
- Higher incidence in people of European ancestry
- With each pregnancy, heterozygous affected parent has a 5% chance of having a child with HD

Genetic Testing

- DNA testing is available
- DNA testing can be done on fetal cells obtained by amniocentesis or chorionic villus sampling
- Preimplantation genetic diagnosis can be done on embryos before implantation and pregnancy
- One copy of altered gene is sufficient to cause HD
- No test is available to predict when symptoms will develop

Clinical Implications

- HD is a progressive, degenerative brain disorder
- Onset of disease usually occurs between 30 and 50 years of age
- No cure is available
- Drugs are available to control movements and behavioural problems
- Genetic counselling may be considered if there is a family history of HD
- Because HD is an autosomal dominant disorder, individuals who are at risk have a strong motivation to seek genetic testing
- A positive result is not considered a diagnosis, since it may be obtained decades before the symptoms begin
- A negative test means that the individual does not carry the mutated gene and will not develop HD

Social Networking in Huntington's Disease

- Many patients with Huntington's disease experience social isolation and depression.
- The patient should be encouraged to participate in an online community where people who have Huntington's disease discuss their condition.
- Social contact and a social network with others who have Huntington's disease will help patients deal better with their illness and improve their quality of life.

Like PD, the pathological process of HD involves the basal ganglia and the extrapyramidal motor system. However, instead of a deficiency of DA, HD involves a deficiency of the neurotransmitters ACh and γ-aminobutyric acid. The net effect is an excess of DA, which leads to symptoms that are the opposite of those of parkinsonism.

The clinical manifestations are characterized by abnormal and excessive involuntary movements (chorea) as well as psychiatric abnormalities. The chorea involves writhing, twisting movements of the face, the limbs, and the body. The movements worsen as the disease progresses. Facial movements used for speech, chewing, and swallowing are affected and may cause aspiration and malnutrition. The gait deteriorates, and ambulation eventually becomes impossible.

Psychiatric symptoms are frequently present in the early stage of the disease, often before the onset of motor symptoms. Depression is common. Other psychiatric symptoms include anxiety, agitation, impulsivity, apathy, social withdrawal, and obsessiveness. Cognitive deterioration is more variable and involves perception, memory, attention, and learning. Eventually, all psychomotor processes, including the ability to eat and talk, are impaired.

Death usually occurs within 15 years after the onset of symptoms (Huntington Society of Canada, 2013). The most common causes of death related to HD are pneumonia and suicide; however, injuries related to a fall or other complications have also been attributed to HD-related mortality (National Institute of Neurological Disorders and Stroke, 2015a).

Because there is no cure, collaborative care is palliative. The first drug of any kind approved specifically for HD is tetrabenazine (Nitoman). It is used to treat the chorea and works to decrease the amount of DA available at synapses in the brain and thus decreases the involuntary movements of chorea.

Other medications used for the movement disorder include neuroleptics such as haloperidol and risperidone (Risperdal), benzodiazepines such as diazepam (Valium) and clonazepam (Rivotril), and DA-depleting agents. Cognitive disorders are treated as needed with nondrug therapies (e.g., counselling, memory books). The psychiatric disorders can be treated with selective serotonin reuptake inhibitors such as sertraline (Zoloft) and paroxetine (Paxil). Antipsychotic medication, such as haloperidol or risperidone (Risperdal), may also be needed. Because of the choreic movements, caloric requirements are high. Patients may require as many as 5 000 calories per day to maintain body weight. As the disease progresses, meeting caloric needs becomes more challenging as the patient has difficulty swallowing and holding the head still. Depression and mental deterioration can also compromise nutritional intake. Alternative sources of nutrition may be indicated as the disease progresses.

HD presents a great challenge to health care providers. The goal of nursing management is to provide the most comfortable environment possible for the patient and the family by maintaining physical safety, treating physical symptoms, and providing emotional and psychological support. End-of-life issues should be discussed with the patient and caregiver. These include care in the home or long-term care facility, artificial methods of feeding, advance directives and cardiopulmonary resuscitation (CPR), use of antibiotics to treat infections, and guardianship.

These topics should be readdressed throughout the course of the disease as the patient and caregiver adapt to increasing disability.

Normal Pressure Hydrocephalus

Normal pressure hydrocephalus (NPH) is an abnormal increase of CSF characterized by an obstruction in the normal flow of CSF throughout the brain, spinal cord, and ventricles. NPH is a relatively uncommon disorder, and symptoms of the condition include mental impairment, dementia, urinary incontinence, and gait and balance disturbances. Meningitis, encephalitis, or head injury may cause the condition. NPH can occur at any age, although it is most common in older adults. If diagnosed early in the disease, NPH is treatable by surgery that involves a shunt insertion to divert the fluid away from the brain into the abdomen to help resolve the symptoms (National Institute of Neurological Disorders and Stroke, 2015b).

Case Study

Parkinson's Disease

Source: Air Images/Shutterstock.com.

Patient Profile

Mr. Jean Dufresne, a 79-year-old retiree, was diagnosed with Parkinson's disease 3 years ago after experiencing months of progressive tremor, rigidity, and bradykinesia. He has been taking L-dopa with carbidopa (Sinemet) since then, and his symptoms had been improving until recently. When his daughter was visiting, she noticed that he had lost

considerable weight over the past month, and his speech had become slower and difficult to understand.

Subjective Data

- Reports increasing difficulty with speech and swallowing
- Dietary intake has decreased
- Reports being constipated for 2 weeks

Objective Data

Physical Examination

- Body weight has decreased by 5 kg in 1 month.
- Gait has developed a mild shuffling and propulsive quality.
- “Pill rolling” motion and tremor are observed in both hands at rest.
- “Cogwheel rigidity” is encountered during passive range of motion exercises.

Discussion Questions

1. What is the pathogenesis of Parkinson's disease?
2. What is the likely explanation for the progression of Mr. Dufresne's condition?
3. What teaching plan should be developed for Mr. Dufresne?
4. ***Priority decision:*** What are the priority nursing interventions for Mr. Dufresne?
5. ***Priority decision:*** What are the priority nursing diagnoses based on the assessment data presented for Mr. Dufresne?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. What of the following is the nurse most likely to recognize as a symptom of a client with a migraine headache?
   a. Withdraws from stimuli
   b. Acts out with bizarre behaviour
   c. Seeks out the company of others
   d. Experiences painful facial spasms and tearing
2. What is the triad of symptoms the nurse would expect to find during assessment of the client with Parkinson's disease?
   a. Spasticity, diplopia, tremor
   b. Tremor, rigidity, bradykinesia
   c. Ataxia, drowsiness, dysarthria
   d. Diplopia, tremor, bradykinesia
3. What would the nurse expect to find during an assessment of the client with amyotrophic lateral sclerosis?
   a. Emotional lability
   b. Mental deterioration
   c. Muscle weakness and wasting
   d. Sensory loss in the extremities
4. Social effects of a chronic neurological disease include which of the following? *(Select all that apply)*
   a. Divorce
   b. Job loss
   c. Depression
   d. Role changes
   e. Loss of self-esteem
5. What is a major goal of treatment for the client with a chronic, progressive neurological disease?
   a. Reversal of pathophysiological features
   b. Total remission of the disease
   c. Continuation of usual lifestyle

d. Adaptation by client and family to the disease

1. a; 2. b; 3. c; 4. a, b, c, d, e; 5. d.

CHAPTER 62

Nursing Management

Delirium, Alzheimer's Disease, and Other Dementias

Written by, Sharon L. Lewis

Adapted by, Lynn McCleary

LEARNING OBJECTIVES

1. Describe the etiology, the pathophysiology, and the clinical manifestations of delirium.
2. Describe the diagnostic studies and the collaborative management of delirium.
3. Define dementia, and describe its effect on society.
4. Compare and contrast etiologies of different types of dementia.
5. Describe the clinical manifestations, the diagnostic studies, and the collaborative management of dementia.
6. Describe the clinical manifestations of mild cognitive impairment.
7. Describe the nursing management of patients with dementia.

KEY TERMS

amyloid plaques, p. 1569
Alzheimer's disease (AD), p. 1569
behavioural and psychological symptoms of dementia (BPSDs), p. 1572

Confusion Assessment Method, p. 1566
Creutzfeldt–Jakob disease (CJD), p. 1569
delirium, p. 1565
dementia, p. 1568
dementia with Lewy bodies (DLB), p. 1570
familial Alzheimer's disease, p. 1569
frontotemporal dementia (FTD), p. 1570
mild cognitive impairment (MCI), p. 1570
neurofibrillary tangles, p. 1569
responsive behaviours, p. 1572
self-protective behaviours, p. 1572
sundowning, p. 1578
vascular dementia, p. 1570

The three most common cognitive problems in adults are delirium, dementia, and depression. These problems often manifest with overlapping clinical features and may coexist in an older adult (O'Sullivan, Inouye, & Meagher, 2014; Gauthier, Patterson, Chertkow, et al., 2012). It is important to identify the distinguishing characteristics because the treatment for each problem is different. This chapter focuses on delirium and dementia. The reader should consult a mental health nursing textbook for additional information about depression.

Delirium

Delirium, a state of acute mental confusion, is a medical emergency. It is one of the most common life-threatening conditions in older individuals. It is preventable in 30% to 40% of cases (Inouye, Westendorp, & Saczynski, 2014). Nurses are at the front line for prevention and early detection of delirium. However, like other health care providers, nurses often fail to recognize delirium. The prevalence of delirium is highest among hospitalized older adults. More than half of hospitalized older adults develop delirium, with rates of up to 50% after fractures or surgery and 82% in the critical care unit. Rates are even higher among patients with pre-existing dementia (Inouye, Westendorp, & Saczynski, 2014). Delirium is associated with longer hospitalizations, loss of brain function, higher rates of institutionalization, and higher rates of mortality (Gage & Hogan, 2014; Inouye, Westendorp, & Saczynski, 2014).

Etiology and Pathophysiology

The pathophysiology of delirium is poorly understood and is related to multiple mechanisms. Inflammation, hypoxia, and other biological and physiological factors are thought to cause neurotransmitter imbalance, particularly acetylcholine deficiency and dopamine excess (Chaput & Bryson, 2012; Inouye, Westendorp, & Saczynski, 2014).

Delirium is usually the result of interaction between the patient's underlying condition and a precipitating event. Delirium can occur after a relatively minor insult in a vulnerable patient. For example, patients with underlying health problems such as heart failure, cognitive impairment, or sensory limitations may develop delirium after a relatively minor change (e.g., a single dose of a sleeping medication). In less vulnerable patients, it may take a combination of factors (e.g., anaesthesia, major surgery, infection, prolonged sleep deprivation) to precipitate delirium (Inouye, Westendorp, & Saczynski, 2014). Delirium can also be a symptom of a serious medical illness such as bacterial meningitis.

Knowing which factors increase vulnerability to delirium (predisposing factors) or precipitate delirium (precipitating factors) facilitates prevention of delirium and effective intervention. These factors are listed in Table 62-1.

TABLE 62-1
RISK FACTORS FOR DELIRIUM

Predisposing Factors
• Age over 75 years • Alcohol misuse • Comorbid or severe illness • Dementia • Depression • Functional impairment • History of cerebro-vascular incident • History of delirium • Pain • Sensory impairment
Precipitating Factors

• Abnormal physiological indices (i.e., electrolytes, BUN, serum urea, serum albumin)
• Bladder catheter
• Coma
• Drugs
  • Multiple drugs prescribed
  • Psychoactive drugs
  • Sedatives or hypnotics
• Iatrogenic event
• Infection
• Metabolic disturbance
• Overstimulating or understimulating environment
• Physical restraints
• Surgery
• Trauma
• Urgent admission

BUN, blood urea nitrogen.

Source: Adapted from in Inouye, S. K., Westendorp, R. G. J., & Saczynski, J. S. (2014). Delirium in elderly people [Table 2]. Lancet, 383, 911–922. doi:10.1016/S0140-6736(13)60688-1; and Tullmann, D. F., Fletcher, K., & Foreman, M. D. (2012). *Nursing standard of practice protocol: Delirium.* Retrieved from *https://consultgeri.org/geriatric-topics/delirium.*

Delirium occurs in children and adults, but older adults are at higher risk. They are more likely to have one of more of the risk factors for delirium. Normal age-related changes (see Chapter 7) limit older adults' abilities to compensate for physiological insults such as hypoxia, hypoglycemia, and dehydration and increase their susceptibility to medication-induced delirium. Patients with dementia are at risk on two fronts: Their risk for developing delirium is higher, and the probability that the delirium will be identified is lower (Morandi, Lucchi, Turco, et al., 2015).

Clinical Manifestations

The core features of delirium are as follows: (a) Disturbance of attention and of awareness of the environment; (b) a change in cognition (such as memory deficit, disorientation, language disturbance, perceptual disturbance) that is not due to neurocognitive disorder such as dementia; and (c) development of the disturbance over a short time (usually hours to days) and a tendency for it to fluctuate during the course of the day (American Psychiatric Association, 2013, p. 596).

There are three subtypes of delirium: hyperactive delirium, which is characterized by restlessness, psychomotor agitation, and hypervigilance; hypoactive delirium, which is characterized by lethargy, drowsiness, and decreased motor activity; and mixed delirium, which has features of both hypoactive and hyperactive delirium. Other common symptoms include hallucinations, illusions, disturbed sleep–wake cycle, and labile emotions (Inouye, Westendorp, & Saczynski, 2014). Hypoactive delirium is more common in older adults and is potentially more serious, because this form is often not identified. It may be overlooked because the patient is quiet, or it may be mistaken for depression.

Delirium is often mistaken for dementia. A key distinction between delirium and dementia is the *sudden* development of symptoms of delirium over a short time period. (A comparison of delirium and dementia is presented in Table 62-2.) To distinguish between dementia and delirium superimposed on dementia, the nurse may need collateral information from a reliable informant about baseline mental status and changes in cognition.

TABLE 62-2

COMPARISON OF THE CLINICAL FEATURES OF DELIRIUM, DEMENTIA, AND DEPRESSION

Feature	Delirium	Dementia	Depression
Onset	Acute	Insidious	Variable
Duration	Days to weeks	Months to years	Variable
Course	Fluctuating	Slowly progressive	Diurnal variation (worse in morning, improves during day)
Consciousness	Impaired, fluctuating	Clear until late in the course of the illness	Unimpaired
Attention and memory	Inattentiveness Poor memory	Poor memory without marked inattention	Difficulty concentrating: memory intact/minimally impaired
Affect	Variable	Variable	Depressed; loss of interest and pleasure in usual activities

Source: Canadian Coalition for Seniors' Mental Health (CCSMH). (2006). *National guidelines for seniors' mental health: The assessment and treatment of delirium* (p. 23, Table 1.1). Toronto: Author.

When effectively treated, delirium usually resolves within 4 to 7 days. However, it can recur, and it may persist for weeks to months after hospital discharge. Discharge planning should account for the safety of patients who have had an episode of delirium.

Diagnostic Studies

Delirium is diagnosed based on behavioural observation and the results of mental status examination. The **Confusion Assessment Method** is a widely used, validated screening instrument and diagnostic aid that is effective in identifying the presence of delirium. This 5- to 10-minute assessment provides a standardized method of identification of delirium (Inouye, van Dyck, Alessi, et al., 1990). Evaluation with the Confusion Assessment Method can be incorporated into routine nursing assessment. Ratings may be based on findings from a brief mental status assessment such as the Mini-Mental State Examination (MMSE; Folstein, Folstein, & McHugh, 1975, and see Table 62-9) or the Mini-Cog (Borson, Scanlan, Brush, et al., 2000). The Mini-Cog takes 3 minutes to administer. Patients repeat three words, draw a clock, and recall the three words. The ConsultGeriRN.org website includes guides for using the Confusion Assessment Method and the Mini-Cog, in addition to streaming videos demonstrating their use (see the Resources at the end of this chapter).

When delirium is diagnosed, identification and treatment of the underlying causes is urgent. The patient's history and physical examination findings, medication history, laboratory test results, additional diagnostic investigation as indicated, and environmental risk factors must be evaluated. Usual investigations include complete blood cell count; biochemistry evaluations (measurements of calcium, albumin, magnesium, phosphate, creatinine, urea, electrolytes, and glucose levels; liver function tests); thyroid function tests; blood, urine, and sputum cultures; oxygen saturation measurement; urinalysis; chest radiography; and electrocardiography (Inouye, Westendorp, & Saczynski, 2014). If meningitis or encephalitis is suspected, a lumbar puncture may be performed (see Chapter 59). If the patient's history includes head injury, appropriate radiographic examinations or scans may be ordered. Brain imaging studies such as computed tomography and magnetic resonance imaging are performed if the patient has a known or suspected head injury or brain lesion.

Nursing and Collaborative Management Delirium

The priority for nursing care is prevention of delirium. The priorities for nursing care are to identify and treat underlying cause or causes, to maintain physiological stability, and to ensure the patient's safety (Canadian Coalition for Seniors' Mental Health [CCSMH], 2006; Tullmann, Fletcher, & Foreman, 2012). Prevention involves recognition of patients at high risk for delirium (see Table 62-1) and providing care that targets each patient's risk factors. Among older adults, the five precipitating factors that are most predictive of delirium in the first 9 days of hospitalization are influenced by nursing interventions (Inouye & Charpentier, 1996):

- Use of physical restraints
- Low serum albumin levels, indicative of malnutrition
- Prescription of more than three new medications
- Use of a urinary catheter
- An iatrogenic event (e.g., cardiopulmonary complications, infections, injury, and complications caused by medications or diagnostic or therapeutic procedures)

There is strong research evidence that proactive multicomponent interventions reduce incidence of new cases of delirium and improve outcomes for patients with delirium (Tullmann, Fletcher, & Foreman, 2012). The Canadian Patient Safety Institute (2013) recommended that hospitals develop delirium management protocols and enable staff to follow them. The Hospital Elder Life Program (HELP) is a well-researched multicomponent program. It has been implemented in more than 600 hospitals, including 10 Canadian hospitals (Agency for Healthcare Research and Quality, 2014). Components of the program are listed in Table 62-3. Details about the program are available on the HELP website (see the Resources at the end of this chapter).

TABLE 62-3
COMPONENTS OF THE HOSPITAL ELDER LIFE PROGRAM (HELP)

1. Systematic screening to identify patients at risk for developing delirium
2. Tailored interventions developed by an interdisciplinary team that consists of a geriatric nurse specialist, elder life specialist, and trained volunteers. Interventions include the following:
    - Daily visit and orientation
    - Sleep deprivation prevention
    - Ambulation three times a day and minimization of immobilizing equipment (e.g., bladder catheters)
    - Visual aids
    - Hearing support
    - Avoiding dehydration
    - Preventing falls
3. Interdisciplinary rounds twice a week
4. Geriatrician and interdisciplinary team consultations
5. Community liaison and postdischarge telephone follow-up

Source: Agency for Healthcare Research and Quality. (2014). *Hospital-based program proactively identifies, addresses delirium risk factors in elderly, leading to less cognitive/functional decline and lower nursing home costs.* Retrieved from *https://innovations.ahrq.gov/profiles/hospital-based-program-proactively-identifies-addresses-delirium-risk-factors-elderly*.

Additional strategies to eliminate or minimize risk factors are listed in Table 62-4. It is important to maintain physiological stability. Many drugs can contribute to delirium. Categories of drugs to use with caution are neuroleptic antipsychotics, anticholinergics, H_2-blocking agents, analgesics, sedative hypnotics, antipsychotics, and dihydropyridine calcium channel blockers (Clegg & Young, 2011; Inouye, Westendorp, & Saczynski, 2014). The publication concerning inappropriate use of medication in older patients (American Geriatrics Society 2015 Beers Criteria Update Expert Panel, 2015) is a good tool for reviewing medications. Resources for using it are available on the American Geriatrics Society website (see the Resources at the end of this chapter).

TABLE 62-4

STRATEGIES TO ELIMINATE OR MINIMIZE RISK FACTORS FOR DELIRIUM

• Adequate nutrition • Assessment and treatment of pain • Judicious use of medication, elimination of nonessential medication, use of the lowest possible dose, avoidance of medications that contribute to delirium • Maximal oxygen delivery • Prevention and prompt treatment of dehydration and electrolyte imbalance • Prevention and prompt treatment of infections • Regulation of bowel and bladder function • Use of sensory aids

Source: Adapted from Tullmann, D. F., Fletcher, K., & Foreman, M. D. (2012). *Nursing standard of practice protocol: Delirium.* Retrieved from *https://consultgeri.org/geriatric-topics/delirium;* and Regional Geriatric Program of Toronto. (2014). *Preventing and managing delirium.* Retrieved from *https://consultgeri.org/geriatric-topics/delirium.*

Adequate pain management is important because undertreated pain significantly increases risk for delirium. However, analgesics, too, can increase risk for delirium. Thus interventions that minimize the use of opioids are recommended; these interventions include the following (Barr, Fraser, Puntillo, et al., 2013):

- Use of nonpharmacological pain management approaches
- Use of nonopioid analgesics as an adjunct to reduce the dose of opioids
- When opioids are needed, use of the minimum effective dose for the shortest appropriate time

Strategies to provide a therapeutic environment for patients with delirium or who are at risk for delirium are provided in Table 62-5. Frequent assessment is required. Mental status should be assessed every shift for patients who have delirium or are at risk for delirium. Close observation is required, especially for patients with hyperactive delirium. Invasive procedures should be minimized (Tullmann, Fletcher, & Foreman, 2012).

TABLE 62-5

THERAPEUTIC ENVIRONMENT FOR PATIENTS WITH DELIRIUM OR RISK FOR DELIRIUM

Strategy	Examples
Foster orientation	• Explanation of all activities • Frequent reassurance and orientation (unless this causes agitation), avoiding confrontation about delusional beliefs • Use of hearing aids and glasses • Visible calendars, clocks, and staff identification
Provide appropriate stimulation	• Adequate light • Music as preferred by the patient • Noise reduction • One task at a time • Quiet room
Facilitate sleep	• Back massage, warm milk, or herbal tea at bedtime • Noise reduction strategies (e.g., vibrating beepers) • Plan care to avoid waking the patient • Provide light during the day and reduce light at night • Relaxation music
Foster familiarity	• Bring familiar objects from home • Encourage family or friends to stay with patient • Minimize relocation • Provide consistent nursing staff
Maximize mobility	• Ambulate or provide range-of-motion exercises three times a day • Avoid bladder catheters • Avoid restraints
Communicate clearly	• Convey warmth, kindness, and calmness • One question or direction at a time • Simple explanations
Reassure and educate patient and family	• Acknowledge emotions • Manage stigma • Provide post-delirium education • Provide written and verbal information and education about delirium and family role in management • Use distraction

(2006). *National guidelines for seniors' mental health: The assessment and treatment of delirium.* Toronto: Author; and Tullmann, D. F., Fletcher, K., & Foreman, M. D. (2012). *Nursing standard of practice protocol: Delirium.* Retrieved from https://consultgeri.org/geriatric-topics/delirium.

Drug Therapy

Drug therapy is reserved for patients with severe agitation, especially when agitation interferes with needed medical therapy (e.g., fluid replacement, intubation) or presents a danger. Antipsychotics (neuroleptic agents) are the recommended drug therapy. Haloperidol, the first-line treatment, is started with low doses (0.25–0.5 mg once or twice a day) and slowly titrated upwards if necessary. Adverse effects of haloperidol include sedation; hypotension; extrapyramidal drug effects, including

tardive dyskinesia (involuntary muscle movements of face, trunk, and arms) and athetosis (involuntary writhing movements of the limbs); muscle tone changes; and anticholinergic effects. Newer antipsychotics, including risperidone (Risperdal), olanzapine (Zyprexa), and quetiapine (Seroquel), may be used. Although these drugs produce fewer adverse effects than does haloperidol, the adverse effects are significant; antipsychotics may worsen the delirium. Close monitoring is required. Drug therapy should be limited to the shortest time needed to manage the symptoms. Benzodiazepines (e.g., lorazepam [Ativan]) are contraindicated, except for treatment of delirium caused by withdrawal from either alcohol or sedative-hypnotics (Gage & Hogan, 2014).

Dementia

Dementia is a collection of symptoms caused by various diseases affecting the brain. Cognitive functioning in multiple areas declines progressively. In addition to impairing memory, dementia affects the individual's judgement, reasoning, and abilities to communicate, to carry out purposeful movements, and to recognize common objects and familiar people. Mood and behaviour are commonly affected. Ultimately, these problems lead to inability to work, carry out social and family responsibilities, and perform activities of daily living (ADLs). The multiple effects on cognition and slow gradual decline differentiate dementia from delirium, which has a sudden onset.

In Canada, approximately 564 000 people are living with dementia, and this number is expected to nearly double in the next 15 years (Alzheimer Society of Canada, 2017). Dementia occurs most often in older adults. Among those between the ages of 65 and 69 years, the prevalence is 2.4%. Prevalence rises with increasing age, up to 21.7% of people older than 85 (Prince, Bryce, & Albanese, 2013).

The cost of dementia in Canada is high. In 2011, family members and friends provided approximately 19.2 million hours of informal unpaid caregiver time to people with dementia, and this number is expected to double by 2031 (Alzheimer Society of Canada, 2016a). The estimated economic value of informal care is almost $1.2 billion per year. The economic burden of dementia, including health care costs and indirect costs (e.g., lost wages and lost productivity) is approximately $33 billion per year (Alzheimer Society of Canada, 2016a).

As the average human lifespan increases and the baby boom generation ages, the number of people affected with dementia is growing. By 2040, the total annual cost of dementia is projected to be $293 billion (Senate Canada, 2016).

The four most common types of dementia are Alzheimer’s disease (approximately 60% to 80% of cases), vascular dementia (approximately 10% of cases), dementia with Lewy bodies, and frontotemporal dementia (Alzheimer’s Association, 2015). Mixed dementia, in which more than one type of dementia is present, occurs in approximately 10% of cases of dementia (Chertkow, 2008). Dementia is also part of the later stages of Parkinson's disease and Huntington's disease. Moreover, in individuals with Down syndrome, the incidence of Alzheimer’s disease is three to five times greater than in the general population (Alzheimer Society of

Canada, 2016b). Another type of dementia is caused by **Creutzfeldt–Jakob disease (CJD),** a very rare, fatal, infectious brain disorder thought to be caused by accumulation in the brain of an abnormally folded prion protein.

Etiology and Pathophysiology

In a small number of patients, dementia symptoms are secondary to a treatable condition such as delirium, depression, subdural hematoma, cerebral tumours, normal-pressure hydrocephalus, heavy metal neurotoxicity, Wilson's disease, and infections such as bacterial meningitis and viral encephalitis. The diagnostic workup for dementia includes ruling out other causes of cognitive impairment (Lee, Weston, Heckman, et al., 2013).

Dementia is not a normal part of aging. Old age and family history are risk factors for the four most common types of irreversible dementias. There are more women than men who have dementia because women have a longer life expectancy and may have different gender-related protective factors, such as access to education (Mielke, Vemuri, & Rocca, 2014). Indigenous Canadians are at higher risk for dementia than are non-Indigenous Canadians, and they are likely to be younger when they develop dementia. This may be related to social determinants of health and to physiological risk factors such as diabetes and hypertension. Among Indigenous Canadians, men are more likely than women to have dementia (Jacklin, Walker, & Shawande, 2013). Etiology and pathophysiology of each of the most common types of dementia are described separately as follows.

Alzheimer's Disease.

Alzheimer's disease (AD) is a chronic, progressive, degenerative disease of the brain. The exact etiology of AD is unknown. As in other forms of dementia, age is the most important risk factor for developing AD. Only a small percentage of people younger than 60 years develop AD. When AD develops in someone younger than 60 years old, it is referred to as **familial Alzheimer's disease** (also known as *early-onset AD*). AD that begins after age 60 is called *late-onset AD.* Early-onset AD has a stronger genetic basis than does late-onset AD (see the Genetics in Clinical Practice box). The pathogenesis is similar in both forms of AD.

Genetics in Clinical Practice

Alzheimer's Disease (AD)

Genetic Basis

Early Onset (Familial; Age <60 Years at Onset)

- Autosomal dominant disorder
- Various mutations in the following genes:
    - Amyloid precursor protein gene on chromosome 21
    - Presenilin-1 *(PSEN1)* gene on chromosome 14
    - Presenilin-2 *(PSEN2)* gene on chromosome 1

Late Onset (Sporadic; Age >60 Years at Onset)

- Genetically more complex than early-onset form
- Apolipoprotein E-4 *(ApoE-4)* allele on chromosome 19 increases the likelihood of developing AD.
- Presence of apolipoprotein E-2 allele is associated with a lower risk of AD

Incidence

Early Onset

- Rare form of AD, accounting for <5% of cases
- Fifty percent risk of disease for children of affected parents
- May occur in people as young as 30 years old

Late Onset

- *ApoE-4* is present in approximately 40% of people with late-onset AD. (It is present in 25%–30% of normal population.)
- Many people with *ApoE-4* do not develop AD, and many people without *ApoE-4* people do.

Genetic Testing

Early Onset

- Genetic screening for mutations on chromosomes 1, 14, and 21 is available.

Late Onset

- Blood test can identify which *ApoE* allele a person has but cannot predict whether the person will develop the disease.*
- *ApoE* testing is used mainly in research to identify people who may have an increased risk of developing AD.

Clinical Implications

- Genetic testing and counselling for family members of patients with early-onset AD may be appropriate.
- If the test for *ApoE-4* yields positive results, it does not mean that the person will develop AD.

**ApoE* testing is useful for studying AD risk in large groups of people but not for determining an individual's specific risk.

Knowing the modifiable risk factors for AD means that nurses can advise individuals about how to reduce their risk of developing AD. Table 62-6 lists risk factors for AD. Mild cognitive impairment, discussed later in this chapter, is a risk factor for developing AD. More research is needed about the following possible risk factors: low education level, low socioeconomic status, smoking, and excessive alcohol consumption (Alzheimer Society of Canada, 2014). More information is available in the *Brain Health* section of the Alzheimer Society of Canada website (listed in the Resources at the end of this chapter).

TABLE 62-6
ALZHEIMER'S DISEASE

Modifiable Risk Factors	Reducing Risk
Medical conditions • Type 2 diabetes • Stroke and transient ischemic attack • Hyperlipidemia • Hypertension • Obesity • Chronic inflammatory conditions (e.g., arthritis)	• Healthy lifestyle choices to reduce the risk of developing these conditions (maintaining healthy weight, regular physical activity, healthy balanced diet, not smoking, stress management) • Appropriate treatment when such conditions are present
Head injury	• Use of recreational/sport helmets
History of clinical depression	• Identification and appropriate treatment of depression • Healthy lifestyle choices and appropriate support for traumatic experiences and stressful life events (may reduce risk for depression)
Inadequate intellectual stimulation	• Active social life • Participation in intellectual activities (reading, playing cards, solving puzzles, playing chess, learning new skills, hobbies)

Sources: Alzheimer Society of Canada. (2014). *Risk factors.* Retrieved from *http://www.alzheimer.ca/en/About-dementia/Alzheimer-s-disease/Risk-factors*; and Alzheimer Society of Canada. (2017). *Brain health.* Retrieved from *http://www.alzheimer.ca/en/About-dementia/Brain-health.*

Characteristic findings of AD are related to changes in the brain's structure and function: (a) amyloid plaques, (b) neurofibrillary tangles, and (c) loss of connections between cells, as well as cell death (National Institute on Aging, 2017). Figure 62-1 depicts the pathological changes in AD.

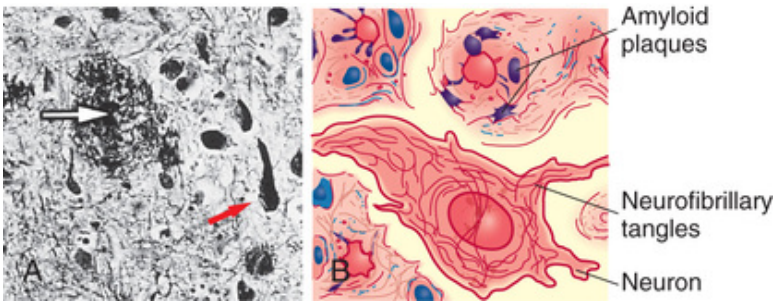

FIGURE 62-1 Pathological changes in Alzheimer's disease. **A,** Senile plaque with central amyloid core *(white arrow)* next to a neurofibrillary tangle *(red arrow)* on the histological specimen from a brain autopsy. **B,** Schematic representation of neuritic plaque and neurofibrillary tangle. Source: **A,** From Damjanov, I., & Linder, J. (Eds.). (1996). *Anderson's pathology* (10th ed.). St. Louis: Mosby.

In AD, **amyloid plaques** are present in the brain in abnormal quantities. These plaques consist of clusters of insoluble deposits of a protein called *beta-amyloid,* other proteins, remnants of neurons, non-nerve cells such as microglia (cells that surround and digest damaged cells or foreign substances), and other cells, such as astrocytes. Beta-amyloid is cleaved from amyloid precursor protein, which is associated with the cell membrane (Figure 62-2). The normal function of amyloid precursor protein is unknown. In AD, plaques develop first in areas of the brain used for memory and cognitive function, including the hippocampus (a structure that is important in forming and storing short-term memories). Eventually, AD attacks the cerebral cortex, especially the areas responsible for language and reasoning.

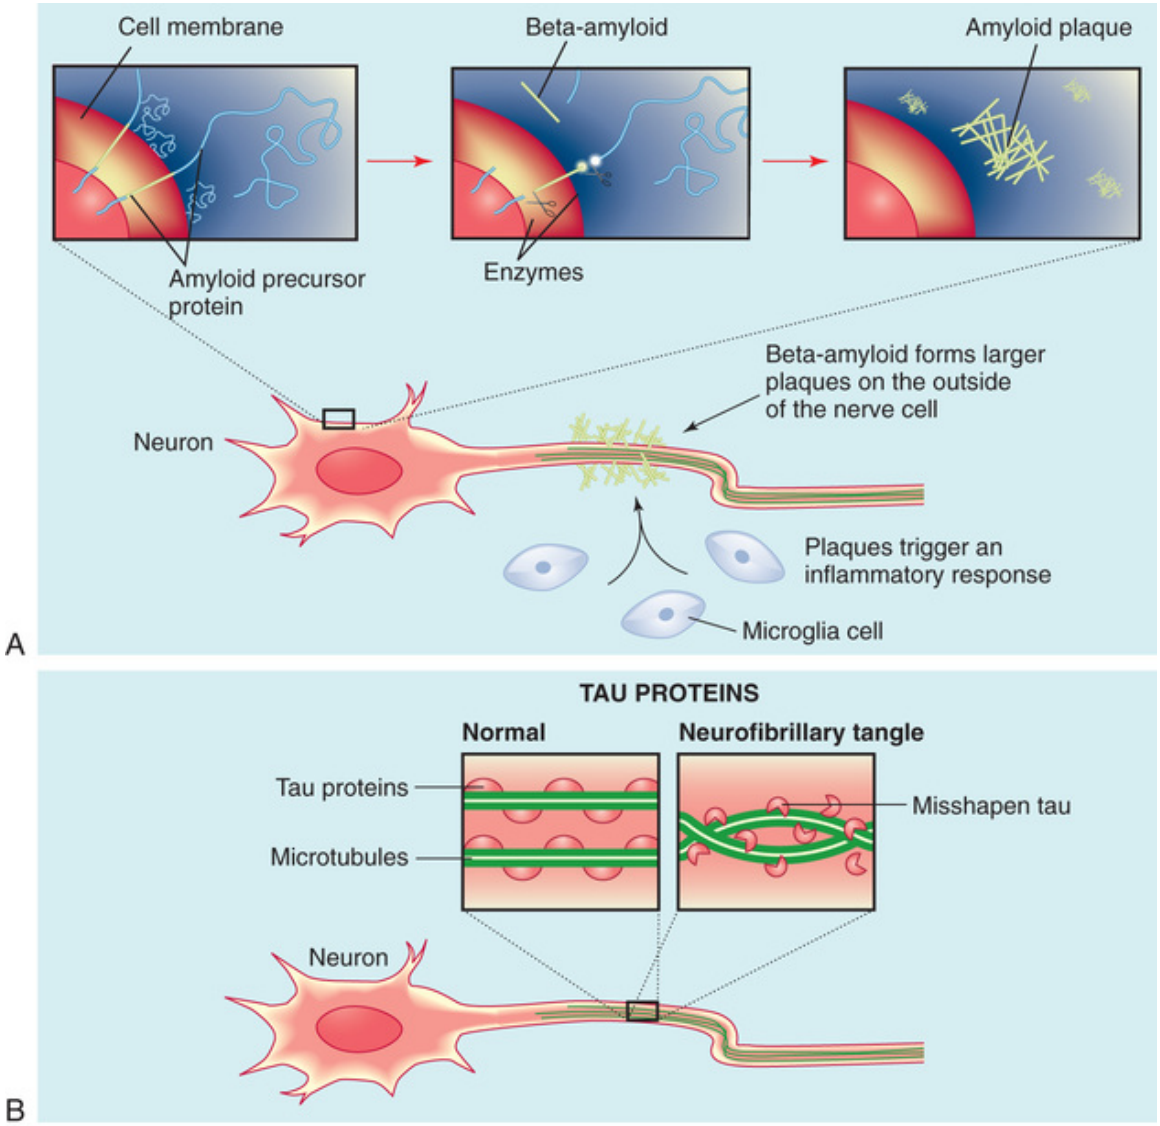

FIGURE 62-2 Current etiological theories for the development of Alzheimer's disease. **A,** Abnormal amounts of beta-amyloid are cleaved from the amyloid precursor protein (APP) and released into the circulation. The beta-amyloid fragments clump together to form plaques that attach to the neuron. Microglia react to the plaque, and an inflammatory response results. **B,** Tau proteins provide structural support for the neuron microtubules. Chemical changes in the neuron produce structural changes in tau proteins. This results in twisting and tangling of the microtubules (neurofibrillary tangles).

Neurofibrillary tangles are abnormal collections of twisted protein threads inside nerve cells seen in the areas of the brain most affected by AD. The main component of these structures is a protein called *tau*. Tau proteins in the central nervous system are involved in intracellular structure through their support of microtubules. Tau proteins hold the

microtubules together. In AD, the tau protein is altered in a way that causes the microtubules to twist together in a helical manner (see Figure 62-2). This twisting ultimately forms the neurofibrillary tangles observed in the neurons of persons with AD.

Plaques and neurofibrillary tangles are not unique to patients with AD. They are also found in the brains of individuals without evidence of cognitive impairment. However, they are more plentiful in the brains of individuals with AD.

The third feature of AD is the gradual loss of connections between neurons. This process leads to damage and then death of the neurons. Affected parts of the brain begin to shrink in a process called *brain atrophy.* By the final state of AD, brain tissue has shrunk significantly (Figure 62-3).

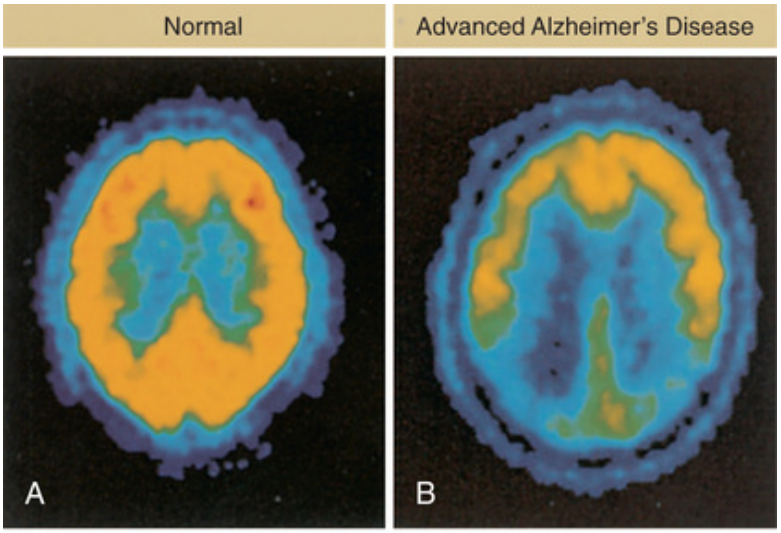

FIGURE 62-3 The effects of Alzheimer's disease on the brain, shown by positron emission tomography (PET). In PET, radioactive fluorine is applied to glucose (fluorodeoxyglucose), and the yellow areas indicate metabolically active cells. **A,** A normal brain. **B,** Advanced AD, evidenced by hypometabolism that indicates cell death in many areas of the brain. Source: From Stuart, G. W. (2009). *Principles and practice of psychiatric nursing* (9th ed., p. 398, Figure 22-4, *A* & *D*). St. Louis: Mosby.

A short video, *How Alzheimer's Changes the Brain,* illustrating and explaining the pathology of AD, is available at the National Institute on Aging website (see the Resources at the end of this chapter).

Cholinergic neurons are lost in people with AD, particularly in regions essential for memory and cognition. Other neurotransmitter systems, including serotonin and norepinephrine, also show losses over time in

patients with AD. Such neurotransmitter changes are the basis of current drug therapies for AD.

Genetic factors may play a critical role in how the brain processes the beta-amyloid protein. Overproduction of beta-amyloid appears to be an important risk factor for AD. Abnormally high levels of beta-amyloid cause cell damage either directly or by eliciting an inflammatory response and ultimately neuron death. Understanding why neurons produce beta-amyloid led researchers to examine the enzymes (and their genes) that are responsible for both the synthesis and processing of amyloid precursor protein. In patients with early-onset AD, mutations in three genes have been identified as causing brain cells to overproduce beta-amyloid (Wu, Rosa-Neto, & Hsiung, et al., 2012). (See the Genetics in Clinical Practice box on Alzheimer's disease, earlier in this chapter.)

Vascular Dementia.

Vascular dementia, also called *multi-infarct dementia,* is a type of dementia that results from ischemic, ischemic-hypoxic, or hemorrhagic brain damage caused by cardiovascular disease. When these events occur, blood and oxygen supply to brain tissues is blocked, which results in cell death. Vascular dementia may be caused by a single stroke (infarct) or by multiple strokes. As with AD, risk for vascular dementia increases with older age. Other risk factors are smoking, hypertension, cardiac diseases, diabetes mellitus, hypercholesterolemia, coronary artery disease, and atrial fibrillation.

Dementia With Lewy Bodies.

Dementia with Lewy bodies (DLB) is characterized by the presence of Lewy bodies (deposits of alpha-synuclein protein) in the brainstem, amygdala, and cortex. The alpha-synuclein protein is also linked to dementia in Parkinson's disease. DLB has features of both AD and Parkinson's disease (changes in thinking and reasoning, confusion, memory loss, balance problems, and muscle rigidity). Men are at higher risk for developing it than are women (Alzheimer Society of Canada, 2016c).

Frontotemporal Dementia.

Frontotemporal dementia (FTD) is characterized by degeneration of the frontal lobe, temporal lobe, or both. Nerve cells die because of abnormal

accumulation of proteins in the neurons. The proteins most commonly found are ubiquitin and transactive response DNA binding protein 43 (TDP-43). Tau proteins are present in approximately 40% of cases. Approximately 10% of patients with FTD have an inherited form of the disorder, and 40% have a family history of FTD. The typical age at onset is between 50 and 60 years (Association for Frontotemporal Degeneration, 2012).

Clinical Manifestations

The onset of symptoms of dementia is usually insidious and gradual, with progressive deterioration. Vascular dementia, however, may have a sudden onset after a cerebro-vascular event. In vascular dementia, mental decline is typically stepwise: Deterioration is followed by stabilization, then deterioration again. The rate of deterioration in AD is highly variable from individual to individual, and the course ranges in duration from 3 to 20 years.

AD may be preceded by **mild cognitive impairment (MCI).** MCI is cognitive decline that is not severe enough to interfere with ADLs. The diagnosis of MCI is made in the presence of several conditions: (a) evidence of change in cognition; (b) objective evidence of impairment in memory or another cognitive domain; (c) preservation of the ability to independently perform ADLs and instrumental ADLs; and (d) the absence of dementia or medical condition that explains the symptoms (Albert, DeKosky, Dickson, et al., 2011). The origin of MCI—whether it is a precursor to AD, a heterogeneous condition with several possible causes, including AD, or a separate clinical condition—is a subject of controversy. Many patients with MCI eventually develop dementia. Between 5% and 10% of people who have MCI develop dementia within a year of the onset of MCI (Peterson, 2011).

The symptoms of dementia can be classified according to the *seven* A*s of dementia* (Alzheimer Society of York Region, 2016): **a**nosognosia, **a**gnosia, **a**phasia, **a**praxia, **a**ltered perception, **a**mnesia, and **a**pathy (Table 62-7). By recognizing these symptoms, the nurse can understand why and how dementia affects the patient's ability to function. These symptoms are common, but patients with dementia do not necessarily exhibit all of them.

TABLE 62-7
THE SEVEN *A*s OF DEMENTIA

Deficit	Definition	Possible Effects on Behaviour
Amnesia	Initially loss of recall of recent events but eventually loss of long-term memory	• Repeated questions • Disorientation • Misplaces items
Aphasia	Loss of ability to express and comprehend spoken and written language	• Social withdrawal • Loss of ability to communicate in a second language • Misunderstandings • Inability to communicate needs
Agnosia	Inability to recognize common objects or faces of familiar people (including one's own face)	• Using wrong objects • Suspiciousness • Mistaking self in the mirror for someone else
Apraxia	Loss of ability to initiate purposeful movement	• Difficulty understanding terms such as *back, front, up,* and *down* • Difficulty performing activities of daily living • Inability to perform previously learned tasks
Altered perception	Misinterpretation of sensory information, loss of depth perception, visual distortions	• Fear when walking down stairs or sitting down • Misinterpreting objects • Bumping into things • Falls
Apathy	Loss of drive or initiative	• Sitting in one place for long periods of time • Inability to initiate conversation or activities, but participation when invited by someone else
Anosognosia	Loss of ability to realize that there is a problem with memory and functioning	• Resistance to care • Self-protective behaviours • Irritability

(2016). *Seven A's of dementia.* Retrieved from *http://www.alzheimer.ca/en/york/About-dementia/What-is-dementia/Seven-A-s-of-dementia;* and from Mount Sinai Hospital. (2013). *Non-pharmacological assessment and management of behavioural and psychological symptoms of dementia in primary care.* Retrieved from *https://www.mountsinai.on.ca/care/psych/patient-programs/geriatric-psychiatry/prc-dementia-resources-for-primary-care/dementia-toolkit-for-primary-care/responsive-behaviours-in-dementia/non-pharmacological-assessment-and-management-of-behavioural-and-psychological*.

The initial changes of dementia may be difficult to recognize. Many people mistakenly think that they are part of normal aging. It can take up to 4 years after the onset of symptoms until patients and their family members seek health care. Reasons for this delay include lack of knowledge about dementia, lack of knowledge about services for dementia, attributing the changes to normal aging, and stigma (McCleary, Persaud, Hum, et al., 2012).

As time goes on, the dementia affects more areas of the brain. Cognitive abilities and functioning are progressively lost. Clinical manifestations of dementia are classified as mild, moderate, and severe, corresponding to the early, middle, and late stages of the disorder (Table 62-8).

TABLE 62-8
CLINICAL MANIFESTATIONS OF DEMENTIA

Early (Mild)
• Anxiety • Confusion about location of familiar places (may become lost) • Difficulty finding the right word • Difficulty recognizing what numbers mean, trouble handling money and paying bills • Loss of initiative and interests • Mild forgetfulness and misplacing items • Poor judgement • Short-term memory impairment, especially for learning new information • Taking longer than usual to accomplish daily tasks
Middle (Moderate)
• Anxiety, mood swings, suspiciousness, jealousy, irritability • Difficulty completing tasks that involve a sequence of steps; interference with activities of daily living • Difficulty learning new things or coping in new and unexpected situations • Difficulty recognizing family members and friends • Difficulty with language and understanding, and problems with reading, writing, and working with numbers • Difficulty with logic and organizing thoughts • Flat affect • Hallucinations and delusions • Impaired attention • Increasing memory loss, including some loss of remote memory • Loss of impulse control (e.g., undressing at inappropriate times or places, vulgar language) • Loss of interest in hygiene • Loss of remote memory • Poor insight and decision making, need for supervision and cuing • Sleep disturbances • Wandering, getting lost
Late (Severe)
• Behaviours that may appear aggressive (verbal [e.g., swearing, screaming, shouting, making threats] or physical [e.g., hitting, pinching, scratching hair-pulling, biting]) but are communicating a need (relief from, e.g., physical discomfort, social isolation, lack of stimulation, emotional distress, confusion, frustration) • Difficulty eating, swallowing • Hallucinations, delusion, agitation • Inability to perform self-care activities • Inability to understand words • Incontinence • Loss of appetite and weight loss • Loss of most memories, inability to process new information • Loss of social skills • Progression to loss of facial expression, primitive reflexes, loss of voluntary movement, loss of speech, recurrent infections • Repetitious words or sounds • Responding to short, simple communication • Seizures • Sexual disinhibition

(2010). *Clinical stages of Alzheimer disease*. Retrieved from *http://geropsychiatriceducation.vch.ca/docs/edu-downloads/dementia/clinical_stages_CPS-MMSE_comparison.pdf.*

The early clinical manifestations of FTD differ from those of AD because FTD initially affects the frontal lobe, temporal lobe, or both lobes of the

brain. Eventually, all areas of the brain are involved diffusely, and the symptoms resemble those of AD. Early in the course of FTD, social conduct and personality are profoundly altered, but little memory loss is evident (UCSF Memory and Aging Center, 2016). Behavioural symptoms include personality changes, blunted emotions, lack of insight, apathy, hyperorality (putting objects in the mouth), hoarding, compulsions and complex rituals, disinhibition, and socially inappropriate behaviour. If the temporal lobe is affected first, the patient experiences problems with speech and language, including loss of knowledge of the meanings of words and objects (Bott, Radke, Stephens, et al., 2014).

Like those of FTD, the early clinical manifestations of DLB differ from those of AD. Patients with DLB have symptoms of Parkinson's disease: In addition to symptoms of dementia, they have least two of the following symptoms: (a) extrapyramidal signs such as bradykinesia, rigidity, and postural instability, but not always a tremor; (b) fluctuating cognitive ability; and (c) hallucinations (McKeith, Dickson, Lowe, et al., 2005). Swallowing problems can lead to impairment in nutrition. Affected patients are at risk for falls because of impaired mobility and balance. Pneumonia is a common complication.

Behavioural and Psychological Symptoms of Dementia.

Some of the clinical manifestations of dementia are called **behavioural and psychological symptoms of dementia (BPSDs).** Behavioural symptoms include appetite changes, slowed or excessive movements and speech, agitation, pacing, wandering, exit seeking, constant requests for help, grabbing on to people, cursing, screaming, socially inappropriate behaviours, sexual disinhibition, and hoarding. Psychological symptoms include anhedonia (loss of pleasure from activities that are usually pleasurable), worry, depressed mood, euphoria, fear, apprehension, panic, tension, irritability, labile mood, psychosis (hallucinations, delusions, illusions), and sleep disturbances (Cerejeira, Lagarto, & Mukaetova-Ladinska, 2012; Murray Alzheimer Research and Education Program [MAREP] & Alzheimer Societies of Hamilton & Halton, Brant, Haldimand-Norfolk, & Niagara Regions, 2006). BPSDs cause distress to patients and negatively affect their functioning. BPSDs are caused by a combination of biological factors (e.g., changes in brain functioning, medical conditions, pain, adverse effects of medication, hearing or visual impairment), environmental factors (e.g., changes in routine, changes in environment),

and social factors (e.g., inadequate support for the patient or family caregiver). These behaviours may be mistakenly interpreted. For example, the grasp reflex may appear in patients in middle to late stages because of frontal lobe damage. Reflexive grasping of care providers or objects on contact may be misinterpreted as intentional. Dementia affects patients' abilities to communicate. Sometimes, BPSDs are the only way in which the affected person can communicate an unmet need. These behaviours are often responses to something in the patient's environment **(responsive behaviours)** or to a perceived threat (**self-protective behaviours;** MAREP et al., 2006; Pizzacalla, Montemuro, Coker, et al., 2015).

Safety Alert

A sudden change in behaviour should trigger a search for underlying causes, including possible delirium.

Diagnostic Studies

Canadian Consensus Conferences on the Diagnosis and Treatment of Dementia produced comprehensive recommendations for diagnosis of dementia (Feldman, Jacova, Robillard, et al., 2008; Gauthier, Patterson, Chertkow, et al., 2012). The process includes making a clinical diagnosis based on the history, interviews with the patient and a caregiver or family member, physical examination, and brief cognitive tests. The next step in the process is laboratory tests to identify treatable medical conditions. Neuropsychological testing and neuroimaging are performed only when certain symptoms are present. Routine laboratory tests include complete blood cell count and measurements of thyroid-stimulating hormone; serum electrolytes; and serum calcium, serum fasting glucose, and serum vitamin B_{12} levels. Measurements of serum folic acid or red blood cell folate levels are optional. Neuropsychological testing may assist with differentiating among normal aging, MCI, and dementia (Feldman, Jacova, Robillard, et al., 2008). Neuroimaging studies (computed tomography or magnetic resonance imaging) are recommended if the patient has one or more of the following characteristics: age younger than 60 years; rapid decline in cognition over 1 to 2 months; less than 2 years' duration of symptoms; recent head trauma; unexplained neurological symptoms; history of cancer that could metastasize to the brain; use of anticoagulants or bleeding disorder; urinary incontinence and gait disorder early in the

course of the dementia; localizing neurological signs (e.g., hemiparesis); atypical cognitive symptoms; or gait disturbance. None of the diagnostic procedures can identify whether the underlying pathological change in the brain is present (e.g., plaques and tangles in AD). This determination can be made only by microscopic examination of brain tissue after the person dies. If MCI is diagnosed, annual monitoring of symptoms and functioning is recommended (Gauthier, Patterson, Chertkow, et al., 2012).

Related Assessments.

Mental status testing is an important component of assessment. Patients with mild dementia may be able to compensate, which makes it difficult to evaluate cognitive function through conversation alone. Cognitive testing is focused on evaluating memory, attention, ability to perform calculations, language, visuospatial skills, and degree of alertness. The Mini-Mental State Examination (MMSE; Folstein, Folstein, & McHugh, 1975) is the most commonly used tool for brief assessment of cognitive functioning (Table 62-9). It cannot be used to diagnose dementia, but it is useful for monitoring change over time. However, the MMSE is not sensitive to very early stages of dementia and MCI. The Montreal Cognitive Assessment (MoCA) is a brief cognitive screening tool that has good sensitivity for detecting early dementia (Nasreddine, Phillips, Bédirian, et al., 2005).

The ConsultGeriRN.org website includes two-page *Try This* summaries of research about three additional mental status assessment tools for nurses, copies of the tools, articles about how to use them, and videos that demonstrate and explain how to use them. These tools include the Mini-Cog (Borson, Scanlan, Brush, et al., 2000), a brief screening tool for dementia; the Brief Evaluation of Executive Dysfunction (Kennedy, 2012); and the Recognition of Dementia in Hospitalized Older Adults tool (Mezey & Maslow, 2016).

Depression is often mistaken for dementia in older adults, and conversely, dementia for depression. Manifestations of depression include excessive sadness, difficulty thinking and concentrating, fatigue, apathy, feelings of despair, and inactivity. When the depression is severe, concentration and attention may be poor, which manifests as memory and functional impairment. When dementia and depression do occur together (which may be the situation in as many as 40% of dementia cases), the intellectual deterioration may be more extreme. Depression, alone or in combination with dementia, is treatable. The challenge is to make an early assessment. Information about how to use the Geriatric Depression Scale (Sheikh & Yesavage, 1986), a short screening instrument for depression in older adults, is available on the ConsultGeriRN.org website (see the Resources at the end of this chapter).

Risk Modification

Many of the risk factors for AD and vascular dementia are modifiable. Individuals who reduce their risk for cardiovascular disease also reduce their risk for vascular dementia. Table 62-6 lists strategies to reduce risk for AD. In a landmark report titled *Rising Tide,* the Alzheimer Society of Canada (2010) showed that national programs to reduce risk of developing dementia are needed. Preventing dementia or delaying its onset would reduce the economic burden of dementia. The *Rising Tide* report demonstrated that a program to increase physical activity in older Canadians would reduce the incidence of dementia and reduce the total economic burden of dementia by $5.6 billion over 10 years and $51.8 billion over 30 years. The report also recommended implementing a comprehensive prevention program targeting all Canadians aged 65 and older. This could reduce risk of developing dementia by 23%, which would result in fewer new cases of dementia, delayed onset of dementia, and lower prevalence of dementia. It would reduce the economic burden of dementia by $24.2 billion over 10 years and $218.6 billion over 30 years.

Collaborative Care

There is no cure for any of the forms of dementia. The goals of collaborative management of dementia are to slow decline in cognition; to maintain and maximize functioning and quality of life of the person with dementia; and to support family caregivers.

Drug Therapy.

Drugs used for dementia do not cure or reverse the progression of the disease. They may slow decline, but the effects are modest (Lee, Hsiung, Seitz, et al., 2011). AD is the only form of dementia for which drugs that affect cognitive decline are approved by Health Canada. However, some experts recommend prescribing these drugs for dementia associated with Parkinson's disease as well (Gauthier, Patterson, Chertkow, et al., 2012). There are no medications that slow cognitive decline in other types of dementia. Drug therapy for AD is listed in Table 62-10.

TABLE 62-10

DRUG THERAPY
Alzheimer's Disease

Problem	Drugs
Decreased memory and cognition	Cholinesterase inhibitors • Donepezil (Aricept) • Galantamine (Reminyl) • Rivastigmine (Exelon) *N*-Methyl-D-aspartate (NMDA) receptor antagonist • Memantine (Ebixa)
Depression	Selective serotonin reuptake inhibitors • Citalopram (Celexa) • Sertraline (Zoloft) Serotonin modulator • Trazodone
Behavioural symptoms	Atypical antipsychotics (neuroleptic agents) • Olanzapine (Zyprexa) • Risperidone (Risperdal) • Aripiprazole (Abilify)

Cholinesterase inhibitors block cholinesterase, the enzyme responsible for the breakdown of acetylcholine in the synaptic cleft (Figure 62-4). Cholinesterase inhibitors include donepezil (Aricept), rivastigmine (Exelon), and galantamine (Reminyl). These drugs may stabilize or improve cognitive function in AD and enhance the patient's functional abilities. Cholinesterase inhibitors increase risk for bradycardia and

syncope—and associated falls (Herrmann, Black, Li, et al., 2011). The bradycardia may be difficult to detect because it is often transient.

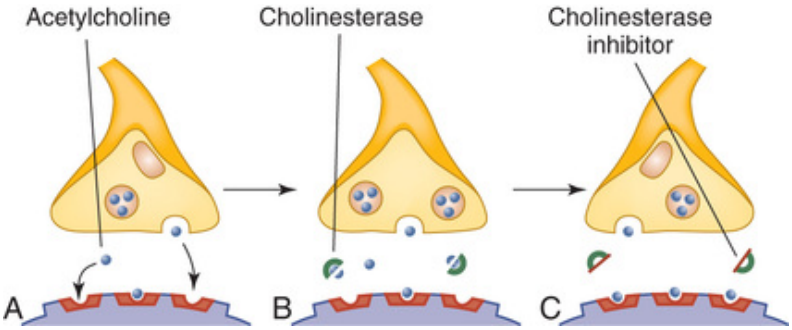

FIGURE 62-4 Mechanism of action of cholinesterase inhibitors. Acetylcholine **(A)** is released from the nerve synapses and carries a message across the synapse. Cholinesterase **(B)** breaks down acetylcholine. Cholinesterase inhibitors **(C)** block cholinesterase, which gives acetylcholine more time to transmit the message.

Drug Alert

Galantamine

The extended-release formulation of galantamine (Reminyl) may cause severe skin reactions. Its use should be discontinued if skin rash is observed.

Drug Alert

Cholinesterase Inhibitors

Fall risk assessment and interventions should be part of care for patients taking cholinesterase inhibitors.

Memantine (Ebixa), an *N*-methyl-D-aspartate (NMDA) receptor antagonist, may be prescribed if cholinesterase inhibitors are ineffective. Memantine appears to protect the brain's nerve cells against excess amounts of glutamate, which is released in large amounts by cells

damaged by AD. The attachment of glutamate to NMDA receptors enables calcium to flow freely into the cell, which in turn may lead to cell degeneration. Memantine may prevent this destructive sequence by adjusting the activity of glutamate. It may reduce behavioural and psychological symptoms in later stages of AD. Memantine is recommended for severe AD. Drugs for AD are prescribed until their clinical benefit can no longer be demonstrated. They are discontinued in very late stages of AD, when patients are bedridden and noncommunicative and cannot perform ADLs (Gauthier, Patterson, Chertkow, et al., 2012).

Antipsychotic drugs should be used for the management of the BPSDs only when nonpharmacological approaches alone are not successful and the patient is experiencing severe psychosis, aggression, or agitation. Even in that case, adverse effects and risk of adverse events may outweigh the benefits of these drugs. Pharmacological therapy for BPSDs begins with the lowest possible dose, with slow increases, if necessary. Patients should be monitored carefully for effectiveness and adverse effects, and routine assessment must be conducted to taper and discontinue the drug (CCSMH, 2006).

Conventional antipsychotic drugs (e.g., haloperidol) should not be administered because of extrapyramidal and anticholinergic adverse effects. The atypical antipsychotic agents reduce aggression and psychosis (see Table 62-10). Adverse drug effects include cardiac and metabolic disturbance, extrapyramidal adverse effects, gait disturbance, sedation, and anticholinergic effects. The risk of cerebro-vascular events and mortality is increased, especially in patients with forms of dementia other than AD. Antipsychotic agents are not used in patients with DLB because they produce severe adverse effects (CCSMH, 2006).

Drug Alert

Risperidone

Risperidone (Risperdal) is not recommended for patients with dementia other than AD.

BPSDs without psychosis can be treated with atypical antipsychotic agents and selective serotonin reuptake inhibitors such as such as

sertraline (Zoloft), fluvoxamine (Luvox), and citalopram (Celexa). Benzodiazepines are generally not recommended because they produce adverse effects such as disinhibition and increase the risk for falls. In urgent situations, very low doses of short-acting benzodiazepines such as lorazepam (Ativan) may be used with caution. Valproate should not be used (Gauthier, Patterson, Chertkow, et al., 2012).

Drug Alert

- Do not give antipsychotics to patients who have dementia with Lewy bodies.
- Psychiatric medications increase the risk of delirium.

For patients who have depression in addition to dementia, the depression should be treated with a combination of pharmacological and nonpharmacological approaches. The first choice of drugs is selective serotonin reuptake inhibitors such as venlafaxine (Effexor), mirtazapine (Remeron), or bupropion (Wellbutrin; Herrmann, Lactôt & Hogan, 2013). Tricyclic antidepressants are not recommended because of negative effects on cognition associated with anticholinergic adverse effects (Herrmann, Lactôt & Hogan, 2013). The patient must be carefully monitored for effectiveness and adverse effects.

Nursing Management Dementia

Nursing care for patients with dementia is based on four principles (Registered Nurses' Association of Ontario [RNAO], 2004/2010):

1. Knowing the person beyond the symptoms.
2. Recognizing retained abilities.
3. Manipulating the social and physical environment to meet the patient's unique needs.
4. Relating effectively, in ways that enable the patient to feel supported, valued, and confident.

Nursing Assessment

Comprehensive assessment is necessary to provide patient-centred care. Assessment should focus on the patient, his or her family or caregivers, and the physical and social environment. Assessment includes mental status, cognition, neurological symptoms, psychiatric symptoms, and functional assessment of ADLs and instrumental ADLs. Many patients with dementia lack awareness of their condition, and communication deficits are frequent. Thus collateral information should be obtained from people who know the patient well. Assessment of communication abilities helps the nurse adapt assessment approaches to the patient's abilities. Objective data from observation are important.

Data that should be obtained are listed in Table 62-11. In addition to cognitive assessment tools described earlier in this chapter, the ConsultGeriRN.org website provides standardized assessment tools, including tools specific to patients with dementia (Table 62-12). The CCSMH's pocket tool for assessment and treatment of behavioural symptoms is useful and can be downloaded from its website (see the Resources at the end of this chapter). A number of assessment tools are provided as appendices to the RNAO's (2004/2010) nursing best practice guideline, *Caregiving Strategies for Older Adults with Delirium, Dementia, and Depression.*

TABLE 62-11

NURSING ASSESSMENT
Patient With Dementia

Subjective Data
Important Information
Past health history: Head trauma, falls, history of previous delirium or psychiatric illness *Medications:* All drugs, including cholinesterase inhibitors, psychotropic drugs, and nonprescription drugs
Symptoms
• Activities of daily living (e.g., dressing, feeding, using the toilet, performing personal hygiene) • Instrumental activities of daily living (e.g., managing money, performing household chores, cooking, using transportation) • Mental status examination (mood, perceptions and beliefs, thinking, orientation, memory and recall, concentration, insight, hallucinations, delusions, apathy) • Pain • Response to stressful situations • Strength and mobility • Symptoms according to mild, moderate, and severe stages of dementia (see Table 62-8)
Objective Data
• Appearance and behaviour • Neurological symptoms (tremors, gait, tone, akathisia, dystonia) • Symptoms according to mild, moderate, and severe stages of dementia • Behavioural changes

Nursing Diagnoses

Nursing diagnoses for dementia may include, but are not limited to, the following:

- *Self-neglect* related to *deficient executive function* (memory deficit, cognitive impairment)

- *Risk for injury* as evidenced by *alteration in cognitive functioning* (impaired judgement, gait instability, sensory/perceptual alteration)
- *Wandering* related to *physiological state* (cognitive impairment)

Additional information on nursing diagnoses for the patient with dementia is presented in Nursing Care Plan (NCP) 62-1, available on the Evolve website.

Planning

The overall goal is that patients with dementia will have a dignified quality of life. Specific goals are (a) enhancement of ADLs and instrumental ADLs (retaining functional abilities as long as possible), (b) enhancement or stabilization of cognition, (c) elimination of pain, (d) prevention or minimization of behaviours that adversely affect functioning, and (e) enhancement of emotional well-being (RNAO, 2004/2010). The goals for the family caregiver of a patient with dementia are to (1) reduce caregiver stress, and (2) maintain personal health. A nursing goal is to developing partnerships with families (RNAO, 2004/2010).

Nursing Implementation

Health Promotion.

Strategies to prevent dementia are described earlier in this chapter. The Alzheimer Society of Canada's *Brain Health* Web page provides helpful information about healthy lifestyle choices for long-term brain health (see the Resources at the end of this chapter).

Dementia must be recognized early so that patients with dementia and their families can have time to make treatment decisions and plan for the future. Sometimes dementia is first identified when patients are admitted to an acute care facility for another condition (McCleary, Persaud, Hum, et al., 2012). Nurses who recognize signs of undiagnosed dementia can help patients access appropriate health care resources. Useful information for patient and family health teaching about early signs of dementia is available on the Alzheimer Society of Canada website.

Health promotion can improve quality of life for patients with dementia and for family caregivers. Exercise programs for patients with dementia may improve the patient's ability to perform ADLs and reduce caregiver burden (Forbes, Forbes, Blake, et al., 2015). Yoga may improve physical health, mental health, and behaviours for patients with dementia (Fan & Chen, 2011).

Acute Intervention.

The diagnosis of dementia can be traumatic for both the patient and the family. It is not unusual for patients to respond with depression, denial, anxiety and fear, isolation, and grieving. The nurse is in an important position to assess for depression and suicidal ideation. Antidepressant drugs and counselling may be appropriate interventions. The nurse must assess the abilities of family members to accept and cope with the diagnosis.

Ongoing assessment of the patient and caregiver is required as the dementia progresses and the patient's functioning changes. An important nursing responsibility is to work in partnership with the caregiver to effectively manage clinical manifestations as they change over time. Effective partnership is enhanced when the nurse provides support, education, and collaboration with a focus on enabling meaningful caregiving roles in all settings (RNAO, 2004/2010). The nurse must consider both the patient with dementia and the caregiver as having overlapping but unique problems. To aid in identifying challenges the caregiver may experience, see NCP 62-2, Family Caregivers of the Patient with Dementia, available on the Evolve website.

Patients with dementia may be hospitalized for other health care problems. Approximately 25% of older patients in hospitals have dementia. This dementia is not necessarily documented on their health record (Russ, Shenkin, Reynish, et al., 2012). They are at higher risk than other older patients for negative outcomes, including delirium, avoidable functional decline, longer admissions, and death (Mukadam & Sampson, 2011; Russ, Shenkin, Reynish, et al., 2012). Access to rehabilitation after acute care is an issue for patients with dementia. The following "Evidence-Informed Practice" box describes a program to improve access to rehabilitation after hip fracture.

Evidence-Informed Practice

Translating Research Into Practice

Rehabilitation After Hip Fracture for Patients With Cognitive Impairment

Clinical Question

In patients with cognitive impairment, after hip fracture surgery (P), does an interdisciplinary patient-centred model of rehabilitation (I), in comparison with routine rehabilitation (C), improve functional gain, cognitive gain, rehabilitation efficiency, and discharge location (O)?

Best Available Evidence

Quasi-experimental study

Critical Appraisal and Synthesis of Evidence

- Participants were patients with and without cognitive impairment who were admitted to a specialized inpatient rehabilitation unit after hip fracture surgery; their outcomes were compared.
- A new interdisciplinary model provided individualized rehabilitation care based on patient- and family-driven goals, with care strategies to minimize BPSDs.
- Participants were patients with cognitive impairment (n = 47) and patients without cognitive impairment (n = 102). Of the total of 149 patients, 73 (including 24 with cognitive impairment) received the new model of care, and their outcomes were compared with those of the patients who did not receive this intervention (n = 76).
- Patients with cognitive impairment had greater functional dependence at baseline.
- Both patients with and without cognitive impairment had significant gains in motor functioning, and 82% were discharged to the community
- Living alone, longer length of stay, and having cognitive impairment were associated with not being discharged to home.

Conclusions

- Patients with dementia benefit from rehabilitation after hip fracture.

Implications for Nursing Practice

- Support of staff to provide appropriate individualized care to patients with dementia was an essential part of the program.
- Nursing and interdisciplinary staff should receive education about dementia and effective dementia care strategies.
- A gerontological advanced practice nurse supported staff to implement the program.

BPSDs, behavioural and psychological symptoms of dementia; *P,* patient population of interest; *I,* intervention or area of interest; *C,* comparison of interest or comparison group; *O,* outcome(s) of interest (see Chapter 1).

Reference for Evidence

McGilton KS, Davis AM, Mahomed N, et al. Evaluation of patient-centred rehabilitation model targeting older persons with a hip fracture, including those with cognitive impairment. *BMC Geriatrics*. 2013;13:135; 10.1186/1471-2318-13-136.

Safety Alert

Patients with dementia who are admitted to hospitals are at risk for delirium, falls, dehydration, inadequate nutrition, untreated pain, drug-related problems, wandering, behavioural symptoms, and functional decline, and the use of restraints is more likely to be necessary.

Patients' inability to communicate symptoms of health problems places the responsibility for assessment and diagnosis on caregivers and health care providers. Patients with dementia who are hospitalized in acute care settings should be observed more closely because of concerns for safety. Consistent assignment of nursing staff, frequent reassurance, and orientation to place and time may reduce anxiety and prevent behavioural symptoms. See the preceding "Evidence-Informed Practice" box.

Ambulatory and Home Care.

Most persons with dementia live in their homes, supported and cared for by family members or friends. The most typical caregiver is a spouse or an adult daughter. Depending on care needs, safety, availability of family caregivers, finances, and availability of formal programs, patients with dementia may eventually move to assisted-living facilities or long-term care homes.

Patients with dementia progress through the stages at variable rates. Nursing care needs of patients with dementia change as the disease progresses. Thus regular assessment, monitoring, and support are necessary. Regardless of the setting, cognition and functioning decline, and the amount of care required intensifies over time. The specific manifestations of the disease depend on the areas of the brain involved.

In the phase of MCI, memory aids (e.g., calendars) may be beneficial. Patients may develop depression in this phase. Depression may occur

because of the neurochemical changes in the brain. Depression may be related to adjusting to a diagnosis of an incurable disorder, as well as the effect of dementia on the person's life (e.g., driving, socializing with friends, participating in hobbies or recreational activities). Drug therapy with cholinesterase inhibitors may be effective. However, adverse effects may deter some people from continuing with the drugs. Adherence to the regimen may be challenging when dementia affects the patient's ability to remember to take drugs.

After the initial diagnosis, patients need to be aware that the progression of the disease is variable. Effective management of the disease can enhance quality of life of the patient and family and may slow the progress of the disease. The patient, family members, and the health care team should collaborate in making decisions related to care early in the disease. The nurse has a role in advising the patient and the family to discuss decision making for health care and planning for advanced care while the patient still has the capacity to do so.

Adult day care programs are an option for patients with dementia. The goals of adult day care programs are to provide respite for the family and to support the patient in the community for as long as possible. During the early and middle stages of dementia, patients benefit from therapeutic activities in a safe environment that support functioning. Services that may be provided at adult day care programs include assistance with ADLs, therapeutic recreation, cognitive stimulation, and transportation to the program. Patients return home more relaxed, content, less frustrated, and ready to be with the family. The respite from the demands of care allows the caregiver to be more responsive to the patient's needs. Other respite options include home visits from community respite workers, overnight care provided by community nursing services, and short-term (1–2 weeks) admission to a respite bed in a long-term care home. In many provinces and territories, this service is subsidized by government funding.

As the disease progresses, the demands on the caregiver may eventually exceed the resources, and the person with dementia may have to move to a long-term care home (Rockwood, Richard, Garden, et al., 2014). Dementia care units are becoming increasingly common in long-term care homes. Patients in the final stages of dementia require total care. Family caregiving responsibility continues when the person moves to a long-term care home. Family caregivers continue to provide personal care, preserve the dignity of the person with dementia, share their unique knowledge of the person with staff, and monitor quality of care.

There are specific issues related to the care of the patient with dementia that span all phases of the disease. Brief, evidence-informed guides to effective nursing intervention help with care planning (Table 62-12). These issues are described in the following sections.

Behavioural Changes.

BPSDs occur in approximately 50% to 60% of patients with dementia. BPSDs are more common in middle and late stages, and most patients with dementia demonstrate BPSDs at some time. Often, the behaviours are not persistent. Caregivers need to be aware that these behaviours are not intentional. Behaviours are a way of communicating. It is up to the nurse to try to understand the meaning of the behaviour and what is being communicated. Behaviours may communicate emotions. By responding to these emotions, the nurse validates the patient's feelings (Pizzacalla, Montemuro, Coker, et al., 2015). BPSDs may worsen in acute care settings when behaviour is influenced by delirium, pain, changes in routine, and the unfamiliar environment. BPSDs often contribute to the decision to move patients to a long-term care home. See the following "Evidence-Informed Practice" box, which describes how training nurses on orthopaedic units to use gentle-persuasive approaches can be helpful to patients.

Evidence-Informed Practice

Research Highlight

What Is the Effect of Training Nurses on Orthopaedic Units to Use Gentle-Persuasive Approaches?

Clinical Question

In nursing staff working on orthopaedic surgery units (P), does education and training to use gentle-persuasive approaches (I), in comparison with no training (C), increase competencies in behavioural management with cognitively impaired patients (O)?

Best Available Evidence

One quasi-experimental study.

Critical Appraisal and Synthesis of Evidence

- Staff and leaders identified distress related to responsive and self-protective behaviours on postoperative patients.
- One-day workshops on the principles of gentle-persuasive approaches (an approach that had been previously shown to be effective in long-term care settings) was provided to 82% of the multidisciplinary staff on the unit.
- The training focused on the following:
    - Person-centred care and understanding the meaning of behaviour as communication
    - Effect of dementia and delirium on the brain and how that relates to behaviour
    - Communication techniques to use with patients with delirium or dementia
    - Respectful self-protective techniques to use when encountering responsive behaviours
- The staff who received this training noted that their confidence in working with patients was significantly improved after the training.
- Most participants recommended training for colleagues.
- Success on one unit led other units in the hospital to adopt the training.

Conclusions

- Staff who receive training and education to understand the reasons for responsive behaviours improve their competence to provide effective safe care to patients with delirium and dementia.

Implications for Nursing Practice

- Hospital administrators should provide education to staff members who work with patients with dementia or delirium and should support them in using their learning in practice.
- Further examination of effects for patients is needed.

P, patient population of interest; *I*, intervention or area of interest; *C*, comparison of interest or comparison group; *O*, outcome(s) of interest (see

Chapter 1).

Reference for Evidence

Pizzacalla A, Montemuro M, Coker E, et al. Gentle persuasive approaches introducing an educational program on an orthopaedic unit for staff caring for patients with dementia and delirium. *Orthopaedic Nursing*. 2014;34(2):101–107; 10.1097/NOR.0000000000000127.

Behaviours do not occur in a vacuum; they are often in response to a precipitating factor (e.g., pain, frustration, temperature extremes, anxiety, perceived danger). The first step to identifying precipitating factors is for to assess the patient's physical status. Physical assessment includes checking for changes in vital signs, urinary and bowel patterns, and pain that could contribute to behavioural changes. Environmental assessment to identify factors that could trigger behaviours is the next step. Extremes in temperature, as well as excessive noise, may result in behaviour change. When the patient is agitated by the environment, either the patient or the stimulus should be moved. The patient can be assisted to call family members if this is reassuring. When a patient resists or pulls at tubes or dressings, these items can be covered with stretch tube gauze or removed from the visual field. The patient should be reassured that the nurse is present to provide safety and protection. Orientation to place and person can be used, depending on the patient's cognitive abilities. Allowing the patient to live in his or her memories is often more appropriate and provides comfort and reassurance. Avoid challenging “why” questions when the patient is anxious or agitated. If the patient cannot verbalize distress, his or her mood should be validated. The patient's statement can be rephrased to validate its meaning. The patient's emotional state should be closely observed.

When nurses communicate effectively with patients during care, patients are less anxious and agitation is reduced. To communicate effectively, it is important that the nurse (a) stay near the patient during care, sit beside the patient, and use touch as appropriate; (b) recognize the patient's rhythm and adapt the pace of care to it; and (c) focus on care beyond the task by acknowledging the personal experience and providing reassurance (RNAO, 2004/2010).

Other strategies to manage behaviour include redirection, distraction, and reassurance. For a patient who is restless or agitated, redirecting would involve changing the patient's focus by having him or her perform

activities such as sweeping, raking, or dusting. Effective strategies to distract the agitated patient might include snacks, car rides, favourite music, looking at family photographs, or walking. Repetitive activities, songs, poems, massage, aromas, or a favourite object can be soothing to some patients.

When nonpharmacological therapies are ineffective and patient safety is of concern, drugs may be used with caution (see Table 62-10). However, the drugs do not treat the unmet needs such as pain, social isolation, or boredom that are often the underlying cause of symptoms such as agitation (Voyer, McCusker, Cole, et al., 2015). Adverse effects should be monitored carefully.

Resources about assessment and treatment of behavioural symptoms are available on the CCSMH website (see the Resources at the end of this chapter). These resources include a practice guideline (CCSMH, 2006), a guide for patients and families, and a pocket tool for clinicians.

Some patients have a pattern of behavioural disturbance that occurs in the late afternoon. This is often referred to as **sundowning.** However, there is controversy about whether sundowning exists. According to some experts, there is no change in behaviour; rather, BPSDs are more disruptive to staff when they occur in the evening and are thus more noticeable to them. Others point out that the symptoms are characteristic of delirium. Possible causes include fatigue, unfamiliar environment, noise (especially in an acute care setting or during shift changes), medications, reduced lighting, restraint use, and sleep fragmentation. Behaviour should be assessed for underlying cause. Maximizing exposure to light during the day, ensuring quiet and uninterrupted nighttime sleep, implementing other sleep hygiene interventions (see Chapter 9), and engaging the patient in activities during the day may be helpful (Yevchak, Steis, & Evans, 2012).

Safety.

The person with dementia is at risk for a number of problems related to personal safety. These problems include injury from falls, wandering in unsafe areas, injury to others and self with sharp objects or from fire and other heat sources, and impaired judgement and decision making. These concerns necessitate careful attention to the home environment to minimize risk and provide supervision. As cognitive function declines over time, patients with dementia may have difficulty navigating physical spaces and interpreting environmental cues. The Alzheimer Society of Canada website (see the Resources at the end of this chapter) has a home

safety checklist that nurses can assist families to use. Environmental modifications include improving lighting; removing tripping hazards; stairway handrails, with the end of rail shaped differently to alert the patient that it is the end of the stairway; wiping wet areas on the floors; removing snow and ice; and grip bars and nonskid surfaces in showers and bathtubs (Alzheimer Society of Canada, 2015; RNAO, 2011).

In hospitals, the risk of falling is 2.6 to 6 times higher in patients with dementia than in patients who do not have dementia (RNAO, 2011). Nursing assessment should include fall risk assessment. Effective fall prevention programs include multiple components such as staff training, environmental modification, and exercises (RNAO, 2011).

Wandering is a major safety concern. Wandering may be the expression of a physical or emotional need or may result from cognitive loss, adverse effects of drugs, restlessness, curiosity, or stimuli that trigger memories of earlier routines. The nurse should observe for factors or events that may precipitate wandering. For example, patients may be sensitive to stress and tension in the environment. In such cases, wandering may reflect an attempt to leave the environment. Patients with dementia can be registered with the Alzheimer Society of Canada's MedicAlert Safely Home Registry. The registry includes identification products (e.g., bracelets, necklaces, watches) that allow police and emergency responders to identify the person quickly and return him or her home (Alzheimer Society of Canada, 2016d).

Pain Management.

Pain management is complex. Often, pain in persons with dementia is not recognized by health professionals. Because of dementia-associated difficulties with oral and written language, affected patients may have difficulty expressing physical complaints, including pain. The nurse must rely on other behavioural clues or distress such as resistance to care, agitation, pacing, grimacing, withdrawal, increased vocalization, and changes in function. If nurses cannot determine the reasons for such behaviours, they should suspect and treat pain and monitor the patient's response. Nonpharmacological approaches such as massage may provide relief. Patients with dementia may not be able to tolerate therapeutic doses of analgesics. Low doses of long-acting opioids with slow titration to higher doses is recommended when trials of acetaminophen [Tylenol] are ineffective (Flegel, 2013; Gallagher, 2013). The *Try This* series on the ConsultGeriRN.org website includes tools for pain assessment with older

adults and patients who have dementia. See Chapter 10 for information about pain assessment and management.

Eating and Swallowing Difficulties.

Loss of interest in food and decreased ability to feed oneself *(feeding apraxia),* as well as comorbid conditions, can result in significant nutritional deficits and possible dehydration in patients with dementia. In long-term care and acute care settings, inadequate assistance with eating may further add to the problem.

Individualized nursing interventions should be based on assessment of the patient's needs and abilities (see Table 62-13). Puréed foods, thickened liquids, and nutritional supplements can be used when chewing and swallowing become problematic for patients. Patients may need to be reminded to chew their food and to swallow. A quiet and unhurried environment for eating is essential. Distractions at mealtimes, including television, should be avoided. Creation of a normal social environment for meals provides supportive cues for patients with dementia. If self-feeding is difficult, finger foods, verbal cuing, demonstrating eating motions, and hand-over-hand techniques can initiate self-feeding. Liquids should be offered frequently.

When oral feeding is not possible, alternative routes may be explored. Nutritional support therapies are described in Chapter 42.

Oral Care.

Ability to perform oral self-care declines as dementia progresses. With decreased toothbrushing and flossing, dental problems are likely to occur. Food may become lodged in pockets in the mouth because of swallowing difficulties, which increases the potential for tooth decay. Dental caries and tooth abscesses cause discomfort and pain, potentially increasing responsive behaviours. The mouth should be inspected regularly and mouth care provided for patients unable to perform self-care. Pocket tools about providing oral care to patients with dementia are available in the resources section of the Regional Geriatric Program Central website (see the Resource at the end of this chapter).

Infection Prevention.

Urinary tract infection and pneumonia are the most common infections in patients with dementia. Such infections are ultimately the cause of death in many patients with dementia. Patients with dementia are at risk for aspiration pneumonia because of feeding and swallowing problems. See Chapters 30 and 48 for additional information about these infections. Manifestations of infection—including changes in behaviour, delirium, fever, cough (pneumonia), and pain on urination (bladder)—are evaluated and appropriately treated. See Chapter 7 for information about normal changes of aging that diminish signs of infection.

Skin Care.

It is important to monitor the patient's skin. Rashes, areas of redness, and skin breakdown should be noted and treated appropriately. In the late stages of dementia, incontinence along with immobility and undernutrition can increase patients' risk for skin breakdown. The nurse must keep the patient's skin dry and clean and change the patient's position regularly to prevent the creation of pressure areas over bony prominences.

Elimination Problems.

During the middle and late stages of dementia, urinary and fecal incontinence become more common. Multifaceted individualized nursing care to reduce incontinence should include regular toileting (with prompting and reminders if necessary), changing incontinence products, increasing fluid and fibre intake, and ensuring that the toilet is accessible.

Constipation is also a common problem. Causes may include immobility, dietary intake (e.g., reduced fibre intake), and decreased fluid intake. Management of constipation is discussed in Chapter 45.

Caregiver Support.

Dementia is a disease that disrupts all aspects of personal and family life. Individuals caring for the person with dementia frequently describe such care as stressful. Caregivers of patients with dementia often experience negative effects on their work and family roles and on their mental and physical health. Caregiver strain is common. Actions that caregivers may take are suggested in Table 62-14. Strategies for reducing caregiver stress are listed in Table 62-15.

TABLE 62-14

PATIENT & CAREGIVER TEACHING GUIDE
Dementia Caregiving

The following information should be included when teaching the caregiver about dementia.
1. Adapt communication to the person with dementia's abilities (e.g., read verbal and nonverbal cues, interpret what the person is trying to communicate). Know that communication is possible at all stages of dementia. Nonverbal communication is important in later stages of dementia. 2. Try to remain positive and encouraging. Avoid criticism and corrections. Focus on abilities. 3. Accept the reality of the person with dementia, and interact with him or her in that reality. Do not correct misstatements or faulty memory. 4. Assess and ensure home safety. 5. Monitor driving ability and discuss with the person with dementia and health care providers. 6. Encourage activities such as household chores, listening to music, reminiscence, exercising, hobbies, and visiting with friends and relatives. 7. Establish routines and simplify tasks (e.g., wearing clothing that is easy to put on, simplifying the table setting, breaking tasks down into small steps). 8. Register with the Alzheimer Society MedicAlert® Safely Home® program.

TABLE 62-15

TEN WAYS TO REDUCE CAREGIVER STRESS

1. Learn about the disease. 2. Be realistic about the disease. 3. Be realistic about how much you can do. 4. Accept your feelings. 5. Share information and feelings with others. 6. Be positive. 7. Look for humour. 8. Take care of yourself. 9. Get help, both practical help and support. 10. Plan for the future.

Source: Alzheimer Society of Canada. (2015). *Reducing caregiver stress.* Retrieved from *http://www.alzheimer.ca/en/Living-with-dementia/Caring-for-someone/Self-care-for-the-caregiver/Reducing-caregiver-stress.*

As the disease progresses, the relationship of the caregiver to the patient changes. Family roles may be altered or reversed (e.g., child caring for parent). Decisions that must be made include when the patient must stop driving or performing activities that might be dangerous, when to ask for assistance, and when to use respite care services or long-term care homes. With early-onset dementia and FTD, the person is often affected during the most productive working years. The financial consequences can be devastating for the individual and the family.

Sexual relations for couples are also seriously affected by dementia. As dementia progresses, sexual interest may decline for both the patient and the partner. A number of reasons account for this, including caregiver fatigue (when the partner is the caregiver), as well as memory impairment, apraxia, and episodes of incontinence in the patient with AD. It is also possible for patients to become sexually disinhibited as the disease progresses.

The nurse works with the caregiver to identify stressors and determine coping strategies to reduce the burden of caregiving. For example, the nurse should ask which behaviours are most disruptive to family life and remind the caregiver that this is likely to change over time as the disease progresses. Establishing what the caregiver views as most disruptive or distressful can help in identifying priorities for care. Risk to the safety of the patient and the caregiver is given high priority. It is also important to assess the caregiver's expectations regarding the patient's behaviour: are the expectations reasonable in view of the progression of the disease? The nurse must work with the caregiver to identify risk factors for complications, including behavioural problems.

Support groups for caregivers and family members (Figure 62-5) provide emotional support and information about dementia and related topics such as safety, legal, ethical, and financial issues. These groups are often facilitated by nurses, social workers, or occupational therapists. The Alzheimer Society of Canada has many educational and support systems available to help family caregivers. Other strategies related to stress management are discussed in Chapters 8 and 12.

FIGURE 62-5 Support groups are an effective way to help caregivers cope. Source: Pressmaster/Shutterstock.com.

Legal Matters and Personal Care Planning.

In the early stage of dementia, while the patient is still capable of making decisions and signing legal papers, it is important for the patient to be part of the decision making about his or her financial and legal affairs. Some important legal documents that must be put in place as soon as possible are a will; an enduring power of attorney (a document naming a substitute decision maker) for financial and legal matters, as well as for future health care decisions; and an advance directive. The names and the required content of these documents vary among the provinces and territories, and the local chapter of the Alzheimer Society of Canada can help locate this information for persons with dementia and their families. Chapters 7 and 13 provide more information about these documents.

Evaluation

Expected outcomes for patients with dementia are addressed in NCP 62-1, available on the Evolve website. See NCP 62-2 for expected outcomes for the caregiver of a patient with dementia.

Case Study

Alzheimer's Disease

Source: Nadino/Shutterstock.com.

Patient Profile

Mr. Yves Bédard, an 80-year-old man, received a diagnosis of AD 3 years ago. Today, his 78-year-old wife brings him to the emergency department because he wandered from his home, fell, and injured his left hip.

Subjective Data

- Can state his name
- Is disoriented regarding place and time
- Cannot recall wandering or falling
- Is agitated, trying to get up
- Denies pain

Objective Data

Physical Examination

- Left leg shorter than right leg
- Patient is tense and anxious
- Grimacing

Diagnostic Studies

- Radiographic study of left hip indicates a fracture.
- Mini-Mental State Examination shows cognitive impairment.

Discussion Questions

1. What is the pathogenesis of AD?

2. What precipitating factors may have resulted in Mr. Bédard's fall?
3. ***Priority decision:*** What are the priority nursing interventions for Mr. Bédard?
4. What precautions must be taken regarding the inpatient care of Mr. Bédard?
5. What teaching plan should be developed for Mr. Bédard and his wife?
6. ***Priority decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
7. ***Evidence-informed practice:*** Mr. Bédard's wife asks whether she should give her husband ginkgo to help his memory. How should the nurse respond?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Which of the following clients is most at risk for developing delirium?
   a. A 50-year-old woman with cholecystitis
   b. A 19-year-old man with a fractured femur
   c. A 42-year-old woman having an elective hysterectomy
   d. A 78-year-old man admitted to the medical unit with complications related to congestive heart failure
2. Which of the following symptoms are the hallmarks of delirium?
   a. Inattention, fluctuating course, hyperactivity, and altered level of consciousness
   b. Disorganized thinking, insidious onset, inattention, and altered level of consciousness
   c. Acute onset, fluctuating course, memory loss, and altered level of consciousness
   d. Acute onset, fluctuating course, inattention or disorganized thinking, and altered level of consciousness
3. Which of the following descriptions best characterizes dementia?
   a. Syndrome that results only in memory loss
   b. Disease associated with abrupt changes in behaviour
   c. Disease that is always due to reduced blood flow to the brain
   d. Syndrome characterized by cognitive dysfunction and loss of memory
4. Which of the following is associated with vascular dementia?
   a. Transient ischemic attacks
   b. Bacterial or viral infection of neuronal tissue
   c. Cognitive changes secondary to cerebral ischemia
   d. Abrupt changes in cognitive function that are irreversible
5. On which of the following findings is the clinical diagnosis of dementia based?
   a. Brain biopsy
   b. Electroencephalography
   c. Patient history and cognitive assessment

d. Computed tomography or MRI

6. Which statement(s) accurately describe(s) mild cognitive impairment? *(Select all that apply)*
   a. Always progresses to AD
   b. Caused by variety of factors and may progress to AD
   c. Should be aggressively treated with acetylcholinesterase drugs
   d. Caused by vascular infarcts that, if treated, will delay progression to AD
   e. Client is usually not aware that there is a problem with his or her memory
7. What is a major goal of treatment for the client with dementia?
   a. Maintain safety
   b. Maintain or increase body weight
   c. Return to a higher level of self-care
   d. Enhance functional ability over time

1. d; 2. d; 3. d; 4. c; 5. c; 6. b; 7. a.

CHAPTER 63

Nursing Management

Peripheral Nerve and Spinal Cord Problems

Written by, Cindy M. Sullivan

Adapted by, Angela Sarro

LEARNING OBJECTIVES

1. Explain the etiology, clinical manifestations, collaborative care, and nursing management of trigeminal neuralgia and Bell's palsy.
2. Explain the etiology, clinical manifestations, collaborative care, and nursing management of Guillain-Barré syndrome, botulism, tetanus, and neuro-syphilis.
3. Describe the classification of spinal cord injuries and associated clinical manifestations.
4. Describe the clinical manifestations, collaborative care, and nursing management of spinal cord injury.
5. Explain the correlation between the severity and location of spinal cord injury and disruption of bodily function and the functional goals for rehabilitation.
6. Describe the nursing management of the major physical and psychological problems of patients with a spinal cord injury.
7. Describe the effects of spinal cord injury on the older-adult population.
8. Explain the types, clinical manifestations, collaborative care, and nursing management of spinal cord tumours.

9. Describe the pathophysiology, clinical manifestations, and the nursing and collaborative management of postpolio syndrome.

tetraplegia, p. 1594
trigeminal neuralgia (TN), p. 1585

Cranial Nerve Disorders

Cranial nerve disorders are commonly classified as peripheral neuropathies. The 12 pairs of cranial nerves are considered the peripheral nerves of the brain. The disorders usually involve the motor or sensory (or both) branches of a single nerve *(mononeuropathies)*. Causes of cranial nerve problems include tumours, trauma, infections, inflammatory processes, and idiopathic (unknown) causes. Two cranial nerve disorders that will be discussed are trigeminal neuralgia and Bell's palsy.

Trigeminal Neuralgia

Etiology and Pathophysiology

Trigeminal neuralgia (TN), also known as *tic douloureux,* is a relatively uncommon cranial nerve disorder. The annual incidence of TN is 5 in 100 000 in Canada (Kastanias, Buzon, & Sarro, 2012). The average age of onset is 60 years; it is rarely diagnosed in individuals under 40 and develops slightly more often in women than men (Larsen, Piepgras, Chyatte, et al., 2011).

The trigeminal nerve is the fifth cranial nerve (cranial nerve V) and has both motor and sensory branches (Boyd & Tymianski, 2012). In TN, the sensory, or afferent, branches, primarily the maxillary and mandibular branches, are involved (Figure 63-1).

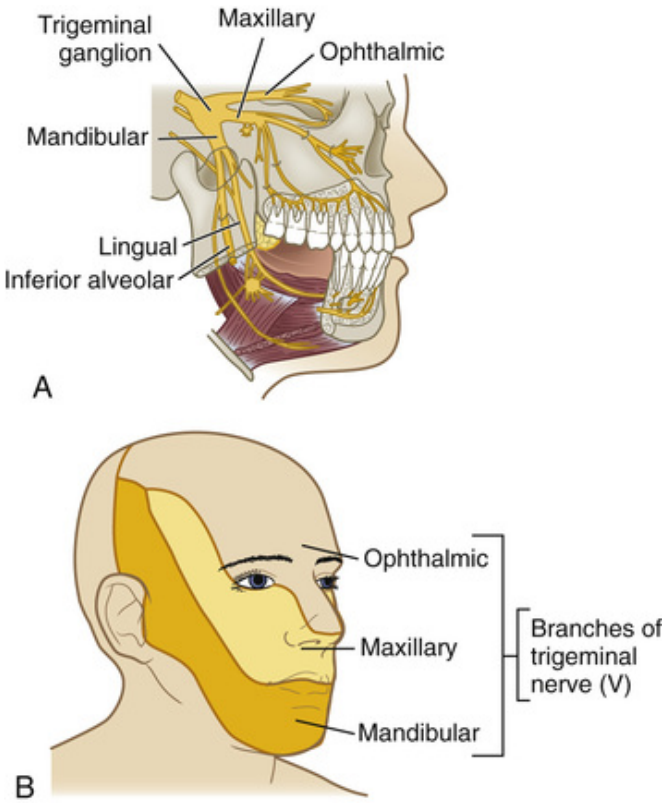

FIGURE 63-1 **A,** Trigeminal nerve (fifth cranial nerve) and its three main divisions: the ophthalmic, maxillary, and mandibular nerves. **B,** Sensory fibres of the trigeminal nerve for three branch nerves (ophthalmic, maxillary, and mandibular nerves), each of which conducts information from a different region of the face. Source: Modified from Patton, K. T., & Thibodeau, G. A. (2016). *Anatomy and physiology* (9th ed., p. 491, Figure 21-11). St. Louis: Mosby.

The pathophysiology of TN is not fully understood. One theory is that blood vessels, the superior cerebellar artery in particular, are compressed. This compression results in chronic irritation of the trigeminal nerve at the root entry zone. This irritation results in increased firing of the afferent or sensory fibre, commonly referred to as *classical TN*. Symptomatic TN is typically caused by a structural, nonvascular lesion (benign tumours, aneurysms, multiple sclerosis) (Al-Quliti, 2015). Other factors that may result in neuralgia include herpesvirus infection, infection of gums and jaw, and a brain stem infarct. The effectiveness of anticonvulsant drug therapy in reducing pain may be related to the ability of these drugs to stabilize the neuronal membrane and decrease paroxysmal afferent impulses of the nerve (Al-Quliti, 2015).

Clinical Manifestations

The classic feature of trigeminal neuralgia is an abrupt onset of paroxysms of flashing, stabbing pain radiating along the course of a branch of the trigeminal facial nerve from the angle of the jaw, described as a burning, knifelike, or lightning-like shock in the lips, the upper or lower gums, the cheek, the forehead, or the side of the nose. Intense pain, twitching, grimacing, and frequent blinking and tearing of the eye occur during the acute attack (hence the term *tic douloureux*). Some patients may experience facial sensory loss. The attacks are usually brief, lasting only seconds to 2 or 3 minutes, and are generally unilateral. Recurrences are unpredictable; they may occur several times a day or weeks or months apart. After the refractory (pain-free) period, a phenomenon known as *clustering* can occur. Clustering is characterized by a cycle of pain and refractoriness that continues for hours.

The painful episodes are usually initiated by a triggering mechanism of light cutaneous stimulation at a specific point *(trigger zone)* along the distribution of the nerve branches. Precipitating stimuli include chewing, brushing teeth, a hot or cold blast of air on the face, washing the face, yawning, and even talking. Touch and tickle seem to predominate as causative triggers, rather than pain or changes in temperature. As a result, the patient may eat improperly, neglect hygienic practices, wear a cloth over the face, and withdraw from interaction with other individuals. The patient may sleep excessively as a means of coping with the pain.

Although this condition is considered benign, the severity of the pain and the disruption of lifestyle can result in almost total physical and psychological dysfunction or even suicide.

Diagnostic Studies

It is important to rule out other problems with similar manifestations, such as other forms of facial and cephalic neuralgias and pain arising from the sinuses, the gums, and the jaws. In young adults with bilateral facial pain, magnetic resonance imaging (MRI) is performed to rule out lesions, vascular abnormalities, and multiple sclerosis (Zakrzewska, 2014). A complete neurological assessment is performed, including audiological evaluation, although results are usually normal. Electromyography (EMG) can be performed to help distinguish between symptomatic and classical trigeminal neuralgia. Once the diagnosis is made, the goal of treatment is relief of pain by either medical or surgical intervention (Table 63-1).

TABLE 63-1

COLLABORATIVE CARE
Clinical Management of Trigeminal Neuralgia

Diagnostic
• EMG studies • Evaluation for symptomatic TN • MRI of brain to assess for secondary causes • Normal neurological examination • Paroxysmal lancinating facial pain in distribution of trigeminal nerve (classic TN)
Collaborative Therapy
Drug Therapy
• First line: carbamazepine (Tegretol), oxcarbazepine (Trileptal) • Second line: baclofen (Lioresal), lamotrigine (Lamictal) • Third line: gabapentin (Neurontin), pregabalin (Lyrica), topiramate (Topamax)
Surgical Options

• Percutaneous
  • Glycerol rhizotomy
  • Radiofrequency rhizotomy

• Intracranial
  • Gamma Knife radiosurgery
  • Microvascular decompression

EMG, electromyography; *MRI,* magnetic resonance imaging.

Collaborative Care

Drug Therapy.

Carbamazepine (Tegretol) is considered the first-line therapy in patients with newly diagnosed trigeminal neuralgia (Zakrzewska, 2014). By acting on sodium channels, carbamazepine and other anticonvulsant drugs lengthen the time needed for neuron repolarization, which results in decreased neuron firing. Adverse effects of carbamazepine may include bone marrow suppression, which leads to blood abnormalities. Therefore, routine complete blood cell (CBC) counts are required. Baclofen (Lioresal), an antispasmodic agent, has demonstrated efficacy in reducing pain from trigeminal neuralgia. Baclofen works synergistically with carbamazepine and can therefore be used as a monotherapy or in conjunction with carbamazepine if pain relief is incomplete. Other anticonvulsant medications that may be used in the management of trigeminal neuralgia are listed in Table 63-1. These anticonvulsant drugs may prevent an acute attack or promote a remission of symptoms. Because drug therapy may not provide permanent pain relief, some patients may seek continued help and make numerous visits to otolaryngologists for assessment or may attempt alternative therapies such as acupuncture and megavitamins.

Conservative Therapy.

Local anaesthetics can be used to block nerves. Local nerve blocking results in complete anaesthesia of the area supplied by the injected branches. Relief of pain is temporary, lasting from 6 to 18 months.

Biofeedback is another strategy that may be helpful for some patients. In addition to controlling the pain, the patient may experience a strong sense of personal control by mastering the technique and altering certain body functions. (Biofeedback is discussed in Chapter 12.)

Surgical Therapy.

If a conservative approach, including drug therapy, is not effective, surgical therapy is available. *Glycerol rhizotomy* is a percutaneous procedure that consists of an injection of glycerol through the foramen ovale into the trigeminal cistern (Figure 63-2). Glycerol injections produce immediate pain relief in 90% of patients, but by 5 years, approximately 50% experience recurrence of pain (Al-Quliti, 2015; Zakrzewska, 2014).

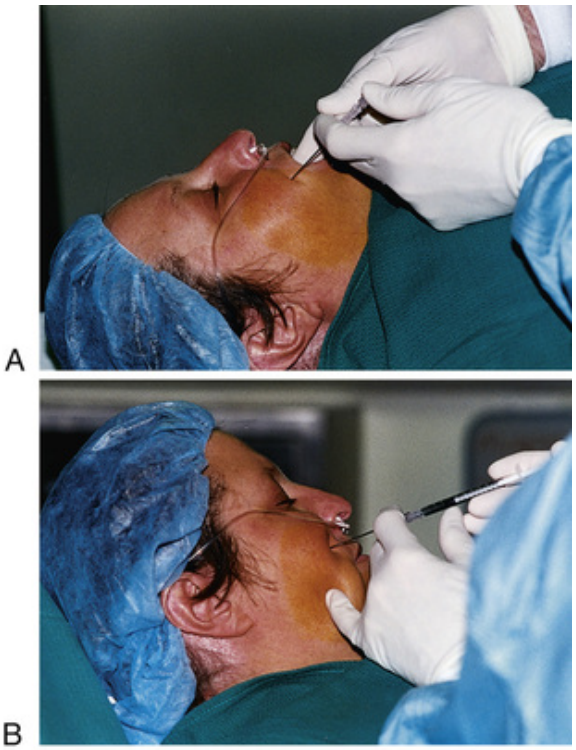

FIGURE 63-2 Glycerol rhizotomy. **A,** Needle placed in face of patient with trigeminal neuralgia. **B,** Physician injecting glycerol.

Source: Courtesy Joe Rothrock, Media, PA.

Percutaneous radiofrequency rhizotomy (electrocoagulation) and microvascular decompression provide the greatest relief of pain. In *percutaneous radiofrequency rhizotomy,* a needle is inserted into the trigeminal rootlets that are adjacent to the pons, and the area is destroyed by means of a radiofrequency current. This can result in facial numbness (although some degree of sensation may be retained), corneal anaesthesia, and trigeminal motor weakness. This procedure is easily performed with few complications and minimal risk to the patient and essentially exchanges pain for numbness. It is usually performed on an outpatient basis. It is tolerated well by older adults and avoids a major operative procedure, which is beneficial for patients at high risk for surgical complications (Al-Quliti, 2015; Zakrzewska, 2014).

Microvascular decompression of the trigeminal nerve, another commonly used procedure, is accomplished by displacing and repositioning blood vessels that appear to be compressing the nerve at the root entry zone where it exits the pons. This procedure relieves pain without residual sensory loss. Microvascular decompression has a long-term success rate equal or superior to that of percutaneous procedures, and the rate of permanent neurological outcomes such as numbness is lower (Al-Quliti, 2015; Zakrzewska, 2014). *Gamma Knife radiosurgery* is another surgical treatment that is used to alleviate trigeminal neuralgia. Radiosurgery with the Gamma Knife provides precise radiation of the proximal trigeminal nerve identified on high-resolution imaging. This approach has been useful both for patients with persistent pain after other surgical procedures and as a primary surgical option (Al-Quliti, 2015; Zakrzewska, 2014).

Nursing Management Trigeminal Neuralgia

Nursing Assessment

Assessment of the attacks—including triggering factors, characteristics, frequency, and pain management techniques—helps the nurse plan for patient care. The nursing assessment should include examination of the patient's nutritional status, hygiene (especially oral), and behaviour (including withdrawal). The degree of pain and its effects on the patient's lifestyle, drug history, emotional state, and depression and suicidal ideation are other important factors to assess.

Nursing Diagnoses

Nursing diagnoses for the patient with trigeminal neuralgia include but are not limited to the following:

- *Acute pain* related to *physical injury agent* (inflammation or compression of the trigeminal nerve)
- *Imbalanced nutrition: less than body requirements* related to *insufficient dietary intake* (fear of triggering pain by eating or chewing)
- *Anxiety* related to *threat to current status* (uncertainty of timing and initiating event of pain)
- *Impaired oral mucous membrane integrity* related to *inadequate oral hygiene* (potential for initiating pain)
- *Social isolation* related to *social behaviour incongruent with norms* (anxiety over pain attacks, desire to maintain nonstimulating environment)

Planning

The overall goals are that the patient with trigeminal neuralgia will (a) be free of pain, (b) maintain adequate nutritional and oral hygiene status, (c)

have minimal to no anxiety, and (d) return to normal or previous socialization and occupational activities.

Nursing Implementation

Health Promotion.

Because the etiology of trigeminal neuralgia remains unknown, health promotion is directed at reducing recurrent episodes in patients who have trigeminal neuralgia. Awareness and reduction of triggering events may be possible in some patients.

Acute Intervention.

Patients with trigeminal neuralgia are usually treated on an outpatient basis. Pain relief is obtained primarily by the administration of the recommended drug therapy. The nurse monitors the patient's response to therapy and notes any adverse effects. Alternative pain relief measures, such as biofeedback, should be explored for patients who are not surgical candidates and whose pain is not controlled by other therapeutic measures. A thorough assessment of pain with a valid and reliable tool, which includes the history of the pain problem and effectiveness of pain relief measures, can assist in selecting appropriate pain management interventions.

The nurse should review with the patient the importance of nutrition, hygiene, and oral care and teach methods to achieve all of this if neglect is apparent. For cleansing the face, the nurse should provide lukewarm water and soft cloths or cotton saturated with solutions that do not necessitate rinsing. A small, soft-bristled toothbrush or a warm mouthwash assists in promoting oral care. Hygiene activities are best performed when pain is managed and analgesic effectiveness is at its peak. Environmental management is essential during an acute period to lessen triggering stimuli.

Food should be high in protein and calories and easy to chew. It should be served lukewarm and offered frequently. When oral intake is sharply reduced and the patient's nutritional status is compromised, a nasogastric tube can be inserted on the unaffected side for enteral feedings.

The patient will probably not engage in extensive conversation during the acute period. Alternative communication methods, such as paper and pencil, should be provided.

The nurse should provide information or instructions related to diagnostic studies used to rule out other problems—such as multiple sclerosis, dental or sinus problems, and neoplasms—and for preoperative teaching if surgery is planned. The nurse may also have to clarify expectations related to postoperative outcomes. Appropriate teaching related to postoperative activities depends on the type of procedure planned (e.g., percutaneous, intracranial). The patient needs to know that he or she will be awake during local procedures so that he or she can cooperate when corneal and ciliary reflexes and facial sensations are checked. Patients are informed about the potential risk of postoperative facial numbness.

After the procedure, the patient's pain is compared with the preoperative level. The corneal reflex, extraocular muscles, hearing, sensation, and facial nerve function are evaluated frequently (see Chapter 58). If the corneal reflex is impaired, special attention must be paid to eye protection. This includes the use of artificial tears or eye shields. General postoperative nursing care after a craniotomy is appropriate if intracranial surgery is performed. (Nursing care related to craniotomy is discussed in Chapter 59.) Caloric intake and ambulation should be increased according to the patient's progress or specific orders.

After a percutaneous radiofrequency electrocoagulation procedure, an ice pack is applied to the jaw on the operative side for 3 to 5 hours. To avoid injuring the mouth, the patient should not chew on the operative side until sensation has returned.

Ambulatory and Home Care.

Regular follow-up care should be planned. The patient needs instruction regarding the dosage and adverse effects of medications. Although relief of pain may be complete, the patient should be encouraged to keep environmental stimuli to a moderate level and to use stress-reduction methods. The patient may have developed protective practices to prevent pain and may need counselling or psychiatric assistance in the readjustment, especially in re-establishing personal relationships. Herpes simplex infection (cold sores) can occur as a result of manipulation of the gasserian ganglion. Treatment consists of antiviral agents such as acyclovir (Zovirax) (see Chapter 26).

Long-term management after surgical intervention depends on the residual effects of the type of procedure. If hypesthesia (decreased sensitivity to stimulation, excluding the special senses) is present or the

corneal reflex is altered, the patient should be taught to (a) chew on the unaffected side; (b) avoid hot foods or beverages, which can burn the mucous membranes; (c) check the oral cavity after meals to remove food particles; (d) practise meticulous oral hygiene and continue with semiannual dental visits; (e) protect the face against extremes of temperature; (f) use an electric razor; and (g) wear a protective eye shield.

Evaluation

The following are expected outcomes for patients with trigeminal neuralgia:

- Relief or decreased pain
- Appearing more comfortable and less anxious
- Normal facial sensation or expected paresthesias and anaesthesias
- Return to previous socialization, or improved socialization, and occupational activities

Bell's Palsy

Etiology and Pathophysiology

Bell's palsy (peripheral facial paralysis, acute benign cranial polyneuritis) is a disorder characterized by a disruption of the motor branches of the facial nerve (cranial nerve VII) on one side of the face in the absence of any other disease such as a stroke. Bell's palsy is an acute, peripheral facial paresis of unknown cause. Average annual incidence rates of Bell's palsy are similar throughout the world, ranging between 11.5 and 40.2 per 100 000. It affects males and females equally and has slightly higher incidence in mid- to later life. (Eviston, Croxson, Kennedy, et al., 2015).

Although the exact etiology is not known, there is evidence associating immune, infective, and ischemic mechanisms as potential contributors. The reactivation of the herpes simplex virus infection is one example. The reactivation causes an inflammatory response with subsequent demyelination of the nerve, causing alterations in motor and sensory function (Eviston, Croxson, Kennedy, et al., 2015). Bell's palsy is considered benign; the majority of patients make a complete recovery. Improvement in facial function occurs in 85% of people within 3 weeks of

onset. Patients with complete facial paralysis at onset who have not experienced some recovery within the first 3 to 4 months are more likely to have incomplete recovery. Chronic facial palsy can be a disabling condition that has an impact on social function, emotional expression, and quality of life (Eviston, Croxson, Kennedy, et al., 2015).

Clinical Manifestations

The characteristic findings of Bell's palsy are acute onset of unilateral facial paralysis affecting muscles of the upper and lower face reaching a peak within 72 hours, resulting in facial drooping, an inability to close the eyelid, or an inability to frown or smile (Figure 63-3). Decreased muscle movement may alter chewing ability. Some patients may experience a loss of or excessive tearing. The muscle weakness causes the lower eyelid to turn out, allowing overflow of normal tear production. These symptoms are frequently accompanied by neck, mastoid, or ear pain; distortion in sense of taste; and altered facial sensation.

FIGURE 63-3 Facial characteristics of Bell's palsy. **A,** At rest the face may look almost normal, but the patient is not able to wrinkle her forehead on the affected (right) side, and the right corner of the mouth droops. **B,** When she tries to close her eyes and show her teeth, the differences between the affected and unaffected sides become more obvious. Source: Forbes, C. D., & Jackson, W. F. (2003). *Color atlas and text of clinical medicine* (3rd ed., p. 453, Figures 11.15 and 11.16). London: Mosby.

Diagnostic Studies

The diagnosis of Bell's palsy is based on clinical presentation. The diagnosis and prognosis are indicated by observation of the typical pattern of onset of symptoms. In situations with complete facial paralysis, neurophysiological testing (EMG studies) is helpful in predicting potential nerve recovery. Computed tomographic (CT) scan or MRI may be performed to rule out stroke or other neurological disease (Eviston, Croxson, Kennedy, et al., 2015).

Collaborative Care

Nonpharmacological treatments for Bell's palsy include eye protection for those with incomplete closure of their eyes. Prolonged irritation and drying can cause keratitis and ulceration and potentially impair eyesight. Eye protection includes barrier protection, lubrication, and taped closure at night. Oral care may include use of a straw for drinking. A change in diet texture toward soft foods may be necessary, and mastication techniques may need to adapt to avoid mucous membrane trauma (Eviston, Croxson, Kennedy, et al., 2015).

Drug Therapy.

Treatment with corticosteroids (prednisone) should be commenced within 72 hours of onset of symptoms. Steroids are given over a 2- to 3-week period with tapering doses after approximately 10 days (Eviston, Croxson, Kennedy, et al., 2015). Usually, the corticosteroid treatment decreases the edema and pain, but analgesics can be used if necessary to manage pain. Combining prednisone with an antiviral drug such as acyclovir (Zovirax) or valacyclovir (Valtrex) can improve the rate of recovery given that the herpes simplex virus can be a causal factor (Eviston, Croxson, Kennedy, et al., 2015). The length of treatment with antiviral medications is usually between 5 and 10 days. It is important to review with the patient and the family the medications that have been prescribed for the treatment of Bell's palsy, including any potential adverse effects.

Nursing Management Bell's Palsy

Nursing Assessment

Early recognition of the possibility of Bell's palsy is important. Because herpes simplex virus is a possible etiological factor, any person who is prone to herpes simplex should be alerted to seek health care if pain occurs in or around the ear. A complete assessment of cranial nerve VII, which includes the facial muscles should be completed, carefully assessing for any signs of weakness; patients should be asked to close their eyes, show their teeth, puff their cheeks and smile (Boyd & Tymianski, 2012).

Nursing Diagnoses

The nursing diagnoses for the patient with Bell's palsy may include but are not limited to the following:

- *Acute pain* related to *physical injury agent* (inflammation of cranial nerve VII—facial nerve)
- *Imbalanced nutrition: less than body requirements* related to *insufficient dietary intake* (inability to ingest food secondary to muscle weakness)
- *Risk for corneal injury* as evidenced by *blinking < 5 times per minute*
- *Disturbed body image* related to *alteration in self-perception* (change in facial appearance)

Planning

The overall goals are that the patient with Bell's palsy will (a) be pain free or be able to manage pain, (b) maintain adequate nutritional status, (c) maintain appropriate oral hygiene, (d) not experience injury to the eye, (e) return to normal or previous perception of body image, and (f) be optimistic about disease outcome.

Nursing Implementation

Bell's palsy is treated on an outpatient basis. The following interventions are used throughout the course of the disease. Mild analgesics can relieve pain. Hot wet packs can reduce the discomfort of herpetic lesions if present, aid circulation, and relieve pain. The face should be protected from cold and drafts because trigeminal *hyperesthesia* (increased sensitivity to stimulation such as touch) may accompany the syndrome. Maintenance of good nutrition is important. The patient should be taught to chew on the unaffected side of the mouth to avoid trapping food and to enjoy the taste of food. Thorough oral hygiene must be carried out after each meal to prevent the development of parotitis, caries, and periodontal disease from accumulated residual food.

Dark glasses may be worn for protective and cosmetic reasons. Artificial tears (methyl cellulose) should be instilled frequently during the day to prevent drying of the cornea. The eye should be inspected for the presence of eyelashes. Ointment and an impermeable eye shield can be used at night to retain moisture. In some patients, taping the lids closed at night may be necessary to provide protection. The patient is taught to report ocular pain, drainage, or discharge.

A facial sling may be helpful to support affected muscles, improve lip alignment, and facilitate eating. The facial sling is usually made and fitted by a physical or occupational therapist. Vigorous massage can break down tissues, but gentle upward massage has psychological benefits even if physical effects, other than the maintenance of circulation, are questionable. When function begins to return, active facial exercises are performed several times a day.

The change in physical appearance as a result of Bell's palsy can be devastating. Affected patients must be reassured that a stroke did not occur and that chances for a full recovery are good. A patient's need for privacy should be respected, especially during meals, but the nurse's assistance in the patient's adjustment to the physical changes should not be delayed. Enlisting support from family and friends is important. It is important to inform the patient that most patients with Bell's palsy recover within about 6 weeks of the onset of symptoms.

Evaluation

The following are expected outcomes for the patient with Bell's palsy:

- Freedom from pain
- No complications (e.g., corneal abrasion)

- Appropriate nutritional intake
- Minimal adverse effects associated with corticosteroid treatment
- Return to previous perception of body image

Polyneuropathies

Guillain-Barré Syndrome

Etiology and Pathophysiology

Guillain-Barré syndrome (GBS), also known as *Landry–Guillain-Barré–Strohl syndrome, postinfectious polyneuropathy,* and *ascending polyneuropathic paralysis,* is an acute, rapidly progressing, and potentially fatal form of polyneuritis. GBS affects the peripheral nervous system and results in loss of myelin (segmental demyelination), edema, and inflammation of the affected nerves. GBS manifests as a symmetrical ascending paralysis. The incidence is 1 to 2 per 100 000 per year. The disease is present worldwide and affects individuals of all age groups (Koopman & Shcharinsky, 2012).

The etiology of this disorder is unknown, but it is believed to be a cell-mediated immunological reaction directed at the peripheral nerves. It is typically preceded by either an upper respiratory (58%) or a gastro-intestinal infection (22%) (Ansar & Valadi, 2015). A possible link between vaccinations and the occurrence of GBS has been proposed, although the evidence for this link is not strong. *Campylobacter jejuni* is the organism most recognized to be associated with GBS (Ansar & Valadi, 2015). Other potential pathogens include *Mycoplasma pneumoniae,* cytomegalovirus, Epstein-Barr virus, varicella-zoster virus, and vaccines (rabies, swine influenza). These stimuli are thought to cause an alteration in the immune system, resulting in sensitization of T lymphocytes to the patient's myelin and, ultimately, myelin damage. Demyelination occurs, and the transmission of nerve impulses is stopped or slowed down. The muscles innervated by the damaged peripheral nerves undergo denervation and atrophy. In the recovery phase, remyelination occurs slowly, and neurological function returns in a proximal-to-distal pattern.

Clinical Manifestations

GBS symptoms range from mild to severe and typically progress over the course of hours to several days. GBS is characterized by relatively symmetrical muscle weakness, mild distal sensory symptoms of paresthesias (first in the feet, then in the hands) with absent or depressed deep tendon reflexes. Weakness develops classically in an ascending pattern involving the lower limbs first, then the upper extremities,

followed by the face and respiratory muscle; weakness may progress to complete paralysis (Koopman & Shcharinsky, 2012).

Four main subtypes of GBS include (a) acute inflammatory demyelinating polyneuropathy (AIDP) (80%–90%); (b) acute motor axonal neuropathy and acute sensorimotor axonal neuropathy (5%–10%); and (c) Miller Fisher syndrome (5%), a rare disorder characterized by ataxia, areflexia, and ophthalmoplegia (weakness or paralysis of the muscles controlling eye movements). In GBS, autonomic nervous system dysfunction results from alterations in both the sympathetic and the parasympathetic nervous systems. Autonomic disturbances are usually observed in patients with severe muscle involvement and respiratory muscle paralysis. The most dangerous autonomic dysfunctions include orthostatic hypotension, hypertension, and abnormal vagal responses (bradycardia, heart block, asystole). Other autonomic dysfunctions include bowel and bladder dysfunction, facial flushing, and diaphoresis (Koopman & Shcharinsky, 2012). Affected patients may also have the syndrome of inappropriate antidiuretic hormone secretion (SIADH, discussed in Chapter 51). Progression of GBS to include the lower brain stem involves the facial, abducens, oculomotor, hypoglossal, trigeminal, and vagus nerves (cranial nerves VII, VI, III, XII, V, and X, respectively). This involvement manifests itself through facial weakness, difficulties with extraocular eye movement, dysphagia, and paresthesia of the face.

Pain is a common symptom in patients with GBS secondary to the neuropathy that is occurring. The pain can be categorized as neuropathic pain and is described as prickling (paresthesia), burning, shooting, or stabbing. Pain appears to be worse at night. Pain may lead to a decrease in appetite and may interfere with sleep. Management of pain can include the use of analgesics such as nonsteroidal anti-inflammatory drugs, opioids, and drugs used to treat neuropathic pain (gabapentin, pregabalin, and carbamazepine). Nonpharmacological measures such as positioning, range-of-motion exercises, massage, and distraction can also be used to help manage pain. Pain management measures should be adapted based on assessment findings and evaluation of the pain management plan.

Complications.

The most serious complication of this syndrome is respiratory failure, which occurs as the paralysis progresses to the nerves that innervate the thoracic area. Constant monitoring of the respiratory system by checking respiratory rate, depth, forced vital capacity, and negative inspiratory force provides information about the need for immediate intervention,

including intubation and mechanical ventilation. Urinary tract infections (UTIs) or respiratory tract infections may occur. Fever is generally the first sign of infection, and treatment is directed at the infecting organism. Immobility from the paralysis can cause problems such as paralytic ileus, muscle atrophy, contractures, deep-vein thrombosis (DVT), pulmonary emboli (PEs), skin breakdown, orthostatic hypotension, and nutritional deficiencies.

Diagnostic Studies

Diagnosis is based primarily on the patient's history and clinical signs. Cerebro-spinal fluid (CSF) is normal or has a low protein content initially, but after 7 to 10 days, the protein level is elevated and the white cell count is normal. Results of EMG and nerve conduction studies are markedly abnormal and show evidence of demyelination (Koopman & Shcharinsky, 2012).

Collaborative Care

Management is aimed at supportive care, particularly ventilatory support, during the acute phase. Prevention of DVT and PE through prophylactic anticoagulation with heparin or low-molecular-weight heparin (LMWH) is routine. Practice guidelines endorse the use of plasma exchange or intravenous administration of immune globulin (IVIG) within 4 weeks of symptom onset in nonambulatory patients and within 2 weeks in ambulatory patients (Ansar & Valadi, 2015). Treatment results in distinct reductions in the length of hospital stay, length of time on a ventilator, and time required to resume walking. IVIG has also been shown to be as effective as plasma exchange (plasmapheresis) and has the advantage of immediate availability and greater safety. However, patients receiving IVIG need to be well hydrated and have adequate renal function. (Plasmapheresis is discussed in Chapter 16.) Once 3 weeks pass after disease onset, plasma exchange and IVIG therapies have little value. A review of the use of corticosteroids in the treatment of GBS has not shown them to be of any benefit (Ansar & Valadi, 2015).

Nutritional Therapy.

Nutritional intake can be compromised in patients with GBS. During the acute phase, patients may experience difficulty swallowing because of cranial nerve involvement. Mild dysphagia can be managed by placing patients in an upright position and flexing the head forward during

feeding. For more severe dysphagia, tube feedings may be required. Patients who experience paralytic ileus or intestinal obstruction may require total parenteral nutrition. Later in the course of the disease, motor paralysis or weakness continues to affect the ability to self-feed. Patients' nutritional status, including body weight, serum albumin levels, and calorie counts, must be evaluated at regular intervals.

Nursing Management Guillain-Barré Syndrome

Nursing Assessment

Assessment of patients with GBS is the most important aspect of nursing care during the acute phase. The nurse must monitor for ascending paralysis; assess respiratory function; monitor arterial blood gas (ABG) levels; and assess the gag, corneal, and swallowing reflexes during the routine assessment. Reflexes are usually decreased or absent.

Monitoring blood pressure and cardiac rate and rhythm is also important during the acute phase because transient cardiac dysrhythmias may occur as a result of autonomic dysfunction. Orthostatic hypotension secondary to muscle atony may occur in severe cases. Vasopressor agents and volume expanders may be needed to treat the low blood pressure. However, if SIADH is present, fluid restriction may be required.

Nursing Diagnoses

Nursing diagnoses for patients with GBS may include but are not limited to the following:

- *Impaired spontaneous ventilation* related to *respiratory muscle fatigue*
- *Risk for aspiration* as evidenced by *depressed gag reflex, impaired ability to swallow*
- *Acute pain* related to *physical injury agent* (paresthesias, muscle aches and cramps, hyperesthesias)
- *Impaired verbal communication* related to *environmental barrier* (intubation)
- *Anxiety* related to *threat to current status* (uncertain outcome and seriousness of the disease)
- *Self-care (bathing, dressing, feeding, toileting) deficits* related to fatigue, weakness, pain

- *Risk for impaired skin integrity* related to pressure over bony prominences (decreased mobility)

Planning

The overall goals are that the patient with GBS will (a) maintain adequate ventilation, (b) be free from aspiration, (c) be able to manage pain, (d) maintain an acceptable method of communication, (e) maintain adequate nutritional intake, and (f) return to usual physical functioning.

Nursing Implementation

The objective of therapy is to support body systems until the patient recovers. In the acute phase, patients are often cared for in the intensive care unit (ICU). Respiratory failure and infection are serious threats. Monitoring the vital lung capacity and ABG values is essential. If the vital capacity drops to less than 800 mL (15 mL/kg, or two-thirds of the patient's normal vital capacity) or the ABG levels deteriorate, endotracheal intubation or tracheostomy may be performed so that the patient can be mechanically ventilated (see Chapter 70). Meticulous suctioning technique is needed to prevent infection if the patient has an endotracheal tube or tracheostomy. Thorough bronchial hygiene and chest physiotherapy help clear secretions and prevent respiratory deterioration. If fever develops, sputum cultures should be obtained to identify the pathogen. Appropriate antibiotic therapy is then initiated.

Fear and anxiety are common feelings for both the patient and the family. These feelings often result from lack of knowledge regarding the disease progression. Answering the patient's and family's questions, clarifying misconceptions, and keeping the patient and the family informed help reduce this fear. Collaboration with other members of the interdisciplinary team, including occupational therapists and speech–language pathologists, is essential. At the peak of a severe episode, the patient may be incapable of communicating, and this can add to the patient's fear. A communication system must be established according to the patient's available abilities. Communication, however, remains extremely difficult if the disease progresses to involve the cranial nerves. The nurse must explain all procedures before performing them and reassure the patient that muscle function will return.

Urinary retention is common for a few days. Intermittent catheterization is preferred to an in-dwelling catheter to decrease the incidence of UTIs.

However, for acutely ill patients receiving a large volume of fluids (>2.5 L/day), in-dwelling catheterization may be safer because it reduces overdistension of a temporarily flaccid bladder and prevents vesico-ureteral reflux. Physiotherapy is indicated early to help prevent problems related to immobility. Passive range-of-motion exercises and attention to body position help maintain function and prevent contractures. Patients who develop facial paralysis must receive meticulous eye care to prevent corneal irritation or damage *(exposure keratitis).* Artificial tears should be instilled frequently during the day to prevent drying of the cornea. The eyes should be inspected for the presence of eyelashes. Ointment and an impermeable eye shield can be used at night to retain moisture.

Nutritional needs must be met despite possible problems associated with delayed gastric emptying, paralytic ileus, and potential for aspiration if the gag reflex is lost. In addition to checking for the gag reflex, nurses should note drooling and other difficulties with secretions, which may be more indicative of an inadequate gag reflex. Initially, tube feedings or parenteral nutrition may be used to ensure adequate caloric intake. Because of delayed gastric emptying, residual volumes of the feedings should be assessed at regular intervals or before feedings (see Chapter 42). Fluid and electrolyte therapy must be monitored carefully to prevent electrolyte imbalances. A bowel program should be initiated because constipation is a common problem related to diet changes, immobility, and decreased gastro-intestinal motility.

Pain assessment should be completed at least daily with a valid and reliable tool and the patient's self-report. A method of assessing pain without the patient's self-report may have to be established if the patient is unable to communicate verbally.

Patients with GBS who are experiencing paralysis are prone to skin breakdown as a result of immobility and decreased sensation. Patients should be assisted or encouraged to turn frequently; a turning schedule can be helpful in this regard. Skin and wound assessment should be performed daily. Specialty pressure-relieving beds can be used to decrease the potential for skin breakdown in these patients.

Throughout the course of the illness, the nurse must provide support and encouragement to the family and the patient. Residual problems and relapses are uncommon except in the chronic form of the disease. Complete recovery can be anticipated, although many patients continue to have a degree of residual pain and fatigue requiring them to change their work and daily activities. Recovery is a slow process that takes months (3–6 on average), with the majority of recovery occurring within the first year.

Further recovery can be seen even up to 3 years (Willison, Jacobs, & van Doorn, 2016).

Evaluation

The following are expected outcomes for the patient with GBS:

- Return to usual level of physical functioning
- Freedom from pain and discomfort
- Maintenance of nutritional status

Botulism

Etiology and Pathophysiology

Botulism is an acute neurological disorder that causes potentially life-threatening neuroparalysis due to a neurotoxin produced by the spore-forming bacterium *Clostridium botulinum,* which is present naturally throughout the environment and can be found in soil, water, and household dust and on surfaces of many foods. There are three main clinical presentations: foodborne botulism, infant botulism, and wound botulism. Botulism, a reportable disease, is rare in Canada. All forms of botulism can cause paralysis and be fatal. It is thought that the botulism neurotoxin destroys or inhibits the neurotransmission of acetylcholine at the myoneural junction, resulting in disturbed muscle innervation. The classic syndrome of botulism is a symmetrical, descending motor paralysis in an alert patient, with no sensory deficits (Public Health Agency of Canada, 2012).

Clinical Manifestations

Symptoms of foodborne botulism generally begin 12 to 36 hours after ingesting contaminated food; however, onset can begin as soon as 6 hours after exposure, or as long as 10 days later. Neurological manifestations develop rapidly over 2 to 4 days. Early symptoms for all types of botulism include fatigue, weakness, dizziness, double or blurred vision, difficulty speaking and swallowing, dry mouth, and headache. Symptoms associated with foodborne botulism include nausea, vomiting, and abdominal cramps. Paralysis typically starts in the shoulders and arms and progresses down the body. The course of the disease depends on the

amount of toxin absorbed. If only a small amount is absorbed, symptoms are mild and recovery is complete. When large amounts are absorbed, death may occur from circulatory failure, respiratory paralysis, or development of pulmonary complications. With proper early treatment, the fatality rate of botulism cases in Canada is as low as 5% to 10% (Public Health Agency of Canada, 2012).

Drug Therapy

The initial treatment of botulism is intravenous administration of botulinum antitoxin. Botulism antitoxin may be readministered in 2 to 4 hours if symptoms persist and again at 12- to 24-hour intervals if required.

The gastro-intestinal tract is purged by high colonic enemas, gastric lavage, and laxatives that do not contain magnesium to decrease the absorption of the toxin. Magnesium is contraindicated because it worsens toxin-induced neuro-muscular blockade.

Most people recover if diagnosed and treated quickly. Recovery can take several weeks to months. Severe botulism can require intensive medical and nursing care. If not diagnosed and treated, botulism can lead to death from respiratory failure within 3 to 10 days.

Tetanus

Etiology and Pathophysiology

Tetanus (lockjaw) is an extremely severe polyradiculitis (inflammation of the nerve roots) and polyneuritis (inflammation of nerves) affecting spinal and cranial nerves. It results from the effects of a potent neurotoxin produced by *Clostridium tetani.* The toxin interferes with the function of the reflex arc by blocking inhibitory transmitters at the presynaptic sites in the spinal cord and the brain stem. The spores of the bacillus are present in soil, garden mould, and manure. Thus *C. tetani* enters the body through contamination of a traumatic wound that provides an appropriate low-oxygen environment for the organisms to mature and produce toxin. The incubation period for tetanus is usually 3 to 21 days, with a range of 1 day to several months.

Tetanus is very rare in Canada thanks to routine immunizations. Over the years, the death rate has fallen to almost zero. Only six deaths had been reported in Canada between 2000 and 2014, with the last death reported in 2010 (Public Health Agency of Canada, 2014).

Clinical Manifestations

Initial manifestations of generalized tetanus include a feeling of stiffness in the jaw *(trismus)* or the neck, fever, and other symptoms of general infection; these symptoms then descend. Generalized tonic spasms occur because of the lack of reciprocal innervation. As the disease progresses, the neck muscles, the back, the abdomen, and the extremities become progressively rigid. In severe forms, continuous tonic convulsions may occur with *opisthotonos* (extreme arching of the back and retraction of the head). Laryngeal and respiratory spasms cause apnea and anoxia. Additional effects are manifested by overstimulation of the sympathetic nervous system, including profuse diaphoresis, labile hypertension, episodic tachycardia, hyperthermia, and dysrhythmias. The slightest noise, jarring motion, or bright light can set off a seizure. These seizures are agonizing. Mortality rates are highest in infants and older adults, and death is usually attributable to asphyxia or heart failure resulting from constantly recurring spasms. Residual injury—such as vertebral fracture, muscle contracture, and brain damage secondary to hypoxia—may be long-term consequences.

Drug Therapy.

The management of tetanus includes administration of tetanus and diphtheria toxoid booster and tetanus immune globulin (TIG) before the onset of symptoms to neutralize circulating toxins (see Chapter 71, Table 71-6). A much larger dose of TIG is administered to patients with manifestations of clinical tetanus. Control of spasms is essential and is managed by deep sedation and skeletal muscle relaxation, usually with diazepam (Valium), barbiturates, and, in severe cases, neuro-muscular blocking agents such as rocuronium (Zemuron) that act to paralyze skeletal muscles. Opioid analgesics such as morphine or fentanyl are also indicated for pain management. A 10- to 14-day course of penicillin, metronidazole, tetracycline, or doxycycline is recommended to inhibit further growth of *C. tetani.*

Because of laryngospasm and the potential need for neuro-muscular blocking drugs, a tracheostomy is usually performed early, and the patient is maintained on mechanical ventilation. Sedative agents and opioid analgesics are given concomitantly to all patients who are pharmacologically paralyzed. Any recognized wound should be debrided, and any abscess drained. Antibiotics may be given to prevent secondary infections. Nutrition is maintained through parenteral nutrition or nasogastric feeding. The mortality rate associated with tetanus is

declining. For patients who recover, convalescence is long and includes extensive physiotherapy.

Nursing Management Tetanus

Health teaching is aimed at ensuring tetanus prophylaxis, which is the most important factor influencing the incidence of this disease. Tetanus prevention and immunization protocols are summarized in Table 71-6 in Chapter 71. Adults should receive a tetanus and diphtheria toxoid booster every 10 years. The patient should be taught that immediate, thorough cleansing of all wounds with soap and water is important to the prevention of tetanus. If a patient sustains an open wound and has not been immunized within the previous 5 years, the health care provider should be contacted so that the patient can receive a tetanus booster.

The acute nursing management of the patient with tetanus is aimed at supportive care based on the treatment of clinical manifestations. The patient should be placed in a quiet, darkened room that is insulated against noise. Sedation should be induced judiciously. Nursing care should be administered with the utmost caution to avoid triggering spasms. Nursing care related to tracheostomy and mechanical ventilation is given as appropriate. An in-dwelling urinary catheter may be used to prevent bladder distension and urinary reflux in the presence of spasms in the muscles of the pelvic floor. Attention is also given to skin care. The patient needs emotional support during the acute phase because of the fear of death. The family also needs support and education.

Neuro-Syphilis

Neuro-syphilis is an infection of any part of the nervous system by the organism *Treponema pallidum* (see Chapter 55). The organism can invade the central nervous system within a few months of the original infection, and the disease can be fatal if not treated. Neuro-syphilis is often referred to incorrectly as "tertiary syphilis," but it can occur at any time in the course of syphilis and occurs in about 30% of untreated cases (Marra, 2015). Except for causing some changes in the CSF, including increases in the white blood cell count and protein levels and positive serological reaction, *T. pallidum* lies dormant for years. Late neuro-syphilis results from degenerative changes in the spinal cord *(tabes dorsalis)* and the brain stem *(general paresis). Tabes dorsalis* (progressive locomotor ataxia) is characterized by vague, sharp pains in the legs; ataxia; "slapping" gait; loss of proprioception and deep tendon reflexes; and zones of hyperesthesia. *Charcot joints,* which are characterized by enlargement,

bone destruction, and hypermobility, also occur as a result of joint effusion and edema. Other manifestations of neuro-syphilis include seizures and problems with vision and hearing.

Neurological symptoms associated with neuro-syphilis are numerous and, in many cases, nonspecific. Neuro-syphilis is a differential diagnosis for patients with neurological and psychiatric symptoms. *Dementia paralytica* is an ongoing spirochetal meningo-encephalitis that causes a general dissolution of mental and physical capabilities. It may mimic a number of major or minor psychoses. Management includes treatment with penicillin, symptomatic care, and protection from physical injury.

Spinal Cord Problems

Spinal Cord Injury

Spinal cord injuries (SCIs) have a devastating effect on health and well-being. The physical effects of SCI, as well as the complications and comorbid conditions associated with SCI, significantly affect quality of life and can even be life-threatening. Associated economic burdens result not only from health care costs but also from physical morbidity and premature mortality that affect productivity at a societal level. SCI is divided into traumatic (result of external physical impact) and nontraumatic (result of disease, infection, or tumour) categories.

The incidence of SCIs in Canada in 2010, based on discharge incidence (those discharged into the community), was reported to be 1 389 cases per year for traumatic SCI and 2 286 per year for nontraumatic SCI (Noonan, Fingas, Farry, et al., 2012). The overall prevalence of SCI in Canada is 85 586 persons (51% traumatic SCI and 49% nontraumatic SCI) (Noonan, Fingas, Farry, et al., 2012). Projected prevalence of SCI by 2025 is estimated to be 121 000 people living with SCI in Canada, with the greatest increase being individuals in the nontraumatic category (Farry & Baxter, 2010). The predicted increase in nontraumatic SCI is due to the aging population, which will result in a greater number of older individuals (60 years and older) living with SCI in the community. Traumatic SCI typically occurs in a younger age group, 20 to 30 years of age, with male-to-female ratio of 4 : 1, with the next largest group being those in the age range of 60 to 70 years of age, with male-to-female ratio of 2 : 1 (Noonan, Fingas, Farry, et al., 2012).

Older adults with traumatic injuries experience more complications, are hospitalized longer, and have a higher rate of mortality. Injuries are most common in the cervical spine, and such injuries are associated with the most devastating neurological impairments. In comparison with the general population, an individual with a traumatic SCI has a shorter life expectancy (15–30 years less), requires 2.7 times more contact with a physician, requires 30 times more hours of home care services, and is rehospitalized 2.6 times more often (Farry & Baxter, 2010).

The most common causes of premature death in the patient with **tetraplegia** (formerly called *quadriplegia* and used interchangeably; paralysis of both arms and legs and the trunk, which occurs with spinal cord damage at C8 or above) are usually related to compromised

respiratory function (pneumonia), impaired renal function (UTI), and impaired skin integrity (pressure injuries). Any combination of these will certainly increase risk for mortality.

Because of the potential for disruption of individual growth and development, altered family dynamics, economic loss in terms of absence from work, and the high cost of rehabilitation and long-term health care, spinal cord trauma is a major problem. Lifetime economic burden of SCI is substantial. For individuals with traumatic SCI, the estimates range from $1.5 million for incomplete **paraplegia** (paralysis and loss of sensation in the lower limbs and the trunk) to a cost of $3.0 million for complete tetraplegia (Krueger, Noonan, Trenaman, et al., 2013). Although many people with SCIs can care for themselves independently, those with the highest level of injury may require round-the-clock care at home or in a long-term care facility.

Etiology and Pathophysiology

Common causes of traumatic SCI include motor vehicle and motorcycle crashes, which account for 50%, and falls and work-related injuries (30%–40%). Falls are more typically causes of SCI in the older adult while motor vehicle crashes are a more common cause among young adults. The most common anatomical region affected by injury is the cervical spine (Singh, Tetreault, Kalsi-Ryan, et al., 2014).

Initial Injury.

SCI can result from cord compression by bone displacement, tumour, or abscess or from interruption of blood supply to the cord. The spinal cord is wrapped in tough layers of dura and is rarely torn or transected by direct trauma. Penetrating trauma, such as gunshot and stab wounds, can result in tearing and transection. The pathophysiology of SCI is best described as *biphasic.* The initial mechanical injury *(primary injury)* with failure of the spinal column (fracture or dislocation) imparts force to the spinal cord, disrupting axons, blood vessels, and cell membranes. This process is followed by a second phase *(secondary injury)* involving vascular dysfunction, edema, ischemia, electrolyte shifts, inflammation, free radical production, and apoptotic cell death (Witiw & Fehlings, 2015).

At the molecular level, *apoptosis* (cell death) occurs and may continue for weeks or months after the initial injury. Thus the complete cord damage in severe trauma is related to autodestruction of the cord. This autodestruction is confirmed by observations that, shortly after the injury,

petechial hemorrhages occur in the central grey matter of the cord. This hemorrhaging further leads to microvascular disruption and hemorrhage in surrounding white matter. Cord ischemia develops and may extend for many segments above and below the injury (Witiw & Fehlings, 2015). By 24 hours or less after injury, the development of edema above and below the level of injury as a result of ischemic damage may cause permanent cord damage. This ongoing destructive process is dominant early on, and it is therefore crucial that the initial care and management of the patient with an SCI limit further activation of these processes.

Figure 63-4 illustrates the cascade of events causing secondary injury after traumatic SCI. The resulting hypoxia reduces the oxygen tension below the level that meets the metabolic needs of the spinal cord. Lactate metabolites and an increase in vasoactive substances—including norepinephrine, serotonin, and dopamine—are noted. At high levels, these vasoactive substances cause vasospasms and hypoxia, leading to subsequent necrosis. Unfortunately, the spinal cord has minimal ability to adapt to vasospasm.

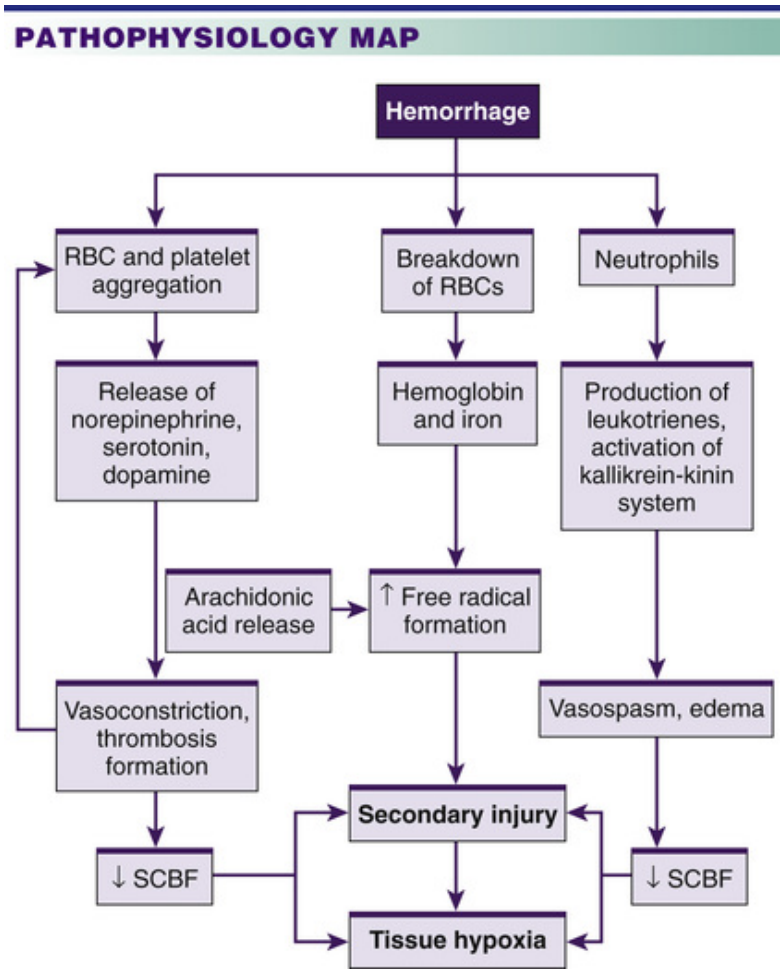

FIGURE 63-4 Cascade of metabolic and cellular events that leads to spinal cord ischemia and the hypoxia of secondary injury. *RBC,* red blood cell; *SCBF,* spinal cord blood flow. Source: Redrawn from Marciano, F. F., Greene, K., Apostolides, P. J., et al. (1995). Pharmacologic management of spinal cord injury. *BNI Quarterly, 11*(2), 6; and from McCance, K. L., & Huether, S. E. (2006). *Pathophysiology: The biologic basis for disease in adults and children* (5th ed.). St. Louis: Mosby.

The extent of the neurological damage caused by an SCI results both from primary injury or damage (actual physical disruption of axons) and from secondary injury damage (ischemia, hypoxia, microhemorrhage, and edema) (Witiw & Fehlings, 2015). Because secondary injury processes occur over time, the extent of injury and the prognosis for recovery are most accurately determined at 72 hours or longer after injury.

Spinal and Neurogenic Shock.

About 50% of people with acute SCI experience a temporary neurological syndrome known as **spinal shock** that is characterized by decreased

reflexes, loss of sensation, and flaccid paralysis below the level of the injury (Chin, 2015). This syndrome lasts days to months and may mask post-injury neurological function. Active rehabilitation may begin in the presence of spinal shock.

Neurogenic shock, in contrast, is caused by SCI at the fifth thoracic (T5) vertebra or above. It is a hemodynamic syndrome of massive vasodilation without compensation that results from the loss of sympathetic nervous system vasoconstrictor tone caused by spinal cord injury. Neurogenic shock is characterized by hypotension, bradycardia, and loss of sympathetic innervation, which produces peripheral vasodilation, venous pooling, and a decreased cardiac output (Chin, 2015).

Classification of Spinal Cord Injury.

SCIs are classified according to the mechanism of injury, the skeletal and neurological level of injury, and the completeness or degree of injury.

Mechanisms of Injury.

The major mechanisms of injury are flexion, hyperextension, flexion-rotation, extension-rotation, and compression (Figure 63-5). The flexion-rotation injury is the most unstable of all injuries because the ligamentous structures that stabilize the spine are torn. This injury is most often implicated in severe neurological deficits.

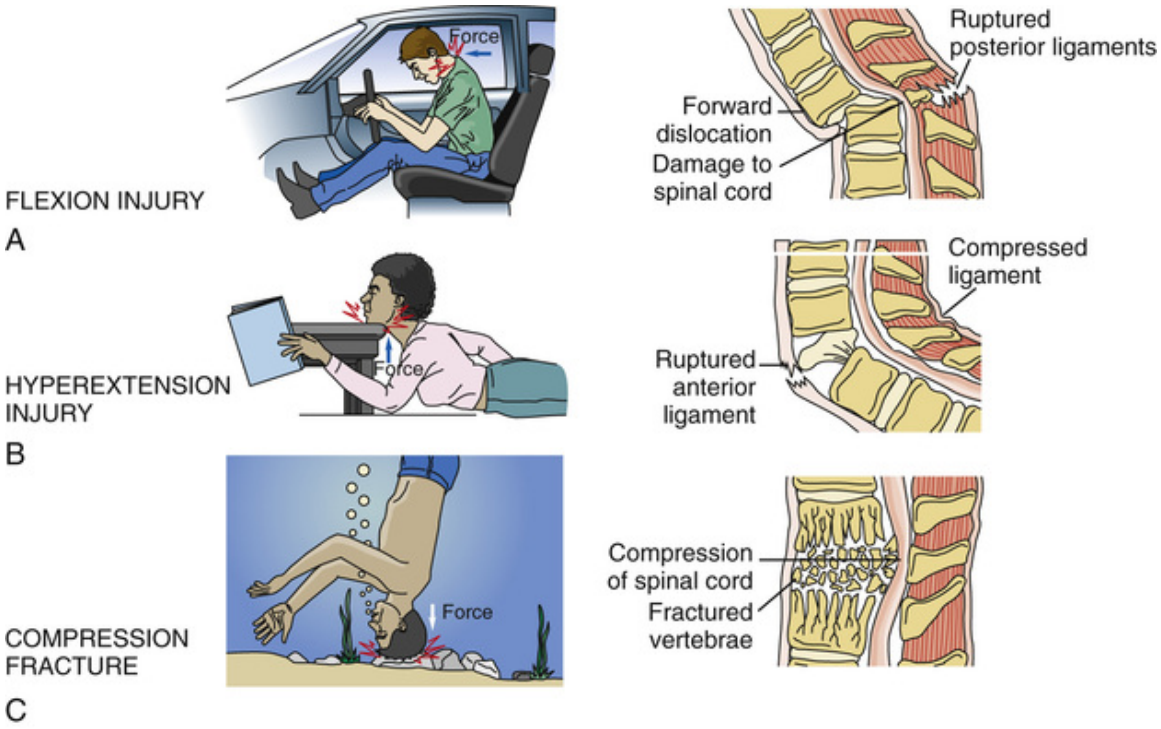

FIGURE 63-5 Mechanisms of spinal cord injury. Many situations can produce these injuries. This figure shows only some examples. **A,** Flexion injury of the cervical spine ruptures the posterior ligaments. **B,** Hyperextension injury of the cervical spine ruptures the anterior ligaments. **C,** Compression fractures crush the vertebrae and force bony fragments into the spinal canal. Source: Copstead-Kirkhorn, L. C., & Banasik, J. L. (2014). *Pathophysiology* (5th ed., p. 937, Figure 45-12). Philadelphia: W. B. Saunders.

Level of Injury.

The *skeletal level* of injury is the vertebral level where damage to vertebral bones and ligaments is most extensive. The *neurological level* of injury is the lowest segment of the spinal cord at which sensory and motor function on both sides of the body are normal. The level of injury may be cervical, thoracic, or lumbar. Cervical and lumbar injuries are most common because these levels are associated with the greatest flexibility and movement. If the cervical cord is involved, paralysis of all four extremities (tetraplegia) occurs. If the thoracic cord or conus in the lumbar spine is damaged, the result is paraplegia. Figure 63-6 shows affected structures and functions at different levels of cord injury.

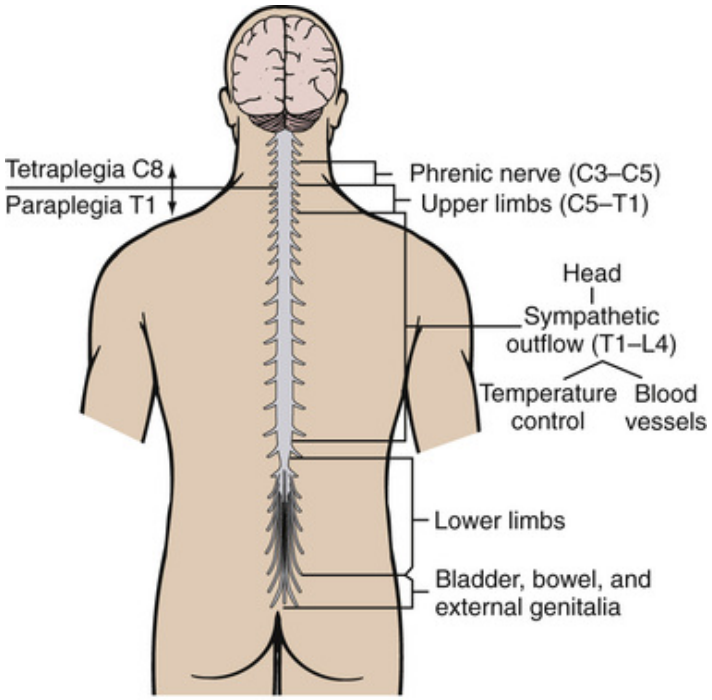

FIGURE 63-6 Results of spinal cord injury, depending on location. Symptoms, degree of paralysis, and potential for rehabilitation depend on the level of the lesion.

Degree of Injury.

The degree of spinal cord involvement may be either complete or incomplete (partial). *Complete cord involvement* (American Spinal Injury Association [ASIA] grade A) results in total loss of sensory and motor function below the level of the lesion (injury). *Incomplete cord involvement* (ASIA grades B–D) results in a mixed loss of motor and sensory function (Figure 63-7). The degree of sensory and motor loss varies depending on the level of the lesion and reflects the specific nerve tracts damaged. Six syndromes are associated with incomplete lesions: central cord syndrome, anterior cord syndrome, Brown-Séquard syndrome, posterior cord syndrome, cauda equina syndrome, and conus medullaris syndrome.

Source: American Spinal Injury Association. (2015). *International standards for neurological classification of spinal cord injury.* Retrieved from http://asia-

Central Cord Syndrome.

Damage to the central spinal cord is termed *central cord syndrome*. It occurs most commonly in the cervical cord region and is common with hyperextension injuries. Motor weakness and sensory loss are present in both the upper and the lower extremities; the upper extremities are more affected than the lower ones.

Anterior Cord Syndrome.

Anterior cord syndrome is caused by damage to the anterior spinal artery. It typically results from acute compression of the anterior portion of the spinal cord, often from a flexion injury. Manifestations include motor paralysis and loss of pain and temperature sensation below the level of injury. Because the posterior cord tracts are not injured, sensations of touch, position, vibration, and motion remain intact.

Brown-Séquard Syndrome.

Brown-Séquard syndrome is a result of damage to half of the spinal cord. This syndrome is characterized by a loss of motor function (spastic paralysis), sense of position (proprioception), and sense of vibration on the same *(ipsilateral)* side as the lesion. The opposite *(contralateral)* side has loss of pain and temperature sensation below the level of the lesion.

Posterior Cord Syndrome.

Posterior cord syndrome results from compression or damage to the posterior spinal artery. It is a very rare condition. In general, the dorsal columns are damaged, which results in loss of proprioception. However, pain, temperature sensation, and motor function below the level of the lesion remain intact.

Conus Medullaris Syndrome and Cauda Equina Syndrome.

Conus medullaris syndrome and *cauda equina syndrome* result from damage to the very lowest portion of the spinal cord *(conus)* and the lumbar and sacral nerve roots *(cauda equina).* Injury to the conus results in motor and sensory impairment, as well as bladder and bowel dysfunction. Injury to the cauda equina results in nerve root symptoms dependent on the level of the lesion; bowel and bladder function are typically affected.

American Spinal Injury Association Impairment Scale.

The ASIA Impairment Scale is the "gold standard" assessment scale used for classifying the severity of impairment resulting from SCI. It combines assessments of motor and sensory function of various myotomes and dermatomes to determine neurological level and completeness of injury. The strength of key muscle groups is graded on a scale of 0 to 5 and is tested bilaterally. Sensation is documented as *absent, impaired,* or *normal*. An ASIA grade (A–E) is then determined based on the assessment findings (Figure 63-8). This grading establishes whether the findings indicate complete or incomplete SCI or are normal. Various incomplete cord syndromes are also defined with this classification system and have been discussed previously. In addition, this scale is useful for recording changes in neurological status and identifying appropriate functional goals for rehabilitation.

Clinical Manifestations

The manifestations of SCI are generally the direct result of trauma that causes cord compression, ischemia, edema, and, rarely, cord transection. Manifestations of SCI are related to the level and the degree of injury. A patient with an incomplete lesion may demonstrate a mixture of symptoms. The higher the injury, the more serious the sequelae because of the proximity of the cervical cord to the medulla and the brain stem. Movement and functional goals related to specific locations of the SCI are described in Table 63-2. In general, sensory function closely parallels motor function at all levels.

TABLE 63-2
FUNCTIONAL GOALS WITH SPINAL CORD INJURY

Level of Injury	Movement and Deficits	Functional Goal	Assistance Needs
C1–4	• Absence of independent respiratory function • Loss of innervation to diaphragm • Movement in neck and above	Breathing	May necessitate ventilator or other devices
		Personal care	Attendant services
		Nutritional needs	Assistance required
		Transfers	Attendant services
		Mobility	Motorized wheelchair
		Environmental control	Devices to control lights, phone, door entry, voice-activated computer
		Housing	Supportive living services
C5	• Decreased respiratory reserve • Full neck • Gross elbow • Inability to roll over or use hands • Partial shoulder and biceps	Breathing	No assistance needed
		Personal care	Attendant services
		Nutritional needs	Assistance to meet needs (devices)
		Transfers	Attendant services
		Mobility	Motorized or manual wheelchair
		Environmental control	Devices to control lights, phone, door entry, voice-activated computer
		Housing	Supportive living services
C6	• Full biceps to elbow flexion • Rotation at shoulder • Shoulder and upper back abduction • Weak grasp of thumb • Wrist extension	Personal care	Independent with most activities (eating, washing, dressing upper body) Attendant services for some dressing, toileting Devices to assist sitting up and rolling over in bed
		Transfers	Minimal assistance
		Mobility	Independent in manual wheelchair; may be able to drive with adaptation to vehicle
C7	• Elbow extension • Finger extensors and flexors • Good grasp with some decreased strength	Personal care	Independent with most self-care activities
		Transfers	Independent with transfers
		Mobility	Independent in wheelchair
C8–T1	• Same as for C7	Personal care	Independent with all self-care activities
		Transfers	Independent
		Mobility	Independent
		Driving	Adaptations to vehicle required
		Housing	Independent living
T2–6	• Decreased trunk stability • Full movement of upper extremities • Full strength and dexterity of grasp • Intrinsic muscles of hand	Personal care	Independent with all self-care activities
		Mobility	May be able to stand in long leg braces with supports
T7–12	• Full, stable thoracic muscles and upper back • Functional intercostal muscles and therefore increased respiratory reserve	Personal care	Independent with all self-care activities
		Mobility	May walk for limited distances with long leg braces and crutches, using swing-through gait
L1–2	• Some instability of lower back • Varying control of legs and pelvis	Personal care	Independent May require assistance with bowel and bladder functioning
		Mobility	Good sitting balance Independent use of wheelchair May walk for limited distances with long leg braces

Level of Injury	Movement and Deficits	Functional Goal	Assistance Needs
L3–4	• Absence of hamstring function • Flail ankles • Quadriceps and hip flexors	Personal care	Independent
		Mobility	Independent ambulation with assistive devices

Source: Adapted from Sarro, A. (2012). Pediatric and adult spine. In *Navigating neuroscience nursing: A Canadian perspective* (Chapter 4). Pembroke, ON: Pappin Communications.

Immediate post-injury care includes maintaining patency of the airway, adequate ventilation, and adequate circulating blood volume and blood pressure to minimize extension of spinal cord damage (secondary injury).

Respiratory System.

Respiratory complications closely correspond to the level of the injury (Grossman, Frankowski, Burau, et al., 2012). Cervical injury above the level of C4 presents special problems because of the total loss of respiratory muscle function. Mechanical ventilation is required to keep the patient alive. At one time, most patients with these injuries died at the scene of the injury, but with improved emergency medical services, more such patients are surviving the initial events of the SCI. Injury or fracture below the level of C4 spares diaphragmatic breathing if the phrenic nerve is functioning. Even if the injury is below C4, spinal cord edema and hemorrhage can affect the function of the phrenic nerve and cause respiratory insufficiency. Hypoventilation almost always occurs with diaphragmatic respirations because of the decrease in vital capacity and tidal volume, which occurs as a result of impairment of the intercostal muscles.

Cervical and thoracic injuries cause paralysis of abdominal muscles and, often, of intercostal muscles. Therefore, the patient cannot cough effectively enough to remove secretions, which can lead to atelectasis and pneumonia. An artificial airway such as an endotracheal or tracheostomy tube provides direct access for pathogens; thus bronchial hygiene and chest physiotherapy to reduce infection are extremely important. Neurogenic pulmonary edema, which is caused by an increase in pulmonary interstitial and alveolar fluid, may occur secondary to a dramatic increase in sympathetic nervous system activity at the time of injury. In addition, pulmonary edema may occur in response to fluid overload.

Cardiovascular System.

Any SCI above the level of T6 greatly decreases the influence of the sympathetic nervous system, thereby resulting in bradycardia. Peripheral vasodilation results in hypotension. A relative hypovolemia exists because of the increase in venous capacitance. Cardiac monitoring is necessary. In marked bradycardia (heart rate <40 beats/min), appropriate drugs (atropine) to increase the heart rate are necessary. Peripheral vasodilation reduces the venous return of blood to the heart and subsequently decreases cardiac output, which results in hypotension. Intravenous fluids or vasopressor drugs may be needed to support blood pressure and maintain a mean arterial pressure of 85 mm Hg to adequately perfuse the spinal cord.

Urinary System.

Urinary retention occurs in acute SCIs and spinal shock. During spinal shock, the bladder is atonic and becomes overdistended. An in-dwelling urinary catheter is inserted to drain the bladder. After the acute phase, the bladder may become hyperirritable, with a loss of inhibition from the brain, which results in reflex emptying. Once the patient is medically and hemodynamically stable and large quantities of intravenous fluids are no longer required, the in-dwelling catheter should be removed and intermittent catheterization should begin as early as possible. Removal of the in-dwelling catheter helps to maintain bladder tone and decrease the risk for infection. (Intermittent catheterization is discussed later on in this chapter and in Chapter 48.)

Gastro-Intestinal System.

If the cord injury has occurred above the level of T5, the primary gastro-intestinal problems are related to hypomotility. Decreased gastro-intestinal motor activity contributes to the development of paralytic ileus and gastric distension. A nasogastric tube for intermittent suctioning may relieve the gastric distension. Metoclopramide may be used to treat delayed gastric emptying. The development of stress ulcers is common because of excessive release of hydrochloric acid in the stomach. Histamine H_2-receptor blockers (such as ranitidine [Zantac] and famotidine [Pepcid AC]) and proton pump inhibitors (e.g., omeprazole [Losec] or lansoprazole [Prevacid]) are frequently administered to prevent the occurrence of stress ulcers during the initial phase. Intra-abdominal bleeding may occur and is difficult to diagnose because the patient exhibits no subjective signs such as pain, tenderness, or guarding. Continued hypotension, despite vigorous

treatment and decreased hemoglobin and hematocrit, may be indications of bleeding. The girth of the abdomen may also expand.

Loss of neurological control over the bowel results in a *neurogenic bowel.* In the early period after injury when spinal shock is present and for patients with an injury level of T12 or below, the bowel is areflexic and sphincter tone is decreased. As reflexes return, the bowel becomes reflexic, sphincter tone is enhanced, and reflex emptying occurs. Both types of neurogenic bowel can be managed successfully with a regular bowel program coordinated with the gastrocolic reflex to minimize untimely incontinence.

Integumentary System.

A major consequence of lack of movement is the potential for skin breakdown over bony prominences in areas of decreased or no sensation. Pressure injuries can occur quickly and can lead to major infection or sepsis. See Chapter 14 for further information on pressure injuries.

Thermoregulation.

Poikilothermism is the adjustment of the body temperature to the room temperature. It occurs in patients with SCIs because the interruption of the sympathetic nervous system prevents peripheral temperature sensations from reaching the hypothalamus. The ability to sweat or shiver is also decreased below the level of the lesion, which affects the ability to regulate body temperature. The degree of poikilothermism depends on the level of injury. Patients with high cervical injuries have a greater loss of the ability to regulate temperature than do those with thoracic or lumbar injuries.

Metabolic Needs.

Nasogastric suctioning may lead to metabolic alkalosis, and decreases in tissue perfusion may lead to acidosis. Electrolyte levels can be altered by gastric suctioning and must be monitored until suctioning is discontinued and normal nutritional requirements are met. Loss of body weight (10% or more) is common, and nitrogen excretion mirrors weight loss (Fraser, McIntyre, Thompson, et al., 2014). Nutritional needs are much greater than what would be expected for an immobilized person. A positive nitrogen balance, which may not occur for more than 2 months after the injury, and a high-protein diet help prevent skin breakdown and infections and decrease the rate of muscle atrophy.

Peripheral Vascular Problems.

DVT is a common problem accompanying SCI during the first 3 months (Chung, Lee, Kim, et al., 2011). It is more difficult to detect a DVT in a person with an SCI because the patient does not exhibit the usual signs and symptoms, such as pain and tenderness. PE is one of the leading causes of death in patients with SCI. Techniques for assessment of DVT include Doppler ultrasound examination and measurement of leg and thigh girth.

Diagnostic Studies

Complete spine radiography may be performed initially to assess for vertebral fracture. However, MRI has become the "gold standard" for imaging neurological tissues, including the spinal cord. It is recommended that MRI be used to direct clinical decision making. An MRI is performed to assess spinal cord compression and damage, ligamentous injury, and soft tissue changes (Morais, de Melo Neto, Meguins, et al., 2014). CT may be used to assess the degree of bony injury and the degree of spinal canal compromise. A comprehensive neurological examination is performed, along with assessment of head, chest, and abdomen for additional injuries or trauma. In patients with cervical injuries who demonstrate altered mental status, vertebral angiography may also be needed to rule out vertebral artery damage.

Collaborative Care

The initial goals for the patient with an SCI are to sustain life and prevent further cord damage. Table 63-3 outlines the emergency management of a patient with an SCI. Systemic and neurogenic shock must be treated to maintain blood pressure. For injury at the cervical level, all body systems must be maintained until the full extent of the damage can be evaluated.

TABLE 63-3

EMERGENCY MANAGEMENT
Spinal Cord Injury

Etiology
Blunt Injury
• Compression, flexion, extension, or rotational injuries to spinal column • Diving • Falls • Motor vehicle accidents • Pedestrian accidents
Penetrating Injury
• Gunshot • Stab wounds • Stretched, torn, crushed, or lacerated spinal cord
Assessment Findings
• Alterations in sensation: temperature, light touch, deep pressure, proprioception • Bowel and bladder incontinence • Cuts; bruises; open wounds over head, face, neck, or back • Difficulty breathing • Diminished rectal sphincter tone • Neurogenic shock: hypotension; bradycardia; dry, flushed skin • Numbness, paresthesias • Pain, tenderness, deformities, or muscle spasms adjacent to vertebral column • Priapism • Spinal shock • Urinary retention • Weakness or heaviness in limbs • Weakness, paralysis, or flaccidity of muscles
Interventions
Initial
• Administer oxygen via nasal cannula or nonrebreather mask. • Assess for other injuries. • Control external bleeding. • Ensure patency of airway. • Establish intravenous access with two large-bore catheters to infuse normal saline or lactated Ringer's solution as appropriate. • Insert Foley catheter. • Stabilize cervical spine with hard collar or sandbags.
Ongoing Monitoring
• Anticipate need for intubation if gag reflex is absent or respiratory function declines. • Keep patient warm. • Monitor vital signs, level of consciousness, oxygen saturation, cardiac rhythm, and urine output.

Collaborative care during the acute phase for a patient with a cervical injury is described in Table 63-4. The systemic support required by the patient is less intense for SCIs of the thoracic and lumbar vertebrae. Respiratory compromise is not as severe, and bradycardia is not a problem. Specific problems are treated symptomatically. After stabilization at the injury scene, the patient is transferred to a medical facility, where further assessment, both clinical and radiological, is completed. A thorough assessment is performed to specifically evaluate the degree of deficit and to establish the level and the degree of injury. A

history is obtained, with emphasis on how the accident occurred and the extent of injury as perceived by the patient immediately after the accident. Assessment involves testing muscle groups rather than individual muscles. Muscle groups should be tested with and against gravity, alone and against resistance, and on both sides of the body. Spontaneous movement should be noted. The patient should be asked to move legs and then hands, spread fingers, extend wrists, and shrug shoulders. After assessment of motor status, a sensory examination, including assessment of touch and pain, should be carried out, starting at the toes and working upward. If time and conditions permit, position sense can also be assessed.

TABLE 63-4

COLLABORATIVE CARE
Cervical Cord Injury

Diagnostic
• History and physical examination, including complete neurological examination • Anteroposterior, lateral, and odontoid spinal radiographs • Arterial blood gas measurements • CT, MRI • Electrolyte measurements, glucose level, coagulation studies, hemoglobin and hematocrit levels • Serial bedside pulmonary function testing • Urinalysis
Collaborative Therapy
Acute Care
• Administration of intravenous fluids • Administration of O_2 by high-humidity mask • Bowel and bladder monitoring and initiation of training when hemodynamically stable • High-dose methylprednisolone therapy if ordered • Insertion of nasogastric tube and attachment to suction • Intubation if indicated • Maintenance of heart rate (e.g., with atropine) and blood pressure (e.g., with dopamine) • Placement and maintenance of halo traction if necessary • Placement of in-dwelling urinary catheter • Prophylaxis for deep-vein thrombosis • Prophylaxis for stress ulcers • Use of pressure-relieving surface
Rehabilitation and Home Care

• Bowel and bladder training
• Occupational therapy (activities of daily living training)
• Patient and caregiver education
• Physiotherapy
  • Chest physiotherapy
  • Mobility training
  • Muscle strengthening
  • Range-of-motion exercises
• Prevention of autonomic dysreflexia
• Prevention of pressure injuries
• Recreation therapy

CT, computed tomography; *MRI,* magnetic resonance imaging; O_2, oxygen.

The types of injury mechanisms that cause spinal cord trauma, especially those involving the cervical cord, may also result in brain injury. The patient should therefore be assessed for history of unconsciousness, signs of concussion, and increased intracranial pressure (see Chapter 59). In addition, a careful assessment for musculo-skeletal injuries and trauma to internal organs should be performed. Because the patient may have no muscle, bone, or visceral sensations, the only clue to internal trauma with hemorrhage may be rapidly falling hematocrit levels or persistent hypotension. Urinary output is examined for volume and hematuria, another indication of internal injuries.

To prevent further injury, the patient must be moved in alignment as a unit, as in log-rolling, during transfers and when repositioned. Respiratory, cardiac, urinary, and gastro-intestinal functions should be monitored closely. The patient may undergo surgery directly after initial immobilization and stabilization or be taken to the ICU for monitoring and management.

Nonoperative Stabilization.

Nonoperative treatments focus on stabilization and realignment of the injured spinal segment through traction. Stabilization methods eliminate damaging motion at the injury site. They are intended to prevent secondary spinal cord damage caused by repeated contusion or compression.

Surgical Therapy.

The decision to perform surgery on a patient with an SCI often depends on the preference of the physician and the availability of surgical services. Surgery stabilizes, realigns, and decompresses the spinal column. There is evidence that early surgical intervention is safe and feasible and that it can improve clinical and neurological outcomes and reduce health care costs (see the "Evidence-Informed Practice: Research Highlight" box). Other criteria used in the decision for early surgery include (a) evidence of cord compression, (b) progressive neurological deficit, (c) compound fracture of the vertebrae, (d) bony fragments (may dislodge and penetrate the cord), and (e) penetrating wounds of the spinal cord or surrounding structures.

Evidence-Informed Practice

Research Highlight

What Is the Effect of Early Versus Delayed Surgery for Patients With Traumatic Spinal Cord Injury?

Clinical Question

In patients with traumatic spinal cord injury *(P)*, what is the effect of early *(I)* versus delayed *(C)* decompressive surgery on patient grades on the ASIA Impairment Scale *(O)*?

Best Available Evidence

A multicentre, international, prospective cohort study was conducted in adults aged 16 to 80 with SCI. Primary outcome was a change in ASIA Impairment Scale grade at the 6-month follow-up visit.

Clinical Appraisal and Synthesis of Evidence

Results of previous studies in the laboratory supported the theory that decompressive surgery of the spinal cord within 24 hours of SCI reduced secondary injury and improved neurological outcome.

- 313 patients with SCI were enrolled
- 182 underwent early surgical decompression
- At 6-month follow-up after the injury, those who underwent early surgery showed an improvement of ≥2 grades on the ASIA Impairment Scale
- Complications occurred in 24.2% of patients who underwent early surgery and in 30.5% of those who underwent late surgery

Conclusions

- Surgical decompression within 24 hours after SCI can be performed safely and is associated with improved neurological outcome (defined as at least a 2-grade improvement on the ASIA Impairment Scale at the 6-month follow-up visit).

Implications for Nursing Practice

- It is important for nurses working in emergency and acute care to realize the effect of early surgical treatment for SCI and advocate for the transfer of the patient to a tertiary care facility that offers specialized care in SCI. A change in grade on the ASIA Impairment Scale for patients with SCI can indicate a huge effect on functional gain and can mean the difference between dependence and independence.

P, patient population of interest; *I,* intervention or areas of interest; *C,* comparison of interest; *O,* outcomes of interest (see Chapter 1).

Reference for Evidence

Fehlings MG, Vaccaro A, Wilson JR, et al. Early versus delayed decompression for traumatic cervical spinal cord injury: Results of the Surgical Timing in Acute Spinal Cord Injury Study (STASCIS). *PLoS ONE*. 2012;7(2):e32037; 10.1371/journal.pone.0032037.

The more common surgical procedures include decompression, realignment, and stabilization with instrumentation. These procedures are performed either posteriorly or anteriorly, depending on the level of injury and the area of cord compression (i.e., anterior versus posterior). If instability is considered severe enough, both anterior and posterior stabilization may be considered.

Drug Therapy.

Clinical trials (National Acute Spinal Cord Injury Studies [NASCIS] I, II, and III) have provided conflicting evidence about steroid treatment in acute SCI (Hurlbert, Hadley, Walters, et al., 2013). Steroid therapy is not without risk. Most patients with acute SCI are treated in ICUs, have polytrauma and impaired lung capacity, and are vulnerable to sepsis. Use of steroids superimposes risks on these compromised patients. The current medical opinion around the use of high-dose steroids is that it should be considered neither a standard treatment nor a guideline for treatment but, rather, a treatment option. If steroid use is considered, the protocol to be followed must be initiated within 8 hours of the SCI. It begins with a loading dose of 30 mg/kg intravenous (IV) over 15 minutes, followed by 5.4 mg/kg IV over the next 23 hours (Bracken, 2012).

Other neuroprotective drugs are being tested, and more treatment options may be available in the near future. Researchers are examining regeneration and repair strategies to induce axonal sprouting and promote remyelination of spared axons. Some of these approaches include anti-Nogo antibodies, BA-210 (Cethrin), bone marrow and stem cell implantation, and various cellular approaches (Wilson, Forgione, & Fehlings, 2013).

Vasopressor agents such as dopamine and norepinephrine are administered in the acute phase as adjuvants to treatment. These agents are used to maintain the mean arterial pressure at a level greater than 85

mm Hg so that perfusion to the spinal cord is improved (Hawryluk, Whetstone, Saigal, et al., 2015).

Pharmacological agents are administered to treat specific autonomic dysfunctions such as bradycardia, orthostatic hypotension, gastrointestinal hypoactivity, inadequate emptying of the bladder, and autonomic dysreflexia (discussed later in this chapter). The nurse must know the intended effects of such agents, observe responses, and provide specific interventions when adverse reactions are seen.

Nursing Management Spinal Cord Injury

Nursing Assessment

Subjective and objective data that should be obtained from a patient with a recent SCI are presented in Table 63-5.

TABLE 63-5

NURSING ASSESSMENT
Spinal Cord Injury

Subjective Data
Important Health Information
Past health history: Motor vehicle accident, sports injury, industrial accident, gunshot or stabbing injury, falls *Current medical history:* Use of alcohol or recreational drugs; risk-taking behaviours
Symptoms
• Dyspnea, inability to breathe adequately ("air hunger") • Fear, denial, anger, depression • Loss of strength, movement, and sensation below level of injury • Presence of tenderness, pain at or above level of injury; numbness, tingling sensation, burning sensation, twitching of extremities
Objective Data
General
Poikilothermism (inability to regulate body heat)
Integumentary
Warm, dry, flushed extremities below level of injury (neurogenic shock)
Respiratory
Lesions at C1–3: apnea, inability to cough Lesions at C4: poor cough, diaphragmatic breathing, hypoventilation Lesions at C5–T6: decreased respiratory reserve
Cardiovascular
Lesions above T5: bradycardia, hypotension, postural hypotension, absence of vasomotor tone
Gastro-Intestinal
Decreased or absent bowel sounds (paralytic ileus in lesions above T5), abdominal distension, constipation, fecal incontinence, fecal impaction
Urinary
Retention (for lesions between T1 and L2); flaccid bladder (acute stages); spasticity with reflex bladder emptying (later stages)
Reproductive
Priapism, loss of sexual function
Neurological
Complete: Flaccid paralysis and anaesthesia below level of injury that results in tetraplegia (for lesions above C8) or paraplegia (for lesions below C8); hyperactive deep tendon reflexes; bilaterally positive response to Babinski test (after resolution of spinal shock) *Incomplete:* Mixed loss of voluntary motor activity and sensation
Musculo-Skeletal
Muscle atony (in flaccid state), contractures (in spastic state)
Possible Findings
Spinal radiography: location of level and type of bony involvement CT: bony destruction and compression MRI: lesions and edema

CT, computed tomography; *MRI,* magnetic resonance imaging.

Nursing Diagnoses

Nursing diagnoses for patients with an SCI depend on the severity of the injury and the level of dysfunction. The nursing diagnoses for patients with an SCI may include but are not limited to the following:

- *Ineffective breathing pattern* related to *respiratory muscle fatigue, body position that inhibits lung expansion, fatigue*
- *Imbalanced nutrition: less than body requirements* related to *insufficient dietary intake* (paralytic ileus, metabolic demands of body)
- *Ineffective peripheral tissue perfusion* related to *sedentary lifestyle* (lack of mobility)
- *Impaired skin integrity* related to *pressure over bony prominence* (immobility)
- *Impaired urinary elimination* related to *multiple causality* (spinal injury, limited fluid intake)
- *Constipation* related to *irregular defecation habits* (neurogenic bowel, immobility)

Additional information on nursing diagnoses for the patient with SCI is presented in Nursing Care Plan (NCP) 63-1, available on the Evolve website.

Planning

The overall goals are that the patient with an SCI will (a) maintain optimal level of neurological functioning; (b) have minimal or no complications of immobility; (c) learn new skills, gain new knowledge, and acquire new behaviours to be able to care for self or successfully direct others to do so; and (d) return to home and the community at an optimal level of functioning.

Nursing Implementation

Health Promotion.

Nursing interventions for injury prevention include identification of at-risk populations, counselling, and education. Support of local legislation related to seat belt use in cars, helmets for motorcyclists and bicyclists, child safety seats, and tougher penalties for drunk driving offences is a professional responsibility. Parachute Canada is a national charitable

organization that is dedicated to preventing injuries and saving lives. It has partnered with organizations including ThinkFirst Canada, Safe Communities Canada, SMARTRISK, and Safe Kids Canada to develop injury-prevention programs.

It is important that the nurse emphasize the importance of other health promotion and health screening in addition to SCI care. After injury, health-promoting behaviours can have a significant effect on the health and well-being of the individual with SCI. Nursing interventions include education; counselling and referral to programs such as smoking cessation classes, recreation and exercise programs, and alcohol treatment programs; and maintenance of routine physical examinations for non-neurological problems. Outpatient health care requires that screening and prevention programs be accessible to people with SCIs. Nurses in these settings should facilitate the availability of wheelchair-accessible examination rooms, adjustable-height examination tables, and scheduling that allows extra time if needed.

Acute Intervention.

Regardless of the mechanism of injury and resultant spinal column damage, care of patients with SCIs is similar. Interventions for care are discussed in this section and may need to be modified on an individual basis.

Immobilization.

Proper immobilization of the neck involves the maintenance of a neutral position. A blanket or rolled towel, a hard cervical collar, and a backboard can be used to stabilize the neck to prevent lateral rotation of the cervical spine. The body should always be correctly aligned, and turning should be performed so that the patient is moved as a unit (e.g., log-rolling) to prevent movement of the spine.

Safety Alert

- A hard cervical collar and a backboard to stabilize the neck should be used to prevent lateral rotation of the cervical spine.
- The body should always be correctly aligned.

- The patient should be moved as a unit (i.e., log-rolling) when turned to prevent movement of the spine.

For cervical injuries, cervical traction is used less frequently. Traction should not be used unless the patient can communicate any changes in clinical status during application and subsequent assessments. When cervical traction is used, realignment or reduction of the injury is the goal. Halo traction involves the placement of a halo ring or crown, secured into the skull with four pins, with subsequent additions of weight to aid in spinal realignment. Traction is provided by a rope that is extended from the centre of the halo crown over a pulley and has weights attached at the end. Traction must be maintained at all times. The initial weight is typically 4.5 to 6.8 kg and thereafter approximately 2.2 kg per level of SCI (e.g., 2.2 kg for C1, 4.4 kg for C2, 6.6 kg for C3) with continual neurological monitoring. Additional weights are added until alignment is achieved, neurological changes occur, or overdistraction within the disc space is noted. Once proper alignment has been established, a halo vest is applied to provide ongoing immobilization of the cervical spine (Sarro, Anthony, Magtoto, et al., 2010). The halo vest stabilizes the injured area and allows ambulation if the patient is neurologically intact (Figure 63-9). Special care of the halo pin sites and halo vest is important for preventing infection and skin breakdown (Sarro, Anthony, Magtoto, et al., 2010) (Table 63-6).

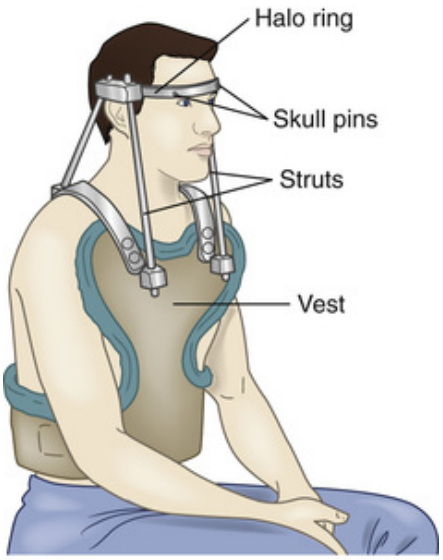

FIGURE 63-9 Halo vest. The halo traction brace immobilizes the cervical spine, which allows the patient to ambulate and perform self-care. Source: Urden, L. D., Stacy, K. M., & Lough, M. E. (2012). *Priorities in critical care nursing* (6th ed., p. 525, Figure 25-6). St. Louis: Mosby.

TABLE 63-6

PATIENT & CAREGIVER TEACHING GUIDE
Halo Vest Care

The following are teaching guidelines for a patient with a halo vest:

1. Visually inspect the pin sites on the halo ring on a regular basis. Report to the health care provider if pins are loose or if there are signs of infection, including redness, tenderness, swelling, or drainage at the insertion sites.
2. Clean pin sites daily with a clean cotton tip applicator or gauze soaked with normal saline for each individual pin site. If crusting or drainage is present, increase the frequency of cleansing to three times a day or as needed.
3. If crusting is present, wrap the pin site with normal saline–soaked gauze for 15–20 minutes and then remove. Using a gentle rolling motion, the crust can then be removed with a cotton-tipped applicator that has been soaked in normal saline.
4. To provide skin care, have the patient lie down on a bed on his or her side. Loosen one side of the vest, and place a towel against the sheepskin to protect it from getting wet. Assess skin for redness or areas of potential skin breakdown. Wash the patient's chest and back with soap and water. Dry the skin thoroughly, and resecure buckle straps. Do not use lotions or powders underneath the vest. Turn the patient onto the opposite side and repeat the steps.
5. A cotton T-shirt can be worn under the sheepskin for comfort and absorption of perspiration.
6. In case of an emergency, keep a wrench taped to the halo vest at all times.

Source: Based on Sarro, A., Anthony, T., Magtoto, R., et al. (2010). Developing a standard of care for halo vest and pin site care including patient and family education: A collaborative approach among three Greater Toronto Area teaching hospitals. *Journal of Neuroscience Nursing*, *42*, 169–175. doi:10.1097/JNN.0b013e3181d4a3be.

Infection at the sites of pin insertion is a potential problem. Preventive care includes cleansing the sites twice a day with normal saline solution. The development of redness or crusting could indicate looseness of pins,

and the physician or designate should be informed. The preventive care of insertion sites may vary, depending on individual hospital standards of care (Sarro, Anthony, Magtoto, et al., 2010).

Specialized beds or mattresses are often used in the management of patients with SCIs to help prevent pressure injury development. Many products are available and are often institution dependent. Mattress overlays often use gel as mediums. Specialized beds are typically dynamic and use a power source to alternate air currents and pressure against the body (Kruger, Pires, Ngann, et al., 2013).

Cervical collars for postsurgical stabilization are used on the basis of the surgeon's preference. With new techniques and better surgical stabilization, a collar is not required postoperatively. Patients with thoracic or lumbar spine injuries are stabilized with a custom thoraco-lumbar-sacral orthosis (TLSO brace), which controls spinal flexion, extension, and rotation, or with a Jewett brace, which restricts forward flexion.

Immobilization of the neck of a patient with SCI prevents further injury, but the effects of immobility are profound. Meticulous skin care is critical because decreased sensation and circulation render the patient particularly susceptible to skin breakdown. Patients should be removed from backboards as soon as possible to prevent coccygeal and occipital area skin breakdown. Cervical collars should be properly fitted or replaced with other forms of stabilization. It is important that areas under the halo vest, braces, and orthoses be inspected regularly to assess skin condition.

Respiratory Dysfunction.

Patients should be monitored in a special care unit to minimize pulmonary complications. During the first 48 hours after injury, spinal cord edema may increase the level of spinal cord dysfunction, and respiratory distress may occur. If the injury is at or above C3, if the patient is exhausted from laboured breathing, or if ABG levels deteriorate (indicating inadequate oxygenation or ventilation), endotracheal intubation and mechanical ventilation should be initiated. Respiratory arrest is a possibility that necessitates careful monitoring of the respiratory system and prompt action. Pneumonia and atelectasis are potential problems because of reduced vital capacity and the loss of intercostal and abdominal muscle function, which can result in diaphragmatic breathing, pooling of secretions, and ineffectiveness of cough (Ryken, Hurlbert, Hadley, et al., 2013). In addition to the neurological injury, predictive factors of potential respiratory complications include tachypnea on admission, older age, and previous respiratory disease. Older adults have a more difficult time

responding to hypoxia and hypercapnia and are extremely intolerant of hypoxia caused by lack of reserve. Therefore, aggressive chest physiotherapy, adequate oxygenation, and proper pain management are essential for maximizing respiratory function and gas exchange. Other problems include nasal stuffiness and bronchospasm.

The nurse must regularly assess (a) breath sounds, (b) ABG levels, (c) tidal volume, (d) vital capacity, (e) skin colour, (f) breathing patterns (especially the use of accessory muscles), (g) subjective comments about the ability to breathe, and (h) the amount and colour of sputum. Partial pressure of oxygen in arterial blood (PaO_2) above 60 mm Hg and partial pressure of carbon dioxide in arterial blood ($PaCO_2$) below 45 mm Hg are acceptable values in a patient with uncomplicated tetraplegia. A patient who is unable to count to 10 out loud without taking a breath needs immediate attention.

In addition to monitoring, the nurse can intervene in maintaining ventilation. Oxygen is administered until ABG levels stabilize. Chest physiotherapy and assisted coughing facilitate the expulsion of secretions. Assisted or augmented coughing simulates the action of the ineffective abdominal muscles during the expiratory phase of a cough. The nurse places the heels of both hands just below the patient's xiphoid process and exerts firm upward pressure to the area, timed with the patient's efforts to cough (see discussion of augmented coughing in Chapter 70). Tracheal suctioning should be performed if crackles or wheezes are present. Incentive spirometry is an additional technique that can be used to improve the patient's respiratory status.

Cardiovascular Instability.

Because of unopposed vagal response, the heart rate slows, often to less than 60 beats per minute. Any increase in vagal stimulation, such as turning or suctioning, can result in cardiac arrest. Loss of sympathetic tone in peripheral vessels results in chronic low blood pressure with potential postural hypotension. Lack of muscle tone to aid venous return can result in sluggish blood flow and predispose the patient to venous thrombo-embolism (VTE), DVT, or PE.

Vital signs should be assessed frequently. If bradycardia is symptomatic, an anticholinergic drug such as atropine is administered. A temporary pacemaker may be inserted. Hypotension is managed with a vasopressor agent, such as dopamine or norepinephrine (Levophed), and fluid replacement.

In older adults, the presence of cardiovascular disease must be considered. The cardiovascular system becomes less able to handle the stress of traumatic injury because heart contractions weaken, and cardiac output decreases. Maximum heart rate is also reduced.

Gradient compression stockings can be used to prevent thrombo-emboli and to promote venous return. The stockings must be removed every 8 hours for skin care. The use of pneumatic compression devices for the calves is advocated, and they must be applied as soon as possible after injury and maintained throughout the hospitalization. Venous duplex studies may be performed before compression devices are applied. The nurse should also help the patient perform range-of-motion exercises and stretch regularly. The thighs and calves of the legs should be assessed every shift for signs of DVT.

Administration of LMWH within 72 hours of injury and for a 3-month duration is recommended to minimize the occurrence of DVT or PE. Furthermore, when surgical intervention is required, LMWH therapy should be withheld the morning of surgery and resumed within 24 hours postoperatively. LMWH is preferable to unfractionated heparin in patients with SCI because of its longer half-life, lower risk for bleeding complications, and more predictable dose effect in comparison with unfractionated heparin (Dhall, Hadley, Aarabi, et al., 2013).

If blood loss has resulted from other injuries, hemoglobin and hematocrit levels should be monitored, and blood should be administered according to protocol. The nurse should also monitor the patient for indications of hypovolemic shock secondary to hemorrhage.

Fluid and Nutritional Maintenance.

During the first 48 to 72 hours after the injury, the gastro-intestinal tract may stop functioning (paralytic ileus), and a nasogastric tube must be inserted. Because the patient cannot have oral intake, fluid and electrolyte needs must be carefully monitored. Specific solutions and additives are ordered based on individual requirements. Once bowel sounds are present or flatus is passed, oral food and fluids can gradually be introduced. Because of severe catabolism, a high-protein, high-calorie diet is necessary for energy and tissue repair. In patients with cervical cord injuries, swallowing must be evaluated before oral feedings are started. Enteral feeding is the optimal route after SCI. When oral feeding is not possible, nasogastric, followed by nasojejunal and then percutaneous, endoscopic gastrostomy is suggested. The acute stage of injury is characterized by a reduction in metabolic activity, as well as a negative nitrogen balance that

cannot be corrected, even with aggressive nutritional support. Metabolic demands need to be accurately monitored to avoid overfeeding (Fraser, McIntyre, Thompson, et al., 2014).

Some patients experience anorexia, which can result from psychological depression, boredom with institutional food, or discomfort with being fed. Some patients have a normally small appetite. On occasion, refusal to eat is used as a means of maintaining control over the environment because of diminished or absent control over one's body (see the "Ethical Dilemmas" box). If the patient is not eating adequately, the cause should be thoroughly assessed. On the basis of this assessment, a contract may be made in which the patient and the nurse set mutual goals regarding the diet. This gives the patient increased control of the situation and often results in improved nutritional intake. General measures such as providing a pleasant eating environment, allowing adequate time to eat (including any self-feeding that the patient can achieve), encouraging the family to bring in special foods, and planning social rewards for eating may be useful. A calorie count should be kept, and the patient's daily weight recorded as a means of evaluating progress. If feasible, the patient should participate in recording calorie intake. Dietary supplements may be necessary to meet nutritional needs. Increased dietary fibre should be included to promote bowel function. The nurse should avoid allowing the patient's nutritional intake to become a basis for a power struggle.

Evidence-Informed Practice

Translating Research Into Practice

A nurse working in the rehabilitation unit for patients recovering from SCIs is assigned to Kelvin Tran, a 26-year-old man who suffered an SCI after his 4-wheeler overturned. Mr. Tran has an areflexic bladder. The nurse has discussed with him the various options for bladder management. He tells the nurse that he would prefer the in-dwelling catheter because he thinks that it would be the least disruptive to his daily schedule of activities.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
Patients using in-dwelling catheters, compared with those using intermittent catheters, have similar satisfaction with life and perceived health status. There may be more complications associated with an in-dwelling catheter (e.g., urinary tract infections) than with intermittent catheterization.	The nurse knows that an areflexic bladder is best managed with either an in-dwelling catheter or intermittent catheterization. The nurse also knows that patients may hesitate to select intermittent catheterization for a variety of reasons (e.g., they believe the procedure is painful, they are afraid of performing the procedure incorrectly and possibly hurting themselves, they do not want their lives interrupted by the need to drain their bladder 5–6 times per day).	After reviewing all the information, Mr. Tran indicates that he would prefer an in-dwelling catheter to intermittent catheterization as the method to self-manage his bladder.

Decision and Action

His nurse respects and supports his decision and plans to teach Mr. Tran and his caregiver how to obtain the necessary supplies and how to care for the catheter once discharged.

Ethical Dilemmas

Right to Refuse Treatment

Situation

A 25-year-old man suffered an SCI to C7–T1 after a motorcycle accident. Anterior cord syndrome was diagnosed, and he has motor paralysis, which may prevent him from riding motorcycles again. He has become extremely depressed and no longer wishes to live. Because of his emotional state, he is now refusing to eat. Can the patient be forced to receive enteral nutrition (tube feeding)?

Important Points for Consideration

- Withholding treatment in a newly injured but otherwise healthy young adult may present an ethical dilemma for health care providers.
- Approximately 20% to 30% of people with a new SCI experience a major depressive disorder as a result of the sudden loss of bodily control and feelings of helplessness.
- A thorough mental health and psychological evaluation is warranted; treatment of depression is necessary before determining the patient's capacity to make decisions.

- Most people (more than 90%) with an SCI who receive health care and have access to appropriate resources report a good quality of life. Therefore, requests to withhold treatment soon after SCI should be scrutinized.
- If, after adequate treatment for pain, depression, or other medical conditions, the patient persists in requests to withhold treatment, his ability to make an informed choice must be reassessed.
- A competent adult can decide to withhold treatment. If possible, action on the request should be delayed to ensure adequate informed consent and to determine whether quality of life is adequate.

Clinical Decision-Making Questions

1. How might the nurse feel about requests to withhold treatment for a young person with a newly acquired disability?
2. What resources are available to help the patient and the staff work through this emotionally charged and ethically complex situation?

Bladder and Bowel Management.

Immediately after injury, urine is retained because of the loss of autonomic and reflex control of the bladder and the sphincter. Because the patient has no sensation of fullness, overdistension of the bladder can result in reflux into the kidneys, with eventual renal failure. Bladder distension may even result in rupture of the bladder. Consequently, an in-dwelling catheter is usually inserted as soon as possible after injury. Its patency must be ensured by frequent inspection and irrigation if necessary. Strict aseptic technique for catheter care is essential to avoid introducing infection.

After patients are stabilized, the best means of managing urinary function is assessed. Usually, an intermittent catheterization program is started. As well as having been shown to reduce UTIs in comparison with use of an in-dwelling catheter, intermittent catheterization is the safest method of bladder management for protecting the kidneys. Many patients are maintained on fluid restriction of 1 800 to 2 000 mL/day to facilitate a bladder training program, and urinary output is monitored closely.

UTIs are a common problem. The best method for preventing UTIs is regular and complete bladder drainage. Catheterization should be performed to prevent bladder volume from exceeding 500 mL. A typical regimen would be to catheterize every 4 hours for volumes of 300 to 500 mL, every 3 hours for volumes greater than 500 mL, and every 6 hours for

volumes less than 300 mL. If the appearance or odour of the urine is suspect or if the patient develops symptoms of a UTI (e.g., chills, fever, malaise), a urine specimen is sent for culture.

Age-related changes in renal function should be considered. Older adults are more likely to develop renal calculi, and older men may have prostatic hyperplasia, which may interfere with urinary flow and complicate management of urinary problems.

Constipation is generally a problem during spinal shock because no voluntary or involuntary (reflex) evacuation of the bowels occurs. A bowel program should be started during acute care. This consists of a rectal stimulant (suppository or mini-enema) to be inserted daily at a regular time of day, followed by gentle digital stimulation or manual evacuation performed by the nurse until evacuation is complete. Initially, the program may be performed in bed in the side-lying position, but as soon as the patient has resumed sitting, it should be performed in the upright position on a padded bedside commode chair.

Temperature Control.

Temperature control is largely external to the patient because there is no vasoconstriction, piloerection, or heat loss through perspiration below the level of injury. The nurse must monitor the environment closely to maintain an appropriate temperature. Body temperature should be monitored regularly. The patient should not be overloaded with covers or unduly exposed (such as during bathing). If an infection with high fever develops, more extensive means of temperature control, such as a cooling blanket, may be necessary.

Stress Ulcers.

Stress ulcers are a problem for the patient with an SCI because of the physiological response to severe trauma, psychological stress, and high-dose corticosteroids if used. The incidence of ulcers peaks 6 to 14 days after injury. Histamine H_2-receptor blockers, such as ranitidine (Zantac) and famotidine (Pepcid AC), or proton pump inhibitors, such as omeprazole (Losec) or pantoprazole (Prevacid), may be given prophylactically to decrease the secretion of hydrochloric acid.

Sensory Deprivation.

To prevent sensory deprivation, the nurse must compensate for the patient's absence of sensations by stimulating the patient above the level of injury. Conversation, music, strong aromas, and interesting flavours

should be a part of the nursing care plan. Every effort should be made to prevent the patient from withdrawing from the environment.

Patients with SCIs often report altered sensorium and vivid dreams during the acute phase of their treatment. Whether this is caused by drugs used to manage pain and anxiety is not known. Patients may also experience disrupted sleep patterns as a result of the hospital environment or post-traumatic stress disorder.

Reflexes.

Once spinal cord shock is resolved, the return of reflexes may complicate rehabilitation. In the absence of control from the higher brain centres, reflexes are often hyperactive, and responses may be exaggerated. Penile erections can result from a variety of stimuli, causing embarrassment and discomfort. Spasms ranging from mild twitches to convulsive movements below the level of the lesion may also occur. This reflex activity may be interpreted by the patient or family as a return of function, and the nurse must tactfully explain the reason for the activity. The patient may be informed of the positive use of these reflexes in sexual, bowel, and bladder retraining. Spasms may be controlled with the use of antispasmodic drugs. Most commonly prescribed are baclofen (Lioresal), dantrolene (Dantrium), and tizanidine. Botulism toxin injections may also be given to treat severe spasticity.

Autonomic Dysreflexia.

The return of reflexes after the resolution of spinal shock means that patients with an injury level at T6 or higher may develop autonomic dysreflexia. **Autonomic dysreflexia** (also known as *autonomic hyper-reflexia*) is a massive, uncompensated cardiovascular reaction mediated by the sympathetic nervous system. It occurs in response to visceral stimulation once spinal shock is resolved in patients with spinal cord lesions. This condition is a life-threatening situation that necessitates immediate resolution. If resolution does not occur, this condition can lead to status epilepticus, stroke, myocardial infarction, or even death.

The most common precipitating cause is distension of the bladder or rectum, although any sensory stimulation may cause autonomic dysreflexia. Contraction of the bladder or the rectum, stimulation of the skin, or stimulation of the pain receptors may also cause autonomic dysreflexia. Manifestations include hypertension (up to 300 mm Hg systolic), throbbing headache, marked diaphoresis or flushing of skin above the level of the lesion, bradycardia (30 to 40 beats per minute),

piloerection (erection of body hair) as a result of pilomotor spasm, blurred vision or spots in the visual fields, nasal congestion, anxiety, and nausea. It is important to measure blood pressure when a patient with an SCI complains of a headache (Krassioukov, Blackmer, Teasell, et al., 2014). A normal blood pressure for a patient with tetraplegic SCI is a systolic blood pressure of 90 to 100 mm Hg. Any pressure higher than this should be considered hypertensive.

The pathology of autonomic dysreflexia involves the stimulation of sensory receptors below the level of the cord lesion. The intact autonomic nervous system below the level of the lesion responds to the stimulation with a reflex arteriolar vasoconstriction that increases blood pressure. Baroreceptors in the carotid sinus and the aorta detect the hypertension and stimulate the parasympathetic system. This stimulation results in a decrease in heart rate, but the visceral and peripheral vessels do not dilate because efferent impulses cannot pass through the cord lesion.

In this serious emergency, nursing interventions include elevating the head of the bed 45 degrees or sitting the patient upright, notifying the physician, and assessing the patient to determine the cause. The most common cause is bladder distension. Immediate catheterization to relieve bladder distension may be necessary. Lidocaine jelly should be instilled in the urethra before catheterization. If a catheter is already in place, it should be checked for kinks or folds. If it is plugged, small-volume irrigation should be performed slowly and gently to open the catheter, or a new catheter may be inserted. Stool impaction can also result in autonomic dysreflexia. A digital rectal examination should be performed only after application of an anaesthetic ointment to decrease rectal stimulation and to prevent an increase of symptoms. If neither bladder nor bowel distension is determined to be causative, the nurse should remove all skin stimuli, such as constrictive clothing, tight shoes, and splints. Blood pressure should be monitored frequently during the episode. If symptoms persist after the source has been relieved, an α-adrenergic blocker or an arteriolar vasodilator (e.g., nifedipine) is administered. Careful monitoring must continue until the vital signs stabilize.

The patient and caregivers should be taught the causes and symptoms of autonomic dysreflexia (Table 63-7). They must understand the life-threatening nature of this dysfunction and know how to relieve the cause.

TABLE 63-7

PATIENT & CAREGIVER TEACHING GUIDE
Autonomic Dysreflexia

The following information should be included in the teaching plan for a patient at risk for autonomic dysreflexia:

1. Signs and symptoms
    - Sudden onset of acute headache
    - Elevation in blood pressure, reduction in pulse rate, or both
    - Flushed face and upper chest (above the level of the lesion) and pale extremities (below the level of the lesion)
    - Sweating above the level of the lesion
    - Nasal congestion
    - Feeling of apprehension
2. Immediate interventions
    - Raise the patient to a sitting position.
    - Remove the stimulus (fecal impaction, distended bladder, tight clothing).
    - Call the health care provider if these actions do not relieve the signs and symptoms.
3. Measures to suppress the incidence of autonomic dysreflexia
    - Maintain regular bladder and bowel function.
    - If manual rectal stimulation is used to promote bowel function, local anaesthetics may prevent autonomic dysreflexia from occurring.
    - Wear a medical alert bracelet indicating a history of autonomic dysreflexia.

Rehabilitation and Home Care.

The physiological and psychological rehabilitation of patients with SCIs is complex and involved. With physical and psychological care and intensive and specialized rehabilitation, patients with SCIs learn to function at the highest level of wellness. It is recommended that all patients with a new SCI receive comprehensive inpatient rehabilitation in a rehabilitation unit or centre that specializes in SCIs.

Many of the problems identified in the acute period become chronic and continue throughout life. Rehabilitation focuses on refined retraining of physiological processes and extensive patient and caregiver teaching about how to manage the physiological and life changes resulting from injury.

Rehabilitation is a multidisciplinary endeavour carried out through a team approach. Team members include rehabilitation nurses, physicians, physiotherapists, occupational therapists, speech–language pathologists, vocational counsellors, psychologists, therapeutic recreation specialists, prosthetists, orthotists, and dietitians. Rehabilitation care is organized around the individual patient's goals and needs. During rehabilitation, patients are expected to be involved in therapies and learn self-care for several hours each day. Such intensive work at a time when the patient is dealing with the sudden change in health and functional status can be very stressful. Progress may be slow, and frequent encouragement may be

required. The rehabilitation nurse has a pivotal role in providing encouragement, specialized nursing care, and patient and caregiver teaching and in helping to coordinate the efforts of the rehabilitation team.

Respiratory Rehabilitation.

The patient with high cervical SCI may have greatly increased mobility with phrenic nerve stimulators or electronic diaphragmatic pacemakers. These devices are not appropriate for all ventilator-dependent patients but may be helpful for those with an intact phrenic nerve. Today, ventilators are also reasonably portable, and ventilator-dependent tetraplegic patients can be mobile and somewhat independent. Patients and caregivers should be taught all aspects of home ventilator care, and referrals should be made to appropriate community agencies. Patients with injuries at the cervical level who are not ventilator dependent should be taught assisted coughing and regular use of incentive spirometry or deep-breathing exercises.

Neurogenic Bladder.

A **neurogenic bladder** is any type of bladder dysfunction related to abnormal or absent bladder innervation. After spinal cord shock resolves, depending on the completeness of the SCI, patients usually have some degree of neurogenic bladder. Normal voiding requires nervous system coordination of urethral and pelvic floor relaxation with simultaneous contraction of the detrusor muscle. Depending on the lesion, a neurogenic bladder may have no reflex detrusor contractions (areflexic, flaccid), may have hyperactive reflex detrusor contractions (hyper-reflexic, spastic), or may lack coordination between detrusor contraction and urethral relaxation (dyssynergia). Common problems with a neurogenic bladder include urgency, frequency, incontinence, inability to void, and high bladder pressures that cause reflux of urine into the kidneys.

Neurogenic bladder can be classified according to reflex detrusor activity, intravesical filling pressure, and continence function. Types of neurogenic bladder are outlined in Table 63-8. Diagnostic and collaborative care of neurogenic bladder is described in Table 63-9. Patients with SCI and a neurogenic bladder require a comprehensive program to manage bladder function.

TABLE 63-8
TYPES OF NEUROGENIC BLADDER

Type	Characteristics	Causes	Clinical Manifestations
Reflexic (spastic, uninhibited, upper motor neuron)	No inhibitions influence time and place of voiding; bladder empties in response to stretching of bladder wall	Cortico-spinal tract lesion; observed in spinal cord injury, stroke, multiple sclerosis, brain tumour, brain trauma	Incontinence, frequency, urgency; voiding is unpredictable and incomplete
Areflexic (autonomous, flaccid, lower motor neuron)	Bladder acts as if all motor functions are paralyzed, fills without emptying	Lower motor neuron lesion caused by trauma involving S2–4; observed in lesions of cauda equina, pelvic nerves	If sensory function intact, patient feels bladder distension and hesitancy; no control of micturition results in overdistension of bladder and overflow incontinence
Sensory	Lack of sensation of need to urinate	Damage to sensory limb of bladder spinal reflex arc; observed in multiple sclerosis, diabetes mellitus	Poor bladder sensation, infrequent voiding of large residual volume

TABLE 63-9
COLLABORATIVE CARE
Neurogenic Bladder

Diagnostic
• History and physical examination, including neurological examination • Urodynamic testing • Urine culture
Collaborative Therapy

• Drug therapy
  • Relaxation of urethral sphincter (α-adrenergic blockers)
  • Suppression of bladder contractions (anticholinergics)
  • Suppression of pelvic floor spasticity (baclofen [Lioresal])
• Fluid intake of 1 800–2 000 mL/day
• Surgery
  • Electrical stimulation
  • Sphincterotomy
  • Urinary diversion
• Urine drainage
  • In-dwelling catheter
  • Intermittent catheterization
  • Voluntary or reflex voiding

After the patient's overall condition is stable and there is evidence of neurological reflexes, urodynamic testing and a urine culture are performed to aid in determining the type of neurogenic bladder dysfunction experienced. The method used for urinary drainage depends on the type of neurogenic bladder dysfunction, the preference of the patient, and availability of a family member or caregiver, the physician, and the nursing staff. Numerous drainage methods are possible. Surgical

options include sphincterectomy, implantation of a functional electrical stimulation device, and urinary diversion.

Many factors are considered when a bladder management strategy is selected: upper extremity function, caregiver burden, and lifestyle choices. The type of bladder dysfunction also defines treatment goals and management options. For a reflexic bladder with detrusor and sphincter dyssynergia, interventions must enable low-pressure storage, low-pressure voiding, and adequate emptying. Anticholinergic drugs (e.g., oxybutynin [Oxytrol], tolterodine [Detrol]) may be used to suppress bladder contraction. α-Adrenergic blockers (e.g., terazosin, alfuzosin, doxazosin [Cardura]) may be used to decrease outflow resistance at the bladder neck, and antispasmodic drugs (e.g., baclofen [Lioresal]) may be used to decrease spasticity of pelvic floor muscles.

Drainage options include intermittent catheterization, placement of an external catheter (condom catheter), or placement of an in-dwelling catheter. A reflexic bladder with detrusor hyper-reflexia may be treated with anticholinergic drugs, intravesical capsaicin, or botulinum A toxin. An areflexic bladder is usually managed with intermittent catheterization or an in-dwelling catheter.

The long-term use of an in-dwelling catheter should be carefully evaluated because of the associated high incidence of UTI, fistula formation, and diverticula. However, for some patients, it is the best option. Adequate fluid intake and patency of the catheter should be ensured. The frequency of routine catheter changes ranges from 1 week to 1 month, depending on the type of catheter used and institutional policy.

Intermittent catheterization is the most commonly recommended method of bladder management (see Chapter 48). Nursing assessment is important in selecting the time interval between catheterizations. Catheterization should be performed to prevent bladder volume from exceeding 500 mL. A typical regimen would be to catheterize every 4 hours for volumes of 300 to 500 mL, every 3 hours for volumes greater than 500 mL, and every 6 hours for volumes less than 300 mL. An overdistended bladder can cause ischemia of the bladder wall, which may predispose tissues to bacterial invasion and infection. Patients often experience diuresis at a regular time during a 24-hour period. The number of intermittent catheterizations per day is usually five or six.

Urinary diversion surgery may be necessary if a patient has repeated UTIs with renal involvement or repeated stones or if therapeutic intervention has been unsuccessful (see Chapter 48). Surgical treatment of neurogenic bladder includes bladder neck revision (sphincterotomy),

bladder augmentation (augmentation cystoplasty), penile prosthesis, artificial sphincter, perineal ureterostomy, cystotomy, vesicotomy, and anterior urethral transplantation.

Regardless of which bladder management strategy is selected, the nurse must teach the patient and the family or caregivers about how to accomplish successful self-management, including management techniques, how to obtain necessary supplies, care of supplies and equipment, and when to seek health care. Resources and referrals for supplies and ongoing care must be arranged.

Neurogenic Bowel.

Careful management of bowel evacuation is necessary in patients with SCIs because voluntary control of this function may be lost. The usual measures for preventing constipation include a high-fibre diet and adequate fluid intake (see Chapter 45, Table 45-9). Patient and caregiver teaching guidelines related to bowel management are presented in Table 63-10. However, these measures by themselves may not be adequate to stimulate evacuation. In addition, suppositories (bisacodyl [Dulcolax] or glycerin) or small-volume enemas and digital stimulation by the nurse or patient may be necessary. In patients with an upper motor neuron lesion, digital stimulation is necessary to relax the external sphincter to promote defecation. A stool softener such as docusate sodium (Colace) can be used to regulate stool consistency. Oral stimulant laxatives should be used only if absolutely necessary for a day or two and not on a regular basis.

TABLE 63-10

PATIENT & CAREGIVER TEACHING GUIDE
Bowel Management After Spinal Cord Injury

The following information should be included when teaching the caregiver and patient with a spinal cord injury:

1. Optimal nutritional intake includes three well-balanced meals each day in accordance with the recommended number of servings from *Eating Well With Canada's Food Guide*.*
2. Daily fibre intake should be approximately 20 to 30 g. The amount of fibre eaten should be increased gradually over 1 to 2 weeks.
3. Three litres of fluid per day should be consumed, unless contraindicated. Water or fruit juices should be used, and caffeinated beverages such as coffee, tea, and cola should be avoided. Fluid softens hard stools; caffeine stimulates fluid loss through urination.
4. Foods that produce gas (e.g., beans) or upper gastro-intestinal upset (spicy foods) should be avoided.
5. *Timing:* A regular schedule for bowel evacuation should be established. A good time is 30 minutes after the first meal of the day.
6. *Position:* If possible, an upright position with feet flat on the floor or on a step stool enhances bowel evacuation. Staying on the toilet, commode, or bedpan for longer than 20 to 30 minutes may cause skin breakdown. Depending on the patient's stability, someone may need to stay with the patient.
7. *Activity:* Exercise is important for bowel function. In addition to improving muscle tone, it increases gastro-intestinal transit time and increases appetite. Muscles should be exercised. Exercise includes stretching, range of motion, position changing, and functional movement.
8. *Drug treatment:* Suppositories may be necessary to stimulate a bowel movement. Manual stimulation of the rectum may also be helpful in initiating defecation. Stool softeners and oral laxatives may be used as needed to regulate stool consistency.

*Health Canada. (2011). *Eating Well With Canada's Food Guide.* Retrieved from *http://www.hc-sc.gc.ca/fn-an/alt_formats/hpfb-dgpsa/pdf/food-guide-aliment/view_eatwell_vue_bienmang-eng.pdf*.

Valsalva manoeuvre and manual stimulation are useful in patients with lower motor neuron lesions. Valsalva manoeuvre requires intact abdominal muscles, and so it is used in patients with injuries below T12.

In general, a bowel movement every other day is considered adequate. However, preinjury patterns should be considered. Incontinence can result from too much stool softener or fecal impaction.

Careful recording of bowel movements, including amount, time, and consistency, is important to overall success. Timing of defecation may also be an important factor. If bowel evacuation is planned for 30 to 60 minutes after the first meal of the day, success may be enhanced by taking advantage of the gastrocolic reflex induced by eating. Again, patient and family education is required to promote successful independent bowel management.

Neurogenic Skin.

Prevention of pressure injuries and other types of injury to insensitive skin is essential for every patient with SCI. The 2013 *Canadian Best Practice Guidelines for the Prevention and Management of Pressure Ulcers in People with*

Spinal Cord Injury (Houghton, Campbell, & CPG Panel, 2013) provides an updated resource for health care providers and considers the unique challenges of pressure injury management. The guidelines take a comprehensive approach to pressure management, including self-management and telehealth approaches. Nurses in rehabilitation are responsible for teaching these skills and providing patients information about daily skin care. A comprehensive visual and tactile examination of the skin should be performed twice daily, with special attention to areas over bony prominences. The areas most vulnerable to breakdown include the ischia, the trochanters, the heels, and the sacrum. Careful positioning and repositioning should be performed every 2 hours, with gradual increases in the times between turns if no redness over bony prominences is apparent at the time of turning. Pressure-relieving cushions must be used in wheelchairs, and special mattresses may also be needed. Movement during turns and transfers should be performed carefully to avoid shear (stretching and folding of soft tissues), friction, or abrasion (Houghton, Campbell, & CPG Panel, 2013).

Nutritional status should be assessed regularly. Both loss and gain in body weight can contribute to skin breakdown. Adequate intake of protein is essential for skin health. Measurement of total protein and albumin can help identify inadequate protein intake. The importance of nutrition to skin health should be stressed to the patient and caregivers.

Protection of the skin also requires avoidance of thermal injury. Burns can be caused by hot food or liquids, bath or shower water that is too warm, radiators, heating pads, and uninsulated plumbing. Thermal injury also can result from extreme cold (frostbite). Injuries may not be noticed until severe damage is done. Anticipatory guidance about potential risks is essential. Patient and caregiver education related to skin care is provided in Table 63-11.

TABLE 63-11

PATIENT & CAREGIVER TEACHING GUIDE
Skin Care for Patients With Spinal Cord Injury

Skin breakdown is a potential problem after spinal cord injury. The following information should be included when teaching the caregiver how to decrease this possibility:
Frequent Change of Position
• Patient in a wheelchair: lift self up and shift weight every 15 to 30 minutes. • Patient in a bed: follow a regular turning schedule (at least every 2 hours) that includes sides, back, and abdomen. • Use special mattresses and wheelchair cushions. • Use pillows to protect bony prominences when in bed.
Monitor Skin Condition
• Inspect skin frequently for areas of redness, swelling, and breakdown. • Keep fingernails trimmed to avoid scratches and abrasions. • If a wound develops, follow standard wound care management procedures.

Sexuality.

The effects of a SCI on sexual functioning, ability to engage in sexual activities, sexual intimacy and relationships, sexual self-view, and fertility and reproductive health vary with each individual. Sexual health is a significant component of a person's overall health and well-being. Both men and women retain desire for sexual activity following SCI.

Male fertility after SCI is often compounded by the difficulties of erectile dysfunction, as well as retrograde ejaculation or anejaculation. Erectile dysfunction often causes erections unreliable or inadequate for sexual intercourse due to difficulties in maintaining an erection. Medications or surgical procedures are available to help overcome this issue. Few men with SCI are able to ejaculate with partner sexual practices alone and require medical assistance to obtain sperm. This sperm is then used for intravaginal/intrauterine insemination or other assisted reproductive technology. Fertility rates resulting in pregnancy are generally lower than those among the general population as a result of the decline in semen quality following SCI (Elliott & McBride, 2014).

Female fertility appears to be unaffected by SCI. Amenorrhea can occur following SCI and last from 4 to 5 months. Women are still able to conceive, carry, and deliver a baby, although they tend to have more complications during pregnancy, labour, and delivery than women in the general population. Bladder problems, spasticity, pressure sores, autonomic dysreflexia, and problems with mobility can pose a threat to the pregnant woman with SCI. A pre-emptive epidural prior to delivery is used to manage autonomic dysreflexia, which otherwise can become uncontrolled. Breastfeeding can also be difficult secondary to possible

autonomic dysreflexia and inhibition of milk ejection reflexes (Elliott & McBride, 2014).

Sexual rehabilitation for both men and women should begin informally after the acute phase of the injury has passed. Questions such as "Have you had an erection since your accident?" and "Have your menstrual periods continued since the accident?" are nonthreatening ways to introduce the topic of sexual functioning. The male patient may pose a question such as "Can I ever be a man again?"

Open discussion with the patient is essential. This important aspect of rehabilitation should be handled by someone specially trained in sexual counselling. A nurse or other rehabilitation professional with such expertise works with the patient and partner to provide support with an emphasis on open communication. The nurse's educational role requires respect for every couple's religious beliefs and cultural norms. Alternative methods of obtaining sexual satisfaction such as oral–genital sex (cunnilingus and fellatio) may be suggested. Explicit video material may also be used, such as a movie demonstrating the sexual activities of a patient with paraplegia with a nondisabled partner. Graphic materials should be used cautiously because they may be too limiting or focus too much on the mechanics of sex rather than on the relationship.

Sexual activities may require more planning and be less spontaneous than before the injury. For example, an attendant may have to undress the patient and remove equipment. A relaxed atmosphere with music and perfume may create an attractive environment. Ample time for caressing, fondling, and kissing is essential. The partners should be encouraged to explore each other's erogenous areas, such as lips, neck, and ears, which can arouse psychogenic erection or orgasm. Few demands should be made initially.

Care should be taken not to dislodge an in-dwelling catheter during sexual activity. If an external catheter is used, it should be removed before sexual activity, and the patient should refrain from drinking fluids. The bowel program should include evacuation the morning after sexual activity. The partner should be informed that incontinence is always possible. The woman with an SCI may need a water-soluble lubricant to supplement diminished vaginal secretions and facilitate vaginal penetration.

Grief and Depression.

Patients with SCI may feel an overwhelming sense of loss. They may temporarily lose control over everyday life activities and must depend on

others for activities of daily living and for life-sustaining measures. Patients may believe that they are useless and burdens to their families. At a stage when independence is often of the greatest importance, they may be totally dependent on others.

The patient's response and recovery differ in some important aspects from those of patients experiencing loss from amputation or terminal illness. First, regression can and does occur at different stages. Working through grief is a difficult, lifelong process for which the patient needs support and encouragement. With advances in rehabilitation, it is usual for the patient to be independent physically and discharged from the rehabilitation centre before completion of the grief process. The goal of recovery is related more to adjustment than to acceptance. Adjustment implies the ability to go on living with certain limitations. Although patients who are cooperative and accepting are easier to treat, the nurse should expect a wide fluctuation of emotions from all patients with SCIs. Depression may not be a component of the recovery process. Societal norms allow depression after severe loss, and persons confronted with death or radical lifestyle changes are almost expected to become depressed. However, not every patient may experience depression.

The nurse's role in grief work is to allow mourning as a component of the rehabilitation process. Table 63-12 summarizes the mourning process and appropriate nursing interventions. Maintaining hope is an important strategy during the grieving process and should not be interpreted as denial (Krause & Edles, 2014). During the shock and denial stage, the nurse reassures the patient and stresses the expertise of the entire health care team. During the anger stage, the nurse assists the patient in achieving control over the environment, particularly by allowing the patient's input into the plan of care. The nurse should not respond to anger or manipulation or become involved in a power struggle with the patient. As self-care abilities increase, the patient's independence increases.

TABLE 63-12

MOURNING PROCESS AND NURSING INTERVENTIONS IN SPINAL CORD INJURY

Patient Behaviour	Nursing Intervention
Shock and Denial	
Struggle for survival, complete dependence, excessive sleep, withdrawal, fantasies, unrealistic expectations	• Employ meticulous nursing care. • Provide honest information. • Use simple diagrams to explain injury. • Encourage patient to begin process of recovery. • Establish agreement to use and improve all current abilities while not denying the possibility of future improvement.
Anger	
Refusal to discuss paralysis, decreased self-esteem, manipulation, hostile and abusive language	• Coordinate care with patient and encourage self-care. • Support family members; prevent them from alleviating their guilt by supporting the patient's dependency. • Use humour liberally. • Allow patient outbursts. • Do not allow fixation on injury.
Depression	
Sadness, pessimism, anorexia, nightmares, insomnia, agitation, psychomotor retardation, "blues," suicidal preoccupation, refusal to participate in any self-care activities	• Encourage family involvement and resources. • Plan graded steps in rehabilitation to give success with minimal opportunity for frustration. • Give cheerful and willing assistance with activities of daily living. • Avoid expressing sympathy. • Use firm kindness.
Adjustment	
Planning for future, active participation in therapy, finding of personal meaning in experience and continuation of growth, return to preinjury personality	• Remember that patients have individual personalities. • Balance support systems to encourage independence. • Set goals with the patient's input. • Emphasize potentials.

Peer support groups can be helpful in helping individuals and their families begin to cope with injury and help them adjust to life with a spinal cord injury. Spinal Cord Injury Ontario connects people living with spinal cord injuries to fully trained volunteers who can share their experience and knowledge. They can also connect family members with others who have gone through this journey. They complement professional services provided in acute hospitals, rehabilitation centres, and community-based health and social service agencies.

The patient's caregiver and family also require counselling to avoid promoting dependency in the patient through guilt or misplaced sympathy. The family and caregiver are also experiencing an intense

grieving process. A support group of family members and friends of patients with SCIs can help increase family members' knowledge and participation in the grieving process, physical difficulties, the rehabilitation plan, and the meaning of the disability in society (Krause & Edles, 2014).

During the stage of depression, the nurse must be patient and persistent and maintain a sense of humour. Sympathy is not helpful. The patient should be treated in an adult manner and be involved in decision making about care, but the nurse must insist that the care be performed. A primary nurse relationship is helpful. Staff planning and sessions in which staff members can express their feelings are helpful in providing consistency of care. To achieve the stage of adjustment, the patient needs continual support throughout the rehabilitation process in the forms of acceptance, affection, and caring. The nurse must be attentive when the patient needs to talk and sensitive to needs at the various stages of the grief process (Krause & Edles, 2014).

Although the stage of depression during the grief process usually lasts days to weeks, some individuals may become clinically depressed and require treatment for depression. Evaluation by a psychiatric nurse or psychiatrist is recommended. Treatment may include drugs and psychotherapy.

Evaluation

Expected outcomes for patients with SCIs are presented in NCP 63-1, available on the Evolve website.

Age-Related Considerations

Spinal Cord Injury

The demographics of patients living with SCI are changing. The fact that persons with SCI now have longer lifespans has contributed to the increasing number of older adults living with SCI. Moreover, increasing numbers of older adults sustain SCIs later in life as a result of falls. Aging is also associated with an increased likelihood of other chronic illnesses that may have a serious effect on older adults with SCI. As patients with SCI age, both individual aging changes and duration since injury affect functional ability. For example, bowel and bladder dysfunction can increase with duration and severity of SCI.

Health promotion and screening are important for older patients with SCI. Daily skin inspections, UTI prevention measures, monthly breast examinations for women, and regular prostate cancer screening for men are recommended. Cardiovascular disease is the most common cause of morbidity and mortality among persons with SCIs. The lack of sensation, including that of angina, in patients with high-level injuries may mask acute myocardial ischemia. Altered autonomic nervous system function and decreases in physical activity can increase the risk for cardiovascular problems, including hypertension.

At the same time, because of increased work and recreational activities of older adults, an increasing number of older adults are experiencing SCI. Health promotion to decrease injury risk includes fall prevention strategies (e.g., using a stepstool or a grab bar to reach high shelves, handrails on stairs). Rehabilitation for older persons who have SCIs may take longer because of other pre-existing illnesses and poorer health status at the time of the initial injury. Studies show that older persons with SCIs can gain the same degree of neurological recovery as those who are younger at the time of injury, but this does not necessarily translate into meaningful functional outcomes. An interdisciplinary team approach to tailored rehabilitation to match specific needs of older individuals is needed to maximize their potential for recovery and reintegration into the community (Hsieh, DeJong, Groah, et al., 2013).

Spinal Cord Injury Research in Canada

The Rick Hansen Institute is a Canadian organization committed to accelerating the translation of discoveries and best practices into improved treatments for individuals with SCIs. Its four distinct programs focus on *cure, care, commercialization,* and *consumers* and support research from the lab to clinical application in an effort to improve the lives of individuals with SCI (see Resources at the end of this chapter).

Spinal Cord Tumours

Etiology and Pathophysiology

Spinal cord tumours account for 0.5% to 1% of all neoplasms. These tumours are classified as primary (arising from some component of cord, dura, nerves, or vessels) or secondary (from primary growths in other places in the body that have metastasized to the spinal cord). Spinal cord tumours are further classified as *extradural* (outside the spinal cord), *intradural extramedullary* (within the dura but outside the actual spinal cord), and *intradural intramedullary* (within the spinal cord itself). Intradural intramedullary tumours are usually astrocytomas or ependymomas (Figure 63-10 and Table 63-13). Approximately 90% of all spinal tumours are extradural. Extradural tumours are usually metastatic and most often arise in the vertebral bodies. These metastatic lesions can invade intradurally and compress the spinal cord. Tumours that commonly metastasize to the spinal epidural space are those that spread to bone, such as prostate, breast, lung, and kidney cancer. Spinal intradural extramedullary tumours account for two-thirds of all intraspinal neoplasms and consist mainly of meningiomas and schwannomas.

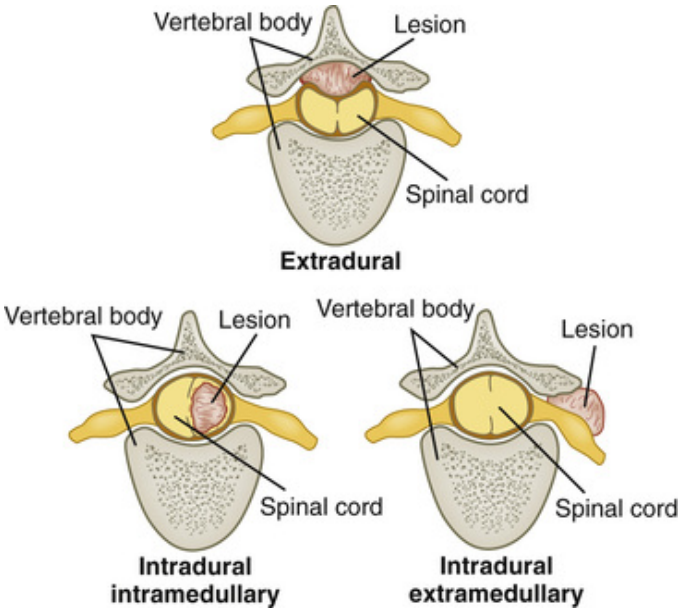

FIGURE 63-10 Types of spinal cord tumours.

TABLE 63-13
CLASSIFICATION OF SPINAL CORD TUMOURS

Type	Incidence	Treatment	Prognosis
Extradural: from bones of spine, in extradural space, or in paraspinal tissue	20%–50% of all intraspinal tumours; mostly malignant metastatic lesions	Relief of cord pressure by surgical laminectomy, radiation, chemotherapy, or combination approach	Dependent on tumour type and stage
Intradural extramedullary: within dura mater, outside spinal cord	Most frequent of intradural tumours (40%), mostly benign meningiomas and neurofibromas	Complete surgical removal of tumour (if possible), partial removal followed by radiation	Usually very good if no damage to cord from compression
Intradural intramedullary: within spinal cord	Least frequent of intradural tumours (5%–10%)	Partial surgical removal, radiation therapy (resulting in only temporary improvement)	Dependent on neurological function before and after decompression

Because many of these tumours are slow growing, their symptoms stem from the mechanical effects of bone destruction, slow compression and irritation of nerve roots, displacement of the cord, or gradual obstruction of the vascular supply. The slow growth does not cause autodestruction (secondary injury), as occurs with traumatic lesions. Therefore, partial to complete functional restoration may be possible when the tumour is removed.

Clinical Manifestations

Both sensory and motor deficits may result; the location and extent of the tumour determine the severity and the distribution of the problem. The most common early symptom of an extradural spinal cord tumour is back pain. Radicular pain may occur as the tumour compresses nerve roots. The location of the pain depends on the level of compression. The pain worsens with activity, coughing, and straining. Some relief may occur with lying down, but there is usually a baseline of pain even in this position secondary to the inflammatory changes within the bone structure. Sensory disruption is manifested by pain, coldness sensation, numbness, and tingling sensation in the dermatomal distribution of the lesion. Motor weakness accompanies the sensory disturbances and consists of slowly increasing clumsiness, weakness, and spasticity, which can lead to paralysis. The sensory and motor disturbances are ipsilateral to the lesion. Bladder dysfunction, if present, is marked by urgency with difficulty in starting the flow and progresses to retention with overflow incontinence.

Manifestations of intradural spinal tumours develop as damage to the long spinal tracts progresses, producing paralysis, sensory loss, and bladder dysfunction. Pain can be severe as a result of compression of spinal roots or vertebrae.

Nursing and Collaborative Management Spinal Cord Tumours

Extradural, intradural, and intramedullary tumours are best detected with MRI. CT may be performed to determine amount of bone destruction. More than 85% of primary neoplasms are benign and can be completely resected; 90% of such patients recover without residual problems.

Compression of the spinal cord is an emergency. Relief of the ischemia related to the compression is the goal of therapy. Dexamethasone is usually used to treat edema, often in large doses (100 mg as a bolus dose). Surgical decompression can involve various approaches (anterior, posterior, or a combination of both), followed by reconstruction and stabilization. In a randomized control study, Patchell, Tibbs, Regine, and colleagues (2005) compared direct decompressive therapy followed by radiotherapy with radiotherapy alone; they demonstrated better patient outcomes in patients receiving both therapies in regard to neurological recovery, decreased postoperative morbidity, and long-term survival. They concluded that the best treatment for spinal cord compression caused by metastatic cancer is surgery as initial treatment, followed by radiotherapy (Patchell, Tibbs, Regine, et al., 2005).

Treatment for nearly all spinal cord tumours is surgical removal. The exception is the metastatic tumour that is sensitive to chemotherapy or radiation and that has caused only minimal neurological deficits (e.g., multiple myeloma). In general, extradural and intradural extramedullary tumours can be completely removed surgically. Intradural intramedullary tumours have a less favourable prognosis. However, exploration and removal are usually attempted.

Standard radiation therapy after surgical decompression is considered if the tumour is radiosensitive. Treatment is started approximately 3 to 4 weeks after surgery and usually consists of five doses. In a newer therapy, intensity-modulated radiotherapy, higher doses of radiation are delivered to the tumour site, which minimizes injury to surrounding normal spinal and paraspinal tissues. Chemotherapy has also been used in conjunction with radiation therapy.

Relief of pain and prevention of continued neurological decline are the ultimate goals of treatment. Nurses must be aware of the neurological status of the patient before and after treatment. Ensuring that the patient receives analgesics to manage pain is an important nursing responsibility.

Depending on the amount of neurological dysfunction exhibited, the patient may need to be cared for as though he or she were recovering from an SCI. Rehabilitation of patients with spinal cord tumours is similar to rehabilitation of patients with SCIs.

Postpolio Syndrome

Polio, also known as *poliomyelitis*, is an infectious viral disease transmitted through the oral route by ingestion of contaminated water or food or by contact with infected sources such as unwashed hands. The virus is shed in the feces of infected individuals for as long as 6 weeks. The disease produces a range of manifestations from influenza-like symptoms (abortive poliomyelitis) that resolve in 24 to 36 hours (nonparalytic) to paralytic poliomyelitis that attacks the motor neurons in the anterior horn of the spinal cord, the brain stem, or both. Polio ravaged North American communities during the 1930s, 1940s, and 1950s. Polio was effectively eradicated in North America by the development of the Salk injectable polio vaccine in 1954 and the Sabin oral polio vaccine in 1961. It is still a threat in developing countries because of a lack of effective immunization programs. Polio survivors who recovered from the disease decades ago, notably those who had paralytic poliomyelitis, are now experiencing a recurrence of neuro-muscular symptoms as they age. These late effects of polio are collectively referred to as **postpolio syndrome (PPS).** On the basis of criteria for diagnosis of PPS, the incidence and prevalence can range from 10% to 40% (Kedlaya, 2017).

Etiology and Pathophysiology

The etiology of PPS is not completely clear. The most commonly accepted theory is that enlarged distal motor neurons that had recovered after polio degenerate and subsequently begin to fail (Kedlaya, 2017). It appears that cellular damage caused by the effects of the polio virus may lead to exhaustion and premature failure of the motor neurons. The result is slowly progressive muscle weakness and fatigue. Factors thought to contribute to PPS include age-related motor neuron loss, musculo-skeletal overuse and disuse, weight gain, pain, and other neuro-muscular or systemic illnesses. There is no evidence to support the theory that PPS is caused by reactivation of the original polio virus.

Clinical Manifestations and Diagnostic Studies

PPS is manifested by a new onset of joint and muscle weakness, easy fatigability, generalized fatigue, and pain. In uncommon cases, individuals may also exhibit speech, swallowing, and respiratory difficulties. Patients should undergo thorough diagnostic testing to rule out other medical conditions that may produce similar symptoms. Criteria used to establish the diagnosis of PPS include a history of polio in the abortive, nonparalytic, or paralytic forms; recovery from polio; a lengthy period of stability of at least 10 to 20 years' duration; and clinical manifestations of PPS that are not associated with other medical disorders. Disabilities caused by PPS can have a significant effect on the patient's quality of life.

Nursing and Collaborative Management Postpolio Syndrome

Management approaches for PPS are targeted at controlling symptoms, particularly fatigue, weakness, and pain. An interdisciplinary team approach is essential for management of the patient. The cornerstone of management is lifestyle modification to conserve energy and support performance of activities of daily living.

During the polio epidemic, polio victims were subjected to rigorous therapy to regain muscle function. A particular challenge may be helping the patient understand that aggressive or strenuous therapy to strengthen muscles is now considered counterproductive and that overexertion can worsen fatigue and weakness. It is important to promote pacing of activities to prevent feelings of fatigue. Planning to include rest periods, as well as using assistive devices such as scooters, canes, and wheelchairs may be beneficial. Adaptive equipment can be helpful to patients who experience difficulty with self-care. Other strategies include arranging for a handicapped licence plate or sticker to facilitate parking close to shops and public buildings, shopping on the Internet to avoid walking, and enlisting the support of family and friends to perform necessary tasks. Physiotherapy can support mobility and fitness in view of the patient's limitations. Weight loss interventions should be considered for affected individuals who are overweight.

Effective pain management through both pharmacological and nonpharmacological approaches with the health care provider or pain management team can enable an individual to remain active and achieve a greater sense of well-being. Nonpharmacological measures include massage, relaxation strategies, and guided imagery (see Chapter 12). Protection from the cold can also aid in pain relief since the individual with PPS may be especially sensitive to a cold environment. For affected individuals with speech, swallowing, or respiratory difficulties, it is important to take measures to prevent aspiration, maintain airway patency, and promote optimal nutrition. Nursing interventions for these problems are similar to those described for patients with GBS and SCI.

Experiencing the re-emergence of symptoms related to polio can have a devastating effect on a patient's psychosocial well-being. Memories of paralysis and the challenges of recovery can cause fear when PPS is diagnosed. Anxiety and depression can occur, as can difficulties with

coping. The nurse can assist the individual by actively listening to concerns, providing information about PPS and available resources, and referring the patient to support groups or counselling when necessary. Gaining a sense of control through active participation in lifestyle modifications and therapy may improve the patient's ability to cope with PPS.

Case Study

Spinal Cord Injury

Source: Joana Lopes/Shutterstock.com.

Patient Profile: Acute Phase

Sal Diaz, a 24-year-old man, is admitted to the emergency department with the diagnosis of a cervical SCI. Mr. Diaz was swimming at a neighbour's backyard pool. He dove into the shallow end, striking his head on the bottom of the pool. His friends noticed that he did not resurface. They rescued him and brought him to the side of the pool. They maintained neck immobilization until the rescue crews arrived.

Subjective Data

- Is awake and alert
- Has complaints of neck pain
- Is anxious and asking why he cannot move his legs and has weak arms
- Is asking to see his family

Objective Data

Physical Examination

- Weak biceps movement bilaterally
- No triceps movement bilaterally
- Gross elbow movement present bilaterally
- No movement bilaterally in lower extremities
- Decreased sensation from the shoulders down
- Loss of anal sphincter contraction
- BP: 85/50 mm Hg; pulse: 56; respirations: 32 and laboured

Diagnostic Studies

- CT of cervical spine shows subluxation and compression fracture at C5–6
- MRI of cervical spine shows a severe spinal cord compression at C5–6

Collaborative Care

- Intubated in the emergency department
- Started on mechanical ventilation
- Placed in halo traction on arrival in the ICU
- Further went on to have surgical decompression and stabilization

Discussion Questions: Acute Phase

1. ***Priority decision:*** What nursing activities would be a priority on Mr. Diaz's arrival in the ICU?
2. What physiological problems are causing Mr. Diaz to have hypotension and bradycardia?
3. What would the first line of treatment be for Mr. Diaz's hypotension and bradycardia?
4. What signs and symptoms would indicate respiratory distress, and what physiological problem would cause respiratory distress in Mr. Diaz's injury state?
5. What can the nurse do to decrease Mr. Diaz's anxiety?

6. ***Priority decision:*** Based on the assessment data provided, what are the priority nursing diagnoses or problem statements? Are there any collaborative problems?

Patient Profile: Rehabilitation Phase

One month after the injury, Mr. Diaz is at a local inpatient SCI rehabilitation facility. He has since been extubated and uses a wheelchair to mobilize. He eats three meals a day with assistance and is on a strict bowel and bladder program.

Subjective Data

- Awake and alert but anxious
- Complaining of severe headache, blurred vision, and nausea

Objective Data

Physical Examination

- Flushed and diaphoretic above the level of injury
- No bowel movement for 2 days
- BP: 180/90 mm Hg; pulse: 32 beats/min; respirations: 30 breaths/min and laboured

Discussion Questions: Rehabilitation Phase

1. ***Priority decision:*** What initial priority nursing interventions would be appropriate?
2. What physiological problem is causing Mr. Diaz's hypertension and bradycardia?
3. Once the physician has been notified, what other interventions would be appropriate?
4. ***Priority decision:*** Based on the assessment data provided, what are the priority nursing diagnoses?
5. ***Evidence-informed practice:*** Mr. Diaz and his family are concerned about the risk for autonomic dysreflexia. What effective strategies to prevent autonomic dysreflexia could the nurse discuss with the patient and family?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. What should the nurse do during assessment of a client with trigeminal neuralgia?
   a. Inspect all aspects of the mouth and teeth.
   b. Lightly palpate the affected side of the face for edema.
   c. Test for temperature and sensation perception on the face.
   d. Ask the client to describe factors that initiate an episode.
2. During routine assessment of a client with GBS, the nurse finds the client to be short of breath. What is the cause of the client's respiratory distress?
   a. Elevated protein levels in the CSF
   b. Immobility resulting from ascending paralysis
   c. Degeneration of motor neurons in the brain stem and the spinal cord
   d. Paralysis ascending to the nerves that stimulate the thoracic area
3. A client is admitted to the ICU with a C7 SCI, and Brown-Séquard syndrome is diagnosed. What would the nurse probably find on physical examination?
   a. Upper extremity weakness only
   b. Complete motor and sensory loss below C7
   c. Loss of position sense and vibration in both lower extremities
   d. Ipsilateral motor loss and contralateral sensory loss below C7
4. A client is admitted to the hospital with SCI after an automobile accident. The nurse recognizes that the pathophysiology of secondary SCI involves which of the following?
   a. Initial infarction of the white matter of the spinal cord
   b. Mechanical transection of the cord by the trauma
   c. Necrotic destruction of the cord from hemorrhage and edema
   d. Release of epinephrine leading to massive vasodilation of spinal cord vessels
5. Goals of rehabilitation for the client with an injury at the C6 level include which of the following? *(Select all that apply)*

a. Stand erect with leg brace
b. Feed self with hand devices
c. Drive a motorized wheelchair
d. Assist with transfer activities
e. Control bowel and bladder function

6. A client with a C7 SCI undergoing rehabilitation tells the nurse he must have the flu because he has a bad headache and nausea. What should the nurse's initial action be?
a. Call the physician.
b. Check the client's temperature.
c. Take the client's blood pressure.
d. Elevate the head of the bed to 90 degrees.

7. For a 65-year-old female client who has lived with a T1 SCI for 20 years, what health teaching information would the nurse emphasize?
a. A mammogram is needed every 2 years.
b. Bladder function tends to improve with age.
c. Heart disease is not common in persons with SCI.
d. As a person ages, the need to change body position is less important.

8. What is the most common early symptom of a spinal cord tumour?
a. Urinary incontinence
b. Back pain that worsens with activity
c. Paralysis below the level of involvement
d. Impaired sensation of pain, temperature, and light touch

9. Which of the following descriptions best characterizes PPS?
a. Autoimmune disease of motor neurons triggered by polio virus
b. Reactivation of poliomyelitis resulting in acute musculo-skeletal disease
c. Degeneration of enlarged motor neurons many years after poliomyelitis
d. Disorder characterized by active viral destruction of the upper motor neurons

1. d; 2. d; 3. d; 4. c; 5. b, c, d; 6. c; 7. a; 8. b; 9. c.

CHAPTER 64

Nursing Assessment

Musculo-Skeletal System

Written by, Michael E. Zychowicz

Adapted by, Jana Lok

LEARNING OBJECTIVES

1. Describe the gross anatomical and microscopic composition of bone.
2. Explain the classification system of joints and movements at diarthroidal joints.
3. Describe the types and structure of muscle tissue.
4. Describe the functions of cartilage, muscles, ligaments, tendons, fascia, and bursae.
5. Describe age-related changes in the musculo-skeletal system and differences in assessment findings.
6. Identify the significant subjective and objective data related to the musculo-skeletal system that should be obtained from a patient.
7. Describe the appropriate techniques used in the physical assessment of the musculo-skeletal system.
8. Differentiate normal from abnormal findings of a physical assessment of the musculo-skeletal system.
9. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the musculo-skeletal

system.

scoliosis, p. 1626, Table 64-6

The unique structures of the musculo-skeletal system allow human beings to complete complex movements. The dexterity of the upper extremities enables an individual to perform complicated technical tasks, whereas stronger lower extremities enable mobility for varied activities. The musculo-skeletal system is composed of voluntary muscle and five types of connective tissue: bones, cartilage, ligaments, tendons, and fascia (Roberts, 2016). Resilient bone and cartilage absorb energy from any impact, minimizing the risk of injury to other body structures. However, this characteristic ability makes the musculo-skeletal system itself particularly vulnerable to injury from external forces. Any damage to bone and related soft tissues can cause functional disruption for an individual. Deformity, alteration in body image, alteration in mobility, pain, or permanent disability may result from musculo-skeletal injury.

Structures and Functions of the Musculo-skeletal System

Bone

Function.

The main functions of bone are support, movement, protection of the body's internal structures, blood cell production, and mineral storage (McCance & Huether, 2014). Bones provide the supporting framework that keeps the body from collapsing and allow the body to bear weight. Bones serve as a point of attachment for muscles, which are connected to bones by tendons. Bones act as a lever for muscles, and movement occurs as a result of muscle contractions applied to these levers. Bones also protect underlying vital organs and tissues. For example, the skull encloses the brain, the vertebrae surround the spinal cord, and the rib cage covers the lungs and heart. Bones contain hematopoietic tissue for the production of red and white blood cells. Bones also serve as a site for storage of inorganic minerals such as calcium and phosphorus.

Bone is a dynamic tissue that continually changes form and composition. It contains both organic material (i.e., collagen) and inorganic material (i.e., calcium, phosphate). The internal and external growth and remodelling of bone are ongoing processes.

Microscopic Structure.

Bone is classified according to structure as *cortical* (compact and dense) or *cancellous* (spongy). In *cortical bone,* cylinder-shaped structural units called *osteons* (Haversian systems) fit closely together to form a dense bone structure (Figure 64-1, *B*). Within the systems, the Haversian canals run parallel to the bone's long axis and contain the blood vessels that travel to the bone's interior from the periosteum. Surrounding each *osteon* are concentric rings known as *lamellae,* which characterize mature bone. Smaller canals *(canaliculi)* extend from the Haversian canals to the *lacunae,* where mature bone

cells are embedded. Cancellous (spongy) bone lacks the organized structure of cortical (compact) bone. The lamellae are arranged not in concentric rings but rather along the lines of maximum stress placed on the bone. Cancellous bone tissue is filled with red or yellow marrow, and blood reaches the bone cells by passing through spaces in the marrow.

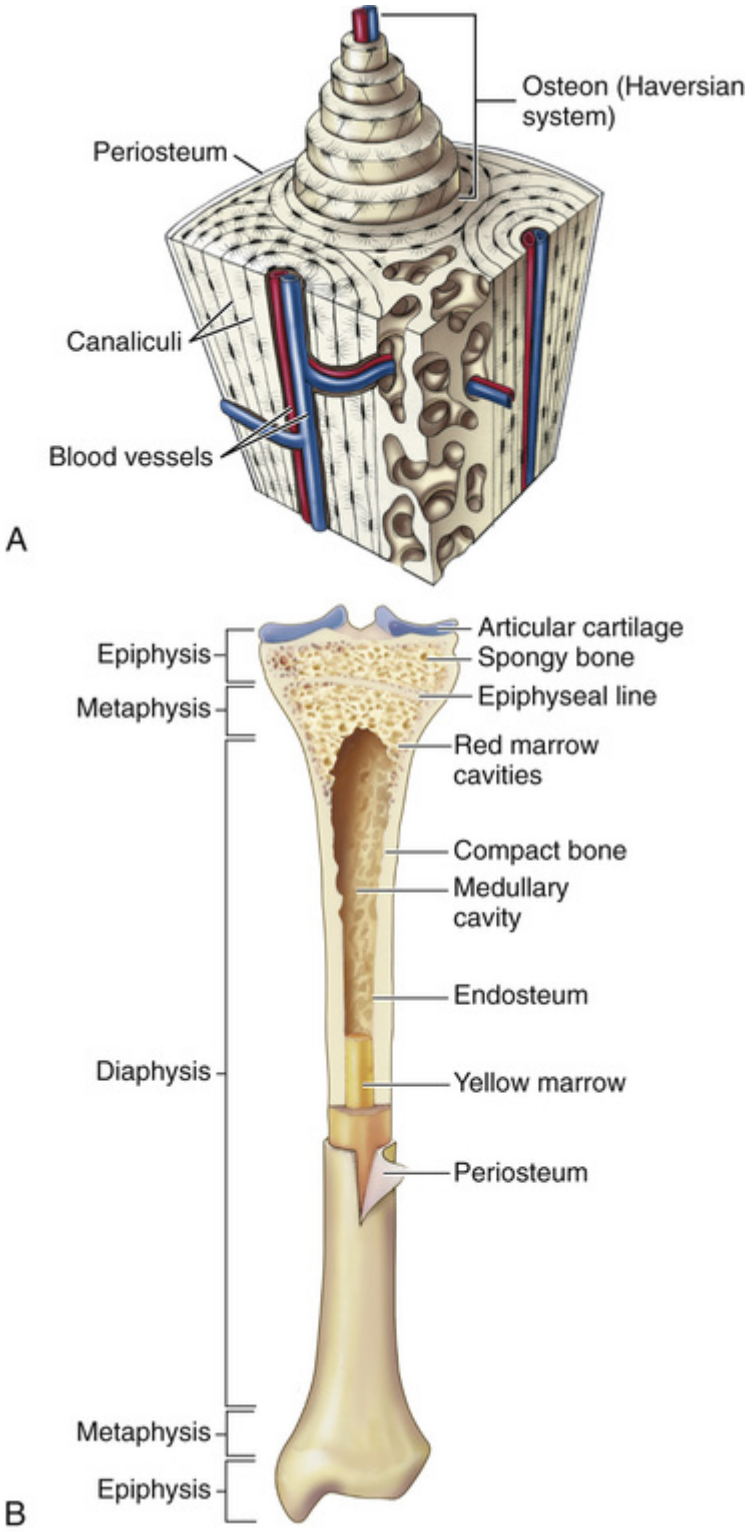

FIGURE 64-1 Illustrations of bone structure. **A,** Cortical (compact) bone showing numerous structural units called *osteons.* **B,** Anatomy of a long bone (tibia), showing cancellous and compact bone. Sources: *A,* Herlihy, B. (2011). *The*

human body in health and illness (4th ed.). Philadelphia: Saunders. *B,* From Patton, K. T., & Thibodeau, G. A. (2013). *Anatomy and physiology* (8th ed.). St Louis: Mosby.

The three types of bone cells are osteoblasts, osteocytes, and osteoclasts (McCance & Huether, 2014). *Osteoblasts* synthesize organic bone matrix (collagen) and are the basic bone-forming cells. *Osteocytes* are the mature bone cells. *Osteoclasts* participate in bone remodelling by assisting in the breakdown of bone tissue. *Bone remodelling* is the removal of old bone by osteoclasts *(resorption)* and the deposition of new bone by osteoblasts *(ossification).* The inner layer of bone is primarily made up of osteoblasts with a few osteoclasts.

Gross Structure.

The anatomical structure of bone is best represented by a typical long bone such as the tibia (see Figure 64-1, *A*). Each long bone consists of the epiphysis, the diaphysis, and the metaphysis. The *epiphysis,* the widened area found at each end of a long bone, is composed primarily of cancellous bone. The width of the epiphysis allows for greater weight distribution and provides stability for the joint. The epiphysis is also the location of muscle attachment. Articular cartilage covers the ends of the epiphysis to provide a smooth surface for joint movement. The *diaphysis* is the main shaft of the bone. It provides structural support and is composed of compact bone. The tubular structure of the diaphysis allows it to more easily withstand bending and twisting forces. The *metaphysis* is the flared area between the epiphysis and the diaphysis. Like the epiphysis, it is composed of cancellous bone. The *epiphyseal plate,* or growth plate, is the cartilaginous area between the epiphysis and the metaphysis. It actively produces bone to allow longitudinal growth in children. Injury to the epiphyseal plate in a growing child can lead to development of a shorter extremity, which can cause significant functional problems. In the adult, the metaphysis and the epiphysis become joined as this plate hardens to become mature bone.

The *periosteum* is composed of fibrous connective tissue that covers the bone. Tiny blood vessels penetrate the periosteum to provide

nutrition to underlying bone. Musculotendinous fibres anchor to the outer layer of the periosteum. The inner layer of the periosteum is attached to the bone by bundles of collagen. No periosteum exists on the articular surfaces of long bones. These bone ends are covered by articular cartilage.

The *medullary* (marrow) cavity is in the centre of the diaphysis and contains either red or yellow bone marrow (Thibodeau & Patton, 2016). In a growing child, red bone marrow is actively involved in blood cell production (hematopoiesis). In the adult, the medullary cavity of long bones contains yellow bone marrow, which is mainly adipose tissue. Yellow marrow is involved in hematopoiesis only in times of great blood cell need. In adults, red marrow is found mainly in the flat bones, such as the pelvis, skull, sternum, cranium, ribs, vertebrae, and scapulae and in the cancellous (spongy) material at the epiphyseal ends of long bones such as the femur and the humerus.

Types.

The skeleton consists of 206 bones, which are classified according to shape as long, short, flat, or irregular.

Long bones are characterized by a central shaft (diaphysis) and two widened ends (epiphyses) (see Figure 64-1, *B*). Examples include the femur, humerus, and radius. *Short bones* are composed of cancellous bone covered by a thin layer of compact bone. Examples include the carpals in the hand and the tarsals in the foot.

Flat bones have two layers of compact bone separated by a layer of cancellous bone. Examples include the ribs, skull, scapula, and sternum. The spaces in the cancellous bone contain bone marrow. *Irregular bones* appear in a variety of shapes and sizes. Examples include the vertebrae, sacrum, and ear ossicles.

Joints

A *joint* (articulation) is a place where the ends of two bones are in proximity and move in relation to each other. Joints are classified according to the degree of movement that they allow.

The most common joint is the freely movable *diarthrodial* (synovial) type. Each joint is enclosed in a capsule of fibrous connective tissue that joins the two bones together to form a cavity (Figure 64-2). The capsule is lined by a synovial membrane, which secretes thick synovial fluid to lubricate the joint and reduce friction. The end of each bone is covered with articular (hyaline) cartilage. Supporting structures (i.e., ligaments, tendons) reinforce the joint capsule and provide limits to joint movement (National Association of Orthopaedic Nurses, 2013). Types of diarthrodial joints are shown in Figure 64-3.

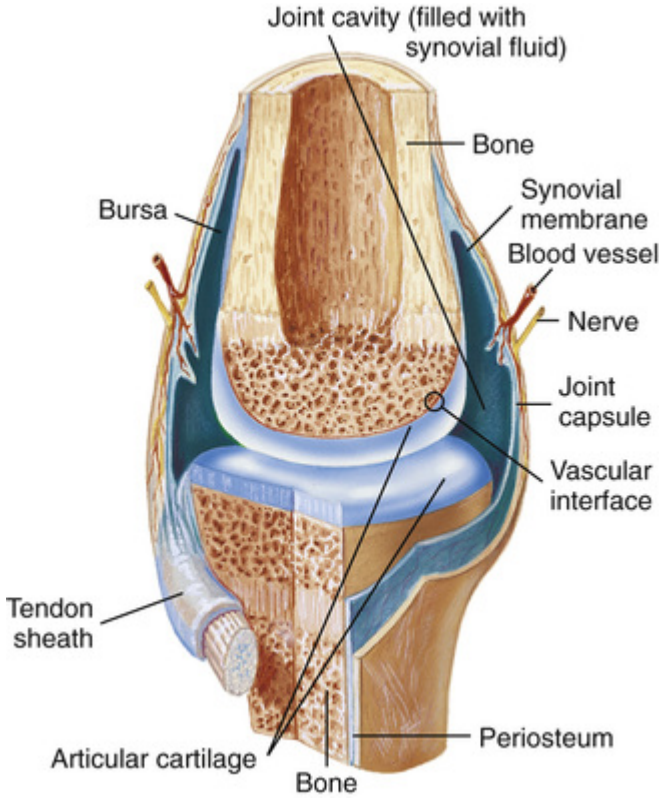

FIGURE 64-2 Structure of a diarthrodial (synovial) joint.

Joint	Movement	Examples	Illustration
Hinge joint	Flexion, extension	Elbow joint (shown), interphalangeal joints, knee joint	
Ball and socket (spheroidal)	Flexion, extension; adduction, abduction; circumduction	Shoulder (shown), hip	
Pivot (rotary)	Rotation	Atlas-axis, proximal radioulnar joint (shown)	
Condyloid	Flexion, extension; abduction, adduction; circumduction	Wrist joint (between radial and carpals) (shown)	
Saddle	Flexion, extension; abduction, adduction; circumduction, thumb-finger opposition	Carpometacarpal joint of thumb (shown)	
Gliding	One surface moves over another surface	Between tarsal bones, sacroiliac joint, between articular processes of vertebrae, between carpal bones (shown)	
FIGURE 64-3 Types of diarthrodial (synovial) joints.

Cartilage

Cartilage is a rigid connective tissue that serves as a support for soft tissue and provides the articular surface for joint movement. It protects underlying tissues. The cartilage in the epiphyseal plate is

also involved in the growth of long bones before physical maturity is reached. Because articular cartilage is relatively avascular, it must receive nourishment by the diffusion of material from the synovial fluid. The lack of a direct blood supply contributes to the slow metabolism of cartilage cells, which is the reason why cartilage tissue heals slowly.

Hyaline cartilage, containing a moderate amount of collagen fibres, is the most common type of cartilage. It is found in the trachea, bronchi, nose, epiphyseal plate, and articular surfaces of bones. *Elastic cartilage,* which contains both collagen and elastic fibres, is more flexible than hyaline cartilage. It is found in the ear, epiglottis, and larynx. *Fibrocartilage* consists mostly of collagen fibres and is a tough tissue that often functions as a shock absorber. It is found between the vertebral discs and also forms a protective cushion between the bones of the pelvic girdle, knee, and shoulder.

Muscle

Types.

The three types of muscle tissue are *cardiac* (striated, involuntary), *smooth* (nonstriated, involuntary), and *skeletal* (striated, voluntary) muscle. Cardiac muscle is found in the heart. Its spontaneous contractions propel blood through the circulatory system. Smooth muscle occurs in the walls of hollow structures such as airways, arteries, gastro-intestinal tract, urinary bladder, and uterus. Smooth muscle contraction is modulated by neuronal and hormonal influences. Skeletal muscle, which requires neuronal stimulation for contraction, accounts for about half of a human being's body weight. It is the focus of the following discussion.

Structure.

The skeletal muscle is enclosed by the *epimysium*, a continuous layer of deep fascia. The epimysium helps muscles slide over nearby structures. Connective tissue surrounding and extending into the muscle can be subdivided into fibre bundles, or fasciculi. These bundles are covered by perimysium and an innermost connective

tissue layer called the *endomysium* that surrounds each fibre (Figure 64-4).

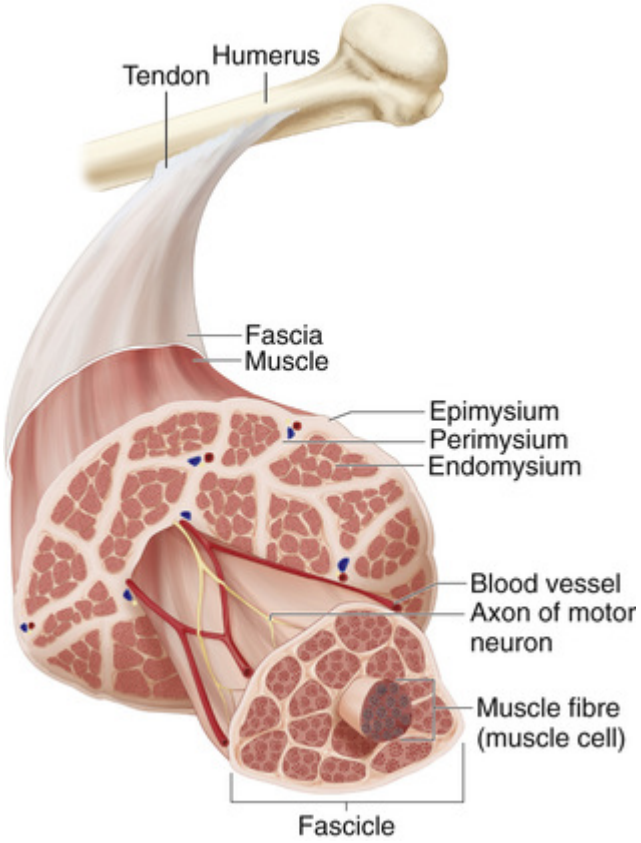

FIGURE 64-4 Structure of a muscle. Source: Patton, K. T., Thibodeau, G. A., & Douglas, M. (2012). *Essentials of anatomy and physiology.* St Louis: Mosby.

The structural unit of muscle is the muscle cell or muscle fibre, which is highly specialized for contraction. Skeletal muscle fibres are long, multinucleated cylinders that contain many mitochondria to support their high metabolic activity. Muscle fibres are composed of *myofibrils,* which in turn are made up of contractile filaments (protein).

The *sarcomere* is the contractile unit of the myofibrils (McCance & Huether, 2014). Each sarcomere consists of myosin (thick) filaments and actin (thin) filaments. The arrangement of the thick and thin filaments accounts for the characteristic banding of muscle when it is seen under a microscope. Muscle contraction occurs as thick and

thin filaments slide past each other, causing the sarcomeres to shorten.

Contractions.

Skeletal muscle contractions enable posture maintenance, movement, and facial expressions. **Isometric contractions** increase the tension within a muscle but do not produce movement. Repeated isometric contractions make muscles grow larger and stronger. **Isotonic contractions** shorten a muscle to produce movement. Most contractions are a combination of tension generation (isometric) and shortening (isotonic). Muscle *atrophy* (wasting of muscle and subsequent decrease in its size) occurs with the absence of contraction that results from immobility, whereas increased muscular activity leads to *hypertrophy* (increase in size).

Skeletal muscle fibres are divided into two groups according to the type of activity they demonstrate. *Slow-twitch muscle fibres* support prolonged muscle activity such as marathon running. Because they also support the body against gravity, they assist in posture maintenance. *Fast-twitch muscle fibres* are used for rapid muscle contraction required for activities such as blinking the eye, jumping, or sprinting. Fast-twitch fibres tend to tire more quickly than slow-twitch fibres.

Neuro-muscular Junction.

Skeletal muscle fibres require a nerve impulse to contract. A nerve fibre and the skeletal muscle fibres it stimulates are called a *motor end plate.* The junction between the axon of the nerve cell and the adjacent muscle cell is called the *myoneural* or *neuro-muscular junction* (Figure 64-5).

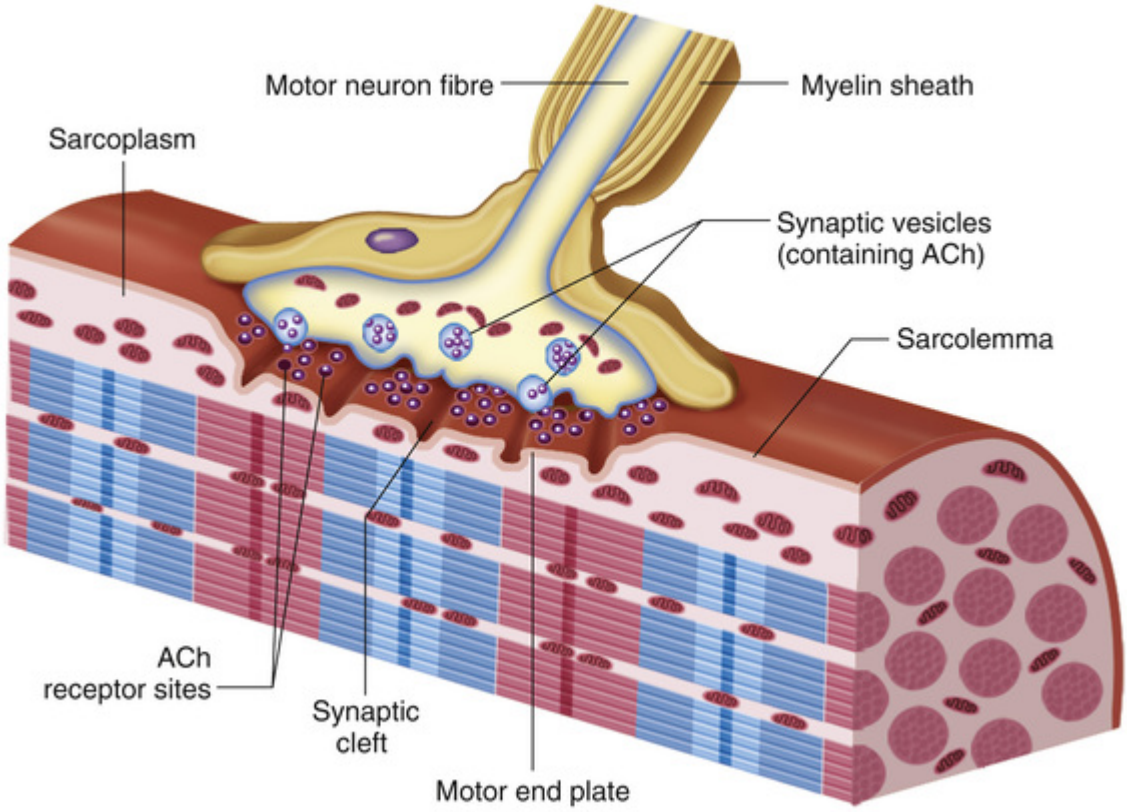

FIGURE 64-5 Neuro-muscular junction. Illustration of a side view of the neuro-muscular junction. Note how the distal end of a motor neuron fibre forms a synapse, or "chemical junction," with an adjacent muscle fibre. Neurotransmitter molecules (specifically, acetylcholine [ACh]) are released from the neuron's synaptic vesicles and diffuse across the synaptic cleft. There they stimulate receptors in the motor end plate region of the sarcolemma. Source: Patton, K. T., & Thibodeau, G. A. (2013). *Anatomy and physiology* (8th ed., p. 353, Figure 12-7). St. Louis: Mosby.

Acetylcholine is released from the motor end plate of the neuron and diffuses across the neuro-muscular junction to bind with receptors on the muscle fibre. In response to this stimulation, the sarcoplasmic reticulum releases calcium ions into the cytoplasm which triggers the contraction in the myofibrils. When calcium is low, *tetany* (involuntary contractions of skeletal muscle) can occur.

Energy Source.

The direct energy source for muscle fibre contractions is adenosine triphosphate (ATP). ATP is synthesized by cellular oxidative metabolism in numerous mitochondria located close to the myofibrils. It is rapidly depleted through conversion to adenosine diphosphate and must be rephosphorylated. Phosphocreatine provides a rapid source for the resynthesis of ATP, but it is in turn converted to creatine and must be recharged. Glycolysis can serve as a source of ATP when the oxygen supply is inadequate for the metabolic needs of the muscle tissue. Glucose is broken down to pyruvic acid, which can be further converted to lactic acid to make more oxygen available. An accumulation of lactic acid in tissues leads to fatigue and pain.

Ligaments and Tendons

Both ligaments and tendons are composed of dense, fibrous connective tissue that contains bundles of closely packed collagen fibres arranged in the same plane for additional strength. *Tendons* attach muscles to bones as an extension of the muscle sheath that adheres to the periosteum. They have greater tensile strength than ligaments. *Ligaments* connect bones to bones (e.g., tibia to femur at knee joint). They are more elastic and flexible than tendons (Herlihy, 2011). Ligaments provide stability while enabling controlled movement at the joint.

Because ligaments and tendons have a relatively poor blood supply, tissue repair after injury to them is a slow process. For example, the stretching or tearing of ligaments that occurs with a sprain may require weeks to months to mend.

Fasciae

Fasciae are layers of connective tissue with intermeshed fibres that can withstand limited stretching. Superficial fasciae lie immediately under the skin. Deep fasciae are dense, fibrous tissue that surrounds the muscle bundles, nerves, and blood vessels. Deep fasciae also enclose individual muscles, allowing them to act independently and to glide over each other during contraction. In addition, they provide strength to muscle tissues.

Bursae

Bursae are small sacs of connective tissue lined with synovial membrane and containing synovial fluid. They are typically located at bony prominences or joints to relieve pressure and prevent friction between moving parts (Jarvis, Browne, MacDonald-Jenkins, et al., 2014). For example, bursae are found between the patella and the skin *(prepatellar bursa)* and between the greater trochanter of the proximal femur and the skin *(trochanteric bursa). Bursitis* is an inflammation of a bursa sac.

Age-Related Considerations

The Musculo-skeletal System

Many of the functional problems experienced by older adults are related to changes in the musculo-skeletal system. Although some changes begin in early adulthood, obvious signs of musculo-skeletal impairment may not appear until later adulthood. Alterations may affect an older adult's ability to complete self-care tasks and pursue other usual activities. Effects of musculo-skeletal changes may range from mild discomfort and decreased ability to perform activities of daily living to severe, chronic pain and immobility. The risk for falls also increases in older adults as a result of a loss of strength, change in balance, and change in *proprioception* (awareness of self in relation to the environment).

The bone remodelling process changes as adults age. Bone resorption increases and bone formation decreases; these events cause a loss of bone density, contributing to development of osteopenia and osteoporosis (see Chapter 66). Muscle mass and strength also decrease with aging. Tendons and ligaments become less flexible, and joints and limbs become more rigid. Joints in aging adults are also more likely to be affected by osteoarthritis (see Chapter 67).

In addition to the usual musculo-skeletal assessment with an emphasis on functional and activity status, the nurse should also determine the effect of age-related musculo-skeletal changes on an older patient's psychosocial well-being and quality of life. Older adults can use various strategies to prevent musculo-skeletal problems (see Chapter 65, Table 65-1).

Diseases such as osteoarthritis and osteoporosis are not the normal consequences of growing old; rather, they are the effects of disease in an aging adult. Symptoms of disease can be treated in many cases, helping the older adult to return to a higher functional level. Age-related changes in the musculo-skeletal system and differences in assessment findings are presented in Table 64-1.

TABLE 64-1

AGE-RELATED DIFFERENCES IN ASSESSMENT
Musculo-Skeletal System

Changes	Differences in Assessment Findings
Muscle	
Decreased number and diameter of muscle cells, replacement of muscle cells by fibrous connective tissue	Decreased muscle strength and bulk, abdominal protrusion, flabby muscle
Loss of elasticity in ligaments and cartilage	Decreased fine motor dexterity, decreased agility
Reduced ability to store glycogen; decreased ability to release glycogen as quick energy during stress	Slowed reaction times and reflexes as a result of slowing of impulse conduction along motor units; earlier fatigue with activity
Joints	
Increased risk for cartilage disruption that contributes to direct contact between bone ends and overgrowth of bone around joint margins	Joint stiffness, possible crepitation on movement; pain with motion, weight bearing, or both
Loss of water from discs between vertebrae; narrowing of intervertebral spaces	Loss of height from disc compression; posture change
Bone	
Decrease in bone density	Loss of height from vertebral compression, back pain; deformity such as kyphosis (dowager's hump) caused by vertebral compression

Assessment of the Musculo-skeletal System

Correct diagnosis of any complaint depends on a complete patient history and a thorough physical examination. Musculo-skeletal assessment focuses on good analyses of symptoms, functional assessment, medical history specific to the musculo-skeletal system, family history, and personal and social history. The most common symptoms of musculo-skeletal impairment include pain, weakness, deformity, limitation of movement, stiffness, and joint crepitation (described in Table 64-6). Neuro-vascular structures are often affected by musculo-skeletal problems, and muscular disorders may be manifestations of neurological problems. A neurological system assessment (discussed in Chapter 58) and head-to-toe physical assessment are often conducted simultaneously.

Subjective Data

Important Health Information.

Appropriate questions to ask during a musculo-skeletal assessment are listed in Table 64-2.

TABLE 64-2

HEALTH HISTORY
Musculo-Skeletal System: Questions for Obtaining Subjective Data

Joints
• Do you have any problems with your joints?* • Do you have any pain?* (If so, ask patient to describe location, quality, severity, onset, timing, frequency; aggravating/relieving factors; refer to Chapter 10 for pain assessment.) • Is the joint pain associated with fever, recent infection, trauma, or repetitive activity?* • Have you noticed any stiffness, swelling, heat, or redness in your joints?* • Do you have any limitations in movement or function of any joint?* Which activities give you problems?
Muscles
• Do you have any problems with your muscles (pain, cramping)?* Is the pain widespread and associated with fatigue? • Do you have any pain in your calf muscles?* With walking? Does it go away with rest? • Are your muscle aches associated with fever, chills, or the "flu"? • Do you have any muscular weakness?* Where? How long have you noticed the weakness? Do the muscles look smaller there?
Bones
• Do you have any bone pain?* Is it affected by movement? How do you manage the pain? • Do you have any deformity of any bone or joint? What is the cause? Does it affect range of motion?* • Have any accidents or trauma ever affected your bones or joints? When? What was the treatment? Have any ongoing limitations resulted?*
Functional Assessment (Activities of Daily Living)

• Do your joint, muscle, or bone problems limit any of your usual daily activities?*
  • Bathing: getting in and out of tub, turning faucets
  • Toileting: voiding, defecating, getting on or off toilet, wiping self
  • Dressing: fastening buttons, zippers, pulling clothes over head, pulling up pants or skirt, tying shoes
  • Grooming: shaving, brushing teeth, fixing hair, applying makeup
  • Eating: preparing meals, pouring liquids, cutting up foods, bringing food to mouth, drinking
  • Mobility: walking up and down stairs, getting in and out of bed, getting out of the house
  • Communicating: talking, using phone, writing

Self-Care Behaviours
• Are there any occupational hazards that could affect your muscles and joints? Does your work involve heavy lifting or repetitive motion?* • Do you use any mechanical assistive devices or prosthetic or orthotic devices?* • Describe your exercise pattern (frequency, warm-up, type of exercise, any pain). • Have you had any recent weight gain or loss?* What is your usual daily diet? What dietary supplements do you take? (Ask specifically about calcium, vitamin D supplements, and herbal products.) Are you taking any medications for the musculo-skeletal system (anti-inflammatory, pain reliever)?* • How do you deal with problems (such as pain or immobility) that have resulted from your musculo-skeletal problem? • Has your illness affected your interaction with friends, family, or the way you view yourself?
Additional History for the Aging Adult
• Have you noticed any change in strength or weakness over the past weeks or months?* • Have you been falling or stumbling more often over the past weeks or months?* • Do you use any mobility aids to help you get around (cane, walker)?*

*If yes, ask patient to describe.

Case Study

Patient Introduction

Source: And-One/Shutterstock.com.

Terry King is a 78-year-old man brought to the emergency department by ambulance after he fell on a patch of ice outside his home. He is accompanied by his wife, who was asleep when he fell. He lay outside in the cold for 2 hours before neighbours found him. He is pale, diaphoretic, and complaining of excruciating pain in his left hip. The paramedics applied O_2 at 2 L via nasal cannula.

Critical Thinking

Throughout this assessment chapter, think about Mr. King's symptoms with the following questions in mind:

1. What is the most likely cause for Mr. King's acute hip pain?
2. What type of assessment would be most appropriate for Mr. King: comprehensive, focused, or emergency? What should the nurse's priority assessment(s) be?
3. What questions should the nurse ask Mr. King?
4. What should be included in the physical assessment? What would the nurse be looking for?

5. What diagnostic studies might the nurse be ordered?

See pp. 1624, 1625, and 1630 for more information on Mr. King.

Past Health History.

Because certain illnesses are known to affect the musculo-skeletal system either directly or indirectly, the patient should be questioned about past medical problems; questions should concern specifically tuberculosis, poliomyelitis, diabetes mellitus, parathyroid problems, hemophilia, rickets, soft tissue infection, and neuro-muscular disabilities. In addition, past or developing musculo-skeletal problems can affect the patient's overall health. Trauma to the musculo-skeletal system is a common reason for seeking medical evaluation. The nurse should record details of emergency treatment for any musculo-skeletal injuries. Questions should also focus on symptoms of arthritic and connective tissue diseases (e.g., gout, psoriatic arthritis, systemic lupus erythematosus), osteomalacia, osteomyelitis, and fungal infection of the bones or joints. The nurse should ask the patient about possible sources of a secondary bacterial infection, such as the ears, tonsils, teeth, sinuses, lungs, or genito-urinary tract. These infections can enter the bones, resulting in osteomyelitis or joint destruction. Obtain a detailed account of the course and treatment of any of these problems.

Genetics in Clinical Practice

Autoimmune Diseases

- Many autoimmune diseases of the musculo-skeletal system have a genetic basis involving human leukocyte antigens.
- Autoimmune diseases include ankylosing spondylitis, rheumatoid arthritis, and systemic lupus erythematosus.

Osteoporosis

- Genetic factors contribute to osteoporosis by influencing not only bone mineral density but also bone size, bone quality, and bone turnover.

Osteoarthritis, Gout, and Scoliosis

- A genetic predisposition is a contributing risk factor in all these diseases.

Muscular Dystrophy

- The most common types of muscular dystrophy are X-linked recessive disorders.

Obtain a family history related to rheumatoid arthritis, systemic lupus erythematosus, ankylosing spondylitis, osteoarthritis, gout, osteoporosis, and scoliosis because a patient may have a genetic predisposition to these or other musculo-skeletal disorders.

Medications.

The nurse should carefully question the patient about use of prescription drugs, over-the-counter drugs, herbal products, and nutritional supplements (especially calcium and vitamin D; refer to Chapter 12, Tables 12-7 and 12-8, for commonly used herbs and dietary supplements). Detailed information should be obtained about each treatment, including its name, the dose and frequency, the length of time it was taken, its effects, and any possible adverse effects. The nurse should inquire specifically about use of any skeletal muscle relaxants, opioids, nonsteroidal anti-inflammatory drugs, and systemic and topical corticosteroids. A patient who has taken anti-inflammatory drugs should be questioned about gastro-intestinal distress or signs of bleeding.

In addition to drugs taken for treatment of a musculo-skeletal problem, the patient should be questioned about drugs that can have detrimental effects on this system. Such drugs and their potential adverse effects include anticonvulsant drugs (osteomalacia),

phenothiazines (gait disturbances), corticosteroids (avascular necrosis, decreased bone and muscle mass), and potassium-depleting diuretics (muscle cramps and weakness). Women should be questioned about their menstrual history; episodes of amenorrhea can contribute to early development of osteoporosis. The nurse should ask postmenopausal women about their use of hormone therapy.

Surgery or Other Treatments.

Information about past hospitalizations related to a musculo-skeletal problem should be obtained. The nurse documents the reason for hospitalization; the date and the duration; and the treatment, including ongoing rehabilitation. The nurse should obtain specific information about any surgical procedure and the postoperative course. If the patient experienced a period of prolonged immobilization, the development of osteoporosis and muscle atrophy should be considered.

Case Study

Subjective Data

Source: And-One/Shutterstock.com.

A focused subjective assessment of Terry King revealed the following information:

History of Current Illness: Rates left hip pain at a 9 on a scale of 0–10. Describes pain as sharp spasms that increase in intensity with any movement. Is asking for pain medicine "as strong as you can give me." Denies any history of musculo-skeletal problems.

Past Health: Type 2 diabetes for 11 yr. COPD for 15 yr; 40 pack-year smoking history.

Medications: Metformin (Glucophage), 500 mg PO bid; glyburide (DiaBeta), 5 mg/day PO; fluticasone and salmeterol combination (Advair), 250/50 mcg, 1 inhalation bid; salbutamol (Ventolin), 2 puffs q4h PRN as rescue inhaler.

Functional Assessment: Until this current fall, has been able to perform ADLs without assistance. Currently smokes 2 to 3 packs of cigarettes per day. Is trying to quit but finding it difficult. Drinks alcohol at night. Is 188 cm tall and weighs 88 kg. Does not take any nutritional supplements and tends to shy away from milk and other dairy products because they make him "gassy." Leads a sedentary lifestyle because of dyspnea on exertion.

See pp. 1622, 1625, and 1630 for more information on Mr. King.

ADLs, activities of daily living; *COPD,* chronic obstructive pulmonary disease.

Objective Data

Physical Examination.

Examination of the musculo-skeletal system involves inspection, palpation, motion, and muscular assessment. The nurse should conduct a general overview, while obtaining data in a careful health history to provide guidance in choosing areas on which to concentrate during the local examination. Specific measurements should be taken as indicated by the results of the local examination.

Inspection.

Inspection begins during the nurse's initial contact with the patient. The nurse notes the use of an assistive device such as a walker or

cane. The nurse also observes general body build, muscle configuration, and symmetry of joint movement. If the patient is able to move independently, the nurse should assess posture and gait by watching the patient walk, stand, and sit. Musculo-skeletal and neurological problems can result in changes from a normal gait.

A systematic inspection is performed, starting at the head and neck and proceeding to the upper extremities, lower extremities, and trunk. The skin is inspected for general colour, scars, or other overt signs of previous injury or surgery. The nurse notes any swelling, deformity, nodules or masses, and discrepancies in limb length or muscle size. The patient's opposite-side body part is observed for comparison when an abnormality is suspected.

Palpation.

Any area that has aroused concern because of a subjective complaint or appears abnormal on inspection should be carefully palpated. Palpation usually proceeds from head to toe to examine neck, shoulders, elbows, wrists, hands, back, hips, knees, ankles, and feet. Both superficial and deep palpation are usually performed, one after the other. The nurse's hands should be warm to prevent muscle spasm, which can interfere with identification of essential landmarks or soft tissue structures. Palpation allows for evaluation of skin temperature, local tenderness, swelling, crepitation, and presence of nodules. Muscles are palpated during active and passive motion for tone, strength, and ease of movement.

Motion.

When assessing the patient's joint mobility, the nurse must carefully evaluate both passive and active ranges of joint motion. Measurements should be similar for both. *Active range of motion* means the patient takes his or her own joints through all movements without assistance. *Passive range of motion* occurs when someone else moves the patient's joints without the patient's participation. The nurse should be cautious in performing passive range of motion because of the risk of injury to underlying structures. Manipulation must cease immediately if pain or resistance is encountered. If deficits in active or passive range of motion are noted, the nurse

must also assess functional range of motion to determine whether performance of activities of daily living has been affected by joint changes. In this assessment, the patient is asked whether activities such as eating and bathing must be performed with assistance or cannot be done at all.

Range of motion is most accurately assessed with a goniometer, which measures the angle of the joint (Figure 64-6). Specific degrees of range of motion of all joints are usually not measured unless a musculo-skeletal problem has been identified. A less exact but valuable assessment method is to compare the range of motion of one extremity with the range of motion on the opposite side. The most common movements that occur at the diarthroidal joints are described in Table 64-3.

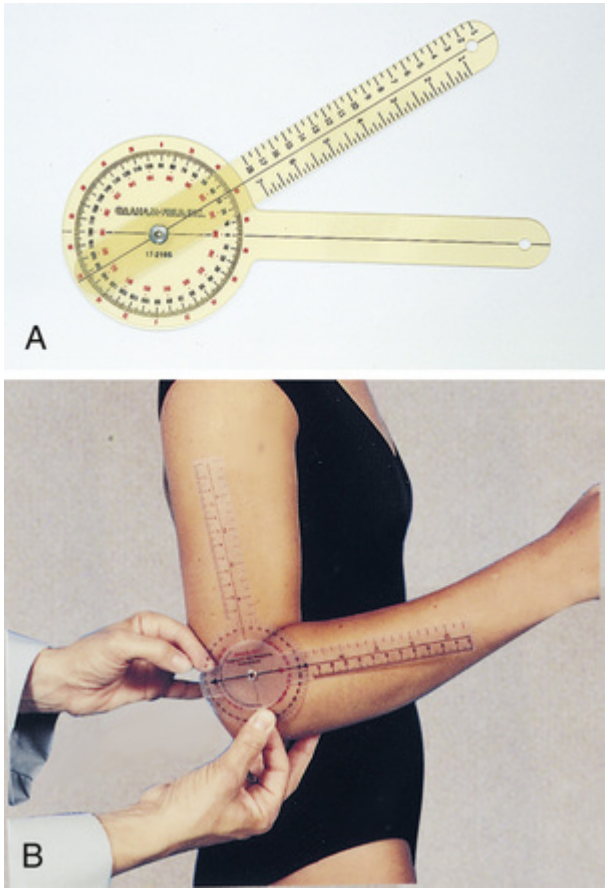

FIGURE 64-6 Measurement of joint motion with a goniometer. Source: **A,** Wilson, S. F., & Giddens, J. F. (2013). *Health assessment for nursing practice* (5th ed., p. 34, Figure 3-23). St. Louis: Mosby; **B,** From Patton, K. T., & Thibodeau, G. A. (2013). *Anatomy and physiology* (8th ed., p. 286, Figure 10-15). St. Louis: Mosby.

TABLE 64-3

MOVEMENT AT DIARTHROIDAL JOINTS

Movement	Description
Abduction	Movement of part away from midline of body
Adduction	Movement of part toward midline of body
Circumduction	Combination of flexion, extension, abduction, and adduction that results in circular motion of a body part
Dorsiflexion	Flexing of toes and foot upward
Eversion	Turning of sole outward away from midline of body
Extension	Straightening of joint that increases angle between two bones
External rotation	Movement along longitudinal axis away from midline of body
Flexion	Bending of joint that results in decreased angle between two bones
Hyperextension	Extension in which angle exceeds 180 degrees or beyond a joint's normal range of motion
Internal rotation	Movement along longitudinal axis toward midline of body
Inversion	Turning of sole inward toward midline of body
Opposition	Moving the thumb tip to meet the tip of each finger
Plantar flexion	Flexing toes and foot downward
Pronation	Turning of palm downward
Supination	Turning of palm upward

Muscle Strength Testing.

The nurse grades the strength of individual muscles or groups of muscles during contraction (Table 64-4). The patient should be instructed to apply resistance to the force exerted by the nurse. For example, if the examiner tries to pull the patient's bent arm down, the patient tries to raise it. Muscle strength should also be compared with the strength of the opposite extremity. Subtle variations in muscle strength may be noted when the patient's dominant side is compared with the nondominant side.

TABLE 64-4

MUSCLE STRENGTH SCALE

0	No detection of muscular contraction
1	A barely detectable flicker or trace of contraction with observation or palpation
2	Active movement of body part with elimination of gravity
3	Active movement against gravity only and not against resistance
4	Active movement against gravity and some resistance
5	Active movement against full resistance without evident fatigue (normal muscle strength)

Measurement.

When length discrepancies or subjective problems are noted, the nurse obtains limb length and circumferential muscle mass measurements. For example, leg length should be measured when gait disorders are observed. The affected limb is measured between two bony prominences, and that measurement is compared with the corresponding measurement of the opposite extremity. Muscle mass is measured circumferentially at the largest area of the muscle. When recording measurements, the nurse documents the exact location at which the measurements were obtained (e.g., the quadriceps muscle is measured 15 cm above the patella). This informs the next examiner of the exact area to be measured and ensures consistency during reassessment.

Other.

Assessment of reflexes is discussed in Chapter 58. Table 64-5 lists the elements of a normal physical assessment of the musculo-skeletal system. Abnormal assessment findings of the musculo-skeletal system are presented in Table 64-6.

TABLE 64-5

EXAMPLE OF A NORMAL PHYSICAL ASSESSMENT OF THE MUSCULO-SKELETAL SYSTEM

• Full range of motion of all joints without pain or laxity (hypermobility) • No joint swelling, deformity, or crepitation • Normal spinal curvatures • No tenderness on palpation of spine • No muscle atrophy or asymmetry • Muscle strength of 5

TABLE 64-6

ASSESSMENT ABNORMALITIES
Musculo-Skeletal System

Finding	Description	Possible Etiology
Achilles tendinitis	Pain in posterior leg initially during running or walking; can progress to pain at rest	Cumulative stress on Achilles tendon, resulting in inflammation
Ankylosis	Stiffness or fixation of a joint, usually resulting from destruction of articular cartilage and subchondral bone with subsequent tissue scarring	Chronic joint inflammation
Antalgic gait	Shortened stride with as little weight bearing as possible on the affected side	Pain or discomfort in the lower extremity on weight bearing; can be related to trauma or other disorders
Ataxic gait	Staggering, uncoordinated gait, often with sway	Neurogenic disorders (e.g., spinal cord lesion)
Atrophy	Decrease in the size of a tissue or organ caused by a reduction in the number or size of the individual cells; characterized by decreased circumference and flabby appearance and leading to decreased function and tone	Muscle denervation, contracture, and prolonged disuse as a result of immobilization
Contracture	Abnormal, usually permanent flexion and fixation of a muscle or joint; resistance to movement is a result of fibrosis of supporting soft tissues	Shortening of muscle or ligaments, tightness of soft tissue, incorrect positioning of immobilized extremity
Crepitation (crepitus)	Crackling sound or grating sensation as a result of friction between bones, broken bone, or cartilage bits in joint	Fracture, dislocation, chronic inflammation, osteoarthritis
Dislocation	Displacement of bone from its normal joint	Trauma, disorders of surrounding soft tissues
Hypertrophy	Increase in size of muscle as a result of enlargement of existing cells	Exercise or other increased stimulation, increased androgens
Kyphosis (dowager's hump)	Forward bending of thoracic spine: exaggerated thoracic curvature	Poor posture, tuberculosis, arthritis, osteoporosis, growth disturbance of vertebral epiphyses
Limited range of motion (ROM)	Failure of joint to achieve the expected degrees of motion	Injury, inflammation, contracture
Lordosis (swayback)	Lumbar spinal deformity that results in exaggerated lumbar curvature	Secondary to other spinal deformities, muscular dystrophy, obesity, flexion contracture of hip, congenital dislocation of hip
Muscle spasticity	Increased muscle tone (rigidity) with sustained muscle contractions (spasms); stiffness or tightness may interfere with gait, movement, speech	Neuro-muscular disorders such as multiple sclerosis or cerebral palsy
Myalgia	General muscle tenderness and pain	Chronic rheumatic syndromes (e.g., fibromyalgia)

Finding	Description	Possible Etiology
Paresthesia	Numbness and tingling, often described as a "pins and needles" sensation	Compromised sensory nerves, often owing to edema in a closed space such as a cast or bulky dressing
Pes planus (flatfoot)	Abnormal flatness of the sole and arch of the foot	Hereditary, muscle paralysis, mild cerebral palsy, early muscular dystrophy, injury to posterior tibial tendon
Plantar fasciitis	Burning, sharp pain on sole of foot; worse in the morning	Chronic degenerative–reparative cycle that results in inflammation
Scoliosis	Deformity resulting from lateral S-shaped curvature of the thoracic and lumbar spine	Idiopathic or congenital condition, fracture or dislocation, osteomalacia
Subluxation	Partial dislocation of joint	Instability of joint capsule and supporting ligaments (e.g., as a result of trauma, arthritis)
Swan neck deformity	Hyperextension of the PIP joint with flexion of the MCP and DIP joints of the fingers (see Chapter 67, Figure 67-4)	Deformity typical of rheumatoid and psoriatic arthritis, caused by contracture of muscles and tendons
Swelling	Enlargement, often of a joint, owing to fluid collection; generally leads to pain, stiffness	Trauma or inflammation
Torticollis (wry neck)	Twisting of neck in unusual position to one side	Prolonged contraction of neck muscles, congenital or acquired
Ulnar deviation (ulnar drift)	Displacement of fingers to ulnar side of forearm (see Chapter 67, Figure 67-4)	Typical deformity of rheumatoid arthritis owing to tendon contracture
Valgum deformity (genu valgum; knock knees)	Condition in which the space between the medial malleoli > 2.5 cm when knees are together	Poliomyelitis, congenital deformity, arthritis
Varum deformity (genu varum; bowleg)	Condition in which the space between the knees > 2.5 cm when the medial malleoli are together	Arthritis, congenital deformity

DIP, distal interphalangeal; *MCP*, metacarpophalangeal; *PIP*, proximal interphalangeal.

Focused Assessment

Musculo-Skeletal System

Use this checklist to ensure that the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses:

Joint pain or stiffness	Y	N
Muscle weakness	Y	N
Bone pain	Y	N

Objective: Diagnostic

Check the following laboratory results for critical values:

Radiograph results	✓
Bone scans	✓
Erythrocyte sedimentation rate	✓

Objective: Physical Examination

Inspect and palpate:

Skeleton and extremities (and compare sides) for alignment, contour, symmetry, size, and gross deformities	✓
Joints for range of motion, tenderness/pain, heat, crepitus, and swelling	✓
Muscles (and compare sides) for size, symmetry, tone, and tenderness/pain	✓
Bones for tenderness or pain	✓

Case Study

Objective Data: Physical Examination

Source: And-One/Shutterstock.com.

A physical examination of Terry King reveals the following:

- BP, 166/94; heart rate, 98; respiratory rate, 36; temperature, 35.8°C; O_2 saturation rate, 91% on 2 L of O_2.
- Alert and oriented × 3.
- Left leg shortened and externally rotated. No external bruising noted.
- + 1 Pedal pulses bilaterally. Lungs with bibasilar crackles and expiratory wheezing.

In continuing to read this chapter, consider diagnostic studies the nurse would anticipate being performed for Mr. King. See pp. 1622, 1624, and 1630 for more information on Mr. King.

BP, blood pressure.

Diagnostic Studies of the Musculo-skeletal System

Diagnostic studies provide important objective data that aid the nurse in monitoring the patient's condition and planning appropriate interventions. Table 64-7 lists diagnostic studies commonly used to evaluate the musculo-skeletal system. Tests must be carefully chosen to enhance or clarify information gained from the patient's history and physical examination.

TABLE 64-7
DIAGNOSTIC STUDIES
Musculo-Skeletal System

Study	Description and Purpose	Nursing Responsibility
Radiological Studies		
Standard radiography (x-ray study)	• Helps determine density of bone • Used to evaluate structural or functional changes of bones and joints • One-dimensional image provided by anteroposterior view because x-ray beam passes from front to back • Two-dimensional image provided by lateral position	• Instruct patient to avoid excessive exposure of patient and self to radiation. • Remove any radiopaque objects that can interfere with results. • Explain procedure to patient. • Instruct the patient to remain still. • Pregnancy is a contraindication to x-ray studies; however, sometimes the benefits outweigh the risks.
Computed tomography (CT)	• Three-dimensional radiography provided by use of an x-ray beam with a computer • Used to identify soft tissue abnormalities, bony abnormalities, and various musculo-skeletal trauma • Iodinated dye often used for better visualization	• Same as for radiography. • Also, assess for adverse reactions to iodinated dye. • Patients with kidney disease or diabetes require adequate hydration to flush out the dye.
Magnetic resonance imaging (MRI)	• Viewing of soft tissue with use of radiofrequency waves and magnetic field • Especially useful in the diagnosis of avascular necrosis, disc disease, tumours, osteomyelitis, ligament tears, and cartilage tears • Patient placed inside scanning chamber • Gadolinium-based contrast dyes used to enhance visualization of the structures, may be injected into a vein • In open MRI, no requirement for placing the patient inside a chamber	• MRI is contraindicated in patients with metallic implants. • Ensure that patient has no metal on clothing (e.g., snaps, zippers, jewellery, credit cards). • Inform patient that procedure is painless, and emphasize importance of remaining still throughout examination. • Claustrophobic patients may require antianxiety agents if indicated and ordered. • Open MRI may be indicated for patients with large chest and abdominal girth or severe claustrophobia.
Arthrography	• Radiography in which contrast medium or air is injected into joint cavity, enabling visualization of joint structures • Joint movement assessed with series of radiographic images	• Same as for radiography. • Assess patient for possible allergy to contrast medium. • Inform patient that procedure is painless.

Study	Description and Purpose	Nursing Responsibility
Discography	• Radiography of cervical or lumbar intervertebral disc, performed after injection of contrast dye into nucleus pulposus • Enables visualization of intervertebral disc abnormalities	• Same as for arthrography.
Bone Mineral Density (BMD) Measurements		
Dual-energy x-ray absorptiometry (DEXA)	• Used to measure bone mass of spine, femur, forearm, and total body • Allows assessment of bone density with minimal radiation exposure • Used to diagnose metabolic bone disease and to monitor changes in bone density with treatment • Widely available; free screening test	• Same as for radiography. • Inform patient that procedure is painless.
Quantitative ultrasonography (QUS)	• Helps evaluate density, elasticity, and strength of bone through the use of ultrasound waves rather than radiation	• Inform patient that procedure is painless.
Radioisotope Studies		
Bone scan	• Radiography in which radioisotope (usually technetium-99m) is injected and taken up by bone • Isotope uptake uniform when bones are normal • Uptake increased in osteomyelitis, osteoporosis, primary and metastatic malignant lesions of bone, and certain fractures • Uptake decreased uptake in areas of avascular necrosis	• Pregnancy and lactation are usually contraindicated. • The technician gives a calculated dose of radioisotope 2 hr before procedure. • The patient's bladder is emptied before the procedure. • The procedure requires 1 hr while patient lies supine. • Increase patient's fluid intake after the examination. • The isotopes are excreted from the body within 6–24 hr.
Endoscopy		
Arthroscopy	• Procedure in which an arthroscope is inserted into the joint (usually knee) for visualization of structure and contents • Can be used for exploratory surgery (removal of loose bodies and biopsy) and for diagnosing abnormalities of meniscus, articular cartilage, ligaments, or joint capsule • Other structures that can be visualized through the arthroscope: shoulder, elbow, wrist, jaw, hip, and ankle	• Inform patient that procedure can be performed in outpatient setting and that local or general anaesthesia may be used. • Patient is on NPO status after midnight on the day of the test. • After procedure, cover wound with sterile dressing. • Explain postprocedure care.
Mineral Metabolism		
Alkaline phosphatase (ALP)	• Enzyme produced by osteoblasts of bone; needed for mineralization of organic bone matrix • Levels elevated in healing fractures, bone cancers, osteoporosis, osteomalacia, and Paget's disease • *Normal:* 35–120 units/L (age dependent) • Blood samples obtained by venipuncture	• Inform patient that fasting is preferred but not required. • Note any medications that may affect test results.* • Observe venipuncture site for bleeding or hematoma formation.

Study	Description and Purpose	Nursing Responsibility
Calcium	• Stored primarily in bone • Provides bone with rigid consistency • Serum level decreased in osteomalacia, renal disease, and hypoparathyroidism • Level increased in hyperparathyroidism, some bone tumours; varies with level of albumin • *Normal:* 2.25–2.75 mmol/L (age dependent)	• Inform patient that fasting is not required. • Note any medications that may affect test results. • Excessive milk ingestion and prolonged tourniquet application may increase calcium levels.*
Phosphate (phosphorus)	• Amount that is present indirectly related to calcium metabolism • Level decreased in osteomalacia • Level increased in chronic renal disease, healing fractures, osteolytic metastatic tumour • *Normal:* 0.97–1.45 mmol/L (age dependent)	• Recent carbohydrate intake (including IV glucose) causes decrease in phosphorus levels. • Patient should be on NPO status after midnight on the day of the test. • Note any medications that may affect test results. • Avoid hemolysis of the blood sample because this can elevate phosphate levels.*
Serological Studies		
Rheumatoid factor (RF)	• Study to assess presence of autoantibody (RF) in serum • Factor not specific for rheumatoid arthritis; present in other connective tissue diseases, as well as in a small percentage of normal population • *Normal:* negative or < 60 units/mL by nephelometric method	• Inform patient that fasting is not required. • In older adults, results are often falsely positive. • False-positive results also occur with hemolysis or lipemia.*
Erythrocyte sedimentation rate (ESR)	• Nonspecific index of inflammation • Used to measure rapidity with which red blood cells settle out of unclotted blood in 1 hr • Results influenced by physiological factors as well as by diseases • Levels elevated with any inflammatory process (especially rheumatoid arthritis, rheumatic fever, osteomyelitis, and respiratory infections) • *Normal:* male, ≤ 15 mm/hr; female, ≤ 20 mm/hr (age dependent).	• Numerous interfering factors can affect test results (e.g., pregnancy, menstruation, anemias, medications). • Withhold medications that may affect results, if indicated.*
Antinuclear antibody (ANA)	• Used to assess presence of antibodies capable of destroying nucleus of body's tissue cells. • Finding positive in 95% of patients with systemic lupus erythematosus and may also be positive in individuals with systemic sclerosis (scleroderma) or rheumatoid arthritis and in a small percentage of normal population • *Normal:* negative at 1 : 40 dilution	• Inform patient that fasting is not required. • Note any medications that may affect test results. • Assess for signs of infection at the venipuncture site in patients with autoimmune diseases.*
C-reactive protein (CRP)	• Used to diagnose inflammatory diseases, infections, and active widespread malignancy. • CRP synthesized by the liver and present in large amounts in serum 18–24 hr after onset of tissue damage • *Normal:* negative or ≤ 10 mg/L	• Fasting may sometimes be required (laboratory specific). • Note any medications that may affect test results.*

Study	Description and Purpose	Nursing Responsibility
Uric acid	• End product of purine metabolism that is normally excreted in urine • Levels not specific to gout but are usually elevated in patients with gout • *Normal:* male, 240–501 mcmol/L; female, 160–430 mcmol/L (age dependent)	• Fasting may sometimes be required (laboratory specific).*
Human leukocyte antigen–B27 (HLA-B27)	• Antigen present in disorders such as ankylosing spondylitis and rheumatoid arthritis.	• Inform patient that fasting or other preparation is not needed.*
Muscle Enzymes		
Creatine kinase (CK)	• Concentration highest in skeletal muscle • Values increased in progressive muscular dystrophy, polymyositis, and traumatic injuries • *Normal:* men, 55–170 units/L; women, 30–135 units/L	• Obtain blood samples by venipuncture. • Observed venipuncture site for bleeding or hematoma formation. • Inform patient that procedure does not necessitate fasting. • Values can be increased after strenuous exercise, recent surgery, and intramuscular injections and with certain medications.*
Serum potassium (K^+)	• Values sometimes increased with muscle trauma because cell destruction releases this electrolyte into the serum (depends on renal function) • *Normal:* 3.5–5.0 mmol/L	• Monitor patients in trauma unit for cardiac dysrhythmias related to hypokalemia or hyperkalemia. • Note any medications that may affect test results. • Hemolysis of the blood sample and prolonged tourniquet application can elevate potassium levels.*
Invasive Procedures		
Arthrocentesis	• Procedure in which a needle is inserted into the joint cavity to aspirate synovial fluid, blood, or pus or to instill medications • Local anaesthesia and aseptic technique required • Useful in diagnosis of joint inflammation, infection, and subtle fractures	• Inform patient that procedure is usually done at bedside or in examination room. • Send samples of synovial fluid to laboratory for examination (if indicated). • After procedure, apply pressure dressing. • Observe dressing for leakage of blood or fluid.

Study	Description and Purpose	Nursing Responsibility
Electromyography (EMG)	• Used to evaluate electrical potential associated with skeletal muscle contraction • Involves insertion of small-gauge needles into certain muscles • Needle probes attached to leads that feed information to EMG machine; recordings of electrical activity of muscle traced on audio transmitter, as well as on oscilloscope and recording paper • Study useful in providing information related to lower motor neuron dysfunction and primary muscle disease	• Inform patient that procedure is usually done in EMG laboratory while patient lies supine on special table. • Keep patient awake to cooperate with voluntary movement. • Inform patient that procedure involves some discomfort from needle insertion. • Contraindications include anticoagulant therapy and extensive skin infection. • Fasting is not required, but some laboratories may restrict intake of stimulants (e.g., coffee, cigarettes) 2–3 hr before procedure.
Miscellaneous		
Thermography	• Infrared detector used to measure degree of heat radiating from skin surface • Useful in investigation of cause of joint inflammation and in following up patient's response to anti-inflammatory drug therapy	• Inform patient that procedure is painless and noninvasive.
Somatosensory evoked potential (SEP)	• Used to evaluate evoked potential of muscle contractions • Electrodes placed on skin and provide recordings of electrical activity of muscle • Useful in identifying subtle dysfunction of lower motor neuron and primary muscle disease • Possible to measure nerve conduction along pathways not accessible by EMG	• Inform patient that procedure is similar to EMG but does not involve needles. • Electrodes are applied to the skin.

*Blood samples are obtained by venipuncture. The nurse should observe venipuncture site for bleeding or hematoma formation.

IV, intravenous; *NPO,* nothing by mouth.

Radiography

The *radiograph* is the diagnostic study most commonly used to assess musculo-skeletal problems and to monitor the effectiveness of treatment. The x-ray beam produces an image on a photographic film; the image appears dark if the x-rays penetrate the body tissues (e.g., lungs) and white if the transmission is partially blocked (e.g., by bones). Radiographs are two-dimensional, and multiple views may be necessary to facilitate diagnosis (e.g., anteroposterior [front-

to-back], lateral [side], oblique [45-degree angle]). The contours and shades of the structures on these images provide useful information, such as showing the presence of deformity, joint congruity, calcification in soft tissue, and bone fractures. Radiographs are also useful in the evaluation of hereditary, developmental, infectious, inflammatory, neoplastic, metabolic, and degenerative disorders.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) can be useful for the early diagnosis of soft tissue disorders, including cartilage or ligament tears and herniated discs, as well as bone disorders such as avascular necrosis, tumours, and multiple myeloma. The body is composed primarily of hydrogen, which possesses magnetic properties that can be scanned by the powerful magnetic fields and radiofrequency waves. Contrast material may be necessary to enhance the images. MRI is contraindicated in patients who have implanted metal objects (e.g., pacemaker, aneurysm clips, prosthesis, implanted cardioverter–defibrillator, electronic devices, hearing aids, shrapnel).

Arthroscopy

A small fibre optic tube called an *arthroscope* is inserted into a joint and used to directly examine or operate on the interior of the joint cavity in a procedure known as **arthroscopy** (see Table 64-7). Arthroscopy is performed under sterile conditions. After local anaesthetic has been administered, a large-bore needle is inserted into the joint, and the joint is distended with fluid or air (Figure 64-7). The arthroscope enables extensive, accurate visualization of the joint cavity. Photographs or videotapes can be made through the arthroscope, and a biopsy of the synovium or cartilage can be obtained. Torn tissue can be repaired through arthroscopic surgery, which eliminates the need for a larger incision and greatly decreases the recovery time.

FIGURE 64-7 Knee arthroscopy in progress. Notice the monitor in the background. Source: From Miller, M. D., Howard, R. F., & Plancher, K. D. (2003). *Surgical atlas of sports medicine.* Philadelphia: Saunders.

Arthrocentesis and Synovial Fluid Analysis

Arthrocentesis, or joint aspiration, is a procedure in which an incision or puncture is made in a joint capsule, usually to obtain samples of synovial fluid from within the joint cavity for a synovial fluid analysis. It may also be used to instill medications for a patient with septic arthritis or to remove excess fluid from joints to relieve pain. After the skin has been cleaned, a local anaesthetic is instilled. An 18-gauge or larger needle is inserted into the joint, and fluid is withdrawn. The appropriate sterile container should be readily available to receive the aspirated fluid, which must be transported immediately to the laboratory. The fluid is examined grossly for volume, colour, clarity, viscosity, and *mucin clot formation.* Normal synovial fluid is transparent, colourless (or straw-coloured), scant in

amount, and of low viscosity. Fluid from an infected joint may be purulent and thick or grey and thin. In gout, the fluid may be whitish yellow. Blood may be aspirated in cases of hemarthrosis because of injury or a bleeding disorder. The mucin clot test indicates the character of the protein portion of the synovial fluid. Normally a white, ropelike mucin clot is formed. In the presence of an inflammatory process, the clot breaks apart and easily fragments. The fluid is examined grossly for floating fat globules, which indicate bone injury.

The fluid is examined microscopically for cell count and identification. Infection would be suspected with an elevated white blood cell count and an increase in polymorphonuclear cells (i.e. neutrophils). Protein content is elevated, and the glucose level is considerably decreased in septic arthritis. The presence of uric acid crystals suggests a diagnosis of gout (Pagana & Pagana, 2013). Specimens for a Gram stain and culture may also be obtained in arthrocentesis.

Muscle Enzymes

Muscle enzymes are released from injured or dead muscle cells. Determinations of muscle enzyme values are used to distinguish between muscle weakness caused by innervation problems and that caused by dystrophic disease of the muscle itself. The level of enzymes reflects the progress of the disorder and the effectiveness of treatment. Creatine kinase is a reliable measure of muscle damage.

Serological Studies

In approximately 80% of people with rheumatoid arthritis and related diseases, an autoantibody known as rheumatoid factor (RF) is present in the serum. RF is an autoantibody directed against immunoglobulin G. RF titres are higher during periods of increased disease activity. Elevated erythrocyte sedimentation rate and C-reactive protein level are nonspecific indicators of active inflammation.

Case Study

Diagnostic Studies

Source: And-One/Shutterstock.com.

The emergency department physician immediately orders the following diagnostic studies for Terry King:

- Radiograph of left hip
- Chest radiograph
- CBC, electrolytes, aPTT, PT/INR
- Arterial blood gases (ABGs)

The radiograph of the left hip reveals an extracapsular fracture. The chest radiographic findings are consistent with COPD without any evidence of pneumonia at present. Hematocrit is 43%; hemoglobin, 140 mmol/L; and WBC is 15.1 × 10^9/L. The remainder of CBC, electrolytes, aPTT, and PT/INR are WNL. The ABGs demonstrate compensated respiratory acidosis.

See pp. 1622, 1624, and 1625 in this chapter for more information on Mr. King. This case is continued in Chapter 65.

aPTT, activated partial thromboplastin time; *CBC,* complete blood cell count; *COPD,* chronic obstructive pulmonary disease; *INR,* international normalized ratio; *PT,* prothrombin time; *WNL,* within normal limits.

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. What are the bone cells that function in the breakdown of bone tissue (resorption) called?
   a. Osteoids
   b. Osteocytes
   c. Osteoclasts
   d. Osteoblasts

2. While performing passive range-of-motion exercises for a client, the nurse puts the ankle joint through the movements of which of the following? *(Select all that apply)*
   a. Flexion and extension
   b. Inversion and eversion
   c. Pronation and supination
   d. Flexion, extension, abduction, and adduction
   e. Pronation, supination, rotation, and circumduction

3. To prevent muscle atrophy, the nurse teaches the client with a leg immobilized in traction to perform which of the following manoeuvres? *(Select all that apply)*
   a. Flexion contractions
   b. Tetanic contractions
   c. Isotonic contractions
   d. Isometric contractions
   e. Extension contractions

4. A client with bursitis of the shoulder asks the nurse what the bursa does. What does the nurse tell the client about the function of the bursa?
   a. Bursae connect bone to bone.
   b. Bursae separate muscle from muscle.
   c. Bursae lubricate joints with synovial fluid.

d. Bursae relieve friction between moving parts.

5. Why are many older adults at increased risk for falls?
   a. Changes in balance
   b. Decrease in bone mass
   c. Loss of ligament elasticity
   d. Erosion of articular cartilage
6. While the nurse is obtaining subjective assessment data related to the musculo-skeletal system, which of the following conditions requires the nurse to ask about family history?
   a. Osteomyelitis
   b. Osteomalacia
   c. Low back pain
   d. Rheumatoid arthritis
7. When a nurse grades muscle strength with a score of 2, what does that indicate?
   a. Active movement against gravity
   b. A barely detectable flicker of contraction
   c. Active movement with elimination of gravity
   d. Active movement against full resistance without evident fatigue
8. Which of the following is a normal finding in the assessment of the musculo-skeletal system?
   a. Muscle strength of 4
   b. A lateral curvature of the spine
   c. Angulation of bone toward midline
   d. Full range of motion of all joints without pain
9. Which of the following are nursing considerations for a client undergoing magnetic resonance imaging (MRI)? *(Select all that apply)*
   a. Ensuring that the client has no metal on clothing
   b. Informing the client that the procedure is painless
   c. Checking for history of claustrophobia

d. Ensuring that the client is on NPO status at least 8 hours before the study

e. Administering a fluid bolus immediately before the study

1. c; 2. a, b; 3. d; 4. d; 5. a; 6. d; 7. c; 8. d; 9. a, b, c.

CHAPTER 65

Nursing Management

Musculo-Skeletal Trauma and Orthopaedic Surgery

Written by, Mary K. Wollan

Adapted by, Maureen A. Barry

LEARNING OBJECTIVES

1. Explain the etiology, pathophysiology, clinical manifestations, and collaborative care of soft tissue injuries, including strains; sprains; dislocations; subluxations; bursitis; repetitive strain injury; carpal tunnel syndrome; and injuries to the rotator cuff, meniscus, and anterior cruciate ligament.
2. Relate the sequential events involved in fracture healing.
3. Compare closed reduction, cast immobilization, open reduction, and traction regarding purpose, complications, and nursing management.
4. Describe a neuro-vascular assessment for a patient with an injured extremity.
5. Explain common complications associated with a fracture and fracture healing.
6. Describe the collaborative care and nursing management of patients with specific fractures.
7. Describe the indications for and the collaborative care and nursing management of the patient with an amputation.
8. Describe the types of joint replacement surgery associated with arthritis and connective tissue diseases.

9. Identify the preoperative and postoperative management of the patient having joint replacement surgery.

KEY TERMS

arthrodesis, p. 1663
arthroplasty, p. 1662
avascular necrosis (AVN), p. 1635
bursitis, p. 1638

fracture, p. 1639
osteotomy, p. 1661
phantom limb sensation, p. 1659
repetitive strain injury (RSI), p. 1636
sprain, p. 1634
strain, p. 1634
subluxation, p. 1635
synovectomy, p. 1661
traction, p. 1641

Musculo-skeletal problems resulting from trauma, along with common orthopaedic surgical procedures, are discussed in this chapter. The nurse's role in the prevention of complications and promotion of function in patients with fractures and orthopaedic surgery is emphasized. The most common cause of musculo-skeletal injuries is a traumatic event resulting in fracture, dislocation, and associated soft tissue injury. Although most of these injuries are not fatal, the cost in terms of pain, disability, medical expense, and lost wages is enormous. Injury is a serious public health issue with a major impact on the lives of Canadians. In 2009, the most recent date for which data are available, injury was the leading cause of death for Canadians between the ages of 1 and 34 and an important cause of

hospitalization. Injury is also a major cause of both short- and long-term impairment and disability in children, young adults, and older adults (Statistics Canada, 2015a). Adolescent males were the age group injured most frequently, mainly while participating in sports. In the working-age adult population, overexertion was the most common cause of injury. Older adults were most often injured from falls while doing household chores or walking (Statistics Canada, 2015a). For all ages, accidents were exceeded only by cancer, heart disease, stroke, and chronic lower respiratory disease as a cause of death (Statistics Canada, 2015b).

The nurse has an important role in educating the public about the basic principles of safety and accident prevention. The morbidity associated with accidents can be significantly reduced if people are aware of environmental hazards, use existing safety equipment, and apply safety and traffic rules. In the occupational and industrial setting, the nurse should teach employees and employers about the use of proper safety equipment and avoidance of hazardous working situations.

Safety Alert

- Falls account for many musculo-skeletal injuries, particularly in older adults.
- Preventive teaching should be provided to high-risk individuals (e.g., people with gait instability or visual or cognitive impairment).
- The nurse should stress the importance of wearing shoes with functional soles and heels, avoidance of wet or slippery surfaces, and removing throw rugs from the home.

Ways to prevent common musculo-skeletal problems in the older adult are listed in Table 65-1.

TABLE 65-1

PATIENT & CAREGIVER TEACHING GUIDE
Prevention of Musculo-Skeletal Problems in the Older Adult

The following instructions should be included when teaching older adults and their caregivers how to prevent musculo-skeletal problems.

- Use ramps in buildings and at street corners instead of steps to prevent falls.
- Eliminate scatter rugs in the home.
- Treat pain and discomfort from osteoarthritis.
  - Rest in a reclining position to decrease discomfort.
  - Discuss use of medication for pain with health care provider.
- Use a walker or cane to help with walking to prevent falls.
- Eat the amount and the kind of foods needed to prevent excess weight gain because obesity adds stress to joints, which may predispose to osteoarthritis.
- Get regular and frequent exercise.
  - ADLs provide ROM exercises. Tai chi may also be helpful.
  - Hobbies (e.g., jigsaw puzzles, needlework, model building) exercise finger joints and prevent stiffness.
  - Performing weight-bearing exercise (e.g., walking) is essential and should be done on a daily basis.
- Use shoes with good support to provide for safety and promote comfort.
- Gradually initiate activities to promote optimal coordination. Rise slowly to a standing position to prevent dizziness, falls, and fractures.
- Avoid walking on uneven surfaces and wet floors.

ADLs, activities of daily living; *ROM,* range of motion.

Soft Tissue Injuries

Soft tissue injuries include sprains, strains, dislocations, and subluxations. These common injuries are usually caused by trauma. Sprains and strains are the most common injury (51%), with fractures and broken bones accounting for 17% of injuries (Statistics Canada, 2015a).

The increasing number of people involved in a fitness program or participating in sports has contributed to the increased incidence of soft tissue injuries. Common sports-related injuries are summarized in Table 65-2. In Canada, 35% of injuries occurred during participation in sports or exercise (Statistics Canada, 2015a).

TABLE 65-2
SPORTS-RELATED INJURIES

Injury	Definition	Treatment
Anterior cruciate ligament tear	Traumatic tearing of ligament by deceleration forces together with pivoting or odd positions of the knee or leg.	• Physiotherapy with rehabilitation, knee brace. • If knee instability or continued injuries, reconstructive surgery may be done.
Impingement syndrome	Entrapment of soft tissue structures under coraco-acromial arch of shoulder.	• NSAIDs; rest until symptoms decrease, and then gradual ROM and strengthening exercises.
Ligament injury	Tearing or stretching of ligament; usually occurs as a result of inversion, eversion, shearing, or torque applied to a joint. Characterized by sudden pain, swelling, and instability.	• Rest, ice, elevation of extremity if possible, NSAIDs; protection of affected extremity by use of brace. • If symptoms persist, surgical repair may be necessary.
Meniscus injury	Injury to fibrocartilage of the knee, characterized by popping, clicking, tearing sensation, effusion, and swelling.	• Rest, ice, elevation of extremity if possible, NSAIDs; gradual return to regular activities. • If symptoms persist, MRI to diagnose meniscal injury and possible arthroscopic surgery.
Rotator cuff tear	Tear within muscle or tendino-ligamentous structures around shoulder.	• *If minor tear:* rest, NSAIDs, and gradual mobilization with ROM and strengthening exercises. • *If major tear:* surgical repair.
Shin splints	Inflammation along anterior aspect of calf from periostitis caused by improper shoes, overuse, or running on hard pavement.	• Rest, ice, NSAIDs, proper shoes; gradual increase in activity. • If pain persists, radiographic study to rule out stress fracture of tibia.
Tendinitis	Inflammation of tendon as a result of overuse or incorrect use.	• Rest, ice, NSAIDs; gradual return to sport activity; protective brace (orthosis) may be necessary if symptoms recur.

MRI, magnetic resonance imaging; *NSAIDs*, nonsteroidal anti-inflammatory drugs; *ROM*, range of motion.

Sprains and Strains

Sprains and strains are common injuries from abnormal stretching or twisting forces that may occur during vigorous activities. These injuries tend to occur around joints and in the spinal musculature.

A **sprain** is an injury related to the ligamentous structures surrounding a joint, usually caused by a wrenching or twisting motion. Most sprains occur in the ankles, knees, or wrists (American Academy of Orthopedic Surgeons [AAOS], 2015). A sprain is classified according to the degree of tearing in the ligament fibres. A *first-degree (mild) sprain* involves tears in only a few fibres, resulting in mild tenderness and minimal swelling. A *second-degree (moderate) sprain* is a partial tearing of the ligament, with

more swelling and tenderness. A *third-degree (severe) sprain* is a complete tearing of the ligament in association with moderate to severe swelling. A gap in the muscle may be apparent or palpated through the skin if the muscle is torn. Because areas around joints are rich in nerve endings, the injury can be extremely painful.

A **strain** is an excessive stretching of a muscle, a muscle's fascial sheath, or a tendon. Most strains occur in the foot, leg (typically hamstrings), or back (AAOS, 2015). Strains may also be classified as first-degree (mild or slightly pulled muscle), second-degree (moderate or moderately torn muscle), and third-degree (severely torn or ruptured muscle).

The clinical manifestations of sprains and strains are similar and include pain, edema, decrease in function, and bruising. Pain aggravated by continued use is common. Edema develops in the injured area because of the local inflammatory response.

Mild sprains and strains are usually self-limiting, with full function returning within 3 to 6 weeks. A severe sprain can result in a concomitant *avulsion fracture,* in which the ligament pulls loose a fragment of bone. Alternatively, the joint structure may become unstable and result in subluxation or dislocation. At the time of injury, *hemarthrosis* (bleeding into a joint space or cavity) or disruption of the synovial lining may occur.

Radiographs of the affected part are usually made to rule out a fracture or widening of the joint structure. However, some health care providers use an assessment protocol called the "Ottawa Rules" (or "Ottawa Guidelines") for the examination of an injured ankle or knee before ordering radiographs (Woods, 2011). These rules specify radiographic studies for a patient, based on age, capability of flexion, location of tenderness, and ability to bear weight immediately after the injury or when examined. Surgical repair may be necessary if the injury is significant enough to produce severe disruption of ligamentous or muscle structures, fracture, or dislocation.

Nursing Management Sprains and Strains

Nursing Implementation

Health Promotion.

Warm-up exercises before exercising and vigorous activity, followed by stretching, significantly reduce the risk for sprains and strains. Strength, balance, and endurance exercises are also important. Strengthening exercises involve working against resistance. These exercises build up

muscle strength and bone density. Balance exercises, which may overlap with some strengthening exercises, help to prevent falling. Endurance exercises should start at a low level of effort and progress gradually to a moderate level of activities. Patients should try to build up to 30 minutes of moderate-intensity endurance activity on most or all days of the week (National Institute on Aging, 2015). Exercise instructions for these types of physical activity are available online at the National Institute of Aging website (see the Resources at the end of this chapter).

Acute Intervention.

If an injury occurs, the immediate care focuses on (1) stopping the activity and limiting movement, (2) application of ice compresses to the injured area, (3) compression of the involved extremity, (4) elevation of the extremity, and (5) providing analgesia as necessary (Table 65-3).

TABLE 65-3

EMERGENCY MANAGEMENT
Acute Soft Tissue Injury

Etiology	Assessment Findings	Interventions
• Falls • Crush injury • Direct blows • Motor vehicle accidents • Sports injuries	• Decreased movement • Decreased pulse, coolness, and capillary refill >2 sec • Decreased sensation with severe edema • Ecchymosis, contusion • Edema • Inability to bear weight when lower extremity involved • Limited or decreased function with upper extremity involvement • Muscle spasms • Pain, tenderness • Pallor • Shortening or rotation of extremity	**Initial** • Ensure airway, breathing, and circulation. • Assess neuro-vascular status of involved limb. • Elevate involved limb. • Apply compression bandage unless dislocation present. • Apply ice packs to affected area. • Immobilize affected extremity in the position found. Do not attempt to realign or reinsert protruding bones. • Anticipate radiographs of injured extremity. • Give analgesia as necessary. • Administer tetanus prophylaxis if skin integrity breached or open fracture. • Administer antibiotic prophylaxis for open fracture, large tissue defects, or mangled extremity injury. **Ongoing Monitoring** • Monitor for changes in neuro-vascular status. • Eliminate weight bearing when lower extremity involved. • Anticipate compartment pressure monitoring if neuro-vascular status changes and compartment syndrome suspected.

RICE (**R**est, **I**ce, **C**ompression, **E**levation) have been found to decrease local inflammation and pain for most musculo-skeletal injuries. Movement should be limited and the extremity rested as soon as pain is felt. Unless the injury is severe, prolonged rest is usually not necessary.

Cold *(cryotherapy)* in several forms can be used to produce hypothermia in the involved part. The cold induces physiological changes in soft tissue,

including vasoconstriction and reduction in the transmission and perception of nerve pain impulses. In addition to pain relief, these changes reduce muscle spasms, inflammation, and edema. Cold is most useful when applied immediately after the injury has occurred. Ice applications should not exceed 20 to 30 minutes per application and ice should not be applied directly to the skin.

An elastic compression bandage can be wrapped around the injured part. To prevent edema and encourage fluid return, the bandage should be wrapped starting distally (at the point farthest from the midline of the body), and progress proximally (toward the midline of the body). If numbness is felt below the area of compression or if there is additional pain or swelling beyond the edge of the bandage, the bandage is too tight. The bandage can be left in place for 30 minutes and then removed for 15 minutes. However, some elastic bandages are left on during training, athletic, and occupational activities.

The injured part should be elevated above the heart level to help mobilize excess fluid from the area and impede further edema. The injured part should be elevated even during sleep. Mild analgesics such as nonsteroidal anti-inflammatory drugs (NSAIDs) may be necessary to manage patient discomfort.

After the acute phase (usually lasting 24 to 48 hours), warm, moist heat can be applied to the affected part to reduce swelling and provide comfort. Heat applications should not exceed 20 to 30 minutes, allowing a "cool-down" time between applications. NSAIDs may be recommended to decrease edema and pain. The patient is encouraged to use the limb, provided that the joint is protected by means of casting, bracing, taping, or splinting. Movement of the joint maintains nutrition to the cartilage, and muscle contraction improves circulation and resolution of the contusion and swelling.

Ambulatory and Home Care.

Most sprains and strains are treated in an outpatient setting. The patient should be instructed in the use of ice and elevation for 24 to 48 hours after the injury to reduce edema. The use of mild analgesics to promote comfort should be encouraged. Use of an elastic bandage may provide additional support during activity. The patient should learn proper measures of strengthening and conditioning to prevent reinjury.

The physiotherapist may help to provide pain relief by means of modalities such as ultrasonography. The therapist may also teach the patient exercises to perform for flexibility and strength.

Dislocation and Subluxation

A **dislocation** is a severe injury of the ligamentous structures around a joint that results in the complete displacement of the bone from its normal position. A **subluxation** is a partial or incomplete displacement of the joint surface. The clinical manifestations of a subluxation are similar to those of a dislocation, but they are less severe. Treatment of a subluxation is similar to that of a dislocation, but a subluxation may require less healing time.

Dislocations characteristically result from overwhelming forces transmitted to the joint that cause a disruption of the soft tissue support structure surrounding the joint. The joints most frequently dislocated in the upper extremity include the thumb, elbow, and shoulder. In the lower extremity, the hip is vulnerable to dislocation occurring as a result of severe trauma, often associated with motor vehicle accidents (Figure 65-1). The patella may dislocate because of a sharp blow to the kneecap or after a sudden twisting inward motion while the planted foot is pointed outward (Buttarovoli & Leffler, 2012).

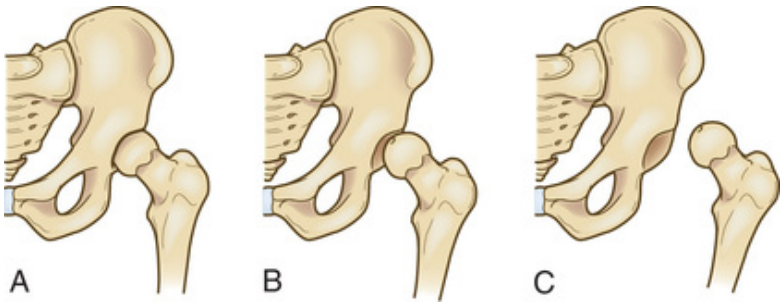

FIGURE 65-1 Soft tissue injury of the hip, causing subluxation or dislocation. **A,** Normal (before injury). **B,** Subluxation (partial dislocation). **C,** Dislocation.

The most obvious clinical manifestation of a dislocation is deformity. For example, if a hip is dislocated in a posterior (or backward) direction, the limb can be shorter and is often internally rotated on the affected side. Additional manifestations include local pain, tenderness, loss of function of the injured part, and swelling of the soft tissues in the region of the joint. The major complications of a dislocated joint are open joint injuries, intra-articular fractures, fractures, **avascular necrosis (AVN)** (bone cell death as a result of inadequate blood supply), and damage to adjacent neuro-vascular tissue.

Radiographic studies are performed to determine the extent of displacement of the involved structures. The joint may also be aspirated to

determine the presence of hemarthrosis or fat cells. Fat cells in the aspirate indicate a probable intra-articular fracture.

Nursing and Collaborative Management Dislocation

A dislocation requires prompt attention and is considered an orthopaedic emergency. The longer the joint remains unreduced, the greater the possibility of AVN. Compartment syndrome (discussed on pp. 1649–1650) may also occur after dislocation, and dislocation is often associated with significant vascular injury. The hip joint is particularly susceptible to AVN. Neuro-vascular assessment is critical (see Neuro-Vascular Assessment on pp. 1644–1645).

The first goal of management is to realign the dislocated portion of the joint in its original anatomical position. This can be accomplished by a closed reduction, which may be performed under local or general anaesthesia or intravenous conscious sedation. Anaesthesia is often necessary to produce muscle relaxation so that the bones can be manipulated. In some situations, surgical open reduction may be necessary. After reduction, the extremity is usually immobilized by bracing, splinting, taping, or using a sling to allow the torn ligaments and capsular tissue time to heal.

Nursing management of subluxation or dislocation is directed toward relief of pain and support and protection of the injured joint. After the joint has been reduced and immobilized, motion is usually restricted. A carefully regulated rehabilitation program can prevent fracture instability and joint dysfunction. Gentle range of motion (ROM) may be started if the joint is stable and the affected joint is well supported. An exercise program slowly restores the joint to its original ROM without causing another dislocation. The patient should gradually return to normal activities.

A patient who has dislocated a joint may be at greater risk for repeated dislocations because of loose ligaments. Activity restrictions of the affected joint may be imposed to decrease the risk for repeated dislocation.

Repetitive Strain Injury

Repetitive strain injury (RSI) and *cumulative trauma disorder* are terms used to describe injuries resulting from prolonged force or repetitive movements and awkward postures. RSI is also reported as *repetitive trauma disorder, nontraumatic musculo-skeletal injury*, *overuse syndrome* (sports medicine), *regional musculo-skeletal disorder,* and *work-related musculo-skeletal*

disorder. The exact cause of these disorders is unknown. There are no specific diagnostic tests, and diagnosis is often difficult.

In 2013–2014, 15% of Canadians (an estimated 4.5 million people) reported having had an RSI (males and females in equal proportions) (Statistics Canada, 2015c). In Canada, RSI most often affects the upper body: 22.6% of cases occur in the shoulders, 15% in the elbows, 14% in the wrists, 12.8% in the knees, and 12.4% in the lower back (Statistics Canada, 2015c). People at risk for RSI include musicians, dancers, butchers, grocery clerks, vibratory tool workers, and those who frequently use a computer mouse and keyboard. Competitive athletes and poorly trained athletes may also develop RSI. Swimming, overhead throwing (e.g., baseball), weightlifting, gymnastics, tennis, skiing, and kicking sports (e.g., soccer) require repetitive motion, and overtraining compounds the effects of RSI.

In addition to the repetitive movements, other factors related to RSI include poor posture and positioning, poor work space ergonomics, badly designed workplace equipment (e.g., computer keyboard), and repetitive lifting of heavy workloads without sufficient muscle rest. The result may be inflammation, swelling, and pain in the muscles, tendons, and nerves of the neck, shoulder, forearm, and hand. Symptoms of RSI include pain, weakness, numbness, or impairment of motor function. RSI can be prevented through education and *ergonomics* (the science that promotes efficiency and safety in the interaction of humans and their work environment). Ergonomic considerations for people who work at a desk and use a computer include keeping the hips and knees flexed to 90 degrees with the feet flat, keeping the wrist straight to type, having the top of the monitor even with the forehead, and taking at least hourly stretch breaks. Once RSI is diagnosed, treatment consists of identification of the precipitating activity; modification of equipment or activity; pain management, including heat or cold application and NSAIDs; rest; physiotherapy for strengthening and conditioning exercises; and lifestyle changes.

Carpal Tunnel Syndrome

Carpal tunnel syndrome (CTS) is a condition caused by compression of the median nerve, which enters the hand through the narrow confines of the carpal tunnel (see Figure 65-2). The carpal tunnel is formed by ligaments and bones in the wrist. CTS is the most common compression neuropathy in the upper extremity. This syndrome is associated with

hobbies or occupations that require continuous wrist movement (e.g., musicians, painters, carpenters, computer operators).

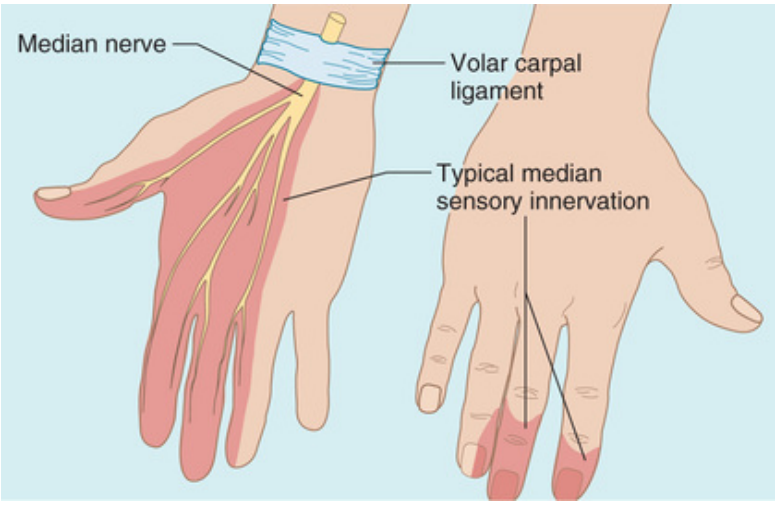

FIGURE 65-2 Wrist structures involved in carpal tunnel syndrome. Median nerve distribution. *Shaded areas* depict the locations of pain in carpal tunnel syndrome. Source: Buttaravoli, P. (2012). *Minor emergencies.* (3rd ed.). Philadelphia: Saunders.

This condition often is caused by pressure from trauma or edema caused by inflammation of a tendon (tenosynovitis), neoplasm, rheumatoid arthritis (RA), or soft tissue masses such as ganglia. Hormones may be involved as initial manifestations often occur during the premenstrual period, pregnancy, and menopause. People with diabetes mellitus or other metabolic disorders have a higher incidence of CTS (National Institute of Neurological Disorders and Stroke [NINDS], 2012). Women are more likely than men to develop CTS, possibly owing to a smaller carpal tunnel.

The clinical manifestations of CTS are weakness (especially of the thumb), burning pain (causalgia), and numbness, or impaired sensation in the distribution of the median nerve and clumsiness in performing fine hand movements. Numbness and tingling may be present, which awaken the patient at night. Shaking the hands will often relieve these symptoms.

Manifestations of CTS include a positive Tinel sign and Phalen sign. The *Tinel sign* can be elicited by tapping over the median nerve as it passes through the carpal tunnel in the wrist (Figure 65-2). A positive response is a sensation of tingling in the distribution of the median nerve over the hand. The *Phalen sign* can be elicited by allowing the wrists to fall freely into maximum flexion and maintaining the position for longer than 60 seconds. A positive response is a sensation of tingling in the distribution of

the median nerve over the hand. In late stages, there is atrophy of the thenar muscles around the base of the thumb, resulting in recurrent pain and eventual dysfunction of the hand.

Nursing and Collaborative Management Carpal Tunnel Syndrome

Prevention of CTS involves educating employees and employers to identify risk factors. Adaptive devices such as wrist splints may be worn to hold the wrist in slight extension to relieve pressure on the median nerve. Special keyboard pads and mice that help prevent repetitive pressure on the median nerve are available for use at computers. Other ergonomic changes include workstation modifications, change in body positions, and frequent breaks from work-related activities.

Collaborative care of the patient with CTS is directed toward relieving the underlying cause of the nerve compression. The early symptoms associated with CTS can usually be relieved by stopping the aggravating movement and by placing the hand and wrist at rest by immobilizing them in a hand splint. Splints worn at night help keep the wrist in a neutral position and may reduce night pain and numbness. Physiotherapy with hand and wrist exercises may lessen symptom severity. Injection of a corticosteroid drug directly into the carpal tunnel may provide short-term relief. The patient may need to consider a change in occupation because of discomfort and sensory changes.

Carpal tunnel release is generally recommended if symptoms last for more than 6 months. Surgery involves severing the band of tissue around the wrist to reduce pressure on the median nerve (see Figure 65-2). Surgery is done under local anaesthesia and does not require an overnight hospital stay. The types of carpal tunnel release surgery include open release and endoscopic surgery (Middleton & Anakwe, 2014). In *open release surgery,* an incision is made in the wrist and then the carpal ligament is cut to enlarge the carpal tunnel. *Endoscopic carpal tunnel release* is performed through one or more small puncture incisions in the wrist and palm. A camera is attached to a tube, and the carpal ligament is cut. The endoscopic approach may allow faster functional recovery and less postoperative discomfort than traditional open release surgery.

Although symptoms may be relieved immediately after surgery, full recovery may take months. After surgery, the neuro-vascular status of the hand is assessed before discharge. The patient is instructed about wound care and the appropriate assessments to perform at home.

Rotator Cuff Injury

The rotator cuff is a complex of four muscles in the shoulder: the supraspinatus, infraspinatus, teres minor, and subscapularis muscles. These muscles act to stabilize the humeral head in the glenoid fossa while assisting with ROM of the shoulder joint and rotation of the humerus.

A tear in the rotator cuff may occur as a gradual, degenerative process resulting from aging, repetitive stress (especially overhead arm motions), or injury to the shoulder while falling. The rotator cuff can tear as a result of sudden adduction forces applied to the cuff while the arm is held in abduction. In sports, repetitive overhead motions, such as in swimming, weightlifting, and swinging a racquet (e.g., tennis, racquetball) often cause injury. Other causative factors include (1) falling onto an outstretched arm and hand, (2) a blow to the upper arm, (3) heavy lifting, or (4) repetitive work motions.

Manifestations of a rotator cuff injury include shoulder weakness and pain and decreased ROM. The patient usually experiences severe pain when the arm is abducted between 60 and 120 degrees (the painful arc). The *drop arm test,* in which the arm falls suddenly after the patient is asked to slowly lower the arm to the side after it has been abducted 90 degrees, is another sign of rotator cuff injury. A radiograph alone is usually not beneficial in the diagnosis. A tear can be confirmed by magnetic resonance imaging (MRI).

The patient with a partial tear or cuff inflammation may be treated conservatively with rest, ice and heat, NSAIDs, corticosteroid injections into the joint, and physiotherapy. If the patient does not respond to conservative treatment in 3 to 6 months or if a complete tear is present, a surgical repair may be necessary. Most surgical repairs are performed through an arthroscope (Figure 65-3). If an extensive tear is present, *acromioplasty* (surgical removal of part of the acromion to relieve compression of the rotator cuff during movement) may be necessary. A sling or, more commonly, a shoulder immobilizer may be used immediately after surgery. However, the shoulder should not be immobilized for too long a period because “frozen” shoulder or arthrofibrosis may occur. Pendulum exercises and physiotherapy begin the first postoperative day. Restrictions for lifting weights are usually given, with full recovery taking up to 6 months.

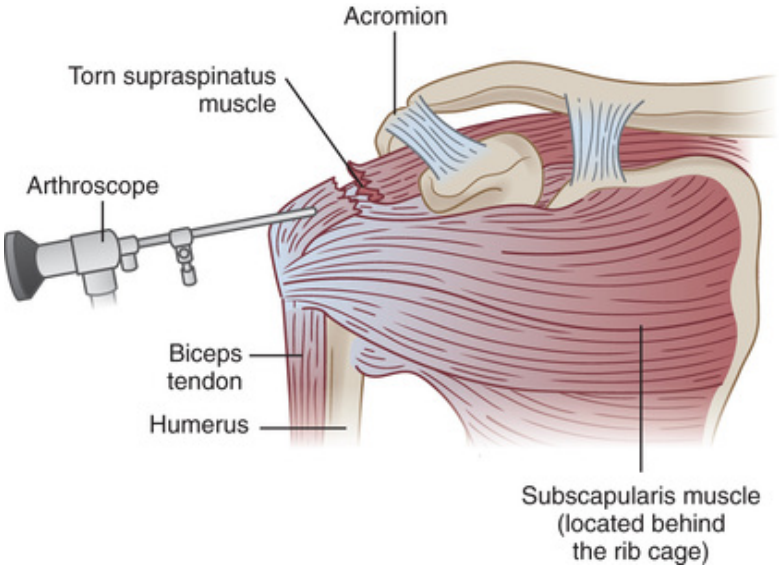

FIGURE 65-3 A torn rotator cuff is repaired using arthroscopic surgery.

Meniscus Injury

The menisci are crescent-shaped pieces of fibrocartilage in the knee. Menisci are also found in other joints. Meniscus injuries are closely associated with ligament sprains, commonly occurring in athletes engaged in sports such as basketball, football, soccer, and hockey. These activities produce rotational stress when the knee is in varying degrees of flexion and the foot is planted or fixed. A blow to the knee can cause the meniscus to be sheared between the femoral condyles and the tibial plateau, resulting in a torn meniscus. Individuals in occupations that require squatting or kneeling, as well as older adults, may be at higher risk for meniscus injuries.

Meniscus injuries alone do not usually cause significant edema because most of the cartilage is avascular. However, an acutely torn meniscus may be suspected when localized tenderness, pain, and effusion are noted (Figure 65-4). Pain is elicited by flexion, internal rotation, and then extension of the knee (called the *McMurray test*). The usual clinical picture is the patient feeling that the knee is unstable and a report that the knee may "click," "pop," "lock," or "give way." Quadriceps atrophy may be evident if the injury has been present for some time. Traumatic arthritis may occur from repeated meniscal injury and chronic inflammation.

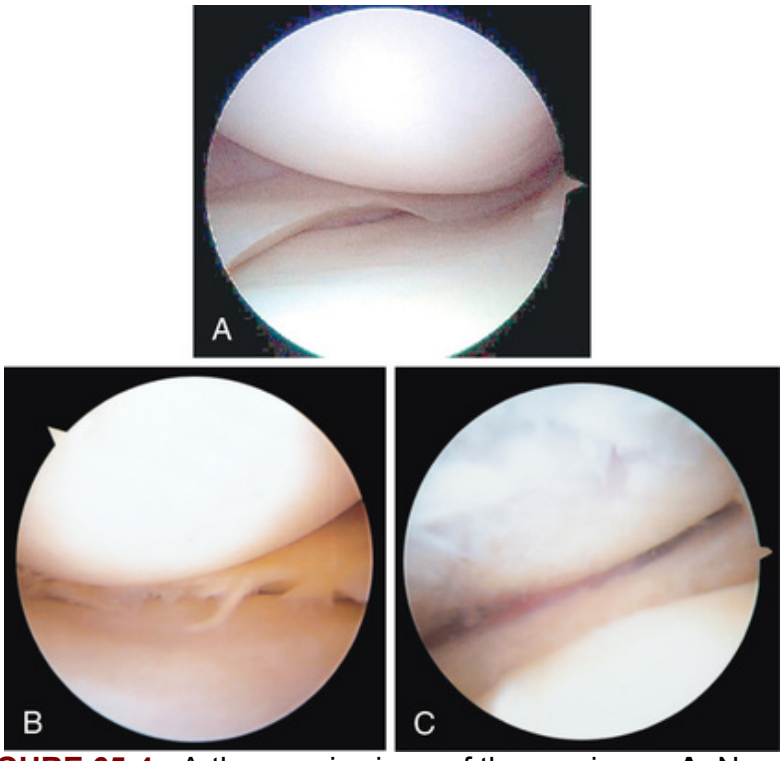

FIGURE 65-4 Arthroscopic views of the meniscus. **A,** Normal meniscus. **B,** Torn meniscus. **C,** Surgically repaired meniscus. Source: **A,** David Lintner, MD, Houston. Retrieved from *http://www.drlintner.com;* **B** and **C,** Courtesy Peter Bonner, San Antonio, TX.

MRI is beneficial for confirming the diagnosis before arthroscopy. The degree of knee pain and dysfunction, occupation, sport activities, and age may affect the patient's decision to have or postpone surgery.

Nursing and Collaborative Management Meniscus Injury

Because meniscal injuries are commonly caused by sports-related activity, athletes should be taught to do warm-up activities. Examination of the acutely injured knee should occur within 24 hours of injury. Initial care of this type of injury involves application of ice, immobilization, and partial weight bearing with crutches. Most meniscal injuries are treated in an outpatient setting. Use of a knee brace or immobilizer during the first few days after the injury protects the knee and offers some pain relief. After acute pain has decreased, physiotherapy can help the patient regain knee flexion and muscle strength to assist in returning to full function. In older adults with degenerative meniscus tears, progressive exercise therapy may

improve neuro-muscular function and muscle strength (Stensrud, Roos, & Risberg, 2012).

Surgical repair or excision of part of the meniscus (meniscectomy) may be necessary. Meniscal surgery is performed by arthroscopy. Pain relief may include NSAIDs or other analgesics. Rehabilitation starts soon after surgery, including quadriceps- and hamstring-strengthening exercises and ROM. When the patient's strength is back to its preinjury level, normal activities may be resumed.

Anterior Cruciate Ligament Injury

Knee injuries account for over 50% of all sport injuries. The most commonly injured knee ligament is the anterior cruciate ligament (ACL). ACL injuries usually occur from noncontact when the athlete pivots, lands from a jump, or slows down when running. Patients often report coming down on the knee, twisting, and hearing a pop, followed by acute knee pain and swelling. Athletes usually cannot continue playing, and the knee may feel unstable. An injury to the ACL can result in a partial tear, a complete tear, or an *avulsion* (tearing away) from the bone attachments that form the knee (Figure 65-5).

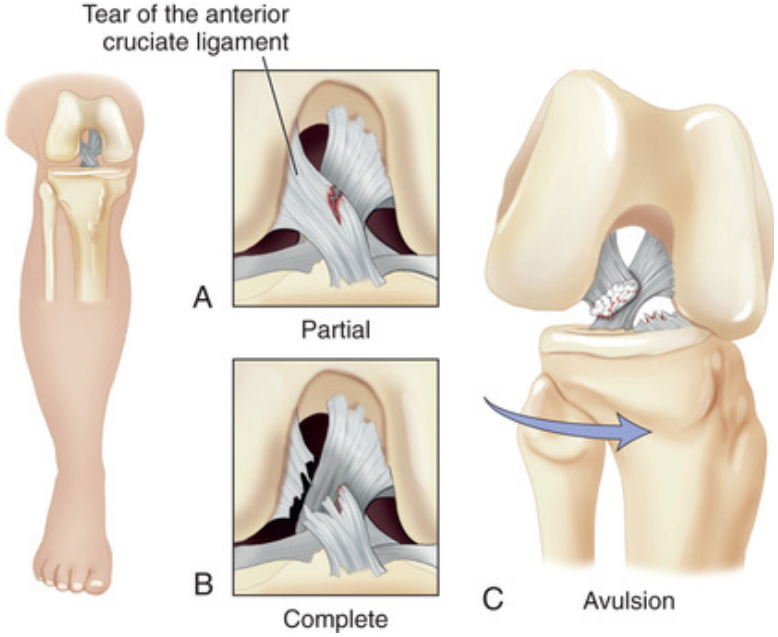

FIGURE 65-5 Anterior cruciate ligament injury. **A,** Partial tear. **B,** Complete tear. **C,** Avulsion.

Examination of the knee with an ACL tear may produce a positive *Lachman test* (Meuffels, Poldervaart, Diercks, et al., 2012). This test is performed by flexing the knee 15 to 30 degrees and pulling the tibia forward while the femur is stabilized. The test is considered positive for an ACL tear if there is forward motion of the tibia with the feeling of a soft or indistinct end point. MRI is often used to diagnose coexisting conditions, including a fracture, meniscus tear, and collateral ligament injuries.

Nursing and Collaborative Management ACL Injury

Prevention programs have been shown to significantly reduce ACL injuries in athletes (Sadoghi von Keudell & Vavken, 2012). Conservative treatment for an intact ACL injury includes rest, ice, NSAIDs, elevation, and ambulation as tolerated with crutches. If there is a tight, painful effusion, it may be aspirated. A knee immobilizer or hinged knee brace may be helpful in supporting the knee. Often, physiotherapy assists the patient in maintaining knee joint motion and muscle tone.

Reconstructive surgery is usually recommended in physically active patients who have sustained severe injury to the ligament and meniscus. In reconstruction, the torn ACL tissue is removed and replaced with autologous or allograft tissue (Shea, Carey, Richmond, et al., 2015). ROM exercises are encouraged soon after surgery and the knee is placed in a brace or immobilizer. Rehabilitation with physiotherapy is critical, with progressive weight bearing determined by the degree of surgical repair. A safe return to the patient's prior level of physical functioning may take 6 to 8 months.

Bursitis

Bursae are closed sacs that are lined with synovial membrane and contain a small amount of synovial fluid. They are located at sites of friction, such as between tendons and bones and near the joints. **Bursitis** (inflammation of a bursa) results from repeated or excessive trauma or friction, gout, RA, or infection.

The primary clinical manifestations of bursitis are warmth, pain, swelling, and limited ROM in the affected part. Sites at which bursitis commonly occurs include the hand, knee, greater trochanter of the hip, shoulder, and elbow. Improper body mechanics, repetitive kneeling (e.g., in carpet layers, coal miners, gardeners), jogging in worn-out shoes, and prolonged sitting with crossed legs are common precipitating activities.

Attempts are made to determine and correct the cause of the bursitis. Rest is often the only treatment needed. Icing the area will decrease pain and may reduce inflammation. The affected part may be immobilized in a compression dressing or splint. NSAIDs may be used to reduce inflammation and pain (Aaron, Patel, Kayiaros, et al., 2011). Aspiration of the bursal fluid and intra-articular injection of a corticosteroid may be necessary. If the bursal wall has become thickened and continues to interfere with normal joint function, surgical excision (bursectomy) may be necessary. Septic bursae usually require surgical incision and drainage.

Fractures

Classification

A **fracture** is a disruption or break in the continuity of the structure of bone. Although traumatic injuries account for the majority of fractures, some fractures are secondary to a disease process (pathological fractures from cancer or osteoporosis).

Fractures can be classified as *open* (formerly called *compound*) or *closed* (formerly called *simple*) depending on communication or noncommunication with the external environment (Figure 65-6). In an *open fracture,* the skin is broken, exposing the bone and causing soft tissue injury. In a *closed fracture,* the skin has not been ruptured and remains intact.

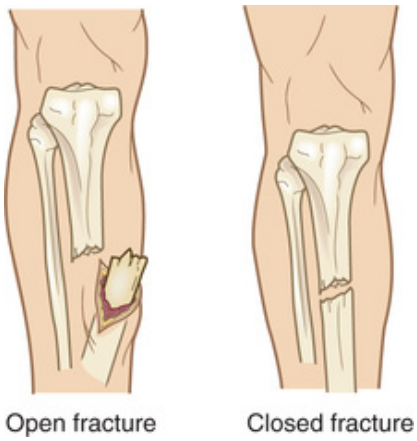

FIGURE 65-6 Fracture classification according to communication with the external environment.

Fractures can also be classified as complete or incomplete. Fractures are termed *complete* if the break is completely through the bone and described

as *incomplete* if the fracture occurs partly across a bone shaft but the bone is still in one piece. An incomplete fracture is often the result of bending or crushing forces applied to a bone.

Fractures are also described and classified according to the direction of the fracture line. Types include linear, oblique, transverse, longitudinal, and spiral fractures (see Figure 65-7 for selected fracture types).

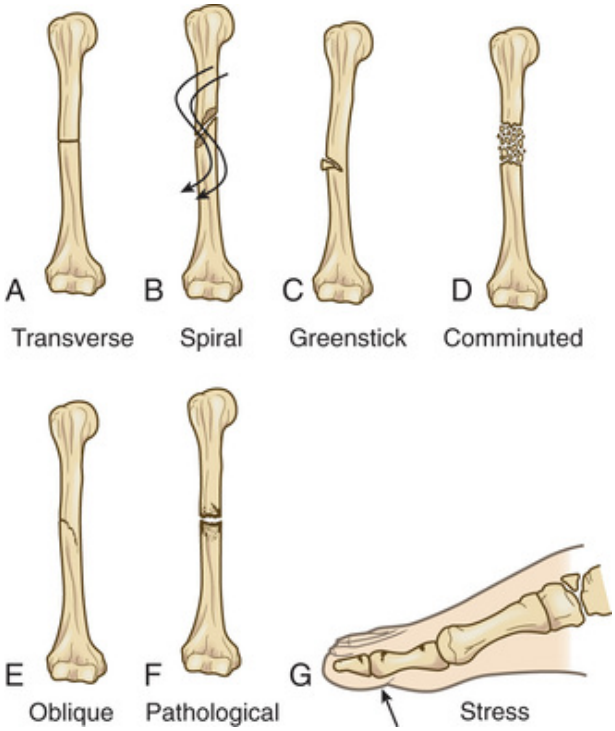

FIGURE 65-7 Types of fractures. **A,** Transverse fracture: the line of the fracture extends across the bone shaft at a right angle to the longitudinal axis. **B,** Spiral fracture: the line of the fracture extends in a spiral direction along the shaft of the bone. **C,** Greenstick fracture: an incomplete fracture with one side splintered and the other side bent. **D,** Comminuted fracture: fracture with more than two fragments. The smaller fragments appear to be floating. **E,** Oblique fracture: the line of the fracture extends in an oblique direction. **F,** Pathological fracture: a spontaneous fracture at the site of a bone disease. **G,** Stress fracture: occurs in normal or abnormal bone that is subject to repeated stress, such as from jogging or running.

Fractures can also be classified as displaced or nondisplaced. In a *displaced* fracture, the two ends of the broken bone are separated from one another and out of their normal positions. Displaced fractures are usually *comminuted* (more than two fragments) or *oblique* (see Figure 65-7). In a

nondisplaced fracture, the periosteum is intact across the fracture and the bone is still in alignment. Nondisplaced fractures are usually transverse, spiral, or greenstick (see Figure 65-7).

Clinical Manifestations

The clinical manifestations of a fracture include immediate localized pain, decreased function, and inability to bear weight on or use the affected part (Table 65-4). The patient guards and protects the extremity against movement. Obvious bone deformity may not be present. If a fracture is suspected, the extremity is immobilized in the position in which it is found. Unnecessary movement increases soft tissue damage and may convert a closed fracture to an open fracture or create further injury to adjacent neuro-vascular structures.

TABLE 65-4
CLINICAL MANIFESTATIONS OF FRACTURE

Manifestation	Significance
Edema and Swelling	
Disruption and penetration of bone through skin or soft tissues, or bleeding into surrounding tissues	Unchecked bleeding, swelling, and edema in closed space can occlude circulation and damage nerves (i.e., risk for compartment syndrome).
Pain and Tenderness	
Muscle spasm as a result of involuntary reflex action of muscle, direct tissue trauma, increased pressure on nerves, movement of fracture parts	Pain and tenderness encourage splinting of musculature around the fracture, with reduction in motion of injured area.
Muscle Spasm	
Irritation of tissues and protective response to injury and fracture	Muscle spasms may displace nondisplaced fracture or prevent it from reducing spontaneously.
Deformity	
Abnormal position of extremity or part as result of original forces of injury and action of muscles pulling fragment into abnormal position; seen as a loss of normal bony contours	Deformity is cardinal sign of fracture; if uncorrected, it may result in problems with bony union and restoration of function of injured part.
Ecchymosis or Contusion	
Discoloration of skin as a result of extravasation of blood into subcutaneous tissues	Ecchymosis may appear immediately after injury and may appear distal to injury. Patient should be reassured that process is normal and that discoloration will eventually resolve.
Loss of Function	
Disruption of bone or joint, preventing functional use of limb or part	Fracture must be managed properly to ensure restoration of function to limb or part.
Crepitation	
Grating or crunching together of bony fragments, producing palpable or audible crunching or popping sensation	Crepitation may increase chance for nonunion if bone ends are allowed to move excessively. Micromovement of bone-end fragments (postfracture) assists in osteogenesis (new bone growth).

Fracture Healing

It is important to understand the principles of fracture healing (Figure 65-8) to provide appropriate therapeutic interventions. Bone goes through a remarkable reparative process of self-healing (termed *union*) that occurs in the following stages (Fazzalari, 2011):

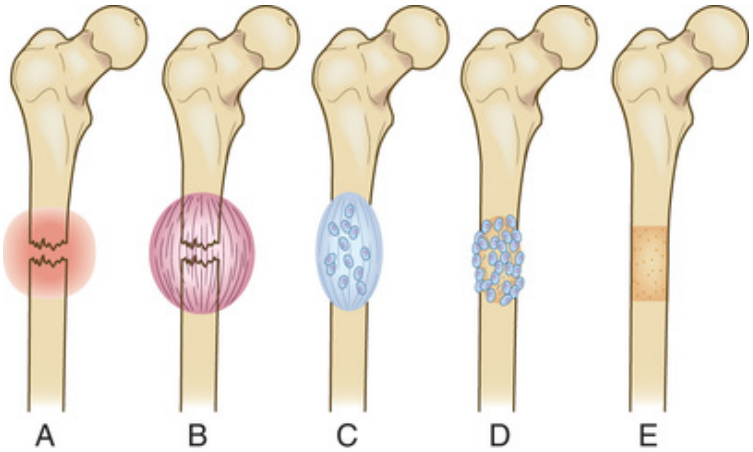

FIGURE 65-8 Bone healing (schematic representation). **A,** Bleeding at broken ends of the bone with subsequent hematoma formation. **B,** Organization of hematoma into fibrous network. **C,** Invasion of osteoblasts, lengthening of collagen strands, and deposition of calcium. **D,** Callus formation: new bone is built up as osteoclasts destroy dead bone. **E,** Remodelling is accomplished as excess callus is reabsorbed and trabecular bone is laid down.

1. *Fracture hematoma.* When a fracture occurs, bleeding creates a hematoma, which surrounds the ends of the fragments. The hematoma is extravasated blood that changes from a liquid to a semisolid clot. This hematoma formation occurs in the initial 72 hours after injury.
2. *Granulation tissue.* During this stage, active phagocytosis absorbs the products of local necrosis. The hematoma converts to granulation tissue. Granulation tissue (consisting of new blood vessels, fibroblasts, and osteoblasts) produces the basis for new bone substance called *osteoid* during days 3 to 14 after injury.
3. *Callus formation.* As minerals (calcium, phosphorus, and magnesium) and new bone matrix are deposited in the osteoid, an unorganized network of bone is formed that is woven about the fracture parts. Callus is composed primarily of cartilage, osteoblasts, calcium, and phosphorus. It usually appears by the end of the second week after injury. Evidence of callus formation can be verified by radiography.
4. *Ossification.* Ossification of the callus occurs from 3 weeks to 6 months after the fracture and continues until the fracture has healed. Callus ossification is sufficient to prevent movement at the fracture site when the bones are gently stressed. However, the

fracture is still evident on a radiograph. During this stage of *clinical union,* the patient may be allowed limited mobility or the cast may be removed.

5. *Consolidation.* As callus continues to develop, the distance between bone fragments diminishes and eventually closes. During this stage, ossification continues. It can be equated with *radiological union,* which occurs when there is radiographic evidence of complete bony union. This phase can occur up to one year following injury.
6. *Remodelling.* Excess bone tissue is reabsorbed in the final stage of bone healing, and union is completed. Gradual return of the injured bone to its preinjury structural strength and shape occurs. Bone remodels in response to physical loading stress, or *Wolff's law*. Initially, stress is provided through exercise. Weight bearing is gradually introduced. New bone is deposited in sites subjected to stress and resorbed at areas where there is little stress.

Many factors influence the time required for complete fracture healing, including displacement and site of the fracture, blood supply to the area, immobilization, and internal fixation devices (e.g., screws, pins). The ossification process may be arrested by inadequate reduction and immobilization, excessive movement of the fracture fragments, infection, poor nutrition, and systemic disease. Healing time for fractures increases with age. For example, an uncomplicated midshaft fracture of the femur heals in 3 weeks in a newborn and in 20 weeks in an adult. Smoking also increases fracture healing time. Fracture healing may not occur in the expected time *(delayed union)* or may not occur at all *(nonunion).* Table 65-5 summarizes complications of fracture healing.

TABLE 65-5

COMPLICATIONS OF FRACTURE HEALING

Problem	Description
Delayed union	Fracture healing progresses more slowly than expected; healing eventually occurs
Nonunion	Fracture fails to heal properly despite treatment; no radiographic evidence of callus formation
Malunion	Fracture heals in expected time but in unsatisfactory position, possibly resulting in deformity or dysfunction
Angulation	Fracture heals in abnormal position in relation to midline of structure (type of malunion)
Pseudoarthrosis	Type of nonunion occurring at fracture site in which a false joint is formed with abnormal movement at site
Refracture	New fracture occurs at original fracture site
Myositis ossificans	Deposition of calcium in muscle tissue at the site of significant blunt muscle trauma or repeated muscle injury

Collaborative Care

The overall goals of fracture treatment are (1) anatomical realignment of bone fragments (reduction), (2) immobilization to maintain realignment, and (3) restoration of normal or near-normal function of the injured part. Table 65-6 summarizes the collaborative care of fractures.

TABLE 65-6

COLLABORATIVE CARE
Fractures

Diagnostic	***Fracture Immobilization***
• History and physical examination	• Casting or splinting
• CT scan, MRI	• External fixation
• Radiographs	• Internal fixation
Collaborative Therapy	• Traction
Fracture Reduction	***Open Fractures***
• Closed reduction	• Immobilization
• Manipulation	• Prophylactic antibiotic therapy
• Open reduction	• Surgical debridement and irrigation
• Skeletal traction	• Tetanus and diphtheria immunization
• Skin traction	

CT, computed tomographic (scan); *MRI,* magnetic resonance imaging.

Fracture Reduction

Closed Reduction.

Closed reduction is a nonsurgical, manual realignment of bone fragments to their previous anatomical position. Traction and countertraction are manually applied to the bone fragments to restore position, length, and

alignment. Usually, closed reduction is performed with the patient under local or general anaesthesia. After reduction, traction, casting, external fixation, splints, or orthoses (braces), the injured part is immobilized to maintain alignment until healing occurs.

Open Reduction.

Open reduction is the correction of bone alignment through a surgical incision. It often includes internal fixation of the fracture with the use of wire, screws, pins, plates, intramedullary rods, or nails. The type and location of the fracture, patient age, and the presence of concurrent disease may influence the decision to use open reduction. The main disadvantages of this form of fracture management are the possibility of infection, the complications associated with anaesthesia, and the effect of pre-existing medical conditions (e.g., diabetes).

If open reduction with internal fixation (ORIF) is used for intra-articular fractures, early initiation of active ROM of the joint is indicated. Machines that provide continuous passive motion (CPM) to various joints (e.g., knee, shoulder) are used to prevent extra-articular and intra-articular adhesions. The use of CPM results in faster reconstruction of the subchondral (beneath cartilage) bone plate, more rapid healing of the articular cartilage, and decreased incidence of post-traumatic arthritis. ORIF facilitates early ambulation, thus decreasing the risk for complications related to prolonged immobility.

Traction.

Traction is the application of a pulling force to an injured or diseased part of the body or extremity. *Countertraction* pulls in the opposite direction. Traction is used to (1) prevent or reduce pain and muscle spasm associated with low back pain or cervical sprain (e.g., whiplash), (2) immobilize a joint or part of the body, (3) reduce a fracture or dislocation, and (4) treat a pathological joint condition (e.g., tumour, infection). Traction is also indicated to (1) provide immobilization to prevent soft tissue damage, (2) promote active and passive exercise, (3) expand a joint space during arthroscopic procedures, and (4) expand a joint space before major joint reconstruction.

Traction devices apply a pulling force on a fractured extremity to attain realignment, while countertraction pulls in the opposite direction. The two most common types of traction are skin traction and skeletal traction. *Skin traction* is generally used for short-term treatment (48–72 hours) until skeletal traction or surgery is possible. Tape, boots, or splints are applied

directly to the skin to maintain alignment, assist in reduction, and help diminish muscle spasms in the injured extremity. The traction weights are usually limited to 2.3 to 4.5 kg. A Buck traction boot is a type of skin traction used to immobilize a fracture, prevent hip flexion contractures, and reduce muscle spasms (Figure 65-9). Pelvic or cervical skin traction may require heavier weights applied intermittently. In skin traction, assessment of the skin is a priority, since pressure points and skin breakdown may develop quickly. Key pressure points are assessed every 2 to 4 hours.

FIGURE 65-9 Buck traction is most commonly used for fractures of the hip and femur. Source: Courtesy Mary Wollan, RN, BAN. Spring Park, MN.

Skeletal traction, generally in place for longer periods than skin traction, is used to align injured bones and joints or to treat joint contractures and congenital hip dysplasia. It provides a long-term pull that keeps the injured bones and joints aligned. To apply skeletal traction, the physician inserts a pin or wire into the bone, either partially or completely, to align and immobilize the injured body part (Marshall & Browner, 2012). Weight for skeletal traction ranges from 2 to 20 kg. The use of too much weight can result in delayed union or nonunion. The major disadvantages of skeletal traction are risk for infection in the area of the bone where the skeletal pin has been inserted and the consequences of prolonged immobility.

When traction is used to treat fractures, the forces are usually exerted on the distal fragment to obtain alignment with the proximal fragment. Several types of traction can be used for this purpose. One of the more common types of skeletal traction is balanced suspension traction (Figure

65-10). Fracture alignment depends on the correct positioning and alignment of the patient while the traction forces remain constant. For extremity traction to be effective, forces must be pulling in the opposite direction (countertraction). Countertraction is commonly supplied by the patient's body weight or by weights pulling in the opposite direction and may be augmented by elevating the end of the bed. It is imperative to maintain traction continuously and keep the weights off the floor and moving freely through the pulleys.

FIGURE 65-10 Balance suspension skeletal traction. Most commonly used for fractures of the femur, hip, and lower leg. Source: Courtesy Zimmer, Inc.

Fracture Immobilization.

Fracture immobilization can be done using casts (including air casts), braces, splints, immobilizing devices, and external and internal fixation devices.

Casts.

A *cast* is a temporary circumferential immobilization device. Casting is a common treatment following closed reduction. It allows the patient to perform many normal activities of daily living (ADLs) while providing

sufficient immobilization to ensure stability. Cast materials are natural (plaster of Paris) or synthetic acrylic; fibreglass-free, latex-free polymer; or a hybrid of materials. A cast generally incorporates the joints above and below a fracture. Immobilization above and below a joint restricts tendon and ligament movement, thus assisting with joint stabilization while the fracture heals.

To apply a plaster cast on an extremity, the affected part is first covered with a stockinette that is cut longer than the extremity (Satryb, Wilson, & Patterson, 2011). Then, padding is placed over the stockinette with the bony prominences given extra padding. If plaster of Paris casting material is used, it is usually immersed in warm water, then wrapped and moulded around the affected part. The number of layers of plaster bandage and the technique of application determine the strength of the cast. Plaster sets within 15 minutes, so patients may soon move around without difficulty. However, the cast is not strong enough for weight bearing until about 24 to 72 hours after application. (The decision about weight bearing is determined by the physician.)

A fresh plaster cast should never be covered because air cannot circulate, heat builds up in the cast that may cause a burn, and drying is delayed. Direct pressure on the cast should be avoided during the drying period. The cast should be handled gently with an open palm to avoid denting it. Once the cast is thoroughly dry, the edges may have to be *petalled* to prevent skin irritation from rough edges and to prevent plaster of Paris debris from falling into the cast and causing irritation or pressure necrosis. Several strips (petals) of tape are placed by the health care provider over the rough areas to ensure a smooth cast edge.

Casts made of fibreglass are being used more often than those made of plaster because they are lightweight, relatively waterproof, stronger and faster-drying than plaster, porous (less risk for skin problems), and allow for almost immediate mobilization (Satryb et al., 2011). Synthetic casting materials (thermolabile plastic, thermoplastic resins, polyurethane, and fibreglass) are activated by submersion in cool or tepid water. Then they are moulded to fit the torso or the extremity.

Upper Extremity Injuries.

Immobilization of an acute fracture or soft tissue injury of the upper extremity is often accomplished by use of a (1) sugar-tong splint, (2) posterior splint, (3) short arm cast, or (4) long arm cast (Figure 65-11). The sugar-tong splint is typically used for acute wrist injuries or injuries that may result in significant swelling. Plaster splints are applied over a well-

padded forearm, beginning at the phalangeal joints of the hand, extending up the dorsal aspect of the forearm around the distal humerus, and then extending down the volar aspect of the forearm to the distal palmar crease. The splinting material is wrapped with either elastic bandage or bias stockinette. The sugar-tong posterior splint accommodates for postinjury swelling in the fractured extremity.

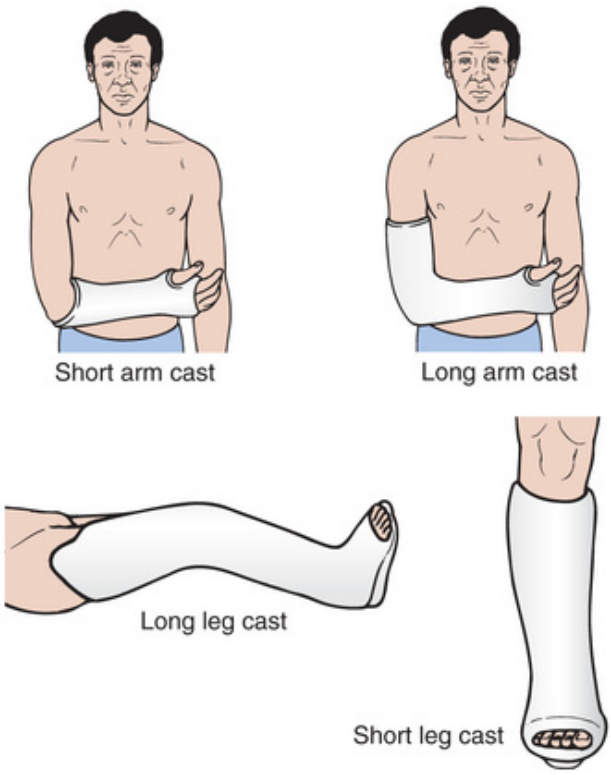

FIGURE 65-11 Common types of casts.

The *short arm cast* is often used for the treatment of stable wrist or metacarpal fractures. An aluminum finger splint can be fabricated into the short arm cast for concurrent treatment of phalangeal injuries. The short arm cast is a circular cast extending from the distal palmar area to the proximal forearm. This cast provides wrist immobilization and permits unrestricted elbow motion.

The *long arm cast* is commonly used for stable forearm or elbow fractures and unstable wrist fractures. It is similar to the short arm cast but extends to the proximal humerus, restricting motion in the wrist and the elbow. Nursing measures should be directed toward supporting the extremity and reducing the effects of edema by maintaining extremity elevation with a sling. However, when a hanging arm cast is used for a proximal

humerus fracture, elevation or a supportive sling is contraindicated because hanging provides traction and maintains fracture alignment.

When a sling is used, the nurse must ensure that the axillary area is well padded to prevent skin excoriation and maceration associated with direct skin-to-skin contact. Placement of the sling should not put undue pressure on the posterior neck. Movement of the fingers (unless contraindicated) should be encouraged to enhance the pumping action of vascular and soft tissue structures to decrease edema. The nurse should also encourage the patient to actively move nonimmobilized joints of the upper extremity to prevent stiffness and contractures.

Vertebral Injuries.

The *body jacket* brace is often used for immobilization and support for stable spine injuries of the thoracic or lumbar spine. This brace goes around the chest and abdomen and extends from above the nipple line to the pubis. After application of the cast, the nurse must assess the patient for the development of superior mesenteric artery syndrome *(cast syndrome).* This condition occurs if the body cast is applied too tightly and compresses the superior mesenteric artery against the duodenum. The patient generally complains of abdominal pain, abdominal pressure, nausea, and vomiting. The abdomen should be assessed for decreased bowel sounds (a window in the brace may be left over the umbilicus). Treatment includes gastric decompression with a nasogastric tube and suction. Nursing assessment also includes observation of respiratory status, bowel and bladder function, and areas of pressure over the bony prominences, especially the iliac crest. The brace may need to be adjusted or removed if any complications occur.

Lower Extremity Injuries.

Injuries to the lower extremity are often immobilized by a long leg cast, short leg cast, cylinder cast, Jones dressing, or prefabricated splint or immobilizer. The usual indications for applying a long leg cast are an unstable ankle fracture, soft tissue injuries, a fractured tibia, and knee injuries. The cast usually extends from the base of the toes to the groin and the gluteal crease. The short leg cast can be used for a variety of conditions, but primarily for stable ankle and foot injuries. A cylinder cast, which is used for knee injuries or fractures, extends from the groin to the malleoli of the ankle. A Jones dressing is composed of bulky padding materials (absorption dressing and cotton sheet wadding), splints, and an elastic wrap or bias-cut stockinette.

After application of a lower extremity cast or dressing, the extremity should be elevated on pillows above the heart level for the first 24 hours. After the initial phase, the casted extremity should not be placed in a dependent position because of the possibility of excessive edema. After cast application, the patient should be observed for signs of compartment syndrome (discussed on pp. 1649–1650 later in this chapter) and increased pressure, especially in the heel, anterior tibia, head of the fibula, and malleoli. This increased pressure is manifested by pain or a burning feeling in these areas.

Prefabricated knee and ankle splints and immobilizers are being used in many settings. This type of immobilization is easy to apply and remove, which permits close observation of the affected joint for signs of swelling and skin breakdown (Figure 65-12). Depending on the injury, removal of the splint or immobilizer facilitates ROM of the affected joint and a faster return to function.

FIGURE 65-12 Knee immobilizer. Source: Maher, A. B., Salmond, S. W., & Pellino, T. A. (Eds.). (2002). *Orthopaedic nursing* (3rd ed.). Philadelphia: Saunders.

The *hip spica cast* is now used mainly for femur fractures in children. The purpose of the hip spica cast is to immobilize the affected extremity and the trunk. The cast extends from above the nipple line to the base of the foot (single spica) and may include the opposite extremity up to an area above the knee (spica and a half) or both extremities (double spica). Assess

the patient with a hip spica cast for the same problems that are associated with the body jacket brace.

External Fixation.

An external fixator is a metallic device composed of metal pins that are inserted into the bone and attached to external rods to stabilize the fracture while it heals. It can be used to apply traction or to compress fracture fragments and to immobilize reduced fragments when the use of a cast or other traction is not appropriate. The external device holds fracture fragments in a manner similar to a surgically implanted internal device. The external fixator is attached directly to the bones by percutaneous transfixing pins or wires (Figure 65-13). External fixation is indicated in closed fractures, complex fractures with extensive soft tissue damage, correction of bony defects (congenital), nonunion or malunion, and limb lengthening.

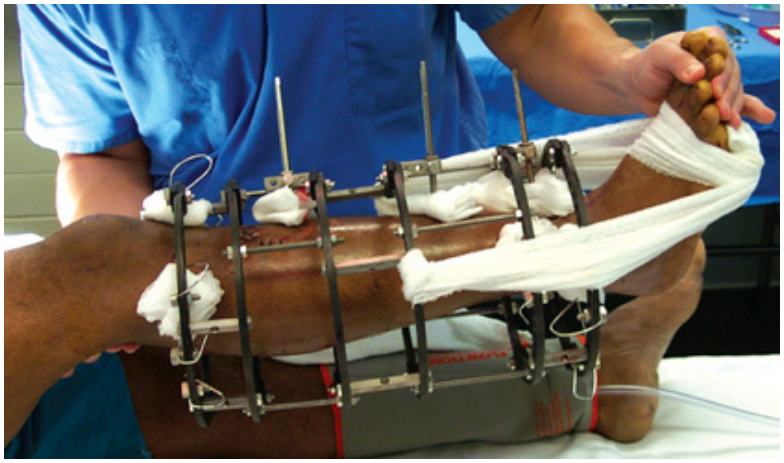

FIGURE 65-13 External fixators. Stabilization of a tibial fracture.

Source: Canale, S.T., &, Beatty, J. H. (2013). *Campbell's operative orthopaedics*. (12th ed.). Philadelphia: Mosby.

Often, external fixation is used in an attempt to salvage extremities that otherwise might require amputation. Because the use of an external device is a long-term process, assessment for pin loosening and infection is critical. Infection—signalled by exudate, erythema, tenderness, and pain—may necessitate removal of the device. The nurse should instruct the patient and caregivers about meticulous pin care. Although each health care provider has a protocol for pin care cleaning, half-strength hydrogen peroxide with normal saline is often used.

Internal Fixation.

Internal fixation devices (pins, plates, intramedullary rods, and metal and bioabsorbable screws) are surgically inserted at the time of realignment (Figure 65-14). These metal devices are biologically inert and made from stainless steel, vitallium, or titanium. Proper alignment is evaluated by radiographs at regular intervals.

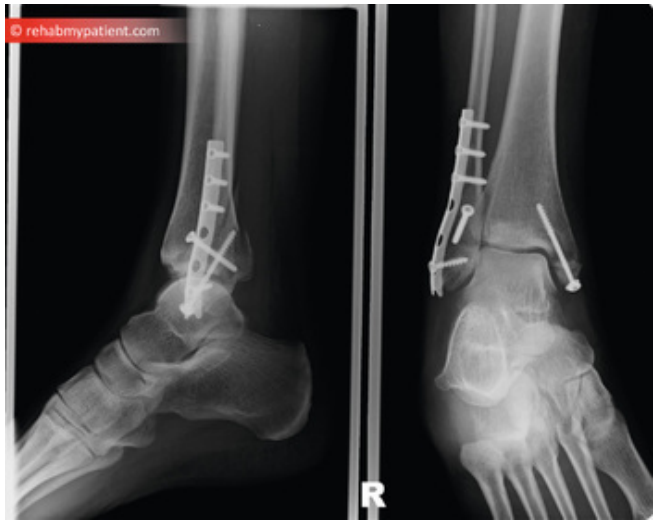

FIGURE 65-14 Views of internal fixation devices to stabilize a fractured tibia and fibula. Source: Courtesy and © *www.rehabmypatient.com*.

Electrical Bone Growth Stimulation.

Electrical bone growth stimulation is used to facilitate the healing process for certain types of fractures, especially those with nonunion or delayed healing. The mechanism of action of electrical bone growth stimulation may include (1) increasing the calcium uptake of bone, (2) activating intracellular calcium stores, and (3) increasing the production of bone growth factors (e.g., bone morphogenic protein).

Noninvasive, semi-invasive, and invasive methods of electrical bone growth stimulation are used. Noninvasive stimulators use direct current or pulsed electromagnetic fields (PEMFs) to generate a weak electrical current. Electrodes are placed over the patient's skin or cast and are used 10 to 12 hours each day, usually while the patient is sleeping. Semi-invasive or percutaneous bone growth stimulators use an external power supply and electrodes that are inserted through the skin and into the bone. Invasive stimulators require surgical implantation of a current generator in

an intramuscular or subcutaneous space. An electrode is implanted in the bone fragments.

Drug Therapy.

Patients with fractures often experience varying degrees of pain associated with muscle spasms. Involuntary reflexes that result from edema following muscle injury cause these spasms. Central and peripheral muscle relaxants, such as cyclobenzaprine or methocarbamol (Robaxin), may be prescribed for relief of pain associated with muscle spasms.

Acute pain management for the patient with a fracture is presented in Nursing Care Plan (NCP) 65-1, available on the Evolve website.

In an open fracture, the threat of tetanus occurring can be reduced with tetanus and diphtheria toxoid or tetanus immunoglobulin for the patient who has not been previously immunized (see Table 65-6). Bone-penetrating antibiotics (such as cefazolin) are used prophylactically before surgery.

Nutritional Therapy.

Proper nutrition is an essential component of the reparative process in injured tissue. An adequate energy source is needed to promote muscle strength and tone, build endurance, and enhance ambulation and gait-training skills. The patient's dietary intake must include ample protein (e.g., 1 g/kg of body weight); vitamins (especially B, C, and D); and calcium, phosphorus, and magnesium to ensure optimal soft tissue and bone healing. Low serum protein levels and vitamin C deficiencies interfere with tissue healing. Immobility and callus formation increase calcium needs.

Three well-balanced meals a day will usually provide the necessary nutrients. The well-balanced meal should be supplemented by a fluid intake of 2 000 to 3 000 mL/day to promote optimal bladder and bowel function. Adequate fluid and a high-fibre diet with fruits and vegetables will prevent constipation. If immobilized in bed with skeletal traction or in a body jacket brace, the patient should be instructed to eat six small meals to avoid overeating and thus abdominal pressure and cramping.

Nursing Management Fractures

Nursing Assessment

A brief history of the traumatic episode, the mechanism of injury, and the position in which the patient was found can be obtained from the patient

or witnesses. As soon as possible, the patient should be transported to an emergency department, where a thorough assessment and treatment can be initiated (Table 65-7). Subjective and objective data that should be obtained from an individual with a fracture are presented in Table 65-8.

TABLE 65-7

EMERGENCY MANAGEMENT
Fractured Extremity

Etiology	Assessment Findings	Interventions
Blunt • Motor vehicle accident • Pedestrian event **Falls** • Direct blows • Forced flexion or hyperextension • Twisting forces **Penetrating** • Blast • Gunshot **Other** • Crush injury • Pathological conditions • Violent muscle contractions (seizures)	• Deformity (loss of normal bony contours) or unnatural position of affected limb • Edema and ecchymosis • Grating (crepitus) • Loss of function • Muscle spasm • Numbness, tingling, loss of distal pulses • Open wound over injured site, exposure of bone • Tenderness and pain • Warmth at site	**Initial** • Treat life-threatening injuries first. • Ensure airway, breathing, and circulation. • Control external bleeding with direct pressure or sterile pressure dressing and elevation of the limb. • Check neuro-vascular status distal to injury before and after splinting. • Elevate injured limb if possible. • Do *not* attempt to straighten fractured or dislocated joints. • Do *not* manipulate protruding bone ends. • Apply ice packs to affected area. • Obtain radiographs of affected limb. • Administer tetanus and diphtheria prophylaxis if there is a break in skin integrity. • Mark location of pulses to facilitate repeat assessment. • Splint fracture site, including joints above and below fracture site. **Ongoing Monitoring** • Monitor vital signs, level of consciousness, oxygen saturation, peripheral pulses, and pain. • Monitor for compartment syndrome, characterized by excessive pain, pain with passive stretch of the affected extremity muscles, pallor, paresthesia, and late signs of paralysis and pulselessness. • Monitor for signs and symptoms of a fat embolism (e.g., dyspnea, chest pain, temperature elevation).

TABLE 65-8
NURSING ASSESSMENT
Fracture

Subjective Data
Important Health Information
Past health history: Traumatic injury; long-term repetitive forces (stress fracture); bone or systemic diseases, prolonged immobility (pathological fracture), osteopenia, osteoporosis *Medications:* Corticosteroids (osteoporotic fractures), analgesics, hormone therapy, calcium supplementation *Surgery or other treatments:* First aid treatment of fracture, previous musculo-skeletal surgeries
Symptoms
• Loss of motion or weakness of affected part; muscle spasms • Sudden and severe pain in affected area; numbness, tingling, loss of sensation distal to injury; chronic pain that increases with activity (stress fracture)
Objective Data
General
Apprehension, guarding of injured site
Integumentary
Skin lacerations, pallor and cool skin or bluish and warm skin distal to injury; ecchymosis, hematoma, edema at site of fracture
Cardiovascular
Reduced or absent pulse distal to injury, decreased skin temperature, delayed capillary refill
Neurological
Paresthesias, decreased or absent sensation, hypersensation
Musculo-Skeletal
Restricted or lost function of affected part; local bony deformities; abnormal angulation; shortening, rotation, or crepitation of affected part; muscle weakness
Possible Findings
Identification and extent of fractures on radiograph, bone scan, CT scan, or MRI

CT, computed tomographic (scan); *MRI*, magnetic resonance imaging.

Special emphasis must be placed on the region distal to the site of injury. Clinical findings must be documented before fracture treatment is initiated to prevent doubts about whether a problem discovered later was missed during the original examination or was caused by the treatment.

Neuro-vascular Assessment.

Musculo-skeletal injuries have the potential to cause changes in the neuro-vascular status of an injured extremity. With musculo-skeletal trauma, application of a cast or constrictive dressing, poor positioning, and the physiological response to the traumatic injury can cause nerve or vascular damage, usually distal to the injury.

The neuro-vascular assessment should consist of a *peripheral vascular assessment* (colour, temperature, capillary refill, peripheral pulses, and edema) and a *peripheral neurological assessment* (sensation, motor function, and pain). Throughout the neuro-vascular assessment, both extremities are compared to obtain an accurate assessment.

An extremity's colour (pink, pale, cyanotic) and temperature (hot, warm, cool, cold) in the area of the affected extremity are assessed. Pallor or a cool to cold extremity below the injury could indicate arterial insufficiency. A warm, cyanotic extremity could indicate poor venous return. A capillary refill (blanching of the nail bed) of less than 3 seconds indicates good arterial perfusion.

Pulses on both the unaffected and the injured extremity are compared to identify differences in rate or quality. Pulses are described as strong, diminished, audible by hand-held Doppler transducer, or absent. A diminished or absent pulse distal to the injury can indicate vascular dysfunction and insufficiency. However, up to 12% of healthy adults do not have a palpable dorsalis pedis or posterior tibial pulse (Roberts & Hedges, 2014). Peripheral edema is also assessed, and pitting edema may be present with severe injury.

Sensation and motor innervation in the upper extremity are assessed by evaluating the ulnar, median, and radial nerves. Neuro-vascular status can be assessed by abduction and adduction of the fingers, opposition of the fingers, and supination and pronation of the hand. In the lower extremity, dorsiflexion and plantar flexion provide information about motor function of the peroneal and tibial nerves. Sensory innervation is evaluated for the peroneal nerve on the dorsal part of the foot between the web space of the great and the second toes. Tibial nerve assessment is performed by stroking the plantar surface (sole) of the foot. Contralateral evaluation is critical. The patient may report paresthesia (abnormal sensation [e.g., numbness, tingling]) and hyperesthesia (hypersensation). Partial or full loss of strength or movement (paresis or paralysis) may be a late sign of neuro-vascular damage. Reduced motion or strength in an injured extremity can alert the nurse to potential limb-threatening complications or disability.

Pain is the final element of the neuro-vascular assessment. The nurse must carefully assess the location, quality, and intensity of the pain (see Chapter 10). Current best practice in pain management is to ask the patient to rate his or her level of pain on a scale of 0 to 10, with 0 being no pain and 10 being the worst pain ever experienced. Increasing pain unrelieved by drugs and out of proportion to the injury can be an indication of compartment syndrome.

Patients should be instructed to report any changes in their neuro-vascular status. Patients must verbalize and demonstrate a thorough understanding of all elements before they are discharged from the treatment setting.

Nursing Diagnoses

Nursing diagnoses for the patient with a fracture may include, but are not limited to, the following:

- *Impaired physical mobility* related to *joint stiffness, pain*
- *Risk for peripheral neuro-vascular dysfunction* as evidenced by *fracture* (vascular insufficiency and nerve compression, mechanical compression by traction, splints, or casts)
- *Acute pain* related to *physical injury agent* (edema, movement of bone fragments, muscle spasms)
- *Readiness for enhanced health management*

Additional information on nursing diagnoses for the patient with a fracture is presented in Nursing Care Plan 65-1 (on the Evolve website).

Planning

The overall goals are that the patient with a fracture will (1) have healing with no associated complications, (2) obtain satisfactory pain relief, and (3) achieve maximal rehabilitation potential.

Nursing Implementation

Health Promotion.

The public should be taught to take appropriate safety precautions to prevent injuries while at home, at work, when driving, and when participating in sports. Nurses should be advocates for personal actions known to reduce injuries such as regular use of seat belts, driving within posted speed limits, stretching and warming up muscles before exercise, use of protective athletic equipment (helmets and knee, wrist, and elbow pads), use of safety equipment at work, and not driving under the influence of alcohol or illicit drugs.

Individuals (especially older adults) should be encouraged to participate in moderate exercise to aid in the maintenance of muscle strength and balance. To reduce falls, they should wear adequate footwear and assess their living environment for safety (e.g., remove scatter rugs, maintain

good lighting, clear paths to the bathroom for nighttime use) (see Table 65-1). The nurse should also stress the importance of adequate calcium and vitamin D intake.

Evidence-Informed Practice

Research Highlight

Do Vitamin D Supplements Improve Strength in Older Adults?

Clinical Question

In older adults (P) does vitamin D supplementation (I) improve strength, balance, and gait (O)?

Best Available Evidence

Systematic review of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence

- Thirteen RCTs (n = 2 268) of older adults (mainly women) were done to determine the effect of supplemental vitamin D without an exercise intervention on muscle strength, gait, and balance.
- Supplemental vitamin D with daily doses of 800 to 1 000 IU consistently demonstrated beneficial effects on strength and balance. An effect on gait was not demonstrated, although further evaluation is recommended.
- Increasing serum vitamin D to normal levels resulted in better muscle strength.

Conclusion

Supplemental vitamin D has beneficial effects on strength and balance in older adults.

Implications for Nursing Practice

- Patients should be assessed for vitamin D deficiencies and strategies offered to improve nutritional uptake, brief sunlight exposure, and

supplementation.
- The importance of vitamin D in reducing the risk for falls should be discussed.

P, Patient population of interest; *I,* intervention or area of interest; *O,* outcomes of interest (see Chapter 1).

Reference for Evidence

Muir SW, Montero-Odasso M. Effect of vitamin D supplementation on muscle strength, gait and balance in older adults: A systematic review and meta-analysis. *Journal of American Geriatrics Society*. 2011;*59*(12):2291–2300; 10.1111/j.1532-5415.2011.03733.x.

Acute Intervention.

Patients with fractures may be treated in an emergency department or a physician's office and discharged to home care, or they may require hospitalization for varying amounts of time. Specific nursing measures depend on the setting and type of treatment used.

Preoperative Management.

If surgical intervention is required to treat the fracture, patients will need preoperative preparation. In addition to the usual preoperative nursing measures (see Chapter 20), the nurse should inform patients of the type of immobilization and assistive devices that will be used and the expected activity limitations after surgery. Assurance that pain medication will be available, if needed, is often beneficial.

Postoperative Management.

In general, postoperative nursing care and management are directed toward monitoring vital signs and applying the general principles of postoperative nursing care (see Chapter 22). Frequent neuro-vascular assessments of the affected extremity are necessary to detect early and subtle neuro-vascular changes. Any limitations of movement or activity related to turning, positioning, and extremity support should be monitored closely. Pain and discomfort can be minimized through proper alignment and positioning. Dressings or casts should be carefully observed for any overt signs of bleeding or drainage. A significant increase in size of the drainage area should be reported. If a wound drainage system is in place, the volume of drainage should be regularly measured and the patency of the system assessed, using aseptic technique to avoid contamination.

Additional nursing responsibilities depend on the type of immobilization used. A blood salvage and reinfusion system that allows for recovery and reinfusion of the patient's own blood may be used. The

blood is retrieved from a joint space or cavity, and the patient receives this blood in the form of an autotransfusion. (Autotransfusion is discussed in Chapter 33.) Additional nursing measures for the patient who has had orthopaedic surgery are discussed in NCP 65-2, available on the Evolve website.

Other Measures.

Patients often have reduced mobility as a result of the fracture. The nurse must plan care to prevent the many complications associated with immobility. Constipation can be prevented by activity and maintenance of a high-fluid intake (>2 500 mL/day unless contraindicated by the patient's health status) and a diet high in bulk and roughage (fresh fruit and vegetables). If these measures are not effective in maintaining the patient's normal bowel pattern, warm fluids, stool softeners, laxatives, or suppositories may be necessary. Maintaining a regular time for elimination helps to promote regularity.

Renal calculi can develop as a result of bone demineralization. The hypercalcemia from demineralization causes a rise in urine pH and stone formation resulting from the precipitation of calcium. Unless contraindicated, a fluid intake of 2 500 mL/day is recommended. (Renal calculi are discussed in Chapter 48.)

Rapid deconditioning of the cardiopulmonary system can occur as a result of prolonged bed rest, resulting in orthostatic hypotension and decreased lung capacity. Unless contraindicated, these effects can be diminished by permitting the patient to sit on the side of the bed, allowing the patient's lower limbs to dangle over the bedside, and having the patient perform standing transfers. When the patient is allowed to increase activity, careful evaluation should be made to assess for orthostatic hypotension. Patients must also be assessed for deep venous thrombosis (DVT) and pulmonary emboli. (DVT and pulmonary embolism are discussed in Chapter 40 and pulmonary embolism is discussed in Chapter 30.)

Traction.

When slings are used with traction, the nurse should inspect exposed skin areas regularly. Pressure over a bony prominence created by the wrinkling of sheets or bedclothes may cause pressure necrosis. Persistent skin pressure may impair blood flow, causing injury to the peripheral neurovascular structures. Skeletal traction pin sites must be observed for signs of infection. Pin-site care varies but usually includes regular removal of

exudates with half-strength hydrogen peroxide, rinsing pin sites with sterile saline, and drying of the area with sterile gauze.

External rotation of the hip can occur when skin traction is used on the lower extremity. The nurse can correct this position by placing a pillow or rolled-up towels (called a *trochanter roll*) along the greater trochanteric region of the femur. Generally, the patient should be in the centre of the bed, in a supine position. Incorrect alignment can result in increased pain, nonunion, or malunion.

To offset some of the problems associated with prolonged immobility, the nurse should discuss activity of a specific patient with the health care provider. If exercise is permitted, the nurse should encourage the patient's participation in a simple exercise regimen within activity restrictions. Activities that the patient should participate in include frequent position changes, ROM exercises of unaffected joints, deep-breathing exercises, isometric exercises, and use of the trapeze bar (if permitted) to raise himself or herself off the bed for linen changes and use of the bedpan. These activities should be performed several times each day. The nurse should encourage and help the hospitalized patient to stay connected with friends and family through social media resources (see the "Informatics in Practice" box).

Informatics in Practice

Staying Connected While Immobilized

A patient in traction or other immobilization devices for a long period may feel lonely or isolated.

There are a number of ways to use a computer or smartphone to ease separation anxiety and help the patient reconnect with family and friends.

The patient can set up a video chat. The nurse should encourage the patient to maintain personal contact through text messaging and email and have the patient catch up on the latest news and blogs on social networking sites.

Ambulatory and Home Care

Cast Care.

Because many fractures are treated in an outpatient setting, the patient often requires only a short hospitalization or none at all. Regardless of the type of cast material, a cast can interfere with circulation and nerve function from being applied too tightly or because of excessive edema after application. Thus, frequent neuro-vascular assessments of the immobilized extremity are critical. The patient must be taught about signs of cast complications so that they can be reported promptly. Elevation of the extremity above the level of the heart to promote venous return, and applications of ice to control or prevent edema, are frequently used measures during the initial phase. (If compartment syndrome is suspected, the extremity should not be elevated above the heart.) The nurse should instruct the patient to exercise joints above and below the cast. Pulling out cast padding and scratching or placing foreign objects inside the cast is forbidden because it predisposes the patient to skin breakdown and infection. For itching, instruct the patient that a hair dryer set on a cool setting can be directed under the cast.

Patient and caregiver teaching is an important nursing responsibility to prevent complications. In addition to providing specific instructions for cast care and recognition of complications, the nurse should encourage the patient to contact the clinic or health care provider if questions arise. Table 65-9 summarizes patient and caregiver instructions for cast care. The nurse should validate the patient's and caregivers' understanding of these instructions before discharging the patient from inpatient and ambulatory settings. Follow-up phone contact is appropriate, and home care nursing visits are warranted, especially with body or spica casts.

TABLE 65-9

PATIENT & CAREGIVER TEACHING GUIDE
Cast Care

After a cast is applied, include the following instructions when teaching the patient and the caregiver about cast care.
Do

• Apply ice directly over fracture site for first 24 hr (avoid getting cast wet by keeping ice in plastic bag and protecting cast with cloth).
• Check with health care provider before getting fibreglass cast wet.
• Dry cast thoroughly after exposure to water.
  • Blot dry with towel.
  • Use hair dryer on low setting until cast is thoroughly dry.
• Elevate extremity above level of heart for first 48 hr.
• Move joints above and below cast regularly.
• Use hair dryer on cool setting for itching.
• Report signs of possible problems to health care provider:
  • Increasing pain despite elevation, ice, and analgesia
  • Swelling associated with pain and discoloration of toes or fingers
  • Pain during movement
  • Burning or tingling under cast
  • Sores or foul odour under cast
• Keep appointment to have fracture and cast checked.

Do Not
• Get plaster cast wet. • Remove any padding. • Insert any objects inside cast. • Bear weight on new cast for 48 hr (not all casts are made for weight bearing; check with health care provider if unsure). • Cover cast with plastic if it will be wet for long periods of time.

Cast removal is done in the outpatient setting. Patients often fear being cut by the oscillating blade of the cast saw. The nurse should reassure the patient. More importantly, the nurse should educate the patient about possible alterations in the appearance of the extremity (e.g., dry, wrinkled skin, atrophied muscle) that has been beneath the cast. The patient may also have anxiety related to using the injured extremity after the cast is removed.

Psychosocial Problems.

Short-term rehabilitative goals are directed toward the transition from dependence to independence in performing simple ADLs and preserving or increasing strength and endurance. Long-term rehabilitative goals are aimed at preventing problems associated with musculo-skeletal injury (Table 65-10). An important part of nursing care during the rehabilitative phase is assisting the patient to adjust to any problems caused by the injury (e.g., separation from family, financial impact of medical care, loss of income from inability to work, potential for lifetime disability). The

nurse has an important role in offering support and encouragement while actively listening to the patient's and the caregiver's concerns.

TABLE 65-10
PROBLEMS ASSOCIATED WITH MUSCULO-SKELETAL INJURIES

Problem	Description	Nursing Considerations
Muscle atrophy	• Decreased muscle mass normally occurs as a result of disuse following prolonged immobilization. • Loss of nerve innervation can precipitate muscle atrophy.	• Isometric muscle-strengthening exercise regimen within the confines of the immobilization device assists in reducing the amount of atrophy. • Muscle atrophy interferes with and prolongs the rehabilitation process.
Contracture	• Abnormal condition of joint characterized by flexion and fixation. • Caused by atrophy and shortening of muscle fibres or by loss of normal elasticity of skin over a joint.	• Can be prevented by frequent position change, correct body alignment, and active and passive range of motion exercises several times a day. • Intervention requires gradual and progressive stretching of the muscles or ligaments in the region of the joint.
Footdrop	• Plantar-flexed position of the foot (footdrop) occurs when the Achilles tendon in the ankle shortens because it has been allowed to assume an unsupported position. • Peroneal nerve palsy (a compression neuropathy) also causes footdrop.	• Management of the patient with long-term injuries must include supporting the foot in a neutral position. • Once footdrop has developed, ambulation and gait training may be significantly hindered. • The patient may require a splint to keep the foot or feet in a neutral position. • High-top athletic shoes may also help.
Pain	• Frequently associated with fractures, edema, and muscle spasm. • Pain varies in intensity from mild to severe and is usually described as aching, dull, burning, throbbing, sharp, or deep.	• Causes of pain include incorrect positioning and alignment of the extremity, incorrect support of the extremity, sudden movement of the extremity, and immobilization devices that are applied too tightly or in an incorrect position, constrictive dressings, and motion occurring at the fracture site. • Determine causes of pain so that corrective nursing action can be taken.
Muscle spasms	• Caused by involuntary muscle contraction after fracture, muscle strain, or nerve injury, these may last as long as several weeks. • Pain associated with muscle spasms is often intense and can last from several seconds to several minutes.	• Measures to reduce the intensity of the muscle spasms are similar to the corrective actions for pain control. • Do not massage muscle spasms. • Thermotherapy, especially heat, may reduce muscle spasm.

Ambulation.

The nurse must know the overall goals of physiotherapy in relation to the patient's abilities, needs, and tolerance. Mobility training and instruction in the use of assistive aids (cane, crutches, walker) constitute major areas of responsibility of the physiotherapist. The patient with lower extremity dysfunction is usually started in mobility training when able to sit in bed and dangle the feet over the side. This activity should be done two or three

times a day for 10 to 15 minutes, with the nurse assisting as necessary. Collaboration of the nurse and physiotherapist to coordinate pain management and thus increase patient participation at therapy sessions is critical.

When the patient begins to ambulate, the nurse should know the patient's weight-bearing status and the correct technique if the patient is using an assistive device. Weight-bearing ambulation occurs in different degrees: (1) non–weight-bearing [NWB] ambulation (no weight on affected leg), (2) touch-down weight-bearing ambulation [TDWB] or toe-touch weight-bearing ambulation [TTWB] (contact with floor only for balance; no weight on affected leg), (3) partial weight-bearing ambulation [PWB] (directions given by physician), (4) weight bearing as tolerated [WBAT] (dictated by patient's pain and tolerance), and (5) full weight-bearing [FWB] ambulation (no limitations) (University of Pittsburgh Medical Center, 2016).

Assistive Devices.

Devices for ambulation range from a cane, which can relieve up to 40% of the weight normally borne by a lower limb, to a walker or crutches, which may allow for complete non–weight-bearing ambulation. The decision about which device is appropriate for a patient involves weighing the need for maximum stability and safety versus manoeuvrability, which is required in small spaces such as bathrooms. It is essential to discuss with patients the requirements of their lifestyles and determining the device with which each patient feels most secure and independent.

The technique for using assistive devices varies. The involved limb is usually advanced at the same time or immediately after the advance of the device. The uninvolved limb is advanced last. In almost all cases, canes are held in the hand opposite the involved extremity.

A transfer belt can be placed around the patient's waist to provide stability during the learning stages. The nurse should discourage the patient from reaching for furniture or relying on another person for support. When there is inadequate upper limb strength or poorly fitted crutches, the patient bears weight at the axilla rather than at the hands, endangering the neuro-vascular bundle that passes across the axilla. If verbal coaching does not correct the problem, the patient should be instructed in another form of ambulation until strength is adequate (e.g., platform crutches, walker).

Patients who must ambulate without weight bearing require sufficient upper limb strength to lift their own weight at each step. Because the

muscles of the shoulder girdle are not accustomed to this work, they require vigorous and diligent training in preparation for this task. Push-ups, pull-ups using the overhead trapeze bar, and lifting weights develop the triceps and biceps. Straight-leg raises and quadriceps-setting exercises strengthen the quadriceps.

Counselling and Referrals.

During the rehabilitative process, the patient's caregiver assumes an important role in the provision and follow-through of long-term care plans. The caregiver should be instructed in the techniques of strength and endurance exercises, assistance with mobility training, and promotion of activities that enhance the quality of daily living. The nurse should also evaluate patients for post-traumatic stress disorder. This is especially important if significant injury to others or fatalities were associated with the patient's injuries.

Evaluation

The following are expected outcomes for the patient with a fracture:

- Report satisfactory relief of pain
- Demonstrate appropriate care of cast or immobilizer
- Experience no peripheral neuro-vascular dysfunction
- Experience uncomplicated bone healing

Complications of Fractures

The majority of fractures heal without complications. If death occurs after a fracture, it is usually the result of damage to underlying organs and vascular structures or from complications of the fracture or immobility. Complications of fractures can be either direct or indirect. *Direct complications* include problems with bone infection, bone union, and AVN. *Indirect complications* are associated with blood vessel and nerve damage resulting in conditions such as compartment syndrome, venous thrombo-embolism, fat embolism, rhabdomyolysis (breakdown of skeletal muscle), and hypovolemic shock. Although most musculo-skeletal injuries are not life-threatening, open fractures, fractures accompanied by severe blood

loss, and fractures that damage vital organs (e.g., lung, heart) are medical emergencies requiring immediate attention.

Infection

Open fractures and soft tissue injuries have a high incidence of infection. An open fracture usually results from high-energy trauma and can lead to significant long-term morbidity and disability (Halawi & Morwood, 2015). Massive or blunt soft tissue injury often has more serious consequences than the fracture. Devitalized and contaminated tissue is an ideal medium for many common pathogens, including gas-forming (anaerobic) bacilli such as *Clostridium tetani*. Treatment of infection is costly in terms of extended nursing and medical care, time for treatment, and loss of patient income. Osteomyelitis can become chronic (Patrice & Hatch, 2011b). (See Chapter 66 for a discussion of osteomyelitis.)

Collaborative Care.

Open fractures require aggressive surgical debridement. The wound is initially cleansed with a sterile saline solution via low-pressure lavage, in the operating room. Gross contaminants are irrigated or mechanically removed. Contused, contaminated, and devitalized tissue such as muscle, subcutaneous fat, skin, and fragments of bone are surgically excised *(debridement).* The extent of the soft tissue damage determines whether the wound is closed at the time of surgery and whether it requires repeat debridement, closed suction drainage, and skin grafting. Depending on the location and the extent of the fracture, reduction may be maintained by external fixation or traction. During surgery, the open wound may be irrigated with antibiotic solution. Antibiotic-impregnated beads may also be placed in the surgical site. During the postoperative phase, the patient will have antibiotics administered intravenously for 3 to 7 days. Antibiotics, in conjunction with aggressive surgical management, have greatly reduced the occurrence of infection.

Compartment Syndrome

Compartment syndrome is a condition in which swelling and increased pressure within a limited space (a compartment) press on and compromise the function of blood vessels, nerves, and tendons that run through that compartment. Compartment syndrome causes capillary perfusion to be reduced below a level necessary for tissue viability. It is classified as acute, subacute, or chronic (Ali, Santy-Tomlinson, & Watson, 2014).

Compartment syndrome usually involves the leg but can also occur in the arm, shoulder, and buttock.

Thirty-eight compartments are located in the upper and lower extremities. Two basic causes of compartment syndrome are (1) decreased compartment size resulting from restrictive dressings, splints, casts, excessive traction, or premature closure of fascia and (2) increased compartment contents related to bleeding, edema, chemical response to snakebite, or intravenous infiltration.

Edema can create sufficient pressure to obstruct circulation and cause venous occlusion, which further increases edema. Eventually, arterial flow is compromised, resulting in inadequate arterial circulation *(ischemia)* to the extremity. As ischemia continues, muscle and nerve cells are destroyed over time, and fibrotic tissue replaces the healthy tissue. Contracture, disability, and loss of function can occur. Delay in diagnosis and treatment can result in irreversible muscle and nerve ischemia, resulting in a functionally useless or severely impaired extremity.

Compartment syndrome is usually associated with trauma, fractures (especially of the long bones), extensive soft tissue damage, and crush injury. Fractures of the distal humerus and proximal tibia are the most common fractures associated with compartment syndrome. Compartment injury can also occur following knee or leg surgery. Prolonged pressure on a muscle compartment may occur when someone is trapped under a heavy object or a person's limb is trapped beneath the body because of an obtunded state such as drug or alcohol overdose. In the upper extremity, this condition is referred to as *Volkmann ischemic contracture,* and in the lower extremity, it is known as *anterior tibial compartment syndrome,* although the underlying pathophysiological mechanism is similar.

Clinical Manifestations.

Compartment syndrome may occur initially from the body's physiological response to the injury, or it may be delayed for several days after the original insult or injury. Ischemia can occur within 4 to 8 hours after the onset of compartment syndrome.

The "six *P*s" are a neuro-vascular assessment mnemonic that can be used to assess for impending compartment syndrome: (1) ***p****ain* distal to the injury that is not relieved by opioid analgesics and pain on passive stretch of muscle travelling through the compartment; (2) increasing ***p****ressure* in the compartment; (3) ***p****aresthesia* (numbness and tingling); (4) ***p****allor,* coolness, and loss of normal colour of the extremity; (5) ***p****aralysis* or loss of function; and (6) ***p****ulselessness* or diminished or absent peripheral pulses.

Collaborative Care.

Prompt, accurate diagnosis of compartment syndrome is critical. Prevention or early recognition is the key. Regular neuro-vascular assessments should be performed and documented on all patients with fractures but especially those with injury of the distal humerus or proximal tibia or soft tissue disruption in these areas.

Carefully assess the location, quality, and intensity of the pain (see Chapter 10). Evaluate the pain on a scale of 0 to 10. Pain unrelieved by drugs and out of proportion to the level of injury and pain on passive muscle stretch appear to be the most effective clinical observations (Ali et al., 2014) and some of the first indications of impending compartment syndrome. Pulselessness and paralysis (in particular) are later signs of compartment syndrome. The health care provider should be notified immediately of a patient's changing condition.

Because of the possibility of muscle damage, urine output should be assessed. Myoglobin released from damaged muscle cells precipitates as a gel-like substance and causes obstruction in renal tubules. This condition results in acute tubular necrosis and acute kidney injury. Common signs are dark, reddish-brown urine and clinical manifestations associated with acute kidney injury (see Chapter 49).

Elevation of the extremity may lower venous pressure and slow arterial perfusion; thus, the extremity should not be elevated above heart level. Similarly, the application of cold compresses may result in vasoconstriction and exacerbate compartment syndrome. It may also be necessary to remove or loosen the bandage and bivalve or split the cast in half. A reduction in traction weight may also decrease external circumferential pressures.

Surgical decompression (e.g., fasciotomy) of the involved compartment may be necessary (Figure 65-15). The fasciotomy site is left open for several days to ensure adequate soft tissue decompression. Infection resulting from delayed wound closure is a potential problem following a fasciotomy. In severe cases of compartment syndrome, an amputation may be required.

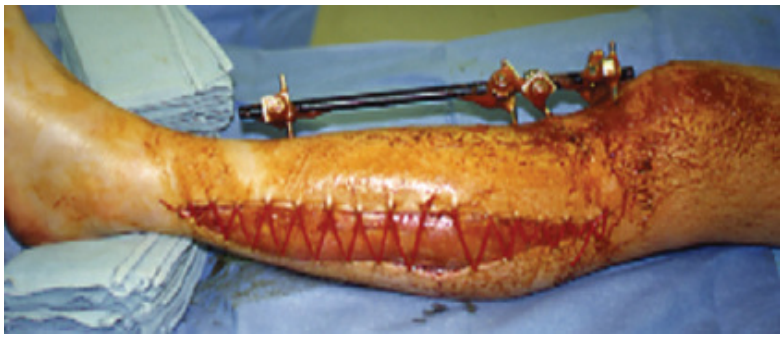

FIGURE 65-15 Fasciotomy associated with compartment syndrome. Stabilization of fracture with external fixator. Source: Browner, B. D., Jupiter, J. B., Levine, A. M., et al. (2009). *Skeletal trauma: Fractures, dislocations, ligamentous injuries*. (4th ed.). Philadelphia: Saunders.

Venous Thrombo-Embolism

The veins of the lower extremities and the pelvis are highly susceptible to thrombus formation after fracture, especially a hip fracture. Venous thrombo-embolism may also occur after total hip or total knee replacement surgery (Welle, 2012). In patients with limited mobility, venous stasis is aggravated by inactivity of the muscles that normally assist in the pumping action of venous blood returning to the extremities.

Because of the high risk for venous thrombo-embolism in the orthopaedic surgical patient, prophylactic anticoagulant drugs such as warfarin, low–molecular weight heparin (LMWH) (e.g., enoxaparin [Lovenox]), or fondaparinux (Arixtra) or rivaroxaban (Xarelto) may be ordered. In addition to wearing compression gradient stockings (antiembolism hose) and using sequential compression devices, the patient should be instructed to move (dorsiflex and plantar flex) the fingers or toes of the affected extremity against resistance and to perform ROM exercises on the unaffected lower extremities. (Assessment and management of venous thrombo-embolism are discussed in Chapter 40.)

Fat Embolism Syndrome

Fat embolism syndrome (FES) is characterized by the presence of systemic fat globules from fractures that are distributed into tissues and organs after a traumatic skeletal injury. FES is fatal in 5% to 15% of patients (Carlson & Pfadt, 2011). The fractures that most often cause FES are those of the long bones, ribs, and pelvis. FES has also been known to occur following total joint replacement, spinal fusion, liposuction, crush

injuries, and bone marrow transplantation. Two theories about fat embolism exist. The mechanical theory is that fat is released from the marrow of injured bone and enters the systemic circulation, where the fat embolizes to other organs such as the brain (Tzioupis & Giannoudis, 2011). Microvascular lodging of droplets produces local ischemia and inflammation. The biochemical theory is that hormonal changes caused by trauma or sepsis stimulate the systemic release of free fatty acids such as chylomicrons, which form the fat emboli.

Clinical Manifestations.

Early recognition of FES is crucial in preventing a potentially lethal course. Most patients manifest symptoms within 24 to 48 hours after injury. Severe forms have occurred within hours of injury. The fat emboli in the lungs cause a hemorrhagic interstitial pneumonitis that produces signs and symptoms of acute respiratory distress syndrome (ARDS), such as chest pain, tachypnea, cyanosis, dyspnea, apprehension, tachycardia, and decreased partial pressure of arterial oxygen (PaO_2). All of these symptoms are caused by poor oxygen exchange. Because they are frequently the first symptoms to manifest, changes in the mental status as a result of hypoxemia are important to recognize. Memory loss, restlessness, confusion, elevated temperature, and headache prompt further investigation so that central nervous system involvement is not mistaken for alcohol withdrawal or acute head injury. The continued change in level of consciousness and petechiae located around the neck, anterior chest wall, axilla, buccal membrane, and eye conjunctiva help distinguish fat emboli from other problems. Petechiae result from intravascular thromboses caused by decreased oxygenation.

The clinical course of a fat embolus may be rapid and acute. Frequently, the patient expresses a feeling of impending disaster. In a short time, skin colour changes from pallid to cyanotic, and the patient may become comatose. No specific laboratory examinations are available to aid in the diagnosis (Tzioupis & Giannoudis, 2011). However, certain diagnostic abnormalities may be present. These include fat cells in the blood, urine, or sputum; a decrease of the PaO_2 to less than 60 mm Hg; ST-segment changes on the electrocardiogram; a decrease in the platelet count and hematocrit levels; and a prolonged prothrombin time resulting from hemorrhaging into the lungs. A chest radiograph may reveal areas of pulmonary infiltrate or multiple areas of consolidation. This appearance is sometimes referred to as the "white-out effect."

Collaborative Care.

Treatment for fat embolism is directed at prevention. Careful immobilization of a long bone fracture is probably the most important element in the prevention of fat embolism. Management of FES is essentially symptom related and supportive. Treatment includes fluid resuscitation to prevent hypovolemic shock, correction of acidosis, and replacement of blood loss. Coughing and deep breathing should be encouraged. The patient should be repositioned as little as possible before fracture immobilization or stabilization because of the danger of dislodging more fat droplets into the general circulation.

Use of corticosteroids to prevent or treat fat embolism is controversial. Oxygen is administered to treat hypoxia. Intubation or intermittent positive-pressure breathing may be considered if a satisfactory PaO_2 cannot be obtained with supplemental oxygen alone. Some patients may develop pulmonary edema, ARDS, or both, leading to an increased mortality rate. Most patients survive FES with few sequelae.

Types of Fractures

Colles Fracture

A *Colles fracture* is a fracture of the distal radius and is one of the most common fractures in adults (Figure 65-16). The styloid process of the ulna may be involved as well. Usually, the injury occurs when the patient attempts to break a fall with an outstretched hand. This type of fracture most often occurs in patients over 50 years old whose bones are osteoporotic. A younger person with a Colles fracture caused by a low-energy force should be referred for an osteoporosis evaluation.

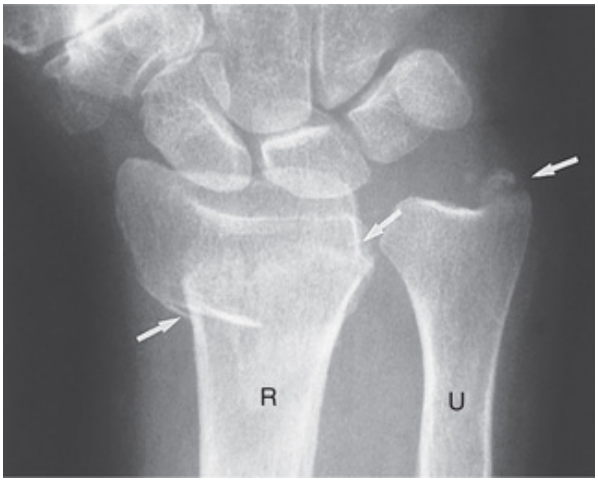

FIGURE 65-16 Colles fracture. Fracture of the distal radius (R) and ulnar (U) styloid from patient falling on the outstretched hand. Source: Mettler, F.A. (2005). *Essentials of radiology.* (2nd ed.). Philadelphia: Saunders.

The clinical manifestations of a Colles fracture are pain in the immediate area of injury, pronounced swelling, and dorsal displacement of the distal fragment (silver-fork deformity). This may appear as an obvious deformity on the wrist. The major complication associated with a Colles fracture is vascular insufficiency as a result of edema. CTS can be a later complication.

A Colles fracture is usually managed by closed manipulation of the fracture and immobilization by either a splint or a cast or, if displaced, by external fixation. The wrist must be immobilized to prevent wrist supination and pronation. Nursing management should include frequent neuro-vascular assessments and measures to prevent or reduce edema.

Support and protection of the extremity should be provided, along with encouragement of active movement of the thumb and fingers. This type of movement helps reduce edema and increases venous return. The patient should be instructed to perform active movements of the shoulder to prevent stiffness or contracture.

Fracture of the Humerus

Fractures involving the shaft of the humerus are a common injury among young and middle-aged adults. The most common clinical manifestations are an obvious displacement of the humerus shaft, shortened extremity, abnormal mobility, and pain. The major complications associated with fracture of the humerus are radial nerve injury and vascular injury to the brachial artery as a result of laceration, transection, or muscle spasm.

The treatment for a fracture of the humerus depends on the location and displacement of the fracture. Nonoperative treatment may include a hanging arm cast, a shoulder immobilizer, or the sling and swathe, which is a type of immobilization that prevents glenohumeral movement. The swathe encircles the trunk and the humerus as an additional binder. It is often used for surgical repairs and shoulder dislocation.

When these devices are used, the head of the bed should be elevated to assist gravity in reducing the fracture. The arm should be allowed to hang freely when the patient is sitting and standing. Nursing care should include measures to protect the axilla and prevent skin maceration by placing absorbable composite dressing pads (i.e., ABD pads) in the axilla and change them twice daily or as needed. Skin or skeletal traction may be used for purposes of reduction and immobilization.

During the rehabilitative phase, an exercise program geared toward improving strength and motion of the injured extremity is extremely important. This program should include assisted motion of the hand and fingers. The shoulder can also be exercised if the fracture is stable. This helps prevent stiffness secondary to frozen shoulder or fibrosis of the shoulder capsule.

Fracture of the Pelvis

Pelvic fractures range from benign to life-threatening, depending on the mechanism of injury and associated vascular insult. Although only a small percentage of all fractures are pelvic fractures, this type of injury is associated with the highest mortality rate. Preoccupation with more

obvious injuries at the time of a traumatic event may result in an oversight of pelvic injuries.

Pelvic fractures may cause serious intra-abdominal injury, such as paralytic ileus; hemorrhage; and laceration of the urethra, the bladder, or the colon. Pelvic fractures can cause acute pelvic compartment syndrome (Ojike, Robers, & Giannoudis, 2012). Patients may survive the initial pelvic injury, only to die from sepsis, FES, or DVT complications.

Physical examination of the abdomen demonstrates local swelling, tenderness, deformity, unusual pelvic movement, and ecchymosis. The neuro-vascular status of the lower extremities and manifestations of associated injuries should be assessed. Pelvic fractures are diagnosed by radiography and computed tomographic (CT) scan (Walker, 2011).

Treatment of a pelvic fracture depends on the severity of the injury. Stable, nondisplaced fractures require limited intervention, and early mobilization is encouraged. Bed rest for stable pelvic fractures is maintained from a few days to 6 weeks. More complex fractures may be treated with pelvic sling traction, skeletal traction, external fixation, open reduction, or a combination of these methods. ORIF of a pelvic fracture may be necessary if the fracture is displaced. Extreme care in handling and moving the patient is important to prevent serious injury from a displaced fracture fragment. The patient should be turned only when ordered by the health care provider. Because a pelvic fracture can lead to damage to other organs, assessment of bowel and urinary tract function and distal neuro-vascular status are important nursing measures. Back care should be provided while the patient is raised from the bed either by independent use of the trapeze or with adequate assistance. Pelvic fractures can be extremely painful and require the appropriate assessment and management of pain to promote recovery and participation in rehabilitation.

Fracture of the Hip

Hip fractures are common in older adults and are serious injuries. There are approximately 30 000 hip fractures per year in Canada and 70% to 90% of them are caused by osteoporosis (Osteoporosis Canada, 2017). Ninety-five percent of hip fractures result from a fall (Centers for Disease Control and Prevention [CDC], 2015).Women older than 75 years are the most likely to have a fractured hip (Moja, Piatti, Pecoraro, et al., 2012). Hip fractures require one of the longest hospital stays, averaging more than 19

days. Of older adults hospitalized with hip fracture, 10% die within 1 month, 20% at 4 months, and 30% at 1 year (Moja et al., 2012).

Patients with hip fractures are "the frailest among those who are admitted to hospital, and their outcomes are likely to depend closely on how their care is managed" (Moja et al., 2012). Timely access to care is critical as longer wait times have been associated with a higher risk for mortality, especially in the older-adult population (Canadian Institute for Health information [CIHI], 2016). Wait times for hip fracture repair are improving in Canada. In 2015, 87% of patients were treated within the benchmark time of 48 hours (8% higher than in 2011) (CIHI, 2016).

A *fracture of the hip* (Figure 65-17) refers to a fracture of the proximal third of the femur, which extends up to 5 cm below the lesser trochanter. Fractures that occur within the hip joint capsule are called *intracapsular fractures.* Intracapsular (femoral neck) fractures are further identified by a name derived from specific locations: (1) *capital* (fracture of the head of the femur), (2) *subcapital* (fractures just below the head of the femur), and (3) *transcervical* (fractures of the neck of the femur). These fractures are often associated with osteoporosis and minor trauma. *Extracapsular fractures* occur outside the joint capsule. They are termed (1) *intertrochanteric* if they occur in a region between the greater and the lesser trochanter or (2) *subtrochanteric* if they occur in the region below the lesser trochanter. Extracapsular fractures are usually caused by severe direct trauma or a fall.

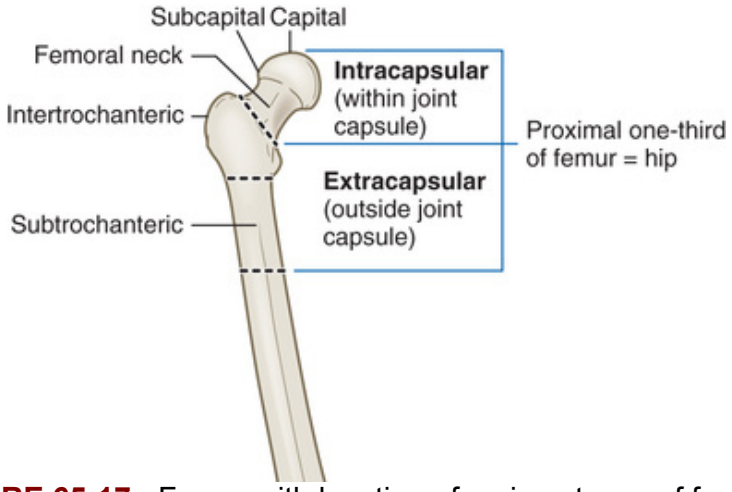

FIGURE 65-17 Femur with location of various types of fracture.

Clinical Manifestations

The clinical manifestations of hip fractures are external rotation, muscle spasm, shortening of the affected extremity, and severe pain and tenderness in the region of the fracture site. Displaced femoral neck fractures cause serious disruption of the blood supply to the femoral head, which can result in AVN of the femoral head.

Collaborative Care

Initially, the affected extremity may be temporarily immobilized by Buck traction (see Figure 65-9) until the patient's physical condition is stabilized and surgery can be performed. Buck traction relieves painful muscle spasms and is used for up to 24 to 48 hours.

Surgical treatment of hip fractures permits early mobilization and decreases the risk for major complications. The type of surgery depends on the location and severity of the fracture and the person's age. Surgical options include (1) repair with internal fixation devices (e.g., hip compression screw, intramedullary devices) (Figure 65-18), (2) replacement of part of the femur with a prosthesis (partial hip replacement) (see Figure 65-18), and (3) total hip replacement (involves both the femur and acetabulum) (see Figures 65-18 and 65-19).

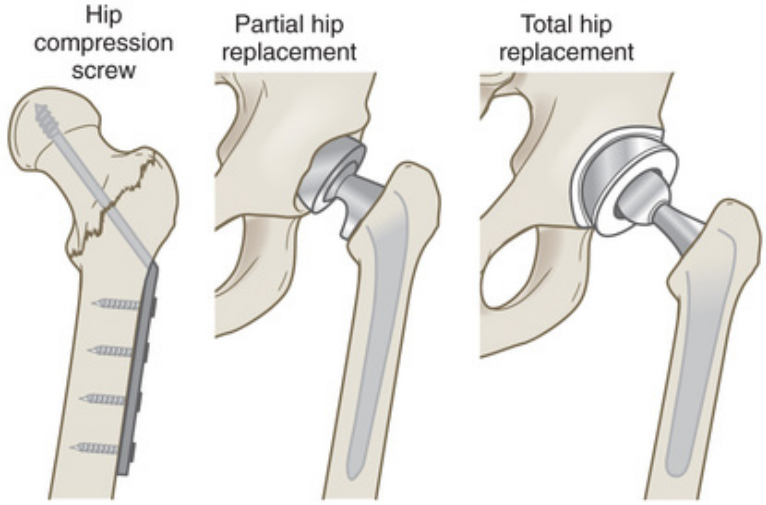

FIGURE 65-18 Types of surgical repair for a hip fracture.

FIGURE 65-19 Total hip replacement (arthroplasty) with a cementless femoral prosthesis of metal alloy with a plastic acetabular socket.

Nursing Management Hip Fracture

Nursing Implementation

Preoperative Management.

The majority of people with hip fractures are older adults. When planning treatment of the hip fracture, consider the patient's chronic health problems (e.g., diabetes mellitus, cardiac disease, and pulmonary disease). Surgery may be delayed for a brief time until the patient's general health is stabilized (Hung, Egol, Zuckerman, et al., 2012).

Before surgery, severe muscle spasms may increase pain. Appropriate analgesics or muscle relaxants, comfortable positioning (unless contraindicated), and properly adjusted traction (if used) can help in managing the spasms.

Often, teaching is done in the emergency department because quick surgical intervention is the standard of care today. Many patients will not have an overnight preoperative period in which to receive instructions, or the patient may not have the cognitive abilities to retain this important patient education.

When possible, the patient can be taught the method and frequency for exercising the unaffected leg and both arms. The patient should also be encouraged to use the overhead trapeze bar and the opposite side rail to

assist in changing positions. A physiotherapist can begin to teach out-of-bed and chair transfers. The family or caregiver must also be informed about the patient's weight-bearing status after surgery. Plans for discharge begin as the patient enters the hospital because the length of stay postoperatively will be only a few days.

Postoperative Management.

The initial postoperative management of a patient following ORIF of a hip fracture is similar to that for any older-adult patient undergoing surgery. The nurse must monitor vital signs, intake, and output; supervise respiratory activities, such as deep breathing and coughing; administer pain medication; and observe the dressing and incision for signs of bleeding and infection. Care for the patient undergoing orthopaedic surgery is presented in Nursing Care Plan 65-2, available on the Evolve website.

In the early postoperative period, there is a potential for neuro-vascular impairment. The nurse assesses the patient's extremity for (1) colour, (2) temperature, (3) capillary refill, (4) distal pulses, (5) edema, (6) sensation, (7) motor function, and (8) pain. Edema is alleviated by elevation of the leg whenever the patient is in a chair. The pain resulting from poor alignment of the affected extremity can be reduced by keeping pillows (or an abductor splint) between the patient's knees when turning to either side.

If the hip fracture has been treated by insertion of a femoral head prosthesis with a *posterior approach* (accessing the hip joint from the back), measures to prevent dislocation must always be used (Table 65-11). Avoid extremes in flexion initially after prosthetic replacement from a posterior approach. The patient and the caregiver must be fully aware of positions and activities that predispose the patient to dislocation (more than 90 degrees of flexion, adduction across the midline [crossing of legs and ankles], internal rotation). Many daily activities may reproduce these positions, including putting on shoes and socks; crossing the legs or feet while seated; assuming the side-lying position incorrectly; standing up or sitting down while the body is flexed more than 90 degrees relative to the chair; and sitting on low seats, especially low toilet seats. The patient should be taught to avoid these activities until the soft tissue capsule surrounding the hip has healed sufficiently to stabilize the prosthesis (usually for at least 6 weeks).

TABLE 65-11

PATIENT & CAREGIVER TEACHING GUIDE
Femoral Head Prosthesis*

The following information should be included when teaching the patient and caregiver about a femoral head prosthesis.
Do
• Use an elevated toilet seat. • Place chair inside shower or tub and remain seated while washing. • Use pillow between legs for first 8 wk after surgery when lying on the side recommended by surgeon or when supine. • Keep hip in neutral, straight position when sitting, walking, or lying. • Notify surgeon if severe pain, deformity, or loss of function occurs. • Inform dentist of presence of prosthesis before dental work so that prophylactic antibiotics can be given if indicated.
Do Not
• Force hip into greater than 90 degrees of flexion (e.g., sitting in low chairs or on low toilet seats). • Force hip into adduction. • Force hip into internal rotation. • Cross legs at knees. • Put on own shoes or stockings without adaptive device (e.g., long-handled shoehorn or stocking-helper) until 8 wk after surgery. • Sit on chairs without arms. They are needed to aid rising to a standing position.

*For patients having surgery by a posterior approach.

Elevated toilet seats and chair alterations (e.g., raising the seat with pillows, maintaining a straight back) are necessary. Towel rolls (i.e., trochanter rolls) or pillows placed on the lateral side of the leg are also used to prevent external rotation. If a foam abduction pillow is used, it should be placed between the legs to prevent dislocation of the new joint (see Figure 65-20). The nurse should ensure that the top straps are above the knee to avoid placing pressure on the peroneal nerve at the lateral tibial tubercle.

FIGURE 65-20 Log rolling a patient. Source: Perry, A. G., Potter, P. A., & Ostendorf, W. R. (2016). *Nursing interventions and clinical skills.* (6th ed., p. 418). St. Louis: Elsevier.

In addition to teaching the patient and caregiver how to prevent prosthesis dislocation, the nurse should also (1) place an abductor pillow or several pillows between the patient's legs when turning and (2) avoid turning the patient on the affected side until this has been approved by the surgeon. Also, some health care providers prefer that the patient keep the leg abductor pillow on except when bathing.

Taking a tub bath and driving a car are not allowed for 4 to 6 weeks. An occupational therapist may teach the patient to use assistive devices, such as reachers or grabbers, to avoid bending over to pick something off the floor; long-handled shoehorns; or sock assists. The knees must be kept apart. Instruct the patient to never cross the legs or twist to reach behind.

When the hip fracture is accessed during surgery with an *anterior* or *anterolateral approach* (joint reached from front of body), the hip muscles are left intact. This approach generally results in a more stable hip in the postoperative period, with a lower rate of complications (e.g., infection, dislocation) (Ferguson & Eastman, 2011). Precautions for the patient related to motion and weight bearing are few and may include instructions to avoid hyperextension.

Usually, the physiotherapist supervises exercises for the affected extremity and ambulation when the surgeon permits it. The patient is usually out of bed on the first postoperative day. In collaboration with the physiotherapist, the nurse monitors the patient's ambulation status for proper use of crutches or a walker. For the patient to be discharged home, the nurse should have the patient demonstrate the proper use of crutches or a walker, the ability to transfer into and from a chair and bed, and the ability to ascend and descend stairs.

Weight bearing on the involved extremity varies. Weight bearing of especially fragile fractures may be restricted until radiological examination indicates adequate healing, usually 6 to 12 weeks.

Complications associated with femoral neck fracture include nonunion, AVN, dislocation, and degenerative arthritis. As a result of an intertrochanteric fracture, the affected leg may be shortened. A cane or built-up shoe may be required for safe ambulation.

Sudden, severe pain; a lump in the buttock; limb shortening; and external rotation indicate prosthesis dislocation. Dislocation requires a closed reduction with conscious sedation or open reduction to realign the femoral head in the acetabulum. If it occurs (regardless of the setting), the patient should be kept on nothing-by-mouth status in anticipation of a possible surgical intervention.

The nurse assists both the patient and caregiver in adjusting to the restrictions and dependence imposed by the hip fracture. Anxiety and depression can easily occur, but creative nursing care and awareness of potential problems can help to prevent them. The nurse should inform the patient and caregiver about community referral services that can assist in the postdischarge rehabilitation phase.

Ambulatory and Home Care.

Hospitalization averages 3 or 4 days. Patients frequently require care in a subacute unit, at a skilled nursing facility, or in a rehabilitation facility for a few weeks before returning home. Regular follow-up care should be arranged for after discharge, including home health nursing.

Home care considerations include ongoing assessment of pain management, monitoring for infection, and prevention of DVT. The incision may be closed with metal staples, which are removed at the surgeon's office. If warfarin is used to decrease the high risk for thrombo-embolism, prothrombin times are determined weekly and anticoagulation adjusted accordingly. Alternatives to warfarin include enoxaparin (Lovenox), fondaparinux (Arixtra), and rivaroxaban (Xarelto). These newer anticoagulants require less monitoring than warfarin does. The patient is who is receiving an anticoagulant should be taught to immediately report signs of bleeding to the health care provider.

Exercises designed to restore strength and muscle tone in the quadriceps and muscles of the hip area are essential to improve function and ROM. These exercises include quadriceps setting (e.g., tightening the kneecap), gluteal muscle setting (e.g., tightening the buttocks), leg raises in supine and prone positions, and abduction exercises from the supine and

standing positions (e.g., swinging the leg out but never crossing midline). The patient continues these exercises for many months after discharge. It is important to teach the exercise program to the caregiver who will be encouraging the patient at home.

A physiotherapist assesses ROM, ambulation, and compliance with the exercise regimen. The patient gradually increases the number of repetitions of exercises, adds weights to ankles, may swim, and may eventually use a stationary bicycle to tone quadriceps and improve cardiovascular fitness. High-impact exercises and sports, such as jogging and tennis, may loosen the implant and should be avoided.

Evaluation

The following are expected outcomes for the patient with a fracture of the hip:

- Report satisfactory pain relief
- Participate in exercise therapy
- Understand prescribed treatment plan

Age-Related Considerations

Hip Fracture

Factors that increase the risk for a hip fracture in older adults include a tendency to fall, inability to correct a postural imbalance, inadequacy of local tissue shock absorbers (e.g., fat, muscle bulk), and reduced skeletal strength. Factors that increase the older adult's risk of falling include gait and balance problems, decreased vision and hearing, slowed reflexes, orthostatic hypotension, and medication use. Leading hazards of falls in the home include “throw rugs and loose, worn or deep pile carpets; electrical cords in walkways; raised door sills; cluttered floors; poor lighting; slippery floors; poorly designed tubs, toilets and fixtures in the bathroom; no aids or poorly installed aids such as grab bars or hand rails; and pets that get under foot” (Public Health Agency of Canada [PHAC], 2014).

Many falls are associated with getting in or out of a chair or bed. Falls to the side, the most common type seen in frail older adults, are more likely to result in a hip fracture than a forward fall (CDC, 2015). External hip protectors may help prevent hip fractures in the frail older-adult patient

(Juby, 2009). Older-adult women often have osteoporosis and accompanying low bone density, which increases their risk for hip and other types of fractures.

Calcium and vitamin D supplementation, estrogen replacement, and bisphosphonate drug therapy decrease bone loss or increase bone density and thus reduce the likelihood of fracture, especially in patients with osteoporosis. (Osteoporosis is discussed in Chapter 66.) Nurses must be vigilant in planning interventions for the older adult that are known to reduce the incidence of falls and hip fractures (Registered Nurses' Association of Ontario [RNAO], 2005, rev. 2011).

Femoral Shaft Fracture

Femoral shaft fracture occurs with a severe direct force because the femur can bend slightly before an actual fracture occurs. Young adults have a higher incidence of this type of fracture. The force exerted to cause the fracture, such as from a motor vehicle accident or gunshot wound, frequently damages the adjacent soft tissue structures. These injuries may be more serious than the bone injury.

Displacement of the fracture fragments often results in open fracture and increased soft tissue damage. This injury can lead to considerable blood loss (1 to 1.5 L). The most common types of femoral shaft fracture include transverse, spiral, comminuted, oblique, and open (see Figures 65-6 and 65-7).

The clinical manifestations of a femoral shaft fracture are usually obvious. They include marked deformity and angulation, shortening of the extremity, inability to move either the hip or the knee, and pain. The common complications associated with fracture of the femoral shaft include fat embolism; nerve and vascular injury; and problems associated with bone union, open fracture, and soft tissue damage.

Initial management of a femoral shaft fracture is directed toward stabilization of the patient and immobilization of the fracture. Traction may be used as a temporary measure before surgical treatment or in patients unable to undergo surgery. The method of treatment most often used for a femoral shaft fracture is *intermedullary nailing* (Faucett, Collinge, & Koval, 2012). A metal rod is placed into the marrow canal of the femur. The rod passes across the fracture to keep it in position. Internal fixation is preferred because it reduces the hospital stay and the complications associated with prolonged bed rest.

In the postoperative period, the patient should be taught to carefully follow the health care provider's instructions for weight bearing. Promotion and maintenance of strength in the affected extremity usually include gluteal and quadriceps isometric exercises. The nurse should ensure that the patient performs ROM and strengthening exercises for all uninvolved extremities in preparation for ambulation. The patient may be allowed to begin non–weight-bearing activities with an ambulatory assistive device (e.g., walker, crutches). Full weight bearing is usually restricted until there is radiological evidence of union of the fracture fragments.

Fracture of the Tibia

Although the tibia is vulnerable to injury because it lacks anterior muscle covering, strong force is required to produce a fractured tibia. As a result, soft tissue damage, devascularization, and open fracture are frequent. The tibia is one of the more common sites of a stress fracture. Complications associated with tibial fractures are compartment syndrome, FES, problems associated with bony union, and possible infection associated with open fracture.

The recommended management for closed tibial fracture is closed reduction followed by immobilization in a long leg cast. ORIF with intramedullary rods, plate fixation, or external fixation is indicated for complex fractures and those with extensive soft tissue damage. Locking plates (screw and plate system) are another type of surgical device. In both types of reduction, emphasis is placed on maintaining the strength of the quadriceps.

The neuro-vascular status of the affected extremity must be assessed at least every 2 hours during the first 48 hours. Patients are instructed to perform active ROM exercises with all uninvolved extremities, as well as exercises for the upper extremities, to build the strength required for crutch walking. When the health care provider has determined that the patient is ready for gait training, the patient is instructed in the principles of crutch walking. The patient may be on non–weight-bearing status for 6 to 12 weeks, depending on healing. Home nursing visits can be initiated to augment outpatient appointments and monitor the patient's progress.

Stable Vertebral Fractures

Stable fractures of the vertebral column are usually caused by motor vehicle accidents, falls, diving, or other athletic injuries. A *stable fracture* is

one in which the fracture or the fragment is not likely to move or cause spinal cord damage. This type of injury is frequently confined to the anterior element (vertebral body) of the spinal column in the lumbar region and involves the cervical and thoracic regions less frequently. The vertebral bodies are usually protected from displacement by the intact spinal ligaments.

Most patients with spinal fractures have stable fractures and experience only brief periods of disability. However, if the ligamentous structures are significantly disrupted, dislocation of the vertebral structures may occur, resulting in instability and injury to the spinal cord *(unstable fracture)*. These injuries generally necessitate surgery. The most serious complication of vertebral fractures is fracture displacement, which can cause damage to the spinal cord (see Chapter 63). Although stable vertebral fractures are not associated with pathological spinal cord conditions, all spinal injuries should initially be considered unstable and potentially serious until diagnostic tests are done and the physician determines that the fracture is stable.

Usually, the patient complains of pain and tenderness in the affected region of the spine. Sudden loss of function below the level of the fracture indicates spinal cord impingement and paraplegia. Stable compression fractures are associated with a *kyphotic deformity* (flexion angulation of several vertebrae). This deformity may be noted during the physical examination. In patients with a stable vertebral fracture secondary to osteoporosis, several vertebral levels may be involved, as evidenced by a *dowager's hump* (abnormal curvature of the thoracic spine) or *lumbar lordosis* (extreme inward curve). The cervical spine may also be involved. Bowel and bladder dysfunction may be an indication of an interruption of the autonomic nervous system or injury to the spinal cord.

The overall goal in management of stable vertebral fractures is to keep the spine in good alignment until union has been accomplished. Many nursing interventions are aimed at assessing for the possibility of spinal cord trauma. Vital signs and bowel and bladder function should be evaluated regularly. The nurse should also monitor the motor and sensory status of the peripheral nerves distal to the injured region. Any deterioration in the patient's neuro-vascular status should be promptly reported.

Treatment includes pain medication followed by early mobilization and bracing. If hospitalized, the patient is usually placed in a standard hospital bed with firm support from the mattress. The aim is to support the spinal column, relax muscles, and prevent any potential compression on nerve

roots. When turning, the patient should be taught to keep the spine straight by turning shoulders and pelvis together. Nursing assistance is necessary for the patient to learn the technique of "log rolling" (Figure 65-20). Several days after the initial injury, the physician may apply a specially constructed orthotic device (e.g., Milwaukee, Jewett, or Taylor brace), a jacket cast, or a removable corset if there is no evidence of neurological deficit.

Vertebral compression fractures (which are often caused by osteoporosis) can be treated with two outpatient procedures: vertebroplasty or kyphoplasty. *Vertebroplasty* uses radioimaging to guide the injection of bone cement into the fractured vertebral body. The cement (when hardened) serves to stabilize and prevent further vertebral compression. *Kyphoplasty* initially involves inserting a balloon into the vertebral body and then inflating it. This procedure creates a cavity that is filled with bone cement under low pressure. Kyphoplasty results in a lower leakage of bone cement when compared with vertebroplasty and helps restore the height of the vertebral body. Vertebroplasty and kyphoplasty result in improved healing, better pain relief, and decreased complications compared to conservative treatment (Asenjo & Rossel, 2012).

If the fracture is in the cervical spine, the patient may wear a hard cervical collar. Some cervical fractures are immobilized by use of a halo vest (see Chapter 63, Figure 63-9). The halo vest consists of a plastic jacket or cast fitted around the chest and attached to a halo that is held in place by skeletal pins inserted into the cranium. These devices immobilize the spine in the fracture area but allow patient mobility.

The patient is discharged after (1) regaining ambulation skills, (2) learning care of the cast or orthotic device, and (3) learning how to cope with the safety and security imposed by injury and treatment. Unstable vertebral fractures and spinal cord injuries are discussed in Chapter 63.

Facial Fractures

Any bone of the face can be fractured as a result of trauma, such as a motor vehicle accident, assault, or fall (Smith, Peek-Asa, Nesheim, et al., 2012). The primary concern after facial injury is to establish and maintain a patent airway and to provide adequate ventilation. Suctioning may be necessary. An alternative airway (tracheostomy) may be needed if a patent airway cannot be maintained.

Concurrent facial fractures and cervical spine injuries are common. All patients with facial injuries should be treated as if they have a cervical injury until proven otherwise by examination and imaging studies (e.g., CT scan, radiographs). Table 65-12 describes the clinical manifestations of common facial fractures.

TABLE 65-12

MANIFESTATIONS OF FACIAL FRACTURES

Fracture	Clinical Manifestation
Frontal bone	Rapid edema that may mask underlying fractures
Mandible	Tooth fractures, bleeding, limited motion of mandible
Maxilla	Segmental motion of maxilla and alveolar fracture of teeth
Nasal bone	Displacement of nasal bones, epistaxis
Periorbital bone	Possible frontal sinus involvement, entrapment of ocular muscles
Zygomatic arch	Depression of zygomatic arch and entrapment of ocular muscles

Associated soft tissue injury often makes assessment of a facial injury difficult. Oral and facial examinations are performed after the patient has been stabilized and any life-threatening situations have been treated. Careful assessment is made of the ocular muscles and cranial nerve involvement (cranial nerves III, IV, and VI) (Patrice & Hatch, 2011a). Radiographs are used to determine the extent of the injury. CT scanning helps differentiate between bone and soft tissue.

Injury to the eye should be suspected when a facial injury occurs, particularly if the injury is near the orbit. If an eye-globe rupture is suspected, the examination should be stopped and a protective shield should be placed over the eye. Signs of globe rupture include the extrusion of vitreous humor or brown tissue (iris or ciliary body) on the surface of the globe or penetrating through a laceration with an eccentric or teardrop-shaped pupil.

Specific treatment depends on the site and extent of the facial fracture and the associated soft tissue injury. Immobilization or surgical stabilization may be necessary. A patent airway and adequate nutrition must be maintained throughout the recovery period.

The nurse needs to be sensitive about the alterations in the patient's appearance that may occur after a facial fracture. The changes may be drastic. Edema and discoloration subside with time, but concurrent soft tissue injuries may result in permanent scarring.

Mandible Fracture

A fracture of the mandible may result from trauma to the face or the jaws. Maxillary fractures may also occur, but they are less common than mandibular fractures. The fracture may be closed, with no bone displacement, or it may involve loss of tissue and bone. The fracture may require immediate and sometimes long-term treatment to ensure survival and restore satisfactory appearance and function.

A mandibular fracture may also be therapeutically performed to correct an underlying malocclusion problem that cannot be corrected by orthodontic procedures alone. The mandible is resected during surgery and manipulated forward or backward, depending on the occlusion problem.

Surgery consists of immobilization, usually by wiring the jaws *(intermaxillary fixation).* Internal fixation may be done with screws and plates. In a closed fracture with no loss of teeth, the lower jaw is wired to the upper jaw. Wires are placed around the teeth, and then cross-wires or rubber bands are used to hold the lower jaw tight against the upper jaw (Figure 65-21). Arch bars may be placed on the maxillary and mandibular arches of the teeth. Vertical wires are placed between the arch bars holding the jaws together. If teeth are missing or bone is displaced, other forms of fixation, such as metal arch bars in the mouth or insertion of a pin in the bone, may be needed. Bone grafting may also be required. Immobilization is usually necessary for only 4 to 6 weeks because the fractures often heal rapidly.

FIGURE 65-21 Intermaxillary fixation. Source: Courtesy Weinstein, R. A., Denver, CO.

Nursing Management Mandibular Fracture

Nursing Implementation

Preoperative Management.

The patient undergoing mandibular surgery should be told preoperatively about the surgical procedure, including what it involves, how the face will look, and alterations caused by the surgery. The patient must be reassured about the ability to breathe normally, speak, and swallow liquids. Usually, hospitalization is brief unless there are other injuries or problems.

Postoperative Management.

Postoperative care should focus on a patent airway, oral hygiene, communication, pain management, and adequate nutrition. Two major potential problems in the immediate postoperative period are airway obstruction and aspiration of vomitus. Because the patient cannot open the jaws, measures to ensure an airway are essential. The nurse must observe for signs of respiratory distress (e.g., dyspnea; alterations in rate, quality, and depth of respirations). The patient should be placed on the side with the head slightly elevated immediately after surgery.

Wire cutters or scissors (for rubber bands) must be taped to the head of the bed and sent with the patient on all appointments and examinations away from the bedside. The wire cutter or scissors may be used to cut the wires or elastic bands in case of an emergency (e.g., cardiac arrest or respiratory distress) requiring access to the pharynx or lungs. Information, including a picture showing the appropriate wires to cut, should be included in the care plan. In some cases, cutting the wires may cause the entire facial and upper jaw structure to shift or collapse and worsen the problem. A tracheostomy or endotracheal tray should always be available.

If the patient begins to vomit or choke, the nurse should try to clear the mouth and airway either by (1) having the patient bend his or her head over or to the side to allow the vomitus to flow out of the mouth and nose or (2) using a suction catheter to clear the mouth and nose. When suctioning is necessary, it can be performed by the nasopharyngeal or oral route, depending on the extent of injury and the type of repair. A nasogastric tube may be used for decompression to remove fluids and gas from the stomach in an effort to help prevent aspiration. This technique also helps prevent vomiting. Antiemetic medications may also be administered.

Oral hygiene is an important part of the nursing care. The mouth should be rinsed frequently, particularly after meals and snacks, to remove food debris. Warm normal saline solution or water may be used. A soft, rubber

catheter or a Water-Pik is effective for a thorough oral cleansing. The nurse should inspect the mouth several times a day to see that it is clean. A flashlight is necessary, and a tongue depressor is used to retract the cheeks. The lips and corners of the mouth as well as the buccal mucosa should be kept moist. Dental wax may be used to cover any sharp edges of the wires to prevent irritation of the buccal mucosa.

Communication may be a problem, particularly in the early postoperative period. An effective way of communicating must be established preoperatively (e.g., use of dry erase board, pad and pencil). Usually, the patient can speak well enough to be understood, especially after the first few postoperative days.

Ingestion of sufficient nutrients poses a challenge because the diet must be liquid. The patient easily tires of sucking through a straw or laboriously using a spoon. The diet must be planned to include adequate calories, protein, and fluids. Liquid protein supplements may be helpful for improving the nutritional status. The nurse works with the dietitian and the patient to ensure adequate nutrition. The low-bulk, high-carbohydrate diet and the intake of air through the straw create a problem with constipation and flatus. Ambulation, prune juice, and bulk-forming laxatives may help relieve these problems.

Usually, the patient is discharged with the wires in place. The nurse should allow the patient to verbalize feelings about the altered appearance. Discharge teaching should include oral care, techniques of handling secretions, diet, how and when to use wire cutters, and when to notify the health care provider about concerns and problems.

Amputation

Major advances in surgical amputation techniques, prosthetic design, and rehabilitation programs are enabling people with amputations to return to productive and satisfying social roles. People in the middle and older-adult age groups have the highest incidence of amputation because of the effects of peripheral vascular disease (PVD), atherosclerosis, and vascular changes related to diabetes mellitus. Amputation in the younger population is usually secondary to trauma (e.g., motor vehicle accidents, land mines, farming-related injuries).

Clinical Indications

Most amputations are performed due to PVD, especially in older-adult patients with diabetes mellitus. These patients often experience peripheral

neuropathy that progresses to trophic ulcers and subsequent gangrene. Fifty percent of lower limb amputations in Ontario are related to diabetes (Canadian Association of Wound Care [CAWC], 2016). More than 4 000 individuals with diabetes had a limb amputation in 2006 (CAWC, 2016). Other common reasons for amputation are trauma and thermal injuries, tumours, osteomyelitis, and congenital limb disorders. Although pain is often present, it is not usually the primary reason for an amputation.

Diagnostic Studies

The types of diagnostic studies performed depend on the underlying problem that makes the amputation necessary (Table 65-13). Test results that show an elevated white blood cell count with abnormal differential may indicate infection. Vascular studies such as arteriography, Doppler studies, and venography provide information about the circulatory status of the extremity.

	• Coordination of prosthesis-fitting and gait-training activities
	• Coordination of muscle-strengthening and physiotherapy regimens

Collaborative Care

If amputation is to be considered “elective,” the patient's general health is carefully assessed. Chronic illnesses and the presence of infection are important considerations. The patient and family should be helped to understand the need for the amputation and be assured that rehabilitation can result in an active, useful life. If the amputation is done on an emergency basis as a result of trauma, the management is physically and emotionally more complicated.

The goal of amputation surgery is to preserve extremity length and function while removing all infected, pathological, or ischemic tissue. (Levels of amputation of upper and lower extremities are illustrated in Figure 65-22.) The type of amputation depends on the reason for the surgery. A closed amputation is performed to create a weight-bearing *residual limb.* An anterior skin flap with dissected soft tissue padding covers the bony part of the residual limb. The skin flap is sutured posteriorly so that it will not be positioned in a weight-bearing area. Special care is necessary to prevent accumulation of drainage, which can produce pressure and harbour bacteria that may cause infection.

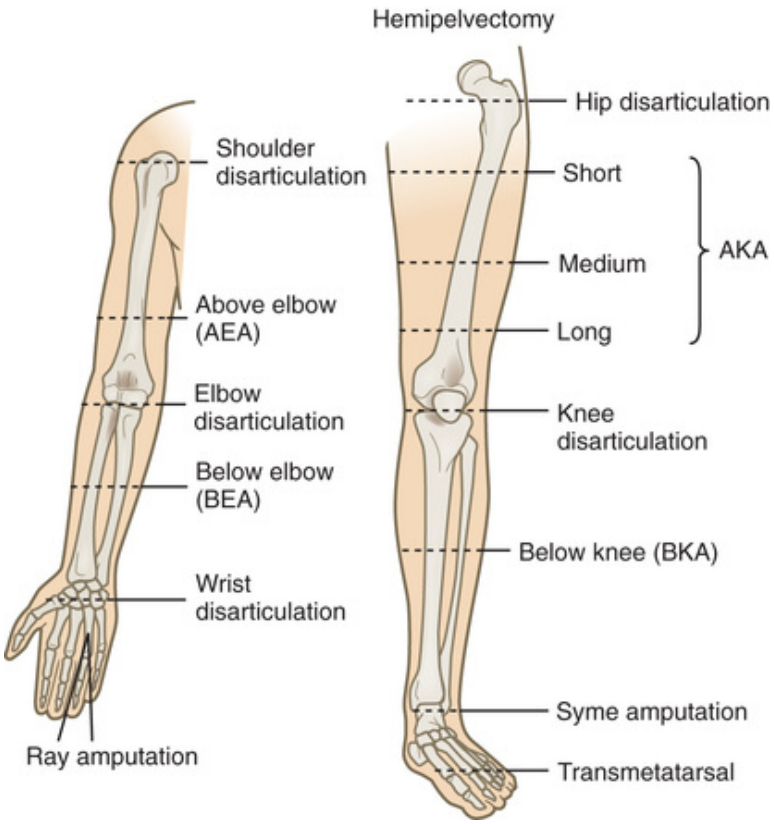

FIGURE 65-22 Location and description of amputation sites of the upper and lower extremities. *AKA*, above-the-knee amputation.

Disarticulation is an amputation performed through a joint. A *Syme amputation* is a form of disarticulation at the ankle. An open amputation leaves a surface on the residual limb that is not covered with skin. This type of surgery is generally indicated for control of actual or potential infection. The wound is usually closed later by a second surgical

procedure or by skin traction surrounding the residual limb. This type of amputation is often called a "guillotine amputation."

Nursing Management Amputation

Nursing Assessment

Pre-existing illnesses must be adequately assessed because most amputations are performed as a result of vascular problems. Assessment of the vascular and neurological status is an important part of this assessment process (see Chapters 34 and 58).

Nursing Diagnoses

Nursing diagnoses for the patient with an amputation may include, but are not limited to, the following:

- *Disturbed body image* related to *alteration in self-perception* (amputation, impaired mobility)
- *Impaired skin integrity* related to *pressure over bony prominence* (improperly fitted prosthesis)
- *Chronic pain* related to *emotional distress, nerve compression* (phantom limb sensation/pain)
- *Impaired physical mobility* related to *pain, physical deconditioning* (amputation of lower limb)

Planning

The overall goals are that the patient with an amputation will (1) have adequate relief from the underlying health problem, (2) have satisfactory pain control, (3) reach maximum rehabilitation potential with the use of a prosthesis (if indicated), (4) cope with the body image changes, and (5) make satisfying lifestyle adjustments.

Nursing Implementation

Health Promotion.

Control of causative illnesses such as PVD, diabetes mellitus, chronic osteomyelitis, and pressure injuries can eliminate or delay the need for amputation. Patients with these problems should be taught to carefully examine their lower extremities daily for signs of potential problems. If the patient cannot assume this responsibility, a caregiver should be instructed in the procedure. Patients and their caregiver should be instructed to report problems such as a change in skin colour or temperature, decrease or absence of sensation, tingling, pain, or the presence of a lesion to the health care provider.

Instruction in proper safety precautions in recreation and in the performance of hazardous work is an important nursing responsibility, especially for occupational health nurses.

Acute Intervention.

The nurse must recognize the tremendous psychological and social implications of an amputation for the patient. The disruption in body image caused by an amputation often causes a patient to go through psychological stages similar to the grieving process (see Chapter 13). Allowing the patient to go through a grieving process or period of depression and recognizing it as a normal consequence may do much to aid the patient's acceptance of the amputation. The patient's family must also be helped to work through the process to arrive at a realistic and positive attitude about the future. The reasons for an amputation and the rehabilitation potential depend on age, diagnosis, occupation, personality, resources, and support systems.

Preoperative Management.

Before surgery, the nurse should reinforce information that the patient and family have received about the reasons for the amputation, the proposed prosthesis, and the mobility training program. To meet the patient's educational needs, the nurse must know the level of amputation, the type of postsurgical dressing to be applied, and the type of prosthesis to be utilized. The patient should receive instruction in the performance of upper extremity exercises such as push-ups in bed or the wheelchair to promote arm strength. This instruction is essential for later crutch walking and gait training. General postoperative nursing care should be discussed, including positioning, support, and residual limb care. If a compression bandage is to be used after surgery, the patient should be instructed about its purpose and how it will be applied. If an immediate prosthesis is planned, the general ambulation program should be discussed.

The patient should be warned that she or he may feel as though the amputated limb is still present after surgery. This phenomenon is termed **phantom limb sensation** (any sensation of the missing limb except pain). Different sources have reported the incidence of phantom limb sensation as anywhere between 60% and 100% of individuals with amputations (Jerath, Crawford, & Jenson, 2015). This sensation can cause patients grave concern unless they are forewarned. It can take various forms, such as the feeling that someone is touching the missing limb, pressure on the missing limb, cold, wetness, itching, tickle, or fatigue (Magee, 2013). Recent studies suggest that 60% to 80% of people with amputations may also experience *phantom limb pain* (any painful sensations that are referred to the absent limb), which often begins immediately after surgery. The pain can be described as shooting, burning, crushing, or severe and agonizing (Chapman, 2011). It is more common for the pain to be intermittent, with short episodes (seconds to minutes) of severe pain occurring several times a day. There is some evidence that the pain present preoperatively may be mimicked in the phantom limb. Often, the patient may be extremely anxious about this pain because the patient knows the limb is gone but still feels pain in it. As recovery and ambulation progress, phantom limb sensation and pain usually subside, although the pain may become chronic.

Postoperative Management.

General postoperative care for the patient who has had an amputation depends largely on the patient's general state of health, the reason for the amputation, and the patient's age. Individuals who undergo amputation as a result of a traumatic injury need to be monitored for post-traumatic stress disorder because they had no time to prepare or perhaps even participate in the decision to have a limb amputated.

Prevention and detection of complications are important nursing responsibilities during the postoperative period. Careful monitoring of the patient's vital signs and dressing can alert the nurse to hemorrhage in the operative area. Careful attention to sterile technique during dressing changes reduces the potential for wound infection.

If an *immediate* postoperative prosthesis has been applied, the nurse must monitor vital signs carefully because the surgical site is heavily covered and may not be visible. A surgical tourniquet must always be available for emergency use. If excessive bleeding occurs, the surgeon should be notified immediately.

The *delayed* prosthetic fitting may be the best choice for patients who have had amputations above the knee or below the elbow, older adults, individuals who are debilitated, and those with infection. The appropriate time for use of a prosthesis depends on satisfactory healing of the residual limb as well as on the general condition of the patient. A temporary prosthesis may be used for partial weight bearing once the sutures are removed. Barring any problems, patients can bear full weight on permanent prostheses by approximately 3 months after their amputation.

Not all patients are candidates for a prosthesis. People who are seriously ill or debilitated may not have the upper body strength and energy required to use a lower extremity prosthesis. Mobility with a wheelchair may be the most realistic goal for patients who are not candidates for prostheses.

Often, patients may be extremely anxious about phantom limb sensation because they still perceive pain in the missing portion of the limb. As recovery and ambulation progress, phantom limb sensation and pain usually subside, although the pain may become chronic. The patient may also complain of shooting, burning, or crushing pain and feelings of coldness, heaviness, and cramping,

Mirror therapy reduces phantom limb sensation and pain in some patients (Rothgangel, Brau, Beurskens, et al., 2011) (Figure 65-23). The mirror is thought to provide visual information to the brain, replacing the sensory feedback expected from the missing limb. However, it is unknown why looking in the mirror at the unaffected limb would decrease phantom limb sensation and pain. Mirror therapy may also improve patient functioning after a stroke.

FIGURE 65-23 A physiotherapist demonstrates mirror therapy, a type of treatment that may reduce phantom limb sensation and pain.

Success of the rehabilitative program depends on the physical and emotional health of the patient. Chronic illness and deconditioning complicate aggressive rehabilitation efforts. Both physiotherapy and occupational therapy must be an integral component of the patient's overall plan of care.

Flexion contractures may delay the rehabilitation process. The most common and debilitating contracture is hip flexion. Hip adduction contracture is rare. Patients should avoid sitting in a chair for more than 1 hour with hips flexed, or having pillows under the surgical extremity, to prevent flexion contractures. Unless specifically contraindicated, patients should lie on their abdomen for 30 minutes, three to four times each day, and position the hip in extension while prone.

Proper residual limb bandaging fosters shaping and moulding for eventual prosthesis fitting (Figure 65-24). The physician usually orders a compression bandage to be applied immediately after surgery to support the soft tissues, reduce edema, hasten healing, minimize pain, and promote residual limb shrinkage and maturation. This bandage may be an elastic roll applied to the residual limb or a residual limb shrinker, which is an elastic stocking that fits tightly over the residual limb and lower trunk area.

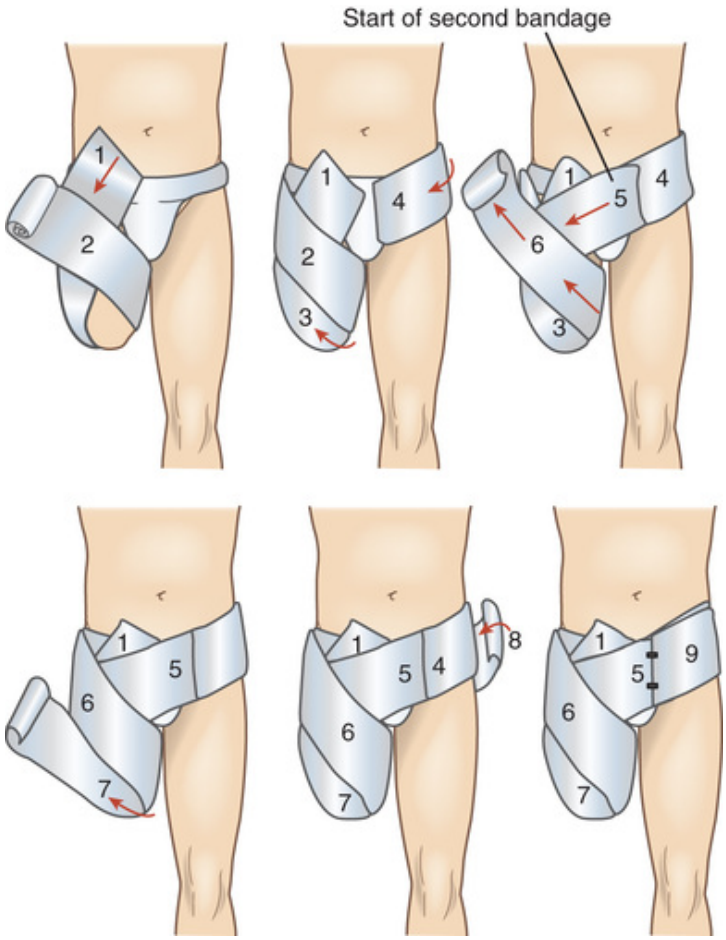

FIGURE 65-24 Bandaging for the above-the-knee amputation residual limb. Figure-of-eight style covers progressive areas of the residual limb. Two elastic wraps are required.

The compression bandage is initially worn at all times except during physiotherapy and bathing. The bandage is taken off and reapplied several times daily, and care is taken so that it is applied snugly but not so tightly as to interfere with circulation. Shrinker bandages should be washed and changed daily. After healing has occurred, the residual limb is bandaged only when the patient is not wearing the prosthesis. The patient should be instructed to avoid dangling the residual limb over the bedside to minimize edema formation.

As the patient's overall condition improves, an exercise regimen is normally started under the supervision of the health care provider and the physiotherapist. Active ROM exercises of all joints should be started as soon after surgery as the patient's pain level and medical status permit. In preparation for mobility, the patient should increase triceps and shoulder strength and lower limb support and learn balance of the altered body.

The loss of the weight of a limb necessitates adaptation of the patient's proprioceptive and coordination mechanisms to prevent falls and injury.

Crutch walking is started as soon as patients are physically able. After an immediate postsurgical fitting, orders related to weight bearing must be carefully followed to avoid injury to the skin flap and delay of the healing process. Before discharge, the patient and caregiver need careful instruction related to residual limb care, ambulation, prevention of contractures, recognition of complications, exercise, and follow-up care. Table 65-14 outlines patient and caregiver teaching following an amputation.

TABLE 65-14
PATIENT & CAREGIVER TEACHING GUIDE
Following an Amputation

After an amputation, patient and caregiver teaching should include the following information.

- Inspect the residual limb daily for signs of skin irritation, especially erythema, excoriation, and odour. Pay particular attention to areas prone to pressure.
- Discontinue use of the prosthesis if an irritation develops. Have the area checked before resuming use of the prosthesis.
- Wash residual limb thoroughly each night with warm water and a bacteriostatic soap. Rinse thoroughly and dry gently. Expose the residual limb to air for 20 min.
- Do not use any substance such as lotions, alcohol, powders, or oil on the residual limb unless prescribed by the health care provider.
- Wear only a residual limb sock that is in good condition and supplied by the prosthetist.
- Change residual limb sock daily. Launder in a mild soap, squeeze, and lay flat to dry.
- Use prescribed pain management techniques.
- Perform ROM to all joints daily. Perform general strengthening exercises, including the upper extremities, daily.
- Do not elevate the residual limb on a pillow.
- Lay prone with hip in extension for 30 min., three to four times daily.

ROM, range of motion.

Ambulatory and Home Care.

When healing has occurred satisfactorily and the residual limb is well moulded, the patient is ready for fitting of a prosthesis. A prosthetist initially makes a mould of the residual limb and measures landmarks for fabrication of the prosthesis. The moulded limb socket allows the residual limb to fit snugly into the prosthesis. The limb is covered with a stocking to ensure good fit and prevent skin breakdown. The limb may continue to shrink, causing a loose fit, in which case a new socket has to be fabricated. The patient may need to have the prosthesis adjusted to prevent rubbing and friction between the residual limb and the socket. Excessive movement of a loose prosthesis can cause severe skin irritation and breakdown.

Artificial limbs become an integral part of the patient's body image. Proper care ensures their long life and useful functioning. The patient should be instructed to clean the prosthesis socket daily with a mild soap and rinse thoroughly to remove irritants. The leather and metal parts of the prosthesis should not get wet. The patient should be encouraged to have regular maintenance of the prosthesis. Consideration of the condition of the shoe is also necessary. A badly worn shoe alters the gait and may cause damage to the prosthesis.

Special Considerations in Upper-Limb Amputation.

The emotional implications of an upper limb amputation are often more devastating than those for lower limb amputation. The enforced dependency brought about by one-handedness may be both frustrating and humiliating to the patient. Because most upper extremity amputations result from trauma, often, the patient has not had the opportunity to adjust psychologically to an amputation or to participate in the decision-making process about amputation.

Both immediate and delayed prosthetic fittings are possible for the person with a below-the-elbow amputation. Prosthetic fitting is delayed for the person with an above-the-elbow amputation. The usual functional prosthesis is the arm and hook. A cosmetic hand is available but has limited functional value. As with the lower limb prosthesis, patient motivation and endurance are major factors contributing to a satisfactory outcome. Technological advances to improve the functionality of upper limb prostheses are an active area of research (Velez & Dellefield, 2011). Many companies are also experimenting with 3D printing to make less expensive prosthetic limbs that also take less time to develop and produce.

Evaluation

The following are expected outcomes for the patient with an amputation:

- Accept changed body image and integrate changes into his or her lifestyle
- Have no evidence of skin breakdown
- Have reduction or absence of pain
- Become mobile within limitations imposed by amputation

Age-Related Considerations

Amputation

If a lower limb amputation has been performed on an older adult, the patient's previous ability to ambulate may affect the extent of recovery. Use of a prosthesis requires a significant amount of energy for ambulation. Walking with a below-the-knee prosthesis requires 40% additional energy, and an above-the-knee prosthesis requires 60% more energy than walking on two legs. Older adults whose general health is weakened by disorders such as cardiac or pulmonary problems may not be candidates for prosthesis use. These patients' ability to ambulate will be limited. If possible, this should be discussed with patients and their families before surgery so that realistic expectations can be set.

Common Joint Surgical Procedures

Surgery plays an important role in the treatment and rehabilitation of patients with various forms of joint disease. Surgery is aimed at relieving chronic pain, improving joint motion, correcting deformity and malalignment, and removing intra-articular erosion. Joint replacement surgery is the most common orthopaedic operation performed on older adults. If decreased functional ability of the joint is not corrected, contractures with permanent limitation of motion often occurs. Limitation of motion at the joint can be demonstrated on physical examination and by joint-space narrowing on radiological examination.

Indications for hip or knee arthroplasty include arthritis, connective tissue disease, failed prior procedures, sepsis, tumours, Paget's disease, congenital hip dysplasia, severe varus or valgus deformity, and spondyloarthropathies.

Types of Joint Surgeries

Synovectomy

Synovectomy (removal of synovial membrane) is used as a prophylactic measure and as a palliative treatment of RA. Removal of the synovial membrane, thought to be the location of the basic pathological changes in joint destruction, helps prevent further progression of joint damage. A synovectomy is best performed early in the disease process to prevent serious destruction of joint surfaces. Removal of the thickened synovium prevents extension of the inflammatory process into the adjacent cartilage, ligaments, and tendons.

It is impossible to surgically remove all the synovium in a joint. The underlying disease process is still present and will again affect the regenerating synovium. However, the disease appears to be milder after synovectomy, and definite improvement in pain, weight bearing, and ROM can be expected. Common sites for this surgery include the elbow, wrist, and fingers. Synovectomy in the knee is done less frequently because knee joint replacement techniques are usually performed.

Osteotomy

An **osteotomy** is performed by removing or adding a wedge or slice of bone to change alignment (joint and vertebral) and to shift weight bearing,

thereby correcting deformity and relieving pain. Cervical osteotomy may be used to correct deformity in some patients with ankylosing spondylitis. Halo and body jackets are worn until fusion occurs (at 3–4 months). Subtrochanteric or femoral osteotomy may provide some relief of pain and improve motion in selected patients with hip osteoarthritis (OA). Osteotomy has proved ineffective in patients with inflammatory joint disease. Osteotomy of the knee (tibia) provides relief of pain in selected patients, but advanced joint destruction is usually corrected by joint replacement surgery.

The postoperative care for osteotomy is similar to the treatment of an internal fixation of a fracture at a comparable site (see pp. 1644–1648). Internal wires, screws and plates, bone grafts, or an external fixator usually fix the bone in place.

Debridement

Debridement is the removal of degenerative debris such as loose bodies, osteophytes, joint debris, and degenerated menisci from a joint. This procedure is usually performed on the knee or the shoulder, using a fibreoptic arthroscope. Usually, the procedure is done on an outpatient basis. A compression dressing is applied postoperatively. Weight bearing is permitted following knee arthroscopy. Patient education includes monitoring for signs of infection, managing pain, and restricting excessive activity for 24 to 48 hours.

Arthroplasty

Arthroplasty is the reconstruction or replacement of a joint to relieve pain, improve or maintain ROM, and correct deformity. There were 49 503 hip and 60 136 knee replacements in Canada for 2013–2014 (a 19.1% increase in hip replacements and a 22.9% increase in knee replacements since 2009–2010) (CIHI, 2015).

Reducing wait times for hip and knee replacement surgeries is a top health care priority in Canada. All provinces are now collecting and reporting wait time data for joint replacements through the Canadian Joint Replacement Registry (CIHI, 2016). In 2015, at least three out of four patients received their hip and knee replacement surgery within the benchmark time frame (182 days or 26 weeks). The median wait time in Canada for a knee replacement was 104 days and for hip replacement, 86 days, compared to 157 and 121 days, respectively, using international comparative data. Wait times across Canada for hip and knee

replacements were stable from 2011 to 2015, but wait times varied considerably among provinces and territories (CIHI, 2016).

The most common uses of arthroplasty are for patients with OA, RA, AVN, congenital deformities or dislocations, and other systemic problems. There are several types of arthroplasty, including surgical reshaping of the bones of the joints, replacement of part of a joint *(hemiarthroplasty),* and total joint replacement. Replacement arthroplasty is available for elbow, shoulder, phalangeal joints of the fingers, wrist, hip, knee, ankle, and foot.

Minimally invasive surgery is available in many centres in Canada for hip and knee replacements. Minimally invasive surgery involves less dissection and smaller incisions (5 to 10 cm in the hip and 10 to 12.7 cm in the knee) and a shorter hospital stay. It is technically demanding and requires extra training for the surgeon. There is an initial quicker recovery with less rehabilitation and a quicker return to ADLs for the patient. Minimally invasive surgery also results in less blood loss and less need for transfusions.

Hip Arthroplasty.

Total hip arthroplasty (THA) provides significant relief of pain and improvement of function for patients with OA, RA, and other conditions. Partial and total hip replacements are also used to treat hip fractures.

In THA, the prosthesis (implant) replaces the ball and socket joint and upper shaft of the femur (see Figure 65-19). The socket can be "cemented" in place with polymethyl methacrylate, which bonds to the bone. The socket may also be inserted and not cemented ("cementless"). Cementless THAs may provide longer-term prosthesis stability by facilitating biological ingrowth of new bone tissue into the porous surface coating of the prosthesis. Although some surgeons use cementless devices for all patients, they are most often recommended for younger, more active patients and patients with good bone quality, where bone ingrowth into the components can be readily achieved.

The nursing care for a patient who has a THA is discussed in the section on nursing management of a patient with a hip fracture, on pp. 1652–1655.

Hip Resurfacing.

An alternative to hip replacement is hip resurfacing, which allows the femoral head to be preserved and reshaped rather than replaced. (In contrast, in a THA, the prosthesis replaces the femoral head.) The resurfaced femoral head (ball) is then capped by a metal prosthesis. The metal appears to have a lower rate of wear, and thus the prosthesis may

have a longer lifetime. Hip resurfacing is a more favourable option for younger, active patients. After surgery, there is generally a 6-month waiting period before strenuous activity, until strong muscles are built around the joint. Patients receiving a smaller femoral head (including many women) have a higher failure rate with a resurfaced implant when compared with patients receiving a THA (Smith, Dieppe, & Howard, et al., 2012).

Knee Arthroplasty.

Unremitting pain and instability as a result of severe destructive deterioration of the knee joint is the main indication for total knee arthroplasty (TKA) or total knee replacement (TKR) (Bartlett, 2012). Osteoporosis may necessitate bone grafting to augment defects and to correct bone deficiencies. Either part or all of the knee joint may be replaced with a metal and plastic prosthetic device. A compression dressing is used to immobilize the knee in extension immediately after the operation. This is usually removed within 24 hours and may be replaced with a knee immobilizer such as a Zimmer immobilizer splint or posterior plastic shell, which stabilizes the knee and maintains extension during ambulation and at rest for about 4 weeks. Knee immobilizers are removed for various portions of physiotherapy. Dislocation is not typical with TKA.

After surgery, an emphasis is placed on physiotherapy. Isometric quadriceps setting begins the first day after surgery. The patient progresses to straight-leg raises and gentle ROM to increase muscle strength and obtain 90-degree knee flexion. Active flexion exercises or passive flexion exercises through the use of a continuous passive motion (CPM) machine postoperatively may promote joint mobility. Full weight bearing is begun before discharge. An active home-exercise program involves progressive ROM with muscle strengthening, and flexibility exercises. Following TKA, many older-adult patients with advanced OA have shown significant improvement in mobility, motor function tests, and ability to complete daily tasks.

Finger Joint Arthroplasty.

A silicone rubber arthroplastic device is used to help restore function in the fingers of the patient with RA. Ulnar deviation is often present, which results in severe functional limitations of the hand. The goal of hand surgery is primarily to restore function related to grasp, pinch, stability, and strength rather than to correct cosmetic deformity. Before surgery, the

patient is instructed in hand exercises, including flexion, extension, abduction, and adduction of the fingers.

Postoperatively, the hand is kept elevated with a bulky dressing in place. Neuro-vascular assessment is conducted postoperatively, and the nurse assesses for signs of infection. The success of the surgery depends largely on the postoperative treatment plan, which is often carried out under the direction of an occupational therapist. Once the dressing is removed, a guided splinting program is initiated. The patient is discharged with splints to use while sleeping and hand exercises to perform for 10 to 12 weeks, at least three or four times a day. The patient is also instructed to avoid lifting heavy objects.

Elbow and Shoulder Arthroplasty.

Although available, total replacement of elbow and shoulder joints is not as common as other forms of arthroplasty. Shoulder replacements are used in patients with severe pain because of RA, OA, AVN, or a previous trauma. The shoulder replacement is usually considered if the patient has adequate surrounding muscle strength and bone stock. If joint replacement is necessary for both elbow and shoulder, the elbow is usually done first because a severely painful elbow interferes with the shoulder rehabilitation program.

Significant pain relief has been achieved following arthroplasty, with most patients having no pain at rest or minimal pain with activity. Functional improvements have resulted in better hygiene and increased ability to perform ADLs in most patients. Rehabilitation is longer and more difficult than with other joint surgeries.

Ankle Arthroplasty.

Total ankle arthroplasty (TAA) is indicated for RA, OA, AVN, and trauma. Although the use of TAA is not widespread, it is becoming a viable alternative to fusion for the treatment of advanced ankle arthritis in selected patients. Devices available include several fixed-bearing devices and a mobile-bearing "cementless" prosthesis. This device more closely imitates natural ankle function.

Ankle fusion is often selected over arthroplasty, although TAA volume has increased dramatically over the past decade (Marx & Mizel, 2015). However, the patient is left with a stiff foot and the inability to change heel height. TAA is advantageous because it achieves a more normal gait pattern (Marx & Mizel, 2015). Postoperatively, the patient may not bear weight for 6 weeks, must elevate the extremity to reduce and prevent

edema, must be extremely careful to prevent postoperative infection, and must maintain immobilization as directed by the physician.

Arthrodesis

Arthrodesis is the surgical fusion of a joint. This procedure is indicated only if articular surfaces are too severely damaged or infected to allow joint replacement or if reconstructive surgery fails. Arthrodesis relieves pain and provides a stable but immobile joint. The fusion is usually accomplished by removal of the articular hyaline cartilage and the addition of bone grafts across the joint surface. The affected joint must be immobilized until bone healing has occurred. Common areas of fusion are wrist, ankle, cervical spine, lumbar spine, and metatarsophalangeal (MTP) joint of the great toe.

Complications of Joint Surgery

Infection is a serious complication of joint surgery, particularly joint replacement surgery (Bartlett, 2012). The most common causative organisms are Gram-positive aerobic streptococci and staphylococci. Infection almost always leads to pain and loosening of the prosthesis, generally necessitating extensive surgery. Efforts to reduce the incidence of infection include the use of specially designed self-contained operating suites, operating rooms with laminar airflow, and prophylactic antibiotic administration. Current recommendations for perioperative antibiotic prophylaxis in elective joint arthroplasty include stopping therapy after 24 hours (Gutowski, Parvizi, & Purtill, 2014).

Thrombo-embolism is another potentially serious complication after joint surgeries, particularly those involving the lower extremities. Prophylactic measures such as warfarin, LMWH, and sequential compression devices of the legs are usually instituted. Patients may be followed postoperatively with venous Doppler ultrasonography to detect DVT, the source of most pulmonary emboli.

Collaborative Care

Preoperative Management.

The primary goal of preoperative assessment is to identify risk factors associated with postoperative complications so that nursing strategies can be implemented to promote optimal positive outcomes. A careful history

will include previous medical diagnoses and complications such as diabetes and thrombo-phlebitis, pain tolerance and management preferences, current functional status and expectations following surgery, and level of social support and home care needs after discharge. The patient should be free from evidence of infection and acute joint inflammation.

If lower extremity surgery is planned, upper extremity muscle strength and joint function are assessed to determine the type of assistive devices needed postoperatively for ambulation and ADLs. Preoperative teaching informs the patient and family of the expected hospital course and postoperative management at home. In addition, it prepares them to maximize the usefulness and longevity of the prosthesis. Patients also need to realize that recovery does not happen quickly. Both patients and their families or significant others need to speak with individuals who have had a total joint arthroplasty to better understand the reality of rehabilitation.

Postoperative Management.

Postoperatively, neuro-vascular assessment is performed to assess nerve function and circulatory status. Anticoagulation therapy, analgesia, and parenteral antibiotics are administered. In general, the affected joint is exercised, and ambulation is encouraged as early as possible to prevent complications of immobility. Specific protocols vary according to patient, type of prosthesis, and surgeon preference. Pain management postoperatively may use epidural or intrathecal analgesia, femoral nerve block (knee only), patient-controlled analgesia (PCA), intravenous injections, and oral opioids or NSAIDs.

The hospital stay after arthroplasty is 3 to 5 days, depending on the patient's course and need for physiotherapy. Physiotherapy and ambulation enhance mobility, build muscle strength, and reduce the risk for thrombus formation. If the patient is taking warfarin, therapy starts on the day of surgery and continues for 3 weeks with an international normalized ratio (INR) done on a regular basis. For those taking LMWH (e.g., enoxaparin), therapy starts after surgery and continues for 2 weeks postoperatively. Daily monitoring of the patient's coagulation status is not necessary with LMWH.

Nursing Management Joint Surgery

The nursing management of the patient undergoing joint surgery begins with preoperative teaching and realistic goal setting. It is important that the patient understands and accepts the limitations of the proposed surgery and realizes that in some cases surgery will not remove or treat the underlying disease. Postoperative procedures such as turning, deep breathing, use of a bedpan and high bedside commode, and use of abductor pillows should be explained and opportunities for practice provided. The patient should be reassured that pain relief will be available. PCA can be helpful. A preoperative visit from a physiotherapist allows practice of postoperative exercises and measurement for crutches or other assistive devices.

Discharge planning begins immediately on admission to the hospital. The duration of the hospital stay and the expected postoperative events should be discussed because the patient and caregiver must prepare ahead. The home environment must be assessed for safety (e.g., presence of scatter rugs and electrical cords) and accessibility. Are the bathroom and bedroom on the first floor? Are door frames wide enough to accommodate a walker? Social support must also be assessed. Is a friend or family member available to assist the patient in the home, or will the patient need extra assistance? Will the patient require a homemaker or meal services? The older-adult patient may need the rehabilitation services of a subacute or long-term care facility for a few weeks postoperatively to progressively develop independent living skills. Specific nursing interventions related to the patient having orthopaedic surgery are summarized in NCP 65-2, available on the Evolve website.

Patient teaching includes instructions on reporting complications, including infection (e.g., fever, increased pain, drainage) and dislocation of the prosthesis (e.g., pain, loss of function, shortening or misalignment of an extremity). The home care nurse acts as the liaison between the patient and the surgeon, monitoring for postoperative complications, assessing comfort and ROM, and facilitating improvements in functional performance.

Case Study

Hip Fracture Surgery

Source: And-One/Shutterstock.com.

Patient Profile

Terry King is a 78-year-old man admitted to the hospital through the emergency department. It appears that he may have sustained a fracture to his left hip (see Chapter 64 case study). He is scheduled for a surgical hip repair in the morning.

Subjective Data

See the case study in Chapter 64.

Collaborative Care

Preoperative

- Pain not relieved by morphine.
- Accompanying Mr. King is his wife of 40 years, who is crying and anxious. Her anxiety is also causing Mr. King to become anxious.

Operative Procedure

Left hip repair using hip compression plate and bone screws

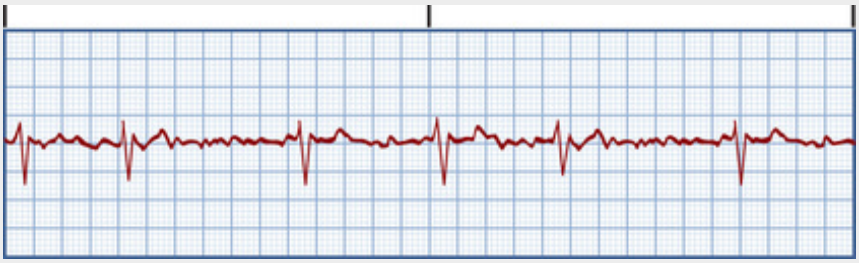
Postoperative

- Cefazolin 1g IV q8hr
- Intake and output for 48 hr
- Morphine via patient-controlled analgesia (PCA) pump

Discussion Questions

1. How do Mr. King's pre-existing medical conditions predispose him to postoperative complications?

2. What actions could be taken to help decrease his wife's anxiety?
3. ***Priority decision:*** As care is planned for Mr. King, what are the preoperative and postoperative priority nursing interventions?
4. What are the most likely postoperative complications that Mr. King could develop?
5. ***Priority decision:*** On assessment of Mr. King on the second postoperative day, an irregular pulse is noted, which is a new finding. The pulse rate is 66 and the ECG tracing is shown below. Which dysrhythmia is this? What is the priority action at this time?



6. ***Priority decision:*** What are the priority teaching interventions that should be done before discharge?
7. ***Evidence-informed practice:*** Why is satisfactory pain relief an important nursing goal in the postoperative period for Mr. King?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. When would the nurse suspect an ankle sprain for the client being seen at the urgent care centre?
   a. Client was hit by another soccer player on the field.
   b. Client has ankle pain after sprinting around the track.
   c. Client dropped a 4.5-kg weight on his lower leg at the health club.
   d. Client had a twisting injury while running bases during a baseball game.
2. The nurse explains to a client with a distal tibial fracture returning for a 3-week checkup that healing is indicated by which of the following?
   a. Callus formation
   b. Complete bony union
   c. Hematoma at the fracture site
   d. Presence of granulation tissue
3. A client with a comminuted fracture of the femur is to have an open reduction with internal fixation (ORIF) of the fracture. In which of the following situations is an ORIF indicated?
   a. The client is able to tolerate prolonged immobilization.
   b. The client cannot tolerate the surgery for a closed reduction.
   c. A temporary cast would be too unstable to provide normal mobility.
   d. Adequate alignment cannot be obtained by other nonsurgical methods.
4. Which of the following indicates a neuro-vascular problem during the nurse's assessment of a client with a fracture?
   a. Exaggeration of extremity movement
   b. Increased redness and heat below the injury
   c. Decreased sensation distal to the fracture site
   d. Purulent drainage at the site of an open fracture
5. A client with a stable, closed fracture of the humerus caused by trauma to the arm has a temporary splint with bulky padding applied with an elastic bandage. For which of the following symptoms would the nurse suspect compartment syndrome and notify the physician?

a. Increasing edema of the limb
b. Muscle spasms of the lower arm
c. Rebounding pulse at the fracture site
d. Pain when passively extending the fingers

6. Which of the following symptoms should the nurse be monitoring for, in a client with pelvic fracture?
   a. Changes in urinary output
   b. Petechiae on the abdomen
   c. A palpable lump in the buttock
   d. Sudden increase in blood pressure
7. During the postoperative period, what should the client with an above-the-knee amputation be told about the problem of routinely elevating the residual limb?
   a. The flexed position can promote hip flexion contracture.
   b. This position reduces the development of phantom pain.
   c. This position promotes clot formation at the incision site and thigh.
   d. Unnecessary movement of the extremity can cause wound dehiscence.
8. A client with rheumatoid arthritis is scheduled for an arthroplasty. How should the nurse explain the purpose of this procedure? *(Select all that apply)*
   a. To fuse the joint
   b. To replace the joint
   c. To prevent further damage
   d. To improve or maintain ROM
   e. To decrease the amount of destruction in the joint
9. What should the nurse teach a client recovering from a total hip replacement to avoid?
   a. Sleeping on the abdomen
   b. Sitting with the legs crossed
   c. Abduction exercises of the affected leg
   d. Bearing weight on the affected leg for 6 weeks

1. d; 2. a; 3. d; 4. c; 5. d; 6. a; 7. a; 8. b, d; 9. b.

CHAPTER 66

Nursing Management

Musculo-Skeletal Problems

Written by, Matthew C. Price

Adapted by, Jacqueline Klemann

LEARNING OBJECTIVES

1. Describe the pathophysiology, clinical manifestations, collaborative care, and nursing management of patients with osteomyelitis.
2. Describe the types, pathophysiology, clinical manifestations, and collaborative care of patients with bone cancer.
3. Differentiate between the causes and characteristics of acute and chronic low back pain.
4. Explain the conservative and surgical therapy of patients with herniated intervertebral disc.
5. Describe the postoperative nursing management of a patient who has undergone spinal surgery.
6. Explain the etiology and the nursing management of patients with common foot disorders.
7. Describe the etiology, pathophysiology, clinical manifestations, and collaborative and nursing management of patients with osteoporosis and Paget's disease.

KEY TERMS

Acute and chronic musculo-skeletal problems are a common source of pain and disability. A variety of problems unrelated to trauma that affect the musculo-skeletal system are presented in this chapter, including osteomyelitis, bone cancer, foot disorders, and metabolic bone diseases. Management of the patient with both acute and chronic low back pain is addressed, and spinal surgery is discussed as an intervention for a herniated disc. Throughout the discussion of all of these problems, the nurse's role in prevention of injury and maintenance of mobility is emphasized.

Osteomyelitis

Etiology and Pathophysiology

Osteomyelitis is a severe infection of the bone, bone marrow, and surrounding soft tissue. The most common infecting microorganism is *Staphylococcus aureus.* A variety of microorganisms can cause osteomyelitis (Matteson & Osmon, 2016) (Table 66-1). Aerobic Gram-negative bacteria, alone or mixed with Gram-positive organisms, are often found. The widespread use of antibiotics in conjunction with surgical treatment has significantly reduced the mortality rate and complications associated with osteomyelitis.

TABLE 66-1

Organisms Causing Osteomyelitis

Organism	Predisposing Problem
Staphylococcus aureus	Pressure injury, penetrating wound, open fracture, orthopaedic surgery, vascular insufficiency disorders (e.g., atherosclerosis; diabetes)
Staphylococcus epidermidis	Indwelling prosthetic devices (e.g., joint replacements, fracture fixation devices)
Streptococcus viridans	Abscessed tooth, gingival disease
Escherichia coli	Urinary tract infection
Mycobacterium tuberculosis	Tuberculosis
Neisseria gonorrhoeae	Gonorrhea
Pseudomonas species	Puncture wounds, intravenous drug use
Salmonella species	Sickle cell disease
Fungi, Mycobacteria species	Immuno-compromised host

The infecting microorganisms can invade by indirect or direct entry. The *indirect (hematogenous) entry* of microorganisms most frequently affects children because the metaphyseal (growing) regions of long bones are highly vascular and susceptible to even minor trauma. Adults with vascular insufficiency disorders (e.g., caused by diabetes mellitus), genito-urinary or respiratory infections are at higher risk for a primary infection to spread via the blood to the bone. The pelvis and the vertebrae, which consist of vascular-rich bone, are the most common sites of infection.

Direct-entry osteomyelitis can occur at any age, when there is an open wound (e.g., fractures, penetrating wounds) and microorganisms gain entry to the body. Osteomyelitis may also occur in the presence of a foreign body such as an implant or an orthopaedic prosthetic device (e.g., plate, total joint prosthesis). After gaining entrance to the bone by way of the blood, the microorganisms then lodge in an area of the bone where circulation slows, usually the metaphysis. The microorganisms grow, resulting in an increase in pressure because of the nonexpanding nature of most bone. This increasing pressure within the rigid bone structure leads to ischemia and vascular compromise of the periosteum. Eventually, the infection spreads through the bone cortex and the marrow cavity, ultimately resulting in cortical devascularization and necrosis. Once ischemia occurs, the bone dies. The area of devitalized bone eventually separates from the surrounding living bone, forming

sequestra (sing., *sequestrum*). The part of the periosteum that continues to have a blood supply forms new bone, called *involucrum* (Figure 66-1).

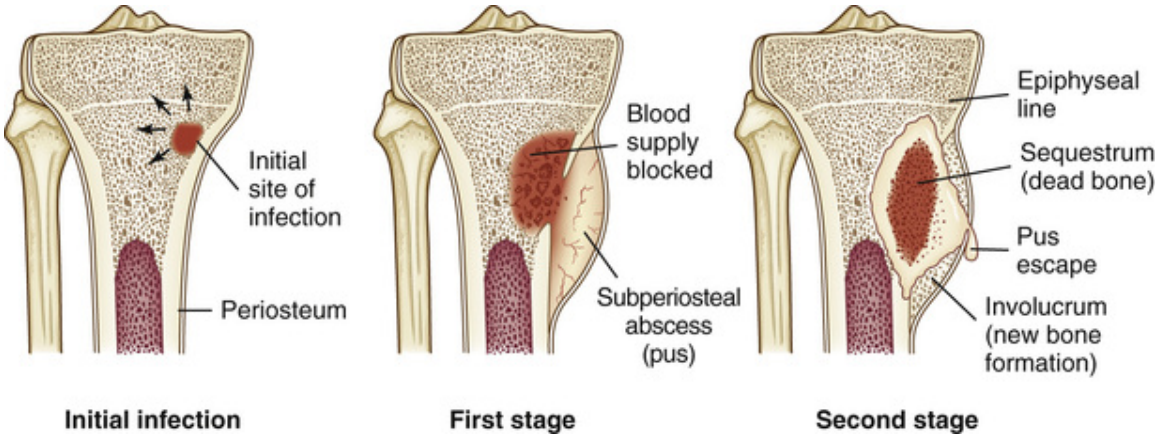

FIGURE 66-1 Development of osteomyelitis infection with involucrum and sequestrum. Source: McCance, K. L., Huether, S. E., Brashers, V. L., et al. (2014). *Pathophysiology: The biologic basis for disease in adults and children* (7th ed., p. 1559, Figure 44-15). St. Louis: Mosby.

Once formed, a sequestrum continues to be an infected island of dead bone surrounded by purulent drainage. It is difficult for bloodborne antibiotics or white blood cells to reach the sequestrum. A sequestrum may serve as a reservoir for microorganisms that spread to other sites, including the lungs and brain. The sequestrum can move out of the bone and into the soft tissue. Once outside of the bone, the sequestrum may revascularize and then undergo removal by the body's normal immune processes. Another possibility is that the sequestrum can be surgically removed through debridement of the necrotic bone. If the necrotic sequestrum is not resolved naturally or surgically, it may develop a sinus tract, resulting in a chronic, purulent cutaneous drainage (see Figure 66-1).

Despite advances in identification of pathogens, current use of antibiotics, and surgical debridement, acute osteomyelitis becomes chronic in 10% to 30% of cases and it is difficult to treat. In recent years, our understanding of bacterial virulence and host defence has improved due to emerging research of bacterial biofilm models (Sanchez, Mende, Beckius, et al., 2013). A biofilm is a cluster of bacterial cells that form a matrix (three-dimensional structure) that requires necrotic tissue and bone. This matrix functions as a barrier, offering the bacteria protection from mechanical influences, antibiotics, and the host's defence cells (Chen

& Wen, 2011). The pathogens pass from planktonic phase to maturation. The biofilm essentially functions as a permanent source of virulent pathogens insensitive to the body's own immune system and antibiotics. Surgical excision of sequestrum and biofilm is required.

Clinical Manifestations

Acute osteomyelitis refers to the initial infection or an infection of less than 1 month in duration. The clinical manifestations of acute osteomyelitis are both systemic and local. Systemic manifestations include fever, night sweats, chills, restlessness, nausea, and malaise. Local manifestations include constant bone pain that is unrelieved by rest and worsens with activity; swelling, tenderness, and warmth at the infection site; and restricted movement of the affected part. Later signs include drainage from sinus tracts to the skin or the fracture site.

Chronic osteomyelitis refers to a bone infection that persists for longer than 1 month or an infection that has failed to respond to the initial course of antibiotic therapy. Chronic osteomyelitis is either a continuous, persistent problem (a result of inadequate acute treatment) or a process of exacerbations and remissions (Figure 66-2). Systemic signs may be diminished; local signs of infection, including constant bone pain and swelling, tenderness, and warmth at the infection site, are more common. Over time, granulation tissue turns to scar tissue. This avascular scar tissue provides an ideal site for continued microorganism growth and is impenetrable by antibiotics. Long-term and rare complications of osteomyelitis include septicemia, septic arthritis, pathological fractures and amyloidosis (condition where abnormal protein called amyloid builds up in tissues and organs and can cause organ failure).

FIGURE 66-2 Resection of femur owing to osteomyelitis. Source: Patton, K. T., & Thibodeau, G. A. (2014). *The human body in health and disease.* (6th ed., p. 199, Figure 8-34). St. Louis: Mosby.

Diagnostic Studies

A bone or soft tissue biopsy is the definitive way to determine the causative microorganism. Once the causative organism is identified, antibiotic treatment can be adjusted. The patient's blood, wound cultures, or both are frequently positive for the presence of microorganisms. An elevated white blood cell and erythrocyte sedimentation rate may also be found. Radiological signs suggestive of osteomyelitis usually do not appear until 10 days to weeks after the appearance of clinical symptoms, by which time the disease will have progressed. Radionuclide bone scans (gallium and indium) are helpful in diagnosis and are usually positive in the area of infection. Magnetic resonance imaging (MRI) and computed tomographic (CT) scans may be used to help identify the extent of the infection, including soft tissue involvement.

Collaborative Care

Vigorous and prolonged intravenous (IV) antibiotic therapy is the treatment of choice for acute osteomyelitis, provided bone ischemia has not yet occurred. Cultures or a bone biopsy should be done, if possible, before drug therapy is initiated. If antibiotic therapy is delayed, surgical debridement and decompression are often necessary. Beginning

antibiotics prior to obtaining cultures or biopsy can lead to a false negative culture result. A false negative culture (no microorganism identified) makes targeted antibiotic therapy impossible. If the patient is in septic shock, however, broad spectrum antibiotics should be started as this is a life-threatening condition.

Often, patients are discharged to home care with IV antibiotics delivered via a central venous catheter or peripherally inserted central catheter. IV antibiotic therapy may initially be started in the hospital and then continued in the home for 4 to 6 weeks or for as long as 3 to 6 months. A variety of antibiotics may be prescribed, depending on the microorganism. These drugs include penicillin, cefazolin, gentamicin, and vancomycin.

Drug Alert

Gentamicin

- Patients should be assessed for dehydration before starting therapy.
- Renal function testing must be done before starting therapy, especially in older-adult patients.
- Peak and trough levels must be monitored for therapeutic effect and to minimize renal and inner ear toxicity (Burchurn & Rosenthal, 2015).
- Patients should be instructed to notify the health care provider if any visual, hearing, or urinary problems develop.

In adults with chronic osteomyelitis, the choice between a palliative and a curative approach should be considered. Surgery is necessary in most cases to cure the infection, but this may not always be the best option (Lima, Oliveira, Carvalho, et al., 2014). Oral antibiotic therapy may also be given after acute IV therapy is complete to ensure resolution of the infection. The patient's response to drug therapy is monitored through various imaging methods (bone scan, CT, MRI) and by monitoring erythrocyte sedimentation rate and C-reactive protein.

Treatment of chronic osteomyelitis includes surgical removal of the poorly vascularized tissue and dead bone and the extended use of antibiotics. Palacos spacers with or without added antibiotics, along with

antibiotic-impregnated bead chains or cement, may be implanted at this time to aid in combating the infection (Walter, Kemmerer, Kappler, et al., 2012). After debridement of the devitalized and infected tissue, the wound may be closed and a suction irrigation system inserted. Intermittent surgical irrigation and debridement of the affected bone may continue. Negative pressure over the site of the infection may be used (vacuum-assisted closure). (Negative-pressure wound therapy is presented in Chapter 14). The limb or surgical site may be protected with a cast or brace during this time.

Hyperbaric oxygen therapy with 100% oxygen may be administered as an adjunct therapy in refractory cases of chronic osteomyelitis. This therapy is thought to stimulate circulation and healing in the infected tissue (see Chapter 14). Orthopaedic prosthetic devices, if a source of chronic infection, must be removed. Muscle flaps or skin grafting provide wound coverage over the dead space (cavity) in the bone. Bone grafts may help to restore blood flow. Amputation of the extremity may be indicated in order to preserve an individual's life or improve quality of life when there is extensive bone destruction due to chronic osteomyelitis.

Nursing ManagementOsteomyelitis

Nursing Assessment

Subjective and objective data that should be obtained from an individual with osteomyelitis are presented in Table 66-2.

TABLE 66-2

Nursing Assessment Osteomyelitis

Subjective Data
Important Health Information
Past health history: Bone trauma, open fracture, open or puncture wounds, other infections (e.g., genito-urinary and respiratory infections); vascular insufficiency disorders (e.g., arising from diabetes mellitus); adults who are immuno-compromised *Medications:* Analgesics or antibiotics *Surgery or other treatments:* Bone surgery, especially implantation of an orthopaedic prosthetic device (e.g., plate, total joint prosthesis)
Symptoms
Constant bone pain that is unrelieved by rest and worsens with activity; restricted movement of the affected part; malaise
Objective Data
General
Restlessness; fever, chills, night sweats
Integumentary
Diaphoresis; erythema, warmth, edema at infected bone
Later signs include drainage from sinus tracts to the skin or the fracture site
Musculo-Skeletal
Restricted movement; wound drainage; spontaneous fractures
Possible Findings
Leukocytosis, positive blood or wound cultures, ↑ erythrocyte sedimentation rate; presence of sequestrum and involucrum on radiographs, radionuclide bone scans, CT, and MRI

CT, computed tomography; *MRI*, magnetic resonance imaging.

Nursing Diagnoses

Nursing diagnoses for the patient with osteomyelitis may include, but are not limited to, the following:

- *Acute pain* related to *biological injury agent* (inflammation secondary to infection)
- *Ineffective health maintenance* related to *insufficient resources* (lack of knowledge regarding long term management of osteomyelitis)
- *Impaired physical mobility* related to *activity intolerance, pain, reluctance to initiate movement*

Planning

The overall goals are that the patient with osteomyelitis will (1) have satisfactory pain and fever control, (2) not experience any complications associated with osteomyelitis, (3) cooperate with the treatment plan, and (4) maintain a positive outlook on the outcome of the disease.

Nursing Implementation

Health Promotion.

The control of infections already in the body (e.g., urinary, respiratory tract) is important in preventing osteomyelitis. Individuals susceptible to osteomyelitis are those who (alone or in combination) are immuno-compromised, have orthopaedic prosthetic devices, or have vascular insufficiencies. These patients should be instructed regarding the local and systemic manifestations of osteomyelitis. Families should also be aware of their role in monitoring the patient's health. Symptoms of bone pain, fever, swelling, and restricted limb movement should be reported immediately to the health care provider.

Acute Intervention.

Some immobilization of the affected limb (e.g., splint) is usually indicated to decrease pain. The involved limb should be handled carefully and excessive manipulation avoided as it increases pain and may cause pathological fracture. An important nursing responsibility is to assess the patient's pain. Nonsteroidal anti-inflammatory drugs (NSAIDs), opioid analgesics, and muscle relaxants may be prescribed to provide patient comfort. Nonpharmacological approaches to pain management (e.g., guided imagery, relaxation breathing) should be encouraged (see Chapters 10 and 12).

Dressings are used to absorb the exudate from draining wounds. Soiled dressings should be handled carefully to prevent cross-contamination of the wound or spread of the infection to other patients. Sterile technique should be practised when changing the dressing.

If the patient is on bed rest, proper body alignment and frequent position changes prevent complications associated with immobility and promote comfort. Flexion contracture, especially of the hip or knee, is a common sequela of osteomyelitis of the lower extremity because the patient frequently positions the affected extremity in a flexed position to promote comfort. Footdrop can develop quickly if the foot is not correctly supported in the neutral position by a splint or if there is excessive

pressure on the peroneal nerve, which can occur with an improperly fitted splint. The patient should be instructed to avoid any activities, such as exercise or heat application, that increase circulation and serve as stimuli to the spread of infection. Uninvolved joints and muscles should continue to be exercised.

The patient should be taught about potential adverse and toxic reactions associated with prolonged and high-dose antibiotic therapy. These reactions include hearing deficit, fluid retention, and neurotoxicity —which can occur with the aminoglycosides (e.g., tobramycin)—and jaundice, colitis, and photosensitivity from the extended use of the cephalosporins (e.g., cefazolin). Tendon rupture (especially the Achilles tendon) can occur with use of the fluoroquinolones (e.g., ciprofloxacin, levofloxacin). Peak and trough blood levels of most antibiotics must be carefully monitored throughout the course of therapy to prevent these adverse effects. Lengthy antibiotic therapy can also result in an overgrowth of *Candida albicans* and *Clostridium difficile* in the genito-urinary tract and oral cavities, especially in patients who are immuno-suppressed and in older-adult patients. The nurse should instruct the patient to report any whitish, yellowish, curdlike lesions or frequent, watery diarrhea to the health care provider. The patient and family are often frightened and discouraged because of the serious nature of the disease, the uncertainty of the outcome, and the lengthy course of treatment. Continued psychological and emotional support is an integral part of the nursing management for patients with osteomyelitis.

Ambulatory and Home Care.

With the introduction of various intermittent venous access devices, IV antibiotics today can be administered to the patient in his or her home setting. The patient and family should be instructed on the proper care and management of the venous access device, the antibiotic schedule, antibiotic administration, and the need for follow-up laboratory testing. The importance of taking antibiotics even after the symptoms have subsided should be stressed.

If there is an open wound, dressing changes are often necessary. The patient and family may require supplies and instruction in the technique. If the osteomyelitis becomes chronic, patients need physical and psychological support for a prolonged period. Periodic home nursing visits for IV medication administration or dressing changes provide the family with support, which helps to reduce anxiety.

Evaluation

The expected outcomes are that the patient with osteomyelitis will:

- Have satisfactory pain relief
- Follow the recommended treatment regimen
- Verbalize confidence in the ability to implement the treatment regimen at home
- Demonstrate a consistent increase in mobility and range of motion

Bone Tumours

Primary benign and malignant bone tumours are rare in adults and occur most often during childhood through young adulthood. Metastatic bone cancer, in which the cancer has spread from another site, is a more common problem. The name given to a bone tumour is based on the area of the bone and surrounding tissue that is affected and on the type of cells forming the tumour. In 2010, 340 new cases of bone cancer occurred in Canada, and there were 185 related deaths (Canadian Cancer Society's Advisory Committee on Cancer Statistics, 2015).

Clinical Manifestations

Persistent nonmechanical bone pain in any bone lasting more than a few weeks is cause for concern and should undergo further evaluation and investigation. Diagnosis of a suspected bone tumour is related to age, family history, presence and location of swelling, patient's mobility, and the presence of regional or local lymph nodes (The European Sarcoma Network Working Group [ESMO], 2012). Recent injury does not rule out a tumour, and the patient should undergo the appropriate diagnostic procedures.

Diagnostic Studies

Conventional radiographs should always be the first investigation when a patient presents with bone pain. If the diagnosis of tumour cannot be excluded with certainty, the next step is to arrange an MRI. A CT scan is helpful in visualizing calcification, periosteal bone formation, cortical destruction, or soft tissue involvement. In order to definitely identify and characterize the tumour, a biopsy for histology and pathology needs to be obtained by either a radiologist (radiology-guided biopsy) or surgeon (open-surgical biopsy). Once the biopsy material has been reviewed and identified, discussions about diagnosis, staging assessment, and treatment can occur with the patient and family.

Benign Tumours

Benign bone tumours are more common than primary malignant tumours. The main types of benign bone tumours are osteochondroma,

osteoclastoma, and endochroma. These types of tumours are often removed by surgery.

Osteochondroma

Osteochondroma is the most common primary benign bone tumour. It is characterized by an overgrowth of cartilage and bone near the end of the bone, at the growth plate. It is more commonly found in the long bones of the leg, pelvis, or scapula.

Clinical manifestations include a painless, hard, immobile mass; lower-than-normal height for age; soreness of muscles in close proximity to the tumour; one leg or arm longer than the other; and pressure or irritation with exercise. Patients may also be asymptomatic. No treatment is necessary for asymptomatic osteochondroma. If the tumour is causing pain or neurological symptoms because of compression, surgical resection is usually done. Patients should have regular screening examinations for early detection of malignant transformation.

Osteoclastoma

Osteoclastoma *(giant-cell tumour)* is a destructive tumour that arises in the cancellous ends of long bones in young adults. Most (98%) of these variant, giant-cell tumours are benign, but about 10% of the time they can be locally aggressive and spread to the lungs. Giant-cell tumours most commonly occur in women between the ages of 20 and 35. Common tumour sites are in the epiphysis of the distal femur, the proximal tibia, and the distal radius. Clinical manifestations are usually swelling, local pain, and some disturbances in joint function. Radiographic evidence of giant-cell tumours usually reveals local areas of bone destruction and eventual expansion of the bone ends (Figure 66-4).

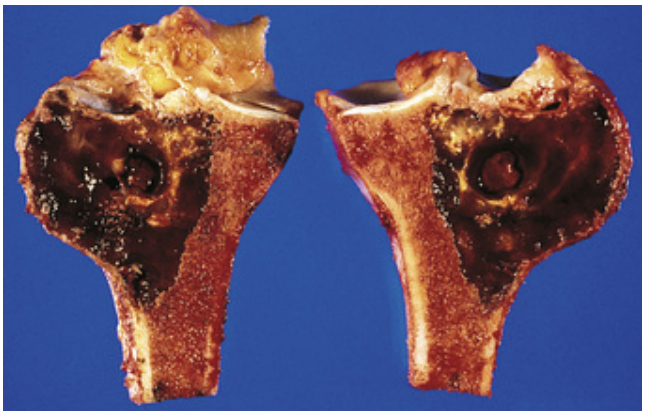

FIGURE 66-4 Osteoclastoma (giant-cell tumour) in a long bone.

Source: Damjanov, I., & Linder, J. (1996). *Anderson's pathology* (10th ed.). St Louis: Mosby.

After diagnosis, surgical curettage of the tumour is usually done, followed by bone grafting or bone cement; however, this treatment has been associated with high recurrence rates. Additional treatments with adjuvants such as zinc chloride, bisphosphonates, phenol, liquid nitrogen, and alcohol are often used to reduce recurrence (Hakim, Pelly, Kulendran, et al., 2015). Recurrent giant-cell tumours may have to be treated with amputation and prosthesis.

Malignant Bone Tumours

A **sarcoma** is a malignant tumour in the connective tissues of the body (fat, muscles, blood vessels, nerves, bones, or cartilage). The most common types of malignant bone tumours are osteosarcoma, chondrosarcoma (see Figure 66-3B), and Ewing sarcoma. Primary malignant tumours occur most often during childhood and young adulthood. They are characterized by their rapid metastasis and bone destruction.

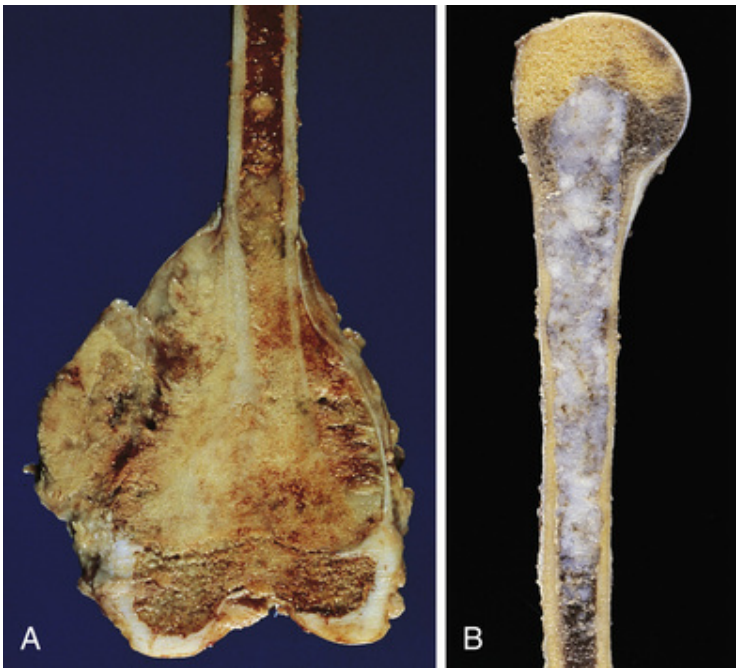

FIGURE 66-3 **A,** Osteosarcoma. **B,** Chondrosarcoma. Source: Damjanov, I., & Linder, J. (1996). *Anderson's Pathology*. (10th ed.). St. Louis: Mosby.

Osteosarcoma

Osteosarcoma is a malignant primary bone tumour that is extremely aggressive and is characterized by rapid growth and metastasis. It usually occurs in the metaphyseal region of the long bones of the extremities, particularly in the regions of the distal femur, proximal tibia, and proximal humerus as well as the pelvis (Figure 66-3A). Osteosarcoma is the most common malignant bone tumour affecting children and young adults; the highest incidence is in boys and men in the 10- to 25-year-old age group. Secondary osteosarcoma is known to occur in adults older than age 60 and is most commonly associated with Paget's disease.

Clinical manifestations of osteosarcoma are usually associated with a gradual onset of pain and swelling, especially around the knee. The neoplasm grows rapidly and can restrict joint motion if the tumour is close to a joint structure. Metastasis is present in 10% to 20% of individuals on diagnosis, with the lung being the most frequent site.

Canadian Terry Fox was diagnosed with osteosarcoma at 18 years of age and underwent an above-knee amputation in early 1977. Influenced by his experience, Terry decided in 1980 to run across Canada to raise

money and awareness about cancer. Since then, more than $550 million has been raised worldwide for cancer research in Terry's name, through the annual Terry Fox Run held across Canada and around the world (Terry Fox Foundation, 2015). Fortunately, major advances continue to be made in the treatment of osteosarcoma.

Preoperative chemotherapy is used to decrease tumour size, and limb-salvage procedures (e.g., wide surgical resection of the tumour) are being used more often. Limb salvage is contraindicated if there is major neurovascular involvement, pathological fracture, infection, skeletal immaturity, or extensive muscle involvement. Quality-of-life considerations also factor into the decision regarding limb salvage compared with amputation. The introduction of multiagent chemotherapy has improved the outcomes for these patients. Chemotherapeutic agents used include methotrexate, doxorubicin, cisplatin, dactinomycin (Cosmegen), and ifosfamide (Ifex).

Ewing Sarcoma Family of Tumours

Ewing sarcoma family of tumours (ESFT) is one of the most common primary malignant neoplasms of bone and soft tissue. It occurs most often in adolescents or young adults, the majority of whom are younger than 30 years of age.

ESFT is characterized by rapid growth within the medullary cavity of long bones, especially the femur, humerus, pelvis, and tibia. Metastasis occurs early, and the most frequent site is the lungs. Common manifestations are progressive local pain, swelling, palpable soft tissue mass, noticeable increase in size of the affected part, fever, and leukocytosis. Multimodal treatment strategies combining local therapy (radiotherapy, surgery) and systemic chemotherapy have improved survival rates; however, for those with disseminated disease or recurrent disease, prognosis is still unfavourable. Chemotherapeutic agents commonly used are vincristine, ifosfamide (Ifex), doxorubicin, and etoposide (VePesid). The 5-year disease-free survival rate for localized Ewing sarcoma treated with radiation, surgical resection, and multiagent chemotherapy is 65% to 76%. Hopefully, as new biology-driven treatment options emerge, the odds of survival can begin to improve (Potratz, Dirksen, Jürgens, et al., 2012).

Metastatic Bone Cancer

The most common type of malignant bone tumour occurs as a result of metastasis from a primary tumour located at another site. Common sites for the primary tumour include breast, prostate, gastro-intestinal tract, lungs, kidney, ovary, and thyroid. The bone is the third-most common site for metastatic disease. Metastatic cancer cells travel from the primary tumour via the lymph and blood supply to other sites in the body. Metastatic bone lesion(s) are commonly found in vertebrae, pelvis, femur, humerus, or ribs. Pathological fractures at the site of metastasis are common because of weakening of the involved bone. High serum calcium levels result as calcium is released from damaged bones.

Once a primary lesion has been identified, often, radionuclide bone scans are done to detect the presence of metastatic lesions before they are visible on radiography. It is important to note that metastatic bone lesions may occur at any time (even years later) following diagnosis and treatment of the primary tumour. Metastasis to the bone should be suspected in any patient who has local bone pain and a past history of cancer. Treatment may be palliative and consists of pain management and radiation (see Chapter 18). Neurosurgical or orthopaedic surgical interventions may include prophylactic fixation at sites of impeding fracture, stabilization after pathological fracture, and stabilization or decompression of spinal cord and nerve roots for spinal instability (Khodabukus, Debattista, Reynolds, et al., 2015). Prognosis depends on the primary type of cancer and the extent of metastasis throughout the body.

Nursing ManagementBone Cancer

Patients with bone cancer should be assessed for location and severity of pain. The tumour site is also assessed for swelling, changes in circulation, and joint function, movement, and sensation. The patient is monitored for weakness caused by anemia and decreased mobility.

The overall goals are that the patient with bone cancer will (1) have satisfactory pain relief; (2) maintain preferred activities as long as possible; (3) demonstrate acceptance of body image changes resulting from chemotherapy, radiation, and surgery; (4) remain free from injury; and (5) verbalize a realistic idea of disease progression and prognosis.

Nursing care of the patient with a malignant bone neoplasm does not differ significantly from the care given to the patient with a malignant disease of any other body system (see Chapter 18). These patients are at high risk for injury due to the nature of their disease as well as the

medications they may be taking so they require special attention and safety precautions while in hospital. Careful handling and support of the affected extremity, and logrolling for those on bed rest, are important to prevent pathological fractures Often, patients suffer from fatigue and weakness. As such, they are often reluctant to participate in activities based on fear of pain and of falling and fracturing a bone. Regular rest periods should be provided between activities. Plans should be discussed for home safety, including wearing nonslip footwear, ensuring a well-lit environment, and removing throw rugs and cords from the floor (Monczewski, 2013).

The pain associated with bone cancer can be severe. Often, the pain is caused by the tumour pressing against nerves and other organs near the bone. The patient's pain should be carefully monitored and the nurse should ensure that the patient has adequate pain medication. Sometimes, radiation therapy is used as a palliative therapy to shrink the tumour and decrease the pain.

The patient and family should be assisted in accepting the guarded prognosis associated with bone neoplasms. Inability to accomplish age-specific developmental tasks can increase the frustrations with this condition. General principles related to cancer nursing are applicable (see Chapter 18 and NCPs 18-1 and 18-2, available on the Evolve website). Special attention is necessary for the problems of pain and disability, chemotherapy, adverse effects of chemotherapy, and postoperative care after surgery such as spinal cord decompression or amputation. As with all types of cancer, the nurse should stress the importance of follow-up examinations.

Low Back Pain

Etiology and Pathophysiology

Chronic back pain is a prevalent and a costly public health issue. The incidence of back pain does not differ significantly across social or demographic groups. Back pain continues to be the leading overall cause of lost productivity in the workplace (National Institute of Neurological Disorders and Stroke [NINDS], 2014). In Canada, it is estimated that medical expenditures for investigation and treatment of lower back pain are between $6 and $12 billion annually (Bone and Joint Canada, 2014).

Low back pain (LBP) is a common problem because the lumbar region (1) bears most of the weight of the body, (2) is the most flexible region of the spinal column, (3) contains nerve roots that are vulnerable to injury or disease, and (4) has an inherently poor biomechanical structure. Several risk factors are associated with LBP, including lack of muscle tone and excess body weight, poor posture, cigarette smoking, and stress. Jobs that require repetitive heavy lifting, operation of vibrating machinery, or prolonged periods of sitting are also associated with LBP. In Canada, those living in more rural and geographically remote areas are more likely than urban dwellers to have LBP (Bath, Trask, McCrosky, et al., 2014).

The causes of LBP of musculo-skeletal origin include (a) acute lumbosacral strain, (b) instability of the lumbosacral bony mechanism, (c) osteoarthritis of the lumbosacral vertebrae, (d) degenerative disc disease (DDD), and (e) herniation of an intervertebral disc.

According to Yassi & Lockhart (2013), international studies have shown a higher prevalence of nonspecific LBP in nurses than in the general population. Overall nursing activities increased the "risk for and were associated with back disorders regardless of nursing technique, personal characteristics, and non-work-related factors" with patient handling conferring the highest risk (Yassi & Lockhart, 2013, p. 223).

Acute Low Back Pain

Acute low back pain usually lasts 6 weeks or less. Most LBP is caused by trauma or some type of activity that causes undue stress (often hyperflexion) of the lower back. Often, symptoms of LBP do not appear

at the time of injury but develop later because of a gradual increase in pressure on the nerve by an intervertebral disc. Symptoms may range from muscle ache to shooting or stabbing pain, limited flexibility or range of motion, or an inability to stand straight.

Few definitive diagnostic abnormalities are present with nerve irritation and muscle strain. Diagnostic imaging, including radiography, MRI, and CT scans, are generally not done unless there are red flags, such as focal neurological deficits, trauma, or systemic disease (e.g., cancer, spinal infection) (Chou, Qaseem, Owens, et al., 2011).

Collaborative Care

If the acute muscle spasms and accompanying pain are not severe and debilitating, the patient is treated with analgesics such as NSAIDs or muscle relaxants. Severe pain may require a short course of opioid analgesics. A brief period (1 to 2 days) of rest at home may be necessary for some people, but most do better with a continuation of their regular activities (Nicholas & George, 2011). Bed rest provides no benefit to patients who have acute LBP, with or without sciatica (see "Evidence-Informed Practice" box). Evidence suggests that to stay active rather than rest in bed means the patient will return to work sooner, improve functional status, and have less pain. Patients who are unable to return to normal activities may have short-term benefits from spinal manipulation, but it may be no more effective than usual care. Multidisciplinary rehabilitation programs in occupational settings may be an option for workers with sick leave of more than 4 to 8 weeks.

Evidence-Informed Practice

Research Highlight

Should Patients With Acute Low Back Pain Do Motor Control Exercises?

Clinical Question

In patients with acute low back pain (P), do motor control exercises (I) as compared to other forms of exercise or doing nothing (C) improve recovery (O)?

Best Available Evidence

Systematic review of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence

- 29 randomized trials (n = 2 431); the impact of using motor control exercises as a treatment for lower back pain was compared to other forms of exercise or doing nothing.
- Acute LBP was defined as pain lasting <6 wk.
- People that used motor control exercises for 20 days to 12 weeks, 1–5 days per week, experienced improvements, especially in pain and disability.
- Targeting the strength and coordination of muscles that support the spine through motor control exercise provided an alternative treatment for lower back pain. It is unclear how motor control exercise compares with other forms of exercise long term.

Conclusions

- Motor exercises are as effective as other types of exercise, so the choice of exercise should account for factors such as patient or therapist preferences, cost, and availability.
- There is no evidence that staying active is harmful.

Implications for Nursing Practice

- Patients with acute LBP should be encouraged to continue daily activities and use motor control exercises within their limitations of pain.
- Patients should be instructed on the potential harm of extended bed rest.
- Research on the effects of staying active for chronic LBP is needed.

P, patient population of interest; *I*, intervention or area of interest; *C*, comparison of interest or comparison group; *O*, outcome(s) of interest (see Chapter 1).

Reference for Evidence

Saragiotto BT, Maher CG, Yamato TP, et al. Motor control exercise for chronic non-specific low back pain. *The Cochrane Database of Systematic Reviews*. 2016;(1); 10.1002/14651858.CD012004 [CD012004].

The effectiveness of invasive treatments, such as epidural corticosteroid injections and implanted devices that deliver pain medication, remains controversial. The latest research evidence suggests that transcutaneous electrical nerve stimulation (TENS) and traction are not effective for the treatment of LBP. Although it is important that the patient remains active and fit, the current scientific evidence does not support the use of specific exercises (e.g., strengthening, stretching, flexion, and extension exercises) as a treatment for acute nonspecific LBP (Hayden, van Tulder, Malmivaara, et al., 2011). Patients experiencing acute nonspecific LBP should avoid bed rest for prolonged periods and activities that aggravate the pain, including lifting, bending, twisting, and prolonged sitting. Most cases spontaneously improve within 2 to 6 weeks.

Chronic Low Back Pain

Chronic low back pain is low back pain that lasts more than 3 months or is a repeated incapacitating episode. Causes include (1) degenerative conditions such as arthritis or disc disease; (2) osteoporosis or other metabolic bone diseases; (3) prior injury (scar tissue weakens the back); (4) chronic strain on the lower back muscles from obesity, pregnancy, or job-related stooping, bending, or other stressful postures; and (5) congenital abnormalities in the spine.

Spinal Stenosis

Spinal stenosis is a narrowing of the vertebral canal or nerve root canals caused by encroachment of bone on the space. The stenosis may be inherited or acquired through degenerative or traumatic changes to the spine. Common acquired causes include osteoarthritis, rheumatoid arthritis, spinal tumours, Paget's disease, and trauma. Inherited

conditions that lead to spinal stenosis include congenital spinal stenosis and scoliosis.

Arthritic changes (bone spurs, calcification of spinal ligaments, degeneration of discs) narrow the space around the spinal canal and nerve roots, eventually leading to compression. Inflammation caused by the compression results in pain, weakness, and numbness.

The pain associated with lumbar spinal stenosis often starts in the low back and then radiates to the buttock and the leg. It worsens with walking and particularly when standing without walking. Numbness, tingling, weakness, and heaviness in the legs and buttocks may also be present. In most cases, the stenosis slowly progresses and does not cause paralysis.

Nursing and Collaborative Management Chronic Low Back Pain

Chronic LBP is not a clinical entity but a symptom in patients with very different stages of impairment, disability, and chronicity. Treatment for chronic LBP is much the same as for acute LBP. Epidural injections have been used since 1901 in managing chronic lower back pain, but their effectiveness is still unclear (Kaye, Manchikanti, Abdi, et al., 2015). Cold, damp weather aggravates back pain, but this can be relieved with rest and local heat application. Relief of pain and stiffness by the use of mild analgesics, such as NSAIDs, is integral to the daily comfort of people with chronic LBP. Weight reduction, sufficient rest periods, local heat or cold application, and exercise and activity throughout the day help to keep the muscles and joints mobilized. Tricyclic antidepressants (e.g., amitriptyline [Elavil]) and selective serotonin reuptake inhibitors (e.g., sertraline) have been shown to improve the chronic symptoms of LBP.

Surgical intervention may be indicated in patients with severe chronic LBP who do not respond to conservative care or have continued neurological deficits. (Surgery for low LBP is discussed on p. 1679.)

Nursing ManagementNonspecific Low Back Pain

Nursing Assessment

Subjective and objective data that should be obtained from the patient with LBP are summarized in Table 66-3.

TABLE 66-3

Nursing Assessment
Low Back Pain

Subjective Data
Important Health Information
Past health history: Acute or chronic lumbosacral strain or trauma, osteoarthritis, degenerative disc disease, obesity; metabolic, circulatory, gynecological, or urological problems Occupation requiring heavy lifting, vibrations, or extended driving *Medications:* Opioid and nonopioid analgesics; muscle relaxants; NSAIDs; corticosteroids; antidepressants; anticonvulsant drugs; over-the-counter remedies, including herbal products and nutritional supplements *Surgery or other treatments:* Previous back surgery, epidural corticosteroid injections
Symptoms
• Pain in back, buttocks, or leg, associated with walking, turning, straining, coughing, leg raising • Numbness or tingling of legs, feet, toes; muscle spasms • Activity intolerance • Interrupted sleep
Objective Data
General
Guarded movement
Neurological
Depressed or absent Achilles tendon reflex or patellar tendon reflex; positive straight leg–raising test, positive cross-over straight leg–raising test, positive Trendelenburg test
Musculo-Skeletal
Tense, tight paravertebral muscles on palpation, decreased range of motion of spine; poor posture
Possible Findings
Localization of site of lesion or disorder on myelogram, CT scan, or MRI; determination of nerve root impingement on electromyography

CT, computed tomography; *MRI*, magnetic resonance imaging; *NSAIDs*, nonsteroidal anti-inflammatory drugs.

Nursing Diagnoses

Nursing diagnoses for the patient with LBP may include, but are not limited to, the following list.

- *Acute pain* related to *physical injury agent* (mechanical disorders or nonmechanical diseases and ineffective comfort measures)
- *Impaired physical mobility* related to *pain*
- *Chronic pain* related to *injury agent* (progressive degenerative changes of the muscles and skeletal structures of the back)

- *Ineffective coping* related to *insufficient sense of control* (chronic pain)
- *Ineffective health management* related to *insufficient knowledge of therapeutic regimen*

Planning

The overall goals are that the patient with LBP will (1) have satisfactory pain relief, (2) avoid constipation secondary to medication and immobility, (3) learn back-sparing practices, and (4) return to the previous level of activity within prescribed restrictions.

Nursing Implementation

Health Promotion.

Patients should also be advised to maintain appropriate body weight. Excess body weight places extra stress on the lower back and weakens the abdominal muscles that support the lower back. Flat shoes or shoes with low heels (<2.5 cm) and shock-absorbing shoe inserts are recommended for women.

The position assumed while sleeping is also important in preventing LBP. Sleeping in a prone position should be avoided because it produces excessive lumbar lordosis, placing excessive stress on the lower back. A firm mattress is recommended. The patient should sleep in either a supine or a side-lying position, with the knees and hips flexed to prevent unnecessary pressure on support muscles, ligamentous structures, and lumbosacral joints. Patients should be educated about the necessity to avoid or cease smoking. Nicotine has been shown to decrease circulation to the vertebral discs, and a causal relationship exists between smoking and some types of LBP.

Acute Intervention.

The primary nursing responsibilities in acute LBP are to assist the patient to maintain activity limitations, promote comfort, and educate the patient about the health problem and appropriate exercises. Other nursing interventions are summarized in NCP 66-1 on the Evolve website. The use of analgesics, NSAIDs, muscle relaxants, antidepressants,

anticonvulsant drugs, and thermotherapy (ice and heat), while avoiding continued bed rest, is incorporated into the plan of care.

Muscle stretching and strengthening exercises may be part of the management plan. Exercises can help to strengthen the back as a preventive measure, but there is no evidence to support their effectiveness as treatment for LBP. Although the actual exercises are often taught by a physiotherapist, it is the nurse's responsibility to ensure that the patient understands the type and the frequency of exercise prescribed as well as the rationale for the program.

As a role model, the nurse should use proper body mechanics at all times. The nurse should assess the patient's use of body mechanics and offer advice when activities that could produce back strain are performed (Table 66-4).

TABLE 66-4

Patient & Caregiver Teaching Guide
Low Back Problems

The following instructions should be included when teaching the patient how to manage low back problems.
Do
• Prevent lower back from straining forward by placing a foot on a step or stool during prolonged standing. • Sleep in a side-lying position with knees and hips bent. • Sleep on back with a lift under knees and legs or on back with 25-cm–high pillow under knees to flex hips and knees. • Exercise 15 minutes in the morning and 15 minutes in the evening, regularly; begin exercises with a 2- or 3-minute warm-up period by moving arms and legs; alternate relaxing and tightening muscles; exercise slowly, with smooth movements, as directed by a physiotherapist. • Carry light items close to your body. • Maintain appropriate body weight. • Use local heat and cold application. • Use a lumbar roll or pillow for sitting. • Use proper body mechanics to avoid low back strain (e.g., when lifting objects, bend at the knees, not at the waist; stand up slowly with the object close to your body).
Do Not
• Lean forward without bending knees. • Lift anything above level of your elbows. • Stand in one position for prolonged time. • Sleep on abdomen or on back or side with legs out straight. • Exercise without consulting your health care provider, if having severe pain. • Exceed prescribed amount and type of exercises without consulting your health care provider.

Ambulatory and Home Care.

The goal of management is to make an episode of acute LBP an isolated incident. If the lumbosacral mechanism is unstable, repeated episodes can be anticipated. The lumbosacral spine may be unable to meet the demands placed on it without strain because of factors such as obesity,

poor posture, poor muscular support, advancing age, or local trauma. Intervention is aimed at strengthening the supporting muscles through exercise. A corset limits extremes of movement and may be useful in decreasing pain and the use of pain medication.

Persistent use of poor body mechanics may also result in repeated episodes of LBP. If the strain is work related, occupational counselling may be necessary. The frustration, pain, and disability imposed on the patient with LBP require emotional support and understanding care by the nurse.

Evaluation

Intervertebral Disc Disease

Etiology and Pathophysiology

An intervertebral disc is interposed between the vertebrae from the cervical axis to the sacrum. Structural degeneration of the lumbar disc is often caused by **degenerative disc disease (DDD).** This progressive degeneration is a normal process of aging and results in the intervertebral discs losing their elasticity, flexibility, and shock-absorbing capabilities. Thinning of the discs occurs as the nucleus pulposus (gelatinous centre of the disc) starts to dry out and shrink. These changes limit the ability of the discs to distribute pressure loads between the vertebrae. The once normal central loading of the intervertebral discs then changes, and the load now is transferred to the annulus fibrosis (strong outside portion of the intervertebral disc), causing structural deterioration. The annulus is now torn or stretched, which allows the nucleus pulposus to herniate or bulge outward between the vertebrae. This phenomenon is called a **herniated intervertebral disc** (slipped disc) (Figure 66-5).

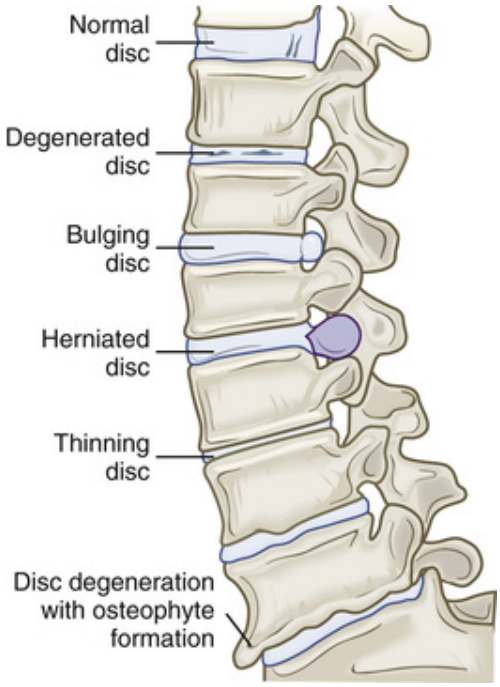

FIGURE 66-5 Common causes of degenerative disc damage.

An acute herniated intervertebral disc (slipped disc) can be the result of natural degeneration with age or repeated stress and trauma to the spine. Herniation of the nuclear material from the intervertebral disc may compress or place tension on a cervical, lumbar, or sacral spinal nerve root, causing acute back pain. The most common sites of rupture are the lumbosacral discs, specifically, L4–5 and L5–S1. Disc herniation may also occur at C5–6 and C6–7.

The spinal nerves emerge from the spinal column through an opening *(intervertebral foramen)* between adjacent vertebrae. Herniated discs can press against these nerves ("pinched nerve"), causing *radiculopathy* (radiating pain, numbness, tingling, and diminished strength or range of motion). Additionally, nerve and vascular ingrowth into the disk and exposure of these nerves to inflammatory mediators contribute to lower back pain (Simon, McAuliffe, Shamim, et al., 2014).

Osteoarthritis of the spine is associated with DDD and the stresses placed on the vertebrae. The joints, which are not adequately lubricated, rub against each other, leading to damage of the protective cartilage and the formation of painful bone spurs, which are one of the changes found in osteoarthritis.

Clinical Manifestations

The most common clinical manifestation of *lumbar disc disease* is LBP. Radicular pain that radiates down the buttock and below the knee, along the distribution of the sciatic nerve, generally indicates disc herniation. (Specific manifestations for lumbar disc herniation are summarized in Table 66-5). The straight leg raise test may be positive, indicating nerve root irritation. Back or leg pain may be reproduced by raising the leg and flexing the foot at 90 degrees. LBP from other causes may not be accompanied by leg pain. Reflexes may be depressed or absent, depending on the spinal nerve root involved. Paresthesia or muscle weakness in the legs, feet, or toes may be reported by the patient. Multiple nerve root *(cauda equina)* compression from a herniated disk, a tumour, or an epidural access may be manifested as bowel and bladder incontinence or erectile dysfunction. This condition is a medical emergency.

TABLE 66-5
Clinical Manifestations Based on Level of Disc Herniation*

Intervertebral Level	Subjective Pain	Affected Reflex	Motor Function	Sensation
L3–4	Back to buttocks to posterior thigh to inner calf	Patellar	Quadriceps, anterior tibialis	Inner aspect of lower leg, anterior part of thigh
L4–5	Back to buttocks to dorsum of foot and big toe	None	Anterior tibialis, extensor hallucis longus, gluteus medius	Dorsum of foot and big toe
L5–S1	Back to buttocks to sole of foot and heel	Achilles	Gastrocnemius, hamstring, gluteus maximus	Heel and lateral foot

*A disc herniation can involve pressure on more than one nerve root.

In *cervical disc disease*, there is often pain radiating into the arms and hands, following the pattern of the nerve involved. Reflexes may or may not be present, and there is often weakness of the hand grips.

Diagnostic Studies

Radiographic studies are done to note any structural defects. A myelogram, MRI, or CT scan is helpful in localizing the damaged site. An epidural venogram or discogram may be necessary if other methods of diagnosis are unsuccessful. An electromyogram of the extremities can be performed to determine the severity of nerve irritation or to rule out other pathological conditions, such as peripheral neuropathy.

Collaborative Care

The patient with suspected disc damage is usually managed first with conservative therapy (Table 66-6). This includes limitation of extremes of spinal movement (brace, corset, or belt), local heat or ice, ultrasonography and massage, traction, and TENS. Drug therapy includes NSAIDs, short-term opioids, muscle relaxants, anticonvulsant drugs, and antidepressants (Cepoiu-Martin, Faris, Lorenzetti, et al., 2011). Epidural corticosteroid injections may be effective in reducing inflammation and relieving acute pain. If the underlying cause remains, the pain tends to recur. Once the symptoms subside, back-strengthening exercises are done twice a day and are encouraged for a lifetime. The patient is taught the principles of good body mechanics. Extremes of flexion and torsion are strongly discouraged. Most patients heal with a conservative (nonoperative) plan after 6 months.

TABLE 66-6

Collaborative Care Intervertebral Disc Disease

Diagnostic
• History and physical examination • Radiography • CT scan • MRI • Myelogram • Discogram • EMG
Collaborative Therapy
Conservative

• Restricted activity for several days, limit total bed rest
• Medication
  • Analgesics
  • Muscle relaxants
  • NSAIDs
• Local ice or heat
• Physiotherapy
• Epidural corticosteroid injections

Surgical
• Intradiscal electrothermoplasty (IDET) • Radiofrequency discal nucleoplasty • Interspinous process decompression system (X Stop) • Laminectomy with or without spinal fusion • Discectomy • Percutaneous laser discectomy • Artificial disc replacement • Spinal fusion with or without instrumentation (e.g., plates, screws)

CT, computed tomography; *EMG*, electromyogram; *MRI*, magnetic resonance imaging; *NSAIDs*, nonsteroidal anti-inflammatory drugs.

Surgical Therapy.

If conservative treatment is unsuccessful, radiculopathy becomes progressively worse, or loss of bowel or bladder control (cauda equina) occurs, surgery may then be indicated. Surgery for a damaged disc is generally performed when diagnostic tests indicate the problem is not responding to conservative treatment and the patient is in constant pain or has a persistent neurological deficit. Surgery should be carefully considered because some patients, for unknown reasons, do not improve and symptoms may actually worsen after surgery.

An *intradiscal electrothermoplasty* (IDET) is a minimally invasive outpatient procedure that may help in treating back and sciatica pain. The procedure involves the insertion of a needle into the affected disc with radiological guidance. A wire is then threaded down through the

needle and into the disc. The wire is then heated, which denervates the small nerve fibres that have grown into the cracks and invaded the degenerating disc. The heat also partially melts the annulus fibrosus, which triggers the body to generate new reinforcing proteins in the fibres of the annulus.

Another outpatient technique is *radiofrequency discal nucleoplasty* (coblation nucleoplasty). A needle is inserted into the disc similar to IDET. Instead of a heating wire, a special radiofrequency probe is used. The probe generates energy that breaks up the molecular bonds of the gel in the nucleus. The result is that up to 20% of the nucleus is removed, which decompresses the disc and reduces the pressure on both the disc and the surrounding nerve roots. Relief from pain varies among patients.

A third procedure is the use of an *interspinous process decompression system* (X Stop). This device is made of titanium and fits onto a mount that is placed on vertebrae in the lower back. The X Stop is used in patients with pain owing to lumbar spinal stenosis. The device works by lifting the vertebrae off the pinched nerve. The effect is similar to and less invasive than a laminectomy.

The most common surgical procedure for lumbar disc disease is a *laminectomy.* It involves the surgical excision of part of the posterior arch of the vertebra (referred to as the *lamina*) to gain access to the protruding disc to remove it. A minimal hospital stay is usually required after the procedure. Laminectomy is a safe and viable option when compared with decompression and fusion for older-adult patients who have failed conservative therapy and those with significant comorbidities.

A *discectomy* is another common type of surgical procedure that may be performed to decompress the nerve root. Microsurgical discectomy is a version of the standard discectomy in which the surgeon uses a microscope to allow better visualization of the disc and disc space during surgery to aid in the removal of the damaged portion. This procedure helps maintain the bony stability of the spine.

A *percutaneous discectomy* is an outpatient surgical procedure using a tube that passes through the retroperitoneal soft tissues to the disc with local anaesthesia and the aid of fluoroscopy. A laser is then used on the damaged portion of the disc. Small stab wounds are used, and minimal blood loss occurs during the procedure. The procedure is effective and safe, and it decreases rehabilitation time.

Total disc replacement is used in patients with disc damage associated with DDD. This artificial disc is made up of a high-density core sandwiched between two cobalt-chromium end plates (Figure 66-6). This

device is surgically placed in the spine through a small incision below the umbilicus after the damaged disc is removed. The disc allows for movement at the level of the implant. When considering long-term benefits of total disc replacement versus nonsurgical options, long-term outcomes are unclear. There is a significant difference in functional outcome immediately postoperatively. However, when considering long-term outcomes (>2 years), there is only a modest difference between total disc replacement and nonsurgical treatment (Hellum, Johnsen, Storheim, et al., 2011).

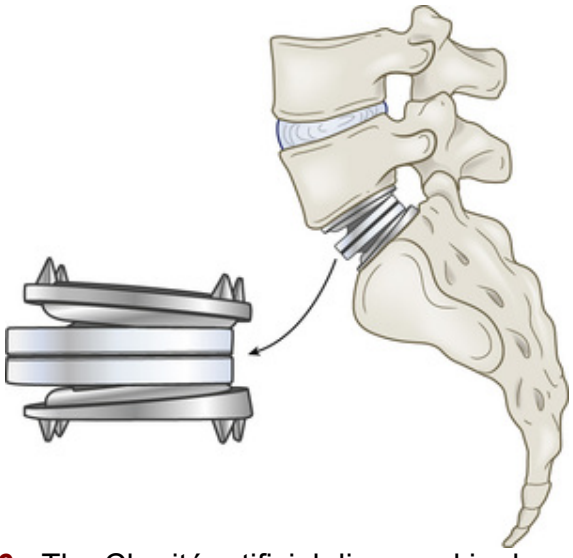

FIGURE 66-6 The Charité artificial disc used in degenerative disc disease to replace a damaged intervertebral disc. The Charité artificial disc consists of two cobalt-chromium alloy end plates sandwiched around a movable high-density plastic core. The design of the disc helps align the spine and preserve its natural ability to move.

A *spinal fusion* may be performed if the spine is unstable. Spinal stabilization is created by an *ankylosis* (fusion) of contiguous vertebrae with a bone graft from the patient's fibula or iliac crest or from donated cadaver bone. Metal fixation with rods, plates, or screws may be implanted at the time of spinal surgery to provide more stability and decrease vertebral motion. A posterior lumbar interbody fusion may be performed in patients to provide extra support for bone grafting or a prosthetic device.

Bone morphogenetic protein (BMP), a genetically engineered protein, may be used to stimulate bone growth of the graft in spinal fusions (Deyo, Ching, Matsen, et al., 2012). A dissolvable sponge soaked with BMP is implanted into the spine. The protein on the sponge stimulates the body's own cells to become active and produce bone. BMP begins the process of fusion, which continues even after the protein and sponge dissolve, leaving living bone behind.

Nursing ManagementSpinal Surgery

Postoperative nursing interventions focus on maintaining proper alignment of the spine at all times until healing has occurred. Depending on the type and extent of surgery, and the surgeon's preference, the patient may be able to dangle the legs at the side of the bed, stand, or even ambulate the first day after surgery.

Pillows can be used under the thighs of each leg when the patient is supine and between the legs when in side-lying positions to provide comfort and ensure alignment. Often, the patient fears turning or any movement that increases pain by straining the surgical area. The patient should be reassured that the proper technique is being used to maintain body alignment. Sufficient staff should be available to move the patient without undue pain or strain on staff members or the patient.

Postoperatively, most patients will require opioids such as morphine, intravenously, for 24 to 48 hours. Patient-controlled analgesia (PCA) allows for optimal analgesic levels and is the preferred method of continued pain management during this time. Once fluids are being taken, the patient may be switched to oral drugs such as acetaminophen with codeine or oxycodone. Medications may be prescribed for muscle relaxation. Pain management and its effectiveness should be monitored and documented.

The spinal canal may be entered during surgery so there is potential for cerebrospinal fluid leakage. Severe headache or leakage of cerebrospinal fluid on the dressing should be reported immediately. Cerebrospinal fluid appears as clear or slightly yellow drainage on the dressing. It has a high glucose concentration and will be positive for glucose when a dipstick test is done. The amount, colour, and characteristics of drainage should be noted.

The patient's peripheral neurological signs should be monitored frequently after spinal surgery. Movement of the arms and legs and assessment of sensation should be unchanged when compared with the

preoperative status. Table 66-7 summarizes a lumbar laminectomy assessment appropriate for the patient who has undergone back surgery. These assessments are repeated every 2 to 4 hours during the first 48 hours after surgery, and findings are compared with the preoperative assessment. Paresthesias, such as numbness and tingling, may not be relieved immediately after surgery. Any new muscle weakness or paresthesias should be documented and reported to the surgeon immediately. Extremity circulation should be assessed by temperature, capillary refill, and pulses.

TABLE 66-7

Postoperative Assessment Following Lumbar Surgery

Sensation*
Assess sensation of extremities for paresthesia in all appropriate dermatomes.
Movement*
Assess ability to move all extremities.
Muscle Strength*
Assess for any weakness of the extremities.
Wound
Assess dressing for drainage, and note amount, colour, and characteristics.
Pain
• Document location of the pain. • Ask patient to rate the pain on a scale of 0 to 10, with 0 being no pain and 10 being the worst pain. • Evaluate pain after analgesia has been administered.

*Postoperative findings should be compared with preoperative assessments. It is not unusual for the patient to continue to experience these symptoms after surgery. Symptoms gradually decrease over several months.

Paralytic ileus and interference with bowel function may occur for several days and may manifest as nausea, abdominal distension, and constipation. The nurse should assess whether the patient is passing flatus, has bowel sounds in all quadrants, and has a flat, soft abdomen. A bowel protocol should be initiated to prevent constipation.

Adequate bladder emptying may be altered because of activity restrictions, opioids, or anaesthesia. If allowed by the surgeon, men should be encouraged to dangle their legs or stand to urinate. Patients should use the commode or ambulate to the bathroom when allowed, to promote adequate emptying of the bladder. Ensure that privacy is maintained. Intermittent catheterization or an indwelling catheter may be necessary for patients who have difficulty urinating.

Loss of sphincter tone or bladder tone may indicate nerve damage. Incontinence or difficulty evacuating the bowel or bladder must be

monitored closely and reported to the surgeon.

In addition to the nursing care appropriate for a patient who has had a laminectomy, there are other nursing responsibilities if the patient has also had a spinal fusion. A bone graft is usually involved, so postoperative healing time maybe prolonged in comparison to a laminectomy. Reduced activity for an extended time may be necessary. A rigid orthosis (thoraco-lumbar-sacral orthosis or chairback brace) is often used during this period. Some surgeons require that the patient be taught to put the orthosis on and take it off by logrolling in bed, whereas others allow their patients to apply the brace in a sitting or standing position. The nurse should verify the preferred method before initiating this activity.

In addition to the primary surgical site, the donor site for the bone graft must be regularly assessed. The posterior iliac crest is the most commonly used donor site, although the fibula may also be used. The donor site usually causes greater postoperative pain than the fused area. The donor site is bandaged with a pressure dressing to prevent excessive bleeding. If the donor site is the fibula, neurovascular assessments of the extremity are a postoperative nursing responsibility.

After a spinal fusion, the patient may experience some immobility of the spine at the fusion site. Instruction in proper body mechanics is essential and should be evaluated during the hospital stay. The patient should be instructed to avoid sitting or standing for prolonged periods. Activities that should be encouraged include walking, lying down, and shifting weight from one foot to the other when standing. The patient should learn to mentally think through an activity before starting any potentially injurious task such as bending, lifting, or stooping. Any twisting movement of the spine is contraindicated. The thighs and knees, rather than the back, should be used to absorb the shock of activity and movement. A firm mattress or bed board is essential.

Neck Pain

Neck pain may occur almost as frequently as LBP. Neck pain may be the result of many conditions, both benign (e.g., poor posture) and serious (e.g., traumatic injury).

Cervical neck sprains and strains occur from hyperflexion and hyperextension injuries. Patients have symptoms of stiffness and neck pain and possible pain radiating into the arm and hand. Pain may also radiate into the head, anterior chest, thoracic spine region, and shoulders.

Cervical nerve root compression from stenosis, DDD, or herniation may be indicated by weakness or paresthesia of the arm and hand. Diagnosing the cause of neck pain is done by history, physical examination, radiography, MRI, CT scan, and electromyography. An electromyogram of the upper extremities is done to diagnose cervical radiculopathy.

Conservative treatment for neck pain that commonly occurs in patients without an underlying disorder includes head support via soft cervical collars, heat and ice applications, massage, rest until symptoms subside, physiotherapy, ultrasound, and NSAIDs. Therapeutic neck exercises and acupuncture may also be used for pain relief. Most neck pain resolves without surgical intervention. Indications for cervical spine surgery are similar to those for the lower back. Types of surgery are also similar, including discectomy, laminectomy, and spinal fusion. If surgery is done on the cervical spine, the nurse must be alert for symptoms of spinal cord edema, such as respiratory distress and a worsening neurological status of the upper extremities. An orthosis or halo may be necessary after surgery, depending on the degree of spine stabilization. After surgery, the patient's neck is immobilized in either a soft or a hard cervical collar.

Preventing benign neck pain that occurs owing to everyday activities such as prolonged sitting at a computer or television, sleeping in nonalignment spinal positions, or jarring movements during exercise is important. Preventive strategies can begin by encouraging patients to practise good posture and maintain neck flexibility (Table 66-8).

TABLE 66-8

Patient & Caregiver Teaching Guide
Neck Exercises

The following instructions should be included when teaching the patient about neck exercises.
• Bend your head backward until you are looking up at the ceiling. Repeat slowly five times. Stop if experiencing dizziness. • Bring your head forward so that your chin touches your chest and your face is looking down at the floor. Repeat slowly five times. • Keep your head facing forward, and bend your ear down toward one shoulder. Alternate this movement with your other ear. Repeat slowly five times on each side. • Turn your head slowly around to one side as far as it will go. Repeat toward the other side. Repeat exercise five times on each side. • Without tipping your head in any direction, pull your chin and head straight back. Relax the chin forward to its neutral position. Repeat slowly five times.

Foot Disorders

The foot is the platform that provides support for the weight of the body and absorbs considerable shock in ambulation. It is a complicated structure, composed of bony structures, muscles, tendons, and ligaments. It can be affected by (1) congenital conditions, (2) structural weakness, (3) traumatic injuries, and (4) systemic conditions such as diabetes mellitus and rheumatoid arthritis. Abnormalities of the foot affect millions of Canadians. Much of the pain, deformity, and disability associated with foot disorders can be directly attributed to or accentuated by improperly fitting shoes, which cause crowding and angulation of the toes and inhibition of the normal movement of foot muscles.

The purposes of footwear are to (1) provide support, foot stability, protection, shock absorption, and a foundation for orthoses; (2) increase friction with the walking surface; and (3) treat foot abnormalities. Table 66-9 summarizes common foot disorders. One of the most common forefoot disorders is a bunion (Figure 66-7). A lateral deviation of the great toe, termed *hallux valgus,* occurs with a bunion (Aly, Mousa, & Elsallakh, 2011).

TABLE 66-9
Common Foot Disorders

Disorder	Description	Treatment
Forefoot		
Hallux valgus (bunion)	Painful deformity of great toe consisting of lateral angulation of great toe toward second toe, bony enlargement of medial side of first metatarsal head, swelling of bursa and formation of callus over bony enlargement (see Figure 66-7)	Conservative treatment includes wearing shoes with wide forefoot or "bunion pocket" and use of bunion pads to relieve pressure on bursal sac. Surgical treatment is removal of bursal sac and bony enlargement and correction of lateral angulation of great toe; may include temporary or permanent internal fixation.
Hallux rigidus	Painful stiffness of first MTP joint, caused by osteoarthritis or local trauma	Conservative treatment includes intra-articular corticosteroids and passive manual stretching of first MTP joint. A shoe with a stiff sole decreases pain in the joint during walking. Surgical treatment is joint fusion or arthroplasty with silicone rubber implant.
Hammer toe	Deformity of second through fifth toes, including dorsiflexion of MTP joint, plantar flexion of PIP joint, and callus on dorsum of PIP joint and end of involved toe; complaints related to hammertoe include burning on bottom of foot and pain and difficulty in walking when wearing shoes	Conservative treatment consists of passive manual stretching of PIP joint and use of metatarsal arch support. Surgical correction consists of resection of base of middle phalanx and head of proximal phalanx and bringing raw bone ends together. Kirschner wire maintains straight position.
Morton's neuroma (Morton's toe or plantar neuroma)	Neuroma in web space between third and fourth metatarsal heads, causing sharp, sudden attacks of pain and burning sensations	Surgical excision is the usual treatment.
Midfoot		
Pes planus (flatfoot)	Loss of metatarsal arch, causing pain in foot or leg	Symptoms are relieved by use of resilient, longitudinal arch supports. Surgical treatment consists of triple arthrodesis or fusion of subtalar joint.
Pes cavus	Elevation of longitudinal arch of foot resulting from contracture of plantar fascia or bony deformity of arch	Treatment is manipulation and casting (in patients <6 yr of age); surgical correction is necessary if it interferes with ambulation (in patients ≥6 yr of age).
Hindfoot		
Painful heels	Complaint of heel pain with weight bearing; common causes include plantar bursitis, plantar fasciitis, or bone spur in adults	Corticosteroids are injected locally into inflamed bursa, and sponge rubber heel cushion is used; surgical excision of bursa or spur is performed. For plantar fasciitis, stretching exercises, NSAIDs, and corticosteroids are used.
Other Problems		
Corn	Localized thickening of skin caused by continual pressure over bony prominences, especially metatarsal head, frequently causing localized pain	Corn is softened with warm water or preparations containing salicylic acid and trimmed with razor blade or scalpel. Pressure on bony prominences caused by shoes is relieved.
Soft corn	Painful lesion caused by bony prominence of one toe pressing against adjacent toe; usual location in web space between toes; softness caused by secretions keeping web space relatively moist	Pain is relieved by placing cotton between toes to separate them. Surgical treatment is excision of projecting bone spur (if present).

Disorder	Description	Treatment
Callus	Similar formation to corn but covers wider area and usual location is on weight-bearing part of foot	Same as for corn.
Plantar wart	Painful papillomatous growth caused by virus that may occur on any part of skin on sole of foot; tend to cluster on pressure points	Remedies containing salicylic acid; liquid nitrogen; excision with electrocoagulation or surgical removal; ultrasonography may also be used. Many disappear without treatment.

MTP, metatarso-phalangeal; *NSAIDs,* nonsteroidal anti-inflammatory drugs; *PIP,* proximal interphalangeal.

FIGURE 66-7 **A,** Severe hallux valgus with bursa formation. **B,** Postoperative correction. Source: Canale, S., & Beaty, J. (Eds). (2013). *Campbell's operative orthopaedics.* (12th ed.). Philadelphia: Saunders.

Nursing ManagementFoot Disorders

Nursing Implementation

Health Promotion.

Well-constructed and properly fitting shoes are essential for healthy, pain-free feet. Instead of considerations of comfort and support, fashion styles, especially for women, often influence selection of footwear. Patient teaching should stress the importance of wearing shoes that conform to the foot rather than to current fashion trends. Shoes must be long enough and wide enough to prevent crowding of the toes and forcing of the great

toe into a position of hallux valgus. At the metatarsal head, the width of shoes should be sufficient to allow free movement of the foot muscles and permit bending of the toes. The shank (narrow part of sole under the instep) of the shoes should be rigid enough to give optimal support. The height of the heels should be realistic in relation to the purpose for which the shoes are worn. Ideally, the heels of the shoes should not rise more than 2.5 cm higher than the forefoot support.

Effective strategies for preventing foot injuries are also required at the workplace. Prolonged standing, especially on hard, unyielding floors, can cause the joints of bones of the feet to become misaligned and inflamed. Special antislip flooring or matting can reduce slipping accidents that can result in sprained ankles or broken foot bones. All jurisdictions in Canada mandate that workers wear adequate protection against workplace hazards. Workers who are exposed to high foot-hazard risk (e.g., those in the construction industry) are required to use footwear certified by the Canadian Standards Association.

Acute Intervention.

Many foot problems require referral to a podiatrist. Depending on the problem, conservative therapies are usually tried first (see Table 66-9). These therapies include NSAIDs, icing, physiotherapy, alterations in footwear, stretching, warm soaks, orthotics, ultrasonography, and corticosteroid injections. If these methods do not offer relief, surgery may then be recommended.

Depending on the type of surgery, pins or wires (hardware) may extend through the toes, or a protective splint that extends over the end of the foot may be in place. Postoperatively, the foot is usually immobilized by a bulky dressing, short leg cast, slipper (plaster) cast, or a platform "shoe" that fits over the dressing and has a rigid sole (known as a *bunion boot*). The foot should be elevated with the heel off the bed to help reduce discomfort and prevent edema. Neurovascular status should be assessed frequently during the immediate postoperative period. Care must be taken to protect hardware as impact or movement cause pain. The hardware may interfere with or preclude assessment for movement. Sensation may be difficult to evaluate because postoperative pain can interfere with the patient's ability to differentiate pain caused by the surgical procedure from pain resulting from nerve pressure or circulatory impairment.

The type and the extent of surgery determine the degree of ambulation allowed. Crutches, a walker, a kneeler scooter, or a cane may be necessary. The patient may experience pain or a throbbing sensation when starting ambulation. The nurse should reinforce instructions given by the physiotherapist and ensure that the patient does not develop a faulty gait pattern, such as walking on the heels, in an attempt to avoid excessive pain or pressure. The nurse also ensures that the patient walks with an erect posture and with proper weight distribution. Dysfunction of gait or continued pain should be reported to the physician. The patient should be instructed on the importance of frequent rest periods with the foot elevated.

Ambulatory and Home Care.

Foot care should include carrying out daily hygienic care and wearing clean socks, which should be long enough to prevent wrinkling and the development of pressure areas. Trimming toenails straight across helps prevent ingrown toenails and reduces the possibility of infection. People with impaired circulation or diabetes mellitus require detailed instruction to prevent serious complications associated with blisters, pressure areas, and infections. (See Chapter 52, Table 52-20 for guidelines on foot care.)

Age-Related Considerations

Foot Problems

The older adult is prone to developing foot problems because of poor circulation, atherosclerosis, and decreased sensation in the lower extremities. This problem is especially true for older-adult patients with diabetes mellitus (Turns, 2012). A patient may develop an open wound but not feel it because of altered sensation. This may be the result of peripheral vascular disease or diabetic neuropathy. Older-adult patients should be instructed to inspect their feet daily and report any open wounds or breaks in the skin to their health care provider (Stolt, Suhonen, Puukka, et al., 2012). If left untreated, wounds may become infected, lead to osteomyelitis, and require surgical debridement. If the infection becomes widespread, lower limb amputation may be necessary. The caregiver of the older adult who needs assistance with hygiene practices should be taught the importance of carefully assessing the feet at regular intervals.

Metabolic Bone Diseases

Normal bone metabolism is affected by hormones, nutrition, and hereditary factors. When there is dysfunction in any of these factors, a generalized reduction in bone mass and strength may result. Examples of metabolic bone diseases include osteoporosis and Paget's disease.

Osteoporosis

Osteoporosis, or porous bone (Figure 66-8), is a chronic, progressive metabolic bone disease. It is characterized by low bone mass and structural deterioration of bone tissue, leading to increased bone fragility, which predisposes the individual to bone fractures at the hip, wrist, and spine. Osteoporosis is known as the "silent thief" because it slowly and insidiously, over many years, robs the skeleton of its banked resources. Fractures from osteoporosis are more common than heart attack, stroke, and breast cancer combined (Osteoporosis Canada, 2017a).

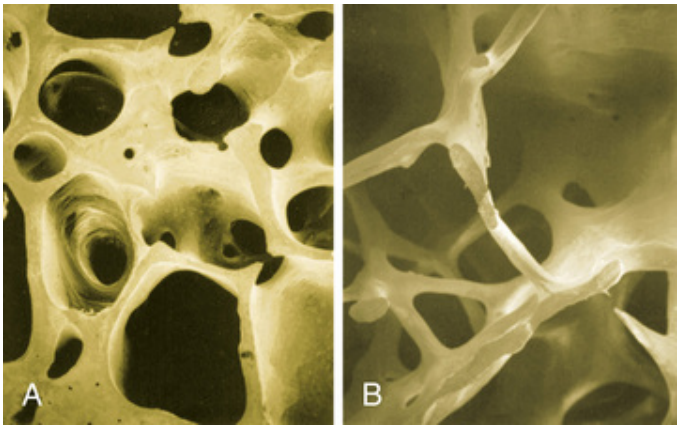

FIGURE 66-8 **A,** Normal bone. **B,** Osteoporotic bone. Source: Patton, K. T., & Thibodeau, G. A. (2016). *Anatomy and physiology* (7th ed., p. 277, Figure 11-25, *B* and *C*). St. Louis: Mosby.

Osteoporotic fractures occur in at least 1 in 3 Canadian women and 1 in 5 Canadian men (Osteoporosis Canada, 2017a). Approximately 30 000 Canadians will suffer a hip fracture, annually. From 70% to 90% of these hip fractures are due to osteoporosis (Osteoporosis Canada, 2017b).

Osteoporotic fractures result in significant morbidity and mortality. It is estimated that 28% of women and 37% of men will suffer a hip fracture due to osteoporosis and die within the following year (Osteoporosis Canada, 2017a). The cost of treating osteoporosis and related fractures is estimated to be $2.3 billion each year, but this cost increases to $3.9 billion as many of the fractures occur in individuals in long-term care facilities (Tarride, Hopkins, Leslie, et al., 2012).

Residents of long-term care facilities need special considerations as many are frail, suffer from dementia, and are at high risk for delirium. They have a fracture rate two to four times greater than that of similar-aged adults living in the community, and one-third of patients with hip fractures are long-term care residents (Papaioannou, Santesso, Morin, et al., 2015). They also have a 30% rate of moderate to severe vertebral fractures. Papaioannou, Santesso, Morin, et al. (2015) developed Fracture Prevention for Long-Term Care Residents, which includes osteoporosis prevention, assessment, and nutritional and drug therapy recommendations.

Secondary prevention through the development of Osteoporosis Canada's Fracture Liaison Services (FLS) and Fracture Registry has proven to decrease the number of subsequent fractures and decrease the associated economic burden to the health care system (Marsh, Akesson, Beaton, et al., 2011). The International Osteoporosis Foundation took the Osteoporosis Canada recommendations and developed a global campaign to facilitate and implement FLS (International Osteoporosis Foundation [IOF], 2015). The FLS is a world class, cost-effective model of postfracture care that ensures that patients over the age of 50 are assessed and treated for osteoporosis (Osteoporosis Canada, n.d.). Canada now has FLS material online, and several provinces have or are in the process of developing and implementing FLS.

Osteoporosis is more common in women than in men for several reasons: (1) women tend to have lower calcium intake than men (men between 15 and 50 years of age consume twice as much calcium as women); (2) women have less bone mass because of their generally smaller frame; (3) bone resorption begins at an earlier age in women and is accelerated at menopause; (4) pregnancy and breastfeeding deplete a woman's skeletal reserve unless calcium intake is adequate; and (5) longevity increases the likelihood of osteoporosis, and women live longer than men. The "Determinants of Health" box lists other factors that contribute to risk for osteoporosis.

Determinants of Health

Osteoporosis

Culture

- There is a higher risk for osteoporosis development in immigrants (especially Asian Canadians) due to differences in nutritional intake (i.e., less calcium, protein, iron).*

Gender

- One in three women and one in five men will develop an osteoporosis-related fracture in their lifetime.†
- Women and men begin to lose bone mass in their mid-thirties†. Women tend to lose bone at a younger age and faster pace than men.‡

Healthy Child Development

- Strong bone formation during childhood reduces the likelihood of osteoporosis in adulthood.†
- Optimal bone mass is developed during adolescence and early adulthood (ages 16–20 in females; ages 20–25 in males).†

Etiology and Pathophysiology

Evaluation of assessment of osteoporosis has shifted from simply treating low bone mineral density to that of an integrated approach of patients with certain clinical factors at increased risk for a fragility fracture. As such, indications for measuring bone mineral density have shifted slightly, as shown in Table 66-10. Decreased risk is associated with regular weight-bearing exercise and calcium and vitamin D ingestion. Low testosterone levels are a risk factor in men.

TABLE 66-10
Indications for Measuring Bone Mineral Density

Older Adults (Age ≥50 yr)	Younger Adults (Age <50 yr)
• Age ≥65 yr (both women and men) • Clinical risk factors for fracture (menopausal women, men age 50–64 yr) • Fragility fracture after age 40 yr • Prolonged use of glucocorticoids* • Use of other high-risk medications† • Parental hip fracture • Vertebral fracture or osteopenia identified on radiography • Current smoking • High alcohol intake • Low body weight (<60 kg) or major weight loss (>10% of body weight at age 25 yr) • Rheumatoid arthritis • Other disorders strongly associated with osteoporosis	• Fragility fracture • Prolonged use of glucocorticoids* • Use of other high-risk medications† • Hypogonadism or premature menopause (age <45 yr) • Malabsorption syndrome • Primary hyperparathyroidism • Other disorders strongly associated with rapid bone loss, fracture, or both

*At least 3 months cumulative therapy in the previous year at a prednisone-equivalent dose ≥7.5 mg daily.

Peak bone mass (maximum bone tissue) is mainly achieved before age 20 and is determined by a combination of four major factors: heredity, nutrition, exercise, and hormone function. Heredity may be responsible for up to 70% of a person's peak bone mass. Bone loss from midlife (age 35–40 years) onward is inevitable, but the rate of loss varies. At menopause, women experience rapid bone loss when the decline in estrogen production is the sharpest. This rate of loss then slows, and eventually matches the rate of bone lost by men at 65 to 70 years old.

Bone is continually being deposited by osteoblasts and resorbed by osteoclasts, a process called *remodelling*. Normally, the rates of bone deposition and resorption are equal to each other so that the total bone mass remains constant (Armas & Recker, 2012). In osteoporosis, bone resorption exceeds bone deposition. Although resorption affects the entire skeletal system, osteoporosis occurs most commonly in the bones of the spine, hips, and wrists. Over time, wedging and fractures of the

vertebrae produce gradual loss of height and a humped back, known as *dowager's hump,* or *kyphosis* (Figure 66-9). The usual first signs of osteoporosis are back pain or spontaneous fractures. The loss of bone substance causes the bone to become mechanically weakened and prone to either spontaneous fractures or fractures from minimal trauma. Specific diseases and conditions associated with osteoporosis include inflammatory bowel disease, intestinal malabsorption, kidney disease, rheumatoid arthritis, hyperthyroidism, chronic alcoholism, cirrhosis of the liver, hypogonadism, and diabetes mellitus.

Many drugs can interfere with bone metabolism, including corticosteroids, anticonvulsant drugs (e.g., phenytoin [Dilantin]), aluminum-containing antacids, heparin, certain cancer treatments, and excessive thyroid hormones. At the time a drug is prescribed, the patient should be informed of this possible adverse effect. Long-term corticosteroid use is a major contributor to osteoporosis. When a corticosteroid is taken, there is a disproportionate loss of bone, resulting from the inhibition of new bone formation.

Clinical Manifestations

Osteoporosis is often called the "silent disease" because bone loss occurs slowly, without symptoms. People may not know they have osteoporosis until their bones become so weak that a sudden strain, bump, or fall causes a hip, vertebra, or wrist fracture. Collapsed vertebrae may initially be manifested as back pain, loss of height, or spinal deformities such as kyphosis or severely stooped posture.

Diagnostic Studies

Osteoporosis often goes unnoticed because it cannot be detected by conventional radiography until more than 25% to 40% of calcium in the bone is lost. Serum calcium, phosphorus, and alkaline phosphatase levels usually are normal, although alkaline phosphatase may be elevated after a fracture.

Bone mineral density (BMD) measurements are typically used to measure bone density. BMD assesses the mass of bone per unit volume, or how tightly the bone is packed. (BMD measurements are presented in Chapter 64, Table 64-7.) Quantitative ultrasonography measures bone density with sound waves in the heel, kneecap, or shin. One of the most common BMD studies is dual-energy X-ray absorptiometry (DEXA), which measures bone density in the spine, hips, and forearm (the most common sites of fractures resulting from osteoporosis). DEXA studies are also useful to evaluate changes in bone density over time and to assess the effectiveness of treatment.

The World Health Organization (2007) released a fracture risk assessment system called FRAX. FRAX tools have been individualized by each country as fracture rates are different. FRAX calculates the 10-year risk for hip fracture and the 10-year risk for a major osteoporotic fracture (spine, forearm, hip, or shoulder). Osteoporosis Canada Best Practice Guidelines (Papaioannou, Morin, Cheung, et al., 2010) included the FRAX as a tool to assess for osteoporosis. The tool can be completed by the health care practitioner or the individual as it includes personal risk factors (e.g., smoking, fracture history) as well as bone mineral density at the hip.

DEXA results are frequently reported as T-scores. A T-score of −1 or higher indicates normal bone density. Osteoporosis is quantitatively defined as a BMD T-score at least 2.5 or more below the mean BMD of young adults. *Osteopenia* is defined as bone loss that is greater than

normal (a T-score greater than a range of −1 to −2.5 standard deviations [SDs] below the mean), but not yet at the level for a diagnosis of osteoporosis. In addition to the BMD T-score, the patient's risk factors are included in determining a 10-year absolute fracture risk. This risk changes with advancing age and the development of new risk factors. Those patients with low risk are assessed in 5 to 10 years, whereas those with moderate risk are assessed in 1 to 5 years. Quantitative ultrasonography may be considered for fracture risk assessment when DEXA is not available, but it is not precise enough to be used for follow-up BMD testing.

Nursing and Collaborative Management Osteoporosis

The reduced quality of life for those with osteoporosis can be enormous. Osteoporosis can result in disfigurement, lowered self-esteem, reduction in or loss of mobility, and decreased independence. Collaborative care of osteoporosis focuses on proper nutrition, calcium supplementation, exercise, prevention of fractures, and medications (Table 66-11). The National Osteoporosis Foundation (2014) recommends that women who are postmenopausal and men age 50 or older should be considered for treatment of osteoporosis if presenting with any of the following: (1) a hip or vertebral fracture; (2) a DEXA hip (femoral neck) or spine T-score of 1.0 to -2.5; or (3) a FRAX score of 3% or higher at the hip or 20% or higher at other sites.

TABLE 66-11
Collaborative Care Osteoporosis

Diagnostic
• History and physical examination • Serum calcium, phosphorus, and alkaline phosphatase levels • Bone mineral densitometry • Dual-energy X-ray absorptiometry (DEXA) • Quantitative ultrasonography (QUS)
Collaborative Therapy

• Diet high in calcium (see Table 66-12)
• Calcium supplements (see Table 66-13)
• Vitamin D supplements
• Exercise program
• Estrogen replacement therapy
• Bisphosphonates
  • Alendronate (Fosamax)
  • Etidronate
  • Risedronate (Actonel)
  • Zoledronic Acid (Aclasta)
• Selective estrogen receptor modulator (SERM)
  • Raloxifene (Evista)
• Teriparatide (Forteo)
• Salmon calcitonin (Calcimar)

Prevention and treatment of osteoporosis focus on adequate calcium intake (1 000 mg/day in women between the ages 19 and 50 and men between the ages 19 and 70; and 1 200 mg in women >50 years of age and men >70 years of age). If dietary intake of calcium is inadequate, supplemental calcium should be taken (Health Canada, 2012). Foods that are high in calcium content include whole and skim milk, yogourt, cottage cheese, ice cream, spinach, almonds, and sardines (Table 66-12). The amount of elemental calcium varies in different calcium preparations (Table 66-13). Calcium supplementation inhibits age-related bone loss; however, it does not stimulate the formation of new bone.

TABLE 66-12

Nutritional Therapy
Sources of Calcium

Food	Calcium (mg)
250 mL (1 cup) milk	
Whole	291
Low-fat	300
Skim	302
30 g (1 oz) cheese	
Processed	174
Cheddar	130
Cottage	130
Mozzarella	207
Parmesan	390
Swiss	272
250 mL (1 cup) yogourt	415
250 mL (1 cup) ice cream	
Hard	176
Soft-serve	272
90 g (3 oz) seafood	
Salmon	167
Sardines with bones	372
Shrimp	98
Oysters	113
1 medium stalk cooked broccoli	158
250 g (1 cup) cooked spinach	200
250 g (1 cup) almonds	304

TABLE 66-13

Elemental Calcium Content of Various Oral Calcium Preparations

Calcium Preparation	Elemental Calcium Content
Calcium carbonate (Tums 500)	500 mg/tablet
Calcium carbonate + 5 mcg vitamin D2 (Os-Cal 250)	250 mg/tablet
Calcium gluconate	40 mg/500 mg
Calcium carbonate	400 mg/g
Calcium lactate	80 mg/600 mg
Calcium citrate	40 mg/300 mg

Vitamin D is important in calcium absorption and function and may have a role in bone formation. Most Canadians do not get enough vitamin D from their diet or naturally through synthesis in the skin from exposure to sunlight. Supplemental vitamin D, for all adults, year round, is recommended by Osteoporosis Canada (2017c). For adults who are healthy and between 19 and 50 years of age, 400–1000 IU of vitamin D daily are required. For adults over 50 years of age and for those younger

adults at high risk (e.g., with osteoporosis, multiple fractures, or conditions affecting vitamin D absorption), 800–2 000 IU daily is recommended (Osteoporosis Canada, 2017c).

Regular physical activity is important to build up and maintain bone mass. Exercise also increases muscle strength, coordination, and balance. The best exercises are weight-bearing exercises that force an individual to work against gravity. These include walking, hiking, weight training, stair climbing, tennis, and dancing. Walking is preferred to high-impact aerobics or running, both of which may put too much stress on the bones, resulting in stress fractures. Walking for 30 minutes, three times a week, is recommended.

Cigarette smoking and excess alcohol intake are risk factors for osteoporosis. Regular consumption of 60 to 90 mL of alcohol a day may increase the degree of osteoporosis, even in young men and women. Patients should be instructed to quit smoking and cut down on alcohol intake to decrease the likelihood of losing bone mass.

Although loss of bone cannot be significantly reversed, further loss can be prevented if the patient follows a regimen of calcium and vitamin D supplementation, exercise, estrogen replacement, and alendronate (Fosamax) or raloxifene (Evista), if indicated. Efforts should be made to keep patients with osteoporosis ambulatory to prevent further loss of bone substance as a result of immobility.

Drug Therapy

Hormone therapy should be considered as first-line therapy for preventing bone loss and fractures in early menopausal women who are symptomatic (e.g., have vasomotor, urogenital, and psychological symptoms). It is believed that estrogen inhibits osteoclast activity, leading to decreased bone resorption and preventing both cortical and trabecular bone loss. Estrogen therapy (for women who have had a hysterectomy) and estrogen–progesterone therapy (for women who have not had a hysterectomy) provide significant protection against osteoporotic fractures. Despite earlier concerns raised by a number of studies, it now seems that women who are younger and recently postmenopausal do not have an increased cardiovascular risk with estrogen or estrogen–progesterone therapy. Considering the risk–benefit profile of hormone therapy, the North American Menopause Society states that the extended use of hormone therapy is suitable for women at risk for osteoporotic fractures who also have moderate to severe

menopausal symptoms. As with any drug therapy, doses and regimens must be individualized according to the patient's needs. (See Chapter 56 for further discussion of hormone therapy.)

Calcitonin is secreted by the thyroid gland and inhibits osteoclastic bone resorption by directly interacting with active osteoclasts. Salmon calcitonin (Calcimar) is available in intramuscular, subcutaneous, and intranasal forms. The nasal form is easy to administer, and patients should be taught to alternate nostrils daily. Nasal dryness and irritation are the most frequent adverse effects. Administration of the intramuscular or subcutaneous form of the drug at night has been shown to decrease the adverse effects of nausea and facial flushing. Nausea does not occur with the nasal spray. When calcitonin is used, calcium supplementation is necessary to prevent secondary hyperparathyroidism.

Bisphosphonates inhibit osteoclast-mediated bone resorption, thereby increasing BMD and total bone mass. This group of drugs has been shown to increase BMD by 5%. Common adverse effects are anorexia, weight loss, and gastritis. Effective osteoporosis treatment has been shown to reduce mortality in older adults and individuals who are frail and at high risk for a fracture. The most commonly used bisphosphonate drug in treating osteoporosis is alendronate (Fosamax). Patients should be instructed on the proper administration of alendronate to aid in its absorption. It should be taken with a full glass of water after rising in the morning. The patient should not eat or drink anything for 30 minutes after taking it. The patient should also be instructed not to lie down after taking the drug. These precautions have been shown to decrease gastrointestinal adverse effects (especially esophageal irritation) and increase absorption. Alendronate is also available as a once-per-week oral tablet. Zoledronic acid (Aclasta) is approved for a once-yearly IV infusion and can prevent osteoporosis for 2 years after a single infusion. One potential adverse effect of bisphosphonates is atypical femur fractures and osteonecrosis of the jaw.

Drug Alert

Bisphosphonates

Patients should be instructed to do the following:

- Take with full glass of water
- Take 30 min before food or other medications
- Remain upright for at least 30 min after taking

Another type of drug used in treating osteoporosis is raloxifene (Evista), a selective estrogen receptor modulator. This drug mimics the effect of estrogen on bone by reducing bone resorption without stimulating the tissues of the breast or uterus. Raloxifene in women who are postmenopausal significantly increases BMD. The most commonly reported adverse effects are leg cramps, hot flashes, and blood clots. Raloxifine may decrease breast cancer risk. Similar to tamoxifen, it blocks the estrogen receptor sites of cancer sites.

Teriparatide (Forteo) is used for the treatment of osteoporosis in men and in women who are postmenopausal and at high risk for fractures. Teriparatide is a recombinant form of human parathyroid hormone and works by increasing the action of osteoblasts. It is the first drug approved for the treatment of osteoporosis that stimulates new bone formation. Most drugs used to treat osteoporosis prevent further bone loss. Teriparatide is administered by subcutaneous injection, once a day. Adverse effects include leg cramps and dizziness. Denosumab (Prolia) may be used for women with osteoporosis who are postmenopausal and at high risk for fractures. It is a monoclonal antibody that binds to a protein (RANKL) involved in the formation and function of osteoclasts. Denosumab is given as a subcutaneous injection every 6 months.

Current guidelines clearly advocate for pharmacological treatment in patients who are at high risk for fractures and are diagnosed with osteoporosis; however, there is no clear guidance about when treatment should be stopped (Lewiecki, Cummings, & Cosman, 2013).

Medical management of patients receiving corticosteroids includes prescribing the lowest possible dose of the drug as well as calcium and vitamin D supplementation. If osteopenia is evident on bone densitometry, treatment with bisphosphonate agents, such as alendronate (Fosamax), should be considered.

Evidence-Informed Practice

Translating Research Into Practice

Rita Farrouk is a 76-yr-old woman who fell in her home and sustained a hip fracture. Her recent laboratory work shows a vitamin D deficiency. The nurse discusses her options for improving this deficiency. She tells the nurse that she is moving to Arizona to be with her daughter and is planning to spend "many hours in the sun" every day.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
Women who are postmenopausal should receive 1 200 mg of calcium and 800 IU of vitamin D daily. Dietary sources and supplements should be used to meet these requirements.	The nurse has worked with many patients recovering from fractures related to osteoporosis. The nurse reviews Ms. Farrouk's usual diet and determines that it is deficient in calcium and vitamin D.	Patient prefers sun exposure over changing her diet (she is a vegetarian) or taking supplements.

Action and Decision

The nurse discusses the risks associated with daily sun exposure and points out that sun exposure will not correct a calcium deficiency. Ms. Farrouk tells the nurse she understands but wants to try before taking "any more pills." The nurse explains the importance of adding foods high in calcium to her diet. The nurse provides her with a list of some choices that meet her vegetarian diet restrictions.

Paget's Disease

Paget's disease of the bone *(osteitis deformans)* is a chronic skeletal bone disorder in which there is excessive bone resorption followed by replacement of normal marrow by vascular, fibrous connective tissue. The new bone is larger, disorganized, and structurally weaker. The regions of the skeleton commonly affected are the pelvis, long bones, spine, ribs, sternum, and cranium. The etiology of Paget's disease is unknown, although there is evidence that the rate of Paget's disease is influenced by genetic and environmental factors (Singer, 2015). Up to 40% of all patients with Paget's disease have at least one relative with the disorder. Men are affected at a rate of 2 : 1 compared to women, and Paget's disease is rarely seen in people younger than 40 years. Viral etiology remains controversial as no specific virus has been isolated thus far.

In milder forms of Paget's disease, patients may remain free of symptoms, and the disease may be discovered incidentally on radiography or serum chemistry. The initial clinical manifestations are usually insidious development of bone pain (which may progress to severe, intractable pain), fatigue, and progressive development of a waddling gait. Patients may complain that they are becoming shorter or that their heads are becoming larger. Headaches, dementia, visual deficits, and loss of hearing can result, with an enlarged, thickened skull. Increased bone volume in the spine can cause spinal cord or nerve root compression. Pathological fracture is the most common complication of Paget's disease and may be the first indication of the disease. Other complications include osteosarcoma, fibrosarcoma, and osteoclastoma (giant cell) tumours.

Safety Alert

The risk for patient harm resulting from falls can be reduced as follows:

- Patients should be evaluated for fall risk.
- High-risk factors should be identified, including medications that increase risk for falls.
- Action should be taken to address any identified risks.
- Patients at risk should be encouraged to attend a fall-prevention class.

Serum alkaline phosphatase levels are markedly elevated (indicating high bone turnover) in advanced forms of the disease. Radiographs may demonstrate that the normal contour of the affected bone is curved and the bone cortex is thickened and irregular, especially the weight-bearing bones and cranium. Bone scans using a radiolabelled biphosphate demonstrate increased uptake in the skeletal areas affected.

Collaborative care of Paget's disease is usually limited to symptomatic and supportive care and correction of secondary deformities by either surgical intervention or braces. Bisphosphonate drugs are the preferred treatment in individuals at risk for pathological fracture(s) since bisphosphonates reduce bone turnover (Singer, Bone, Hosking, et al., 2014). Often, calcium and vitamin D are given to decrease hypocalcemia, a common adverse effect with these drugs. Drug effectiveness may be monitored by serum alkaline phosphatase levels.

Calcitonin therapy is recommended for patients who cannot tolerate bisphosphonate drugs. Human calcitonin inhibits osteoclastic activity, prevents bone resorption, relieves acute symptoms, and lowers the serum alkaline phosphatase levels. This drug is available as a subcutaneous injection. Salmon calcitonin can also be used as a subcutaneous or intramuscular injection for treating Paget's disease. Salmon calcitonin has a longer half-life and greater milligram potency than human calcitonin. Response to calcitonin therapy is not permanent and often stops when therapy is discontinued. Pain from Paget's disease is usually managed by NSAIDs or acetaminophen. Orthopaedic surgery for fractures, hip and knee replacements, and knee realignment may be necessary.

A firm mattress should be used to provide back support and to relieve pain. The patient may be required to wear a corset or light brace to relieve back pain and provide support when in the upright position. The

patient should be proficient in the correct application of such devices and know how to regularly examine areas of the skin for friction damage. Activities such as lifting and twisting should be discouraged. Physiotherapy may increase muscle strength. Good body mechanics are essential. A properly balanced nutritional program is important in the management of metabolic disorders of bone, especially pertaining to vitamin D, calcium, and protein, which are necessary to ensure the availability of the components for bone formation. Prevention measures such as patient education, use of an assistive device, and environmental changes should be actively pursued to prevent falls and subsequent fractures.

Age-Related Considerations

Metabolic Bone Diseases

Osteoporosis and Paget's disease are common in older adults. Patients should be instructed in proper nutritional management to prevent further bone loss such as that occurring from osteoporosis.

Since metabolic bone disorders increase the possibility of pathological fractures, extreme caution should be used when turning or moving the patient. Hip fractures in particular can adversely affect quality of life and may lead to admission to a long-term care facility. It is important to keep the patient as active as possible to slow demineralization of bone resulting from disuse or extended immobilization. A supervised exercise program is an essential part of the treatment program. If the patient's condition permits, ambulation without causing fatigue must be encouraged.

Protection from falls is paramount for prevention of osteoporotic fracture among older adults. Osteoporosis-related fractures cause considerable morbidity and an enormous financial burden through the use of health services. In Canada, 1 in 3 older adults will experience a fall each year, and half of those will fall more than once. Falls are the leading cause of injury among older Canadians and the cause of 95% of all hip fractures; also, 85% of falls are the cause of injury-related hospitalizations (Public Health Agency of Canada [PHAC], 2015). The frequency of falls increases dramatically with age, with women being more likely to fall than men.

Medical conditions, medications, and environmental factors have been implicated as predisposing factors to injurious falls among older adults.

Best practice guidelines (Registered Nurses' Association of Ontario [RNAO], 2017) should be implemented to prevent falls and fall injuries in older adults, who may already have bone mass below the threshold for fracture. Fall prevention could have a significant impact on the incidence of fracture in this susceptible population.

Case Study

Osteoporosis

Source: Blaj Gabriel/Shutterstock.com.

Patient Profile

Antonija Roncevic is a 56-year-old retired librarian who had a total hysterectomy and salpingo-oophorectomy for removal of a benign ovarian cyst, 4 years ago. She also has a history of a seizure disorder since childhood, and Addison's disease.

Subjective Data

- Acute, severe lumbar pain and tenderness that radiate to her right hip and lateral thigh after falling and landing on her buttocks last week
- Walking and bending increases pain
- Stress fracture in wrist 6 months ago
- Reports no noticeable loss of height
- Maternal history of osteoporosis
- Taking corticosteroids and mineralocorticoids for past 6 years for Addison's disease

- Taking phenytoin (Dilantin) every evening
- Drinks two alcoholic beverages every evening
- Dislikes dairy products

Objective Data

- 167 cm tall, 72 kg

Diagnostic Studies

- Bone mass measurement tests show decreased bone mineral density at spine and hip
- Lumbar spine radiographs reveal a slightly displaced L4 compression fracture
- Normal serum calcium, phosphorus, and alkaline phosphatase levels

Collaborative Care

- L4 vertebroplasty
- Thoraco-lumbar-sacral orthosis (TLSO) brace postoperatively
- Alendronate (Fosamax) 70 mg once weekly PO
- Total calcium intake of 1 200 mg/day PO (supplement + dietary intake)
- High-calcium diet
- Reduction in alcohol intake
- Regular, low-impact weight-bearing exercise program

Discussion Questions

1. What factors place Ms. Roncevic at risk of developing osteoporosis?
2. Why does walking and bending increase Ms. Roncevic's pain?
3. What is the purpose of the TLSO brace prescribed for Ms. Roncevic?
4. ***Priority decision:*** What are the priority teaching needs for Ms. Roncevic?

5. How might the nurse assist Ms. Roncevic in increasing her intake of calcium?
6. Why would regular exercise be important for Ms. Roncevic?
7. ***Priority decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
8. ***Evidence-informed practice:*** Ms. Roncevic asks why taking corticosteroids increases her risk of developing osteoporosis. How should the nurse respond to her?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. A client with osteomyelitis is treated with surgical debridement with implantation of antibiotic beads. When the client asks why the beads are used, what should the nurse answer? *Select all that apply.*
   a. "The beads are used to directly deliver antibiotics to the area of the infection."
   b. "There are no effective oral or IV antibiotics to treat most cases of bone infection."
   c. "This is the safest method of delivering long-term antibiotic therapy for a bone infection."
   d. "The beads are used for deep infections in addition to removing the damaged tissue and oral and IV antibiotics."
   e. "The lack of blood flow and bone death that occur with osteomyelitis make IV antibiotics less effective."
2. A client has been diagnosed with osteosarcoma of the humerus. Which of the following statements would indicate that he has an understanding of his treatment options?
   a. "I accept that I have to lose my arm with surgery."
   b. "The chemotherapy before surgery will shrink the tumour."
   c. "This tumour is related to the melanoma I had 3 years ago."
   d. "I'm glad they can take out the cancer with such a small scar."
3. Which of the following individuals does the nurse identify as being high risk for low back pain? *Select all that apply.*
   a. A 63-year-old man who is a long-distance truck driver
   b. A 36-year-old construction worker who is 190 cm tall and weighs 118 kg
   c. A 28-year-old female yoga instructor who is 170 cm tall and weighs 59 kg
   d. A 30-year-old male nurse who works on an orthopaedic unit and smokes
   e. A 44-year-old female chef with prior compression fracture of the spine

4. What is the primary nursing responsibility in caring for a client with a suspected disc herniation who is experiencing acute pain and muscle spasms?

a. Encourage total bed rest for several days.

b. Teach the principles of back strengthening exercises.

c. Stress the importance of straight-leg raises to decrease pain.

d. Promote the use of cold and hot compresses and pain medication.

5. When caring for a client after a spinal fusion, which of the following symptoms would the nurse immediately report to the physician?

a. The client experiences a single episode of emesis.

b. The client is unable to move the lower extremities.

c. The client is nauseated and has not voided in 4 hours.

d. The client complains of pain at the bone graft donor site.

6. What instructions should the nurse give the client who is being discharged from same-day surgery after surgical correction of bilateral hallux valgus?

a. Rest frequently, with the feet elevated.

b. Soak the feet in warm water several times a day.

c. Expect the feet to be numb for several days postoperatively.

d. Expect continued pain in the feet, since this is not uncommon.

7. The nurse is teaching a client with osteopenia. What is important to include in the teaching plan?

a. Lose weight.

b. Stop smoking.

c. Eat a high-protein diet.

d. Start swimming for exercise.

1. a, d, 2. b, 3. a, b, d, e, 4. d, 5. b, 6. a, 7. b.

CHAPTER 67

Nursing Management

Arthritis and Connective Tissue Diseases

Written by, Dottie Roberts

Adapted by, Erica Cambly

LEARNING OBJECTIVES

1. Compare and contrast the sequence of events leading to joint destruction in osteoarthritis and rheumatoid arthritis.
2. Detail the clinical manifestations, collaborative care, and nursing management of osteoarthritis and rheumatoid arthritis.
3. Describe the pathophysiology, clinical manifestations, and collaborative care of gout, Lyme disease, and septic arthritis.
4. Summarize the pathophysiology, clinical manifestations, collaborative care, and nursing management of ankylosing spondylitis, psoriatic arthritis, and reactive arthritis.
5. Differentiate the pathophysiology, clinical manifestations, collaborative care, and nursing management of systemic lupus erythematosus, scleroderma, polymyositis, dermatomyositis, and Sjögren syndrome.
6. Explain the drug therapy and related nursing management associated with arthritis and connective tissue diseases.
7. Compare and contrast the possible etiologies, clinical manifestations, collaborative care, and nursing management of fibromyalgia and systemic exertion tolerance disease.

spondyloarthropathies, p. 1710
systemic exertion intolerance disease (SEID), p. 1722
systemic lupus erythematosus (SLE), p. 1712

This chapter discusses *rheumatic diseases,* which primarily affect body joints, tendons, ligaments, muscles, and bones. These diseases are often characterized by inflammation. Rheumatic diseases result from the loss of function in one or more of the connective or bone structures of the body. There are more than 100 kinds of rheumatic diseases, affecting millions of Canadians.

Arthritis

Arthritis, a type of rheumatic disease, involves inflammation of a joint or joints. Most forms of arthritis affect women more frequently than men (Arthritis Society, 2017a). The most common types of arthritis are osteoarthritis, rheumatoid arthritis, and gout.

Osteoarthritis

Osteoarthritis (OA), the most common form of joint (articular) disease in North America, is a slowly progressive noninflammatory disorder of the diarthrodial (synovial) joints. Currently, more than 3 million Canadians are affected by OA, and the numbers are expected to increase greatly as the population ages (Arthritis Society, 2017b).

Etiology and Pathophysiology

OA involves the formation of new joint tissue in response to cartilage destruction (Sovani & Grogan, 2013). OA is not considered a normal part of the aging process, but aging is one risk factor for disease development (Arthritis Society, 2017b). Cartilage destruction may begin between ages 20 and 30 and the majority of adults are affected by age 40. Few patients experience symptoms until after age 50 or 60, but more than half of those older than 65 years have radiographic evidence of the disease in at least one joint. Women are affected by OA more often than men (Arthritis Society, 2017b).

OA is usually caused by a known event or condition that directly damages cartilage or causes joint instability (Table 67-1). The increased incidence of OA in older-adult women is believed to be due to estrogen reduction at menopause. Modifiable risk factors for OA have been identified, including obesity, which contributes to hip and knee OA. Regular moderate exercise, which also helps with weight control, has been shown to decrease the likelihood of disease development and progression. Anterior cruciate ligament injury, which is associated with quick stops and pivoting as in football and soccer, has been linked to an increased risk for knee OA (Sovani & Grogan, 2013). Occupations that require frequent kneeling and stooping are also linked to a higher risk for knee OA.

TABLE 67-1

CAUSES OF OSTEOARTHRITIS

Cause	Effects on Joint Cartilage
Drugs	Drugs such as indomethacin, colchicine, and corticosteroids can stimulate collagen-digesting enzymes in joint synovium.
Hematological or endocrine disorders	Chronic hemarthrosis (e.g., hemophilia) can contribute to cartilage deterioration.
Inflammation	Release of enzymes in response to local inflammation can affect cartilage integrity.
Joint instability	Damage to supporting structures causes instability, placing uneven stress on articular cartilage.
Mechanical stress	Repetitive physical activities (e.g., sports) cause cartilage deterioration.
Neurological disorders	Pain and loss of reflexes from neurological disorders, such as diabetic neuropathy, and in Charcot's joint cause abnormal movements that contribute to cartilage deterioration.
Skeletal deformities	Congenital or acquired conditions such as Legg–Calvé–Perthes disease or dislocated hip contribute to cartilage deterioration.
Trauma	Dislocations or fractures may lead to avascular necrosis or uneven stress on cartilage.

The pathogenesis of OA is complex, with genetic, metabolic, and local factors that interact and cause a process of cartilage deterioration. OA results from cartilage damage that triggers a metabolic response at the level of the chondrocytes (Figure 67-1). Progression of OA causes the normally smooth, white, translucent articular cartilage to become dull, yellow, and granular. Affected cartilage gradually becomes softer, less elastic, and less able to resist wear with heavy use.

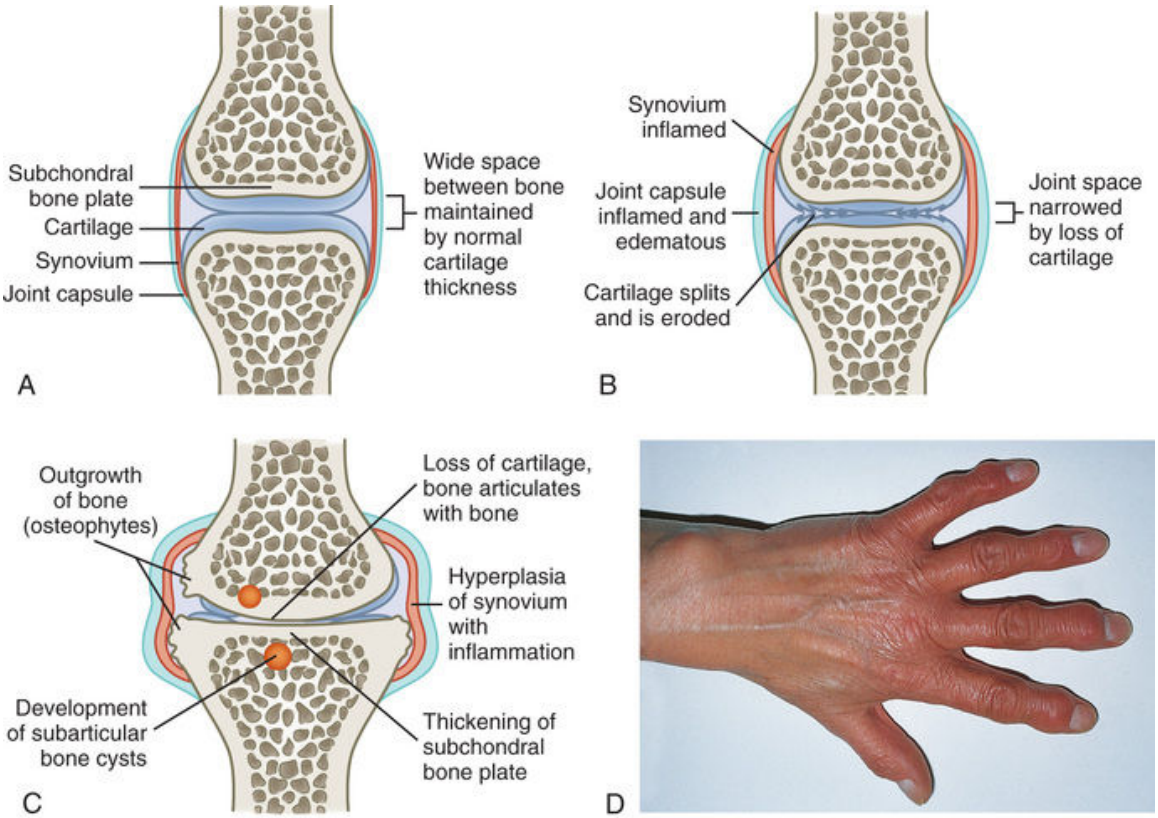

FIGURE 67-1 Pathological changes in osteoarthritis. **A,** Normal synovial joint. **B,** Early change in osteoarthritis is destruction of articular cartilage and narrowing of the joint space. Inflammation and thickening of the joint capsule and synovium occur. **C,** With time, thickening of subarticular bone is caused by constant friction of the two bone surfaces. Osteophytes form around the periphery of the joint by irregular outgrowths of bone. **D,** In osteoarthritis of the hands, osteophytes on the interphalangeal joints of the fingers, termed *Heberden nodes,* appear as small nodules. Source: **D,** Stevens, A., & Lowe, J. (2000). *Pathology: Illustrated review in colour* (2nd ed.). London: Mosby.

The body's attempts at cartilage repair cannot keep up with the destruction that is occurring. Continued changes in the collagen structure of the cartilage lead to fissuring and erosion of the articular surfaces. As the central cartilage becomes thinner, cartilage and bony growth *(osteophytes)* increase at the joint margins. The resulting incongruity in joint surfaces creates an uneven distribution of stress across the joint and contributes to a reduction in motion.

Although inflammation is not characteristic of OA, a secondary synovitis may result when phagocytic cells try to rid the joint of small pieces of cartilage torn from the joint surface. These inflammatory changes contribute to the pain and stiffness of early OA. The pain of later disease

results from contact between exposed bony joint surfaces after the articular cartilage has deteriorated completely.

Clinical Manifestations

Systemic.

Systemic manifestations, such as fatigue, fever, and organ involvement, are not present in OA. This is an important distinction between OA and inflammatory joint disorders such as rheumatoid arthritis.

Joints.

Manifestations of OA range from mild discomfort to significant disability. Joint pain is the predominant symptom and the typical reason that affected patients seek medical attention. Pain generally worsens with joint use. In the early stages of OA, joint pain is relieved by rest. However, in advanced disease, patients may complain of pain with rest or experience sleep disruptions caused by increasing joint discomfort. Pain may also become worse as the barometric pressure falls before inclement weather. As OA progresses, increasing pain can contribute significantly to disability and loss of function. The pain of OA may be referred to the groin, the buttock, or the medial side of the thigh or knee. Sitting down becomes difficult, as does rising from a chair when the hips are lower than the knees. As OA develops in the intervertebral (apophyseal) joints of the spine, localized pain and stiffness are common.

Unlike pain, which is typically provoked by activity, joint stiffness occurs after periods of rest or static position. Early morning stiffness is common but generally resolves within 30 minutes, a factor distinguishing OA from inflammatory arthritic disorders such as rheumatoid arthritis. Overactivity can cause a mild joint effusion that temporarily increases stiffness. *Crepitation,* a grating sensation caused by loose particles of cartilage in the joint cavity, can also contribute to stiffness. Crepitation is a common sign in patients with knee OA.

OA usually affects joints asymmetrically. The most commonly involved joints are the distal interphalangeal (DIP) and proximal interphalangeal (PIP) joints of the fingers, the metacarpo-phalangeal (MCP) joint of the thumb, weight-bearing joints (hips, knees), the metatarso-phalangeal (MTP) joint of the foot, and the cervical and lower lumbar vertebrae (Figure 67-2).

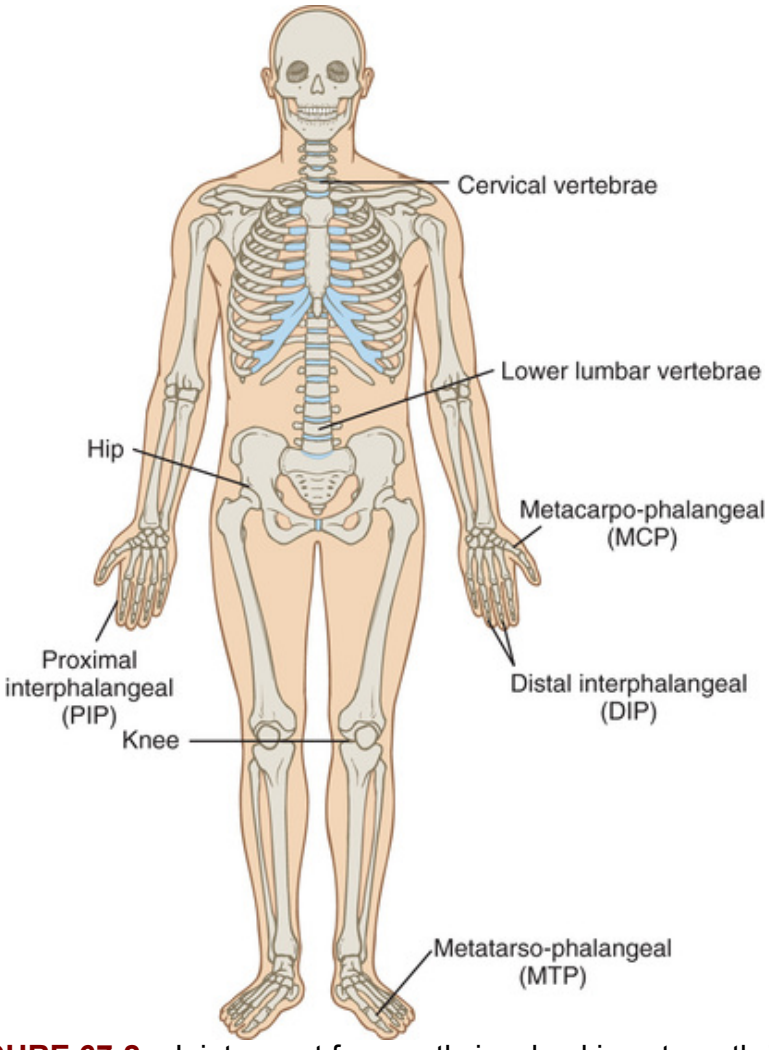

FIGURE 67-2 Joints most frequently involved in osteoarthritis.

Deformity.

Deformity or instability associated with OA is specific to the involved joint. For example, *Heberden nodes* occur on the DIP joints as an indication of osteophyte formation and loss of joint space (see Figure 67-1). They can appear in patients with OA as early as age 40 and tend to be seen in family members. *Bouchard nodes* on the PIP joints indicate similar disease involvement. Heberden and Bouchard nodes are often red, swollen, and tender. Although these bony enlargements do not usually cause significant loss of function, patients may be distressed by the visible disfigurement.

Knee OA often leads to joint malalignment as a result of cartilage loss in the medial compartment. Affected patients have a characteristic bow-legged appearance, and may develop an altered gait in response to the

obvious deformity. In advanced hip OA, one of the patient's legs may become shorter as a result of a loss of joint space.

Diagnostic Studies

A bone scan, computed tomographic (CT) scan, or magnetic resonance imaging (MRI) may be useful for diagnosing OA because of the sensitivity of these tests in detecting early joint changes. Radiological studies are helpful in confirming disease and staging the progression of joint damage. As OA progresses, radiographs typically show joint space narrowing, bony sclerosis, and osteophyte formation. However, these changes do not always correlate with the degree of pain that the patient experiences. Despite significant radiological indications of disease, patients may be relatively free of symptoms. Conversely, other patients may have severe pain with only minimal radiographic changes.

No laboratory abnormalities or biomarkers have been identified that are specific diagnostic indicators of OA. The erythrocyte sedimentation rate (ESR) is normal except in instances of acute synovitis, when minimal elevations may be noted. Other routine blood tests (e.g., complete blood cell count [CBC], kidney and liver function tests) are useful only in screening for related conditions or for establishing baseline values before the initiation of therapy. Synovial fluid analysis allows differentiation between OA and other forms of inflammatory arthritis. In OA, the fluid remains clear yellow with little or no sign of inflammation.

Collaborative Care

Because OA has no cure, collaborative care focuses on managing pain and inflammation, preventing disability, and maintaining and improving joint function (Table 67-2). Nonpharmacological interventions are the foundation for OA management and should be maintained throughout a patient's treatment period. Drug therapy serves as an adjunct to nonpharmacological treatments.

TABLE 67-2

COLLABORATIVE CARE
Osteoarthritis

Diagnostic
• History and physical examination
• Radiological studies of involved joints (e.g. radiographs, CT scan, MRI, bone scan)
• Synovial fluid analysis
Collaborative Therapy
• Nutritional and weight management counselling
• Rest and joint protection, use of assistive devices
• Therapeutic exercise
• Heat and cold applications
• Complementary and alternative therapies
  • Herbs and nutritional supplements (e.g., glucosamine)
  • Movement therapies (e.g., yoga, tai chi)
  • Transcutaneous electrical nerve stimulation (TENS)
  • Acupuncture
	• Drug therapy*
	  • Acetaminophen
	  • Nonsteroidal anti-inflammatory drugs
	  • Antibiotics
	  • Intra-articular hyaluronic acid
	  • Intra-articular corticosteroids
	  • Opioid analgesics
	• Reconstructive joint surgery

*See Table 67-3.

CT, computed tomographic (scan); *MRI*, magnetic resonance imaging.

Rest and Joint Protection.

The patient with OA must understand the importance of a balance between rest and activity. The affected joint(s) should be rested during any periods of acute inflammation and maintained in a functional position with splints or braces if necessary. However, immobilization should not exceed 1 week because of the risk for joint stiffness with inactivity. Patients may need to modify their usual activities to decrease stress on affected joints. Teach patients with knee OA to avoid prolonged periods of standing, kneeling, or squatting. Using an assistive device such as a cane, walker, or crutches can also help decrease stress on arthritic joints.

Heat and Cold Applications.

Applications of heat and cold may help reduce complaints of pain and stiffness. Although ice is not used as often as heat in the treatment of OA, it can be appropriate if patients experience acute inflammation. Heat therapy—including hot packs, whirlpool baths, ultrasound, and paraffin wax baths—is especially helpful for stiffness.

Nutritional Therapy and Exercise.

If a patient is overweight, a weight-reduction program is a critical part of the total treatment plan. The nurse should help the patient evaluate the current diet to make appropriate changes. (Chapter 42 describes ways to

assist patients in attaining and maintaining a healthy body weight.) Because the load on the joints and the degree of joint mobilization are essential to the preservation of articular cartilage integrity, exercise is a fundamental part of OA management (Arthritis Society, 2017b). Aerobic conditioning, range-of-motion exercises, and specific programs for strengthening the quadriceps have been beneficial for many patients with knee OA.

Complementary and Alternative Therapies.

Complementary and alternative therapies for symptom management of arthritis are popular with patients who have failed to find relief through traditional medical care. Acupuncture is effective in decreasing chronic arthritis pain (Vickers, Cronin, Maschino, et al., 2012). Other therapies include yoga, massage, guided imagery, and therapeutic touch (see Chapter 12). Nutritional supplements such as glucosamine and chondroitin sulphate may be helpful in some patients for relieving moderate to severe arthritis pain in the knees and improving joint mobility (Hochberg, Martel-Pelletier, Monfort, et al., 2016) (see the "Complementary & Alternative Therapies" boxes in this chapter).

Complementary & Alternative Therapies

Acupuncture

Acupuncture is a traditional Chinese medical practice of inserting very fine needles into the skin to stimulate specific anatomical points in the body (called *acupoints*) for therapeutic purposes.

Scientific Evidence*

The evidence is moderately strong for reducing chronic pain from osteoarthritis; chronic headache; and back, neck, and shoulder pain.

Nursing Implications

- Acupuncture is an effective treatment to suggest to patients with chronic pain.
- Refer interested patients to a practitioner who is appropriately trained and licensed (see Chapter 12).

*Source: Vickers, A., Cronin, A., Maschino, A., et al. (2012). Acupuncture for chronic pain: Individual patient data meta-analysis. *Archives of Internal Medicine, 172*(19), 1444–1453.

Complementary & Alternative Therapies

Glucosamine and Chondroitin

Scientific Evidence*

Both glucosamine and chondroitin provide some relief for moderate to severe arthritic pain but not for mild arthritic pain. Pain outcomes over 2 years were similar to those of patients taking celecoxib (Celebrex) or placebo.

Nursing Implications

- Can be suggested to patients who are unable to take celecoxib or other nonsteroidal anti-inflammatory drugs (NSAIDs).
- Discontinue if no effects after consistent use over 90–120 days.
- May decrease effectiveness of insulin or other drugs used to control blood glucose.
- May increase the risk of bleeding.

*Source: Hochberg, M., Martel-Pelletier, J., Monfort, J., et al. (2016). Combined chondroitin sulfate and glucosamine for painful knee osteoarthritis: A multicenter, randomized, double-blind, non-inferiority trial versus celecoxib. *Annals of Rheumatic Diseases, 75*(1), 37–44. doi:10.1136/annrheumdis-2014-206792

Drug Therapy.

Drug therapy is based on the severity of the patient's symptoms (Table 67-3). Patients with mild to moderate joint pain may get relief from acetaminophen (Tylenol). The patient may receive up to 1 000 mg every 6 hours, with the daily dose not to exceed 4 g. A topical agent such as capsaicin cream may also be beneficial, either alone or in conjunction with acetaminophen. It blocks pain by locally interfering with substance P, which is responsible for the transmission of pain impulses. A concentrated product is available by prescription, but creams of 0.025% to 0.075%

capsaicin are available over the counter (OTC). Other OTC products that contain camphor, eucalyptus oil, and menthol (e.g., BenGay, Arthricare) may also provide temporary pain relief. Topical salicylates (e.g., Aspercreme) that can be absorbed into the blood are an alternative for patients who are able to take acetylsalicylic acid (ASA; Aspirin)–containing medication. Because effects of topical agents are not sustained, several applications daily may be needed.

TABLE 67-3

DRUG THERAPY
Arthritis and Connective Tissue Disorders

Drug	Mechanism of Action	Adverse Effects	Nursing Considerations
Salicylates			
ASA (Aspirin, Asaphen)	Analgesic Anti-inflammatory Antipyretic Inhibits prostaglandin synthesis	Exacerbation of asthma (ASA [Aspirin]-sensitive asthma) GI irritation (dyspepsia, nausea, ulcer, hemorrhage) Prolonged bleeding time Tinnitus, dizziness with repeated large doses	Administer drug with food, milk, antacids as prescribed, or full glass of water; enteric-coated ASA (Aspirin) may be administered. Report signs of bleeding (e.g., tarry stools, bruising, petechiae, nosebleeds).
Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)			
Celecoxib (Celebrex) Diclofenac (Voltaren) Ibuprofen (Motrin, Advil) Indomethacin Ketoprofen Ketorolac tromethamine (Toradol) Meloxicam (Mobicox) Nabumetone (Apo-Nabumetone) Naproxen (Naprosyn, Aleve) Piroxicam (Teva-Piroxicam) Sulindac (Teva-Sulindac)	Analgesic Anti-inflammatory Antipyretic Inhibits prostaglandin synthesis	Acute renal insufficiency and other renal medullary changes Exacerbation of asthma (cross-reactivity with ASA [Aspirin]) GI irritation (dyspepsia, nausea, ulcer, hemorrhage) Headache, tinnitus Prolonged bleeding time Rash	Administer drug with food, milk, or antacids as prescribed. Report signs of bleeding (e.g., tarry stools, bruising, petechiae, nosebleeds), edema, skin rashes, persistent headaches, visual disturbances. Monitor BP for elevations related to fluid retention. Drug must be administered regularly for maximal effect.
Antibiotics			
Doxycycline Minocycline	Antirheumatic effect, possibly related to immuno-modulatory or anti-inflammatory properties Decreases action of enzymes on cartilage degradation	Dizziness GI effects (nausea and vomiting, diarrhea, stomach cramps) Monilial vaginitis, sensitivity to direct sunlight or ultraviolet light, nonspecific GI irritation Photosensitivity (severe)	This is a possible treatment alternative for mild disease.
Topical Analgesics			

Drug	Mechanism of Action	Adverse Effects	Nursing Considerations
Capsaicin cream	Depletes substance P from nerve endings, interrupting pain signals to the brain	Erythema Localized burning sensation Rash Urticaria	Drug must be administered regularly over time for maximal effect. Aloe vera cream may modify burning sensation. Advise patient not to use cream with external heat source (heating pad) because of risk for burns. Available in OTC and prescriptive strengths.
Diclofenac diethylamine (Voltaren Emulgel)	Anti-inflammatory Analgesic	Adverse GI effects similar to those of systemic NSAIDs Skin irritation	Advise patient to avoid sun and ultraviolet exposure. Drug should not be used in combination with other oral NSAIDs or ASA (Aspirin) because of potential for increased adverse effects.
Corticosteroids			
Intra-Articular Injections			
Methylprednisolone acetate (Depo-Medrol) Triamcinolone	Analgesic Anti-inflammatory Inhibit synthesis and release of mediators of inflammation	Dermal or subdermal changes leading to depression at injection site Local osteoporosis Neuropathic arthropathy from frequent injection Possibility of local infection Tendon rupture	Use strict aseptic technique for joint fluid aspiration or corticosteroid injection. Inform patient that joint may feel worse immediately after injection. Inform patient that improvement lasts weeks to months after injection. Advise patient to avoid overusing affected joint after injection.
Systemic			

Drug	Mechanism of Action	Adverse Effects	Nursing Considerations
Dexamethasone (Apo-dexamethasone) Hydrocortisone sodium succinate (Cortef) Methylprednisolone sodium succinate (Solu-Medrol) Prednisone Triamcinolone	Analgesic Anti-inflammatory Inhibit synthesis and release of mediators of inflammation	Acne Bruising Cushing's syndrome (including fluid retention) Diabetes mellitus GI irritation Hirsutism Hypertension Insomnia Menstrual irregularities Osteoporosis Risk for antibiotic-resistant infection Steroid psychosis	Use only in life-threatening exacerbation or when symptoms persist after treatment with less potent anti-inflammatory drugs. Administer for limited time only, tapering dose slowly. Be aware that symptom exacerbation occurs with abrupt withdrawal of drug. Monitor BP, weight, CBC, and potassium level. Limit sodium intake. Have patient report signs of infection to health care provider.
Disease-Modifying Antirheumatic Drugs (DMARDs)			
Methotrexate	Antimetabolite Inhibits DNA, RNA, and protein synthesis	Hepatotoxicity (occurs more often with frequent small doses than with large intermittent doses); symptoms related to drug's antineoplastic activity (e.g., GI and skin toxicity, bone marrow depression, neuropathy); smaller dose and different administration schedule for RA decrease likelihood that these adverse effects will develop	Monitor CBC and hepatic and renal function. Advise patient to report signs of anemia (fatigue, weakness). Keep patient well hydrated. Because of teratogenic potential, drug should not be administered to children or women of child-bearing age. Inform patient that contraception should be used during and for 3 months after treatment.

Drug	Mechanism of Action	Adverse Effects	Nursing Considerations
Sulphasalazine (Salazopyrin)	Anti-inflammatory Blocks prostaglandin synthesis Sulphonamide	Bleeding, bruising, jaundice GI effects (anorexia, nausea and vomiting) Headache Rash, urticaria, pruritus	Advise patient that drug may cause orange-yellow discoloration of urine or skin. Space doses evenly around the clock, administering drug with 250 mL water after meals. Treatment may be continued even after symptoms are relieved. Monitor CBC.
Leflunomide (Arava)	Anti-inflammatory Immuno-modulatory agent that inhibits proliferation of lymphocytes	Alopecia Diarrhea Hepatotoxicity (especially if patient is also taking methotrexate or has history of prior alcohol abuse) Nausea Rash Respiratory tract infection	Evaluate for relief of pain, swelling, and stiffness and for increase in joint mobility. Advise women of child-bearing age to avoid pregnancy.
D-penicillamine (Cuprimine)	Anti-inflammatory Exact mechanism of action in RA unknown, but may suppress cell-mediated immune response	GI irritation (nausea and vomiting, anorexia, diarrhea) Iron deficiency (especially in menstruating women) Proteinuria, hematuria Rash Reduced or altered taste	Monitor WBCs, platelets, urinalysis. Advise patient to take medication 1 hr before or 2 hr after meals or at least 1 hr before or after any other drug, food, or milk. Advise women of child-bearing age to avoid pregnancy.
Gold Compounds			
Oral (auranofin [Ridaura]) Parenteral (gold sodium aurothiomalate [Myochrysine])	Alters immune responses, suppressing synovitis of active RA Antirheumatic	Decreased hemoglobin Leukopenia, thrombo-cytopenia Proteinuria, hematuria Stomatitis	Rule out pregnancy before beginning treatment. Monitor CBC, urinalysis, and hepatic and renal function. Advise patient that therapeutic response may not occur for 3 to 6 mo. Advise patient to immediately report pruritus, rash, sore mouth, indigestion, or metallic taste.
Antimalarials			

Drug	Mechanism of Action	Adverse Effects	Nursing Considerations
Hydroxychloroquine (Plaquenil)	Antirheumatic action unknown, but may suppress formation of antigens	Ocular toxicity (retinopathy) may progress even after drug is discontinued Ototoxicity Peripheral neuritis, neuromyopathy, hypotension, electrocardiographic changes with prolonged therapy	Monitor CBC and hepatic function. Advise patient that therapeutic response may not occur for up to 6 mo. Advise patient to immediately report visual difficulties, muscular weakness, and decreased hearing or tinnitus.
Immuno-suppressants			
Azathioprine (Imuran) Cyclophosphamide (Procytox)	Inhibit DNA, RNA, and protein synthesis	GI irritation (nausea and vomiting; anorexia with large doses) Rash	Evaluate for relief of pain, swelling, and stiffness and for increase in joint mobility. Advise patient to immediately report unusual bleeding or bruising. Advise patient that therapeutic response may take up to 12 wk. Advise women of child-bearing age to avoid pregnancy.
JAK (Janus Kinase) Inhibitors			
Tofacitinib (Xeljanz)	Inhibits the action of the JAK enzymes, which are signalling pathways inside the cell and have an important role in the inflammation involved in RA		Patients are at increased risk for serious infections, including opportunistic infections. Monitor patient for any sign or symptom of infection so it can be treated early.
Biological and Targeted Therapies			
Tumour Necrosis Factor (TNF) Inhibitors			

Drug	Mechanism of Action	Adverse Effects	Nursing Considerations
Adalimumab (Humira) Certolizumab (Cimzia) Etanercept (Enbrel) Golimumab (Simponi) Infliximab (Remicade)	Binds to TNF, blocking its interaction with TNF cell surface receptors to decrease inflammatory and immune responses	Abdominal pain, vomiting Dizziness, headache Injection site reaction including erythema, pain, itching, swelling Rhinitis, pharyngitis, cough	Evaluate for relief of pain, swelling, and stiffness and for increase in joint mobility. Advise patient of increased risk for tuberculosis. Advise patient to have yearly TB skin test. Monitor for infection, bleeding, and emergence of malignancies. Advise patient that psoriasis may worsen. Advise patient that injection site reaction generally occurs in first month of treatment and decreases with continued therapy. Advise patient not to receive live virus vaccines during treatment.
Interleukin-1 Receptor Antagonist			
Anakinra (Kineret)	Blocks the action of interleukin-1 and thus decreases the inflammatory response	Abdominal pain Headache Injection site reaction Leukopenia Rash	Evaluate for relief of pain, swelling, and stiffness and for increase in joint mobility. Advise patient that injection site reaction generally occurs during first month of treatment and decreases with continued therapy. Evaluate renal function. Monitor for infection. Do not administer drug with other TNF inhibitors.
Interleukin-6 Receptor Antagonist			

Drug	Mechanism of Action	Adverse Effects	Nursing Considerations
Tocilizumab (Actemra)	Blocks action of interleukin-6	↑ BP ↑ liver enzyme levels Headache Inflammation of nose or nasal passage Upper respiratory tract infections	Administered to patients with RA in whom other therapies have failed. Monitor BP and for infection. Advise patient of adverse GI effects (e.g., perforation). Monitor liver enzyme and LDL levels.
T-Cell Activation Inhibitor			
Abatacept (Orencia)	Modulates T-cell activation; suppresses immune response	Headache Injection site reaction Nausea Sore throat Upper respiratory infection	Not recommended for concomitant use with TNF inhibitors. Evaluate for relief of pain, swelling, and stiffness and for increase in joint mobility.
B-Cell Depleting Agent			
Rituximab (Rituxan)	Monoclonal antibody that targets B cells	Difficulty breathing Dizziness Fever Itching Palpitations Sore throat	Administer in combination with methotrexate. Monitor for infection and bleeding. Advise patient to not receive live virus vaccines during treatment. Monitor for low BP if patient is also taking antihypertensives.
Tocilizumab (Actemra)	Blocks action of interleukin-6	↑ BP ↑ liver enzyme levels Headache Inflammation of nose or nasal passage Upper respiratory tract infections	Administered to patients with RA in whom other therapies have failed. Monitor BP and for infection. Advise patient of adverse GI effects (e.g., perforation). Monitor liver enzyme and LDL levels.

BP, blood pressure; *CBC,* complete blood cell count; *GI,* gastro-intestinal; *LDL,* low-density lipoprotein; *NSAIDs,* nonsteroidal anti-inflammatory drugs; *OTC,* over-the-counter; *RA,* rheumatoid arthritis; *TNF,* tumour necrosis factor; *TNF-α,* tumour necrosis factor–alpha; *WBC,* white blood cell.

For patients who do not obtain adequate pain management with acetaminophen or for patients with moderate to severe OA pain or signs of joint inflammation, an NSAID may be more effective for pain treatment. NSAID therapy is typically initiated in low-dose OTC strengths (e.g., ibuprofen [Motrin, Advil]) of 200 mg, up to four times daily, with the dosage increased as the patient's symptoms indicate. If a patient is at risk for or experiences adverse gastro-intestinal (GI) effects with a conventional NSAID, supplemental treatment with a protective agent such as misoprostol may be indicated. Arthrotec, a combination of misoprostol and the NSAID diclofenac, is also available. Diclofenac gel may be applied to the affected joint.

Because traditional NSAIDs block the production of prostaglandins from arachidonic acid by inhibiting the production of cyclo-oxygenase–1 (COX-1) and cyclo-oxygenase–2 (COX-2), the risk for GI erosion and bleeding is increased. Traditional NSAIDs affect platelet aggregation, which prolongs bleeding time. Patients taking both warfarin (Coumadin) and an NSAID are at high risk of bleeding. Concerns have also been raised regarding the possible negative effects of long-term NSAID treatment on cartilage metabolism, particularly in older-adult patients, in whom cartilage integrity may already be diminished. As an alternative to traditional NSAIDs, treatment with the COX-2 inhibitor celecoxib (Celebrex) may be considered in selected patients.

When given in equivalent anti-inflammatory dosages, all NSAIDs are considered comparable in efficacy but vary widely in cost. Individual responses to the NSAIDs are also variable. Some patients still prefer ASA (Aspirin), but it is no longer a common treatment and should not be used in combination with NSAIDs because both inhibit platelet function and prolong bleeding time. Intra-articular injections of corticosteroids may be appropriate for older adults with local inflammation and effusion. Four or more injections without relief suggest the need for additional intervention. Systemic use of corticosteroids is not indicated and may actually accelerate the disease process.

Another treatment for mild to moderate OA is hyaluronic acid (HA) injection, a type of viscosupplementation. HA is found in normal joint fluid and articular cartilage. It contributes to both the viscosity and the elasticity of synovial fluid, and its degradation can result in joint damage. Synthetic and naturally occurring HA derivatives (e.g., NeoVisc, OrthoVisc, Synvisc-One) are administered in three injections, a week apart, directly into the joint space. Synvisc-1, a newer, single-injection HA drug, may offer pain relief for up to 6 months. HA may also be added to oral

supplements of glucosamine, chondroitin, and methylsulphonylmethane (MSM). Few adverse effects have been reported with HA.

Medications thought to slow the progression of OA or support joint healing are known as *disease-modifying osteoarthritis drugs (DMOADs).* To date, no drugs have been approved to modify OA progression, despite numerous clinical trials. A variety of molecular targets are under investigation, including the use of anticatabolic agents to stimulate new cartilage growth and slow OA progression (Le Graverand-Gastineau, 2010).

Surgical Therapy.

Symptoms of disease are often managed conservatively for many years, but the patient's loss of joint function, unrelieved pain, and diminished ability to independently perform self-care may prompt a recommendation for surgery. In patients less than 55 years of age, arthroscopic surgery for knee OA may delay the need for more serious surgery, such as knee replacement. The main indication for arthroscopic surgery for OA is to remove debris (i.e., bits of cartilage known as *loose bodies*) that may be causing problems with joint motion. Reconstructive surgical procedures (e.g., hip and knee replacements) are discussed in Chapter 65.

Nursing Management Osteoarthritis

Nursing Assessment

The nurse should carefully assess and document the type, location, severity, frequency, and duration of the patient's joint pain and stiffness and the extent to which these symptoms affect his or her ability to perform activities of daily living (ADLs). The nurse should note pain management practices and question the patient about the duration and success of each treatment. Physical examination of the affected joint or joints includes assessment of tenderness, swelling, limitation of movement, and crepitation. An involved joint should be compared with the contralateral joint if it is not affected.

Nursing Diagnoses

Nursing diagnoses for patients with OA may include, but are not limited to, the following:

- *Acute pain* related to *physical injury agent* (painful physical activity)
- *Impaired physical mobility* related to *activity intolerance, decrease in muscle strength, joint stiffness*
- *Obesity* related to *average daily physical activity is less than recommended for gender and age*
- *Ineffective coping* related to *inadequate confidence in ability to deal with a situation*

Planning

The overall goals are that patients with OA will (a) maintain or improve joint function through a balance of rest and activity, (b) use joint protection measures (Table 67-4) to improve activity tolerance, (c) achieve independence in self-care and maintain optimal role function, and (d) use pharmacological and nonpharmacological strategies to manage pain satisfactorily.

TABLE 67-4

PATIENT & CAREGIVER TEACHING GUIDE
Joint Protection and Energy Conservation

The following should be included when teaching patients with arthritis to protect joints and conserve energy:

- Avoid forceful repetitive movements.
- Avoid positions of joint deviation and stress.
- Develop organizing and pacing techniques for routine tasks.
- Maintain appropriate weight.
- Modify home and work environment to create less stressful ways to perform tasks.
- Seek assistance with necessary tasks that may cause pain.
- Use assistive devices, if indicated.
- Use good posture and proper body mechanics.

Nursing Implementation

Health Promotion.

Prevention of primary OA is possible in many cases. Community education should focus on altering modifiable risk factors through weight loss and the reduction of occupational and recreational hazards. Athletic instruction and physical fitness programs should include safety measures that protect and reduce trauma to the joints. Traumatic joint injuries should be treated promptly to prevent the development of OA.

Acute Intervention.

Patients with OA most often complain of pain, stiffness, limitation of function, and the frustration of coping with these physical difficulties on a daily basis. Older adults may believe that OA is an inevitable part of the aging process and that nothing can be done to ease the discomfort and related disability.

Patients with OA are usually treated on an outpatient basis, often by an interdisciplinary team of health care providers that includes a family health care provider, a rheumatologist, a nurse, an occupational therapist, and a physiotherapist. Often, health assessment questionnaires are used to pinpoint areas of decreased function. Questionnaires are repeated at regular intervals to document disease and treatment progression. Treatment goals can be developed on the basis of data from the questionnaires and the physical examination, with specific interventions to target identified problems. Usually, patients are hospitalized only if joint surgery is planned (see Chapter 65).

Medications are administered for the treatment of pain and inflammation. Nonpharmacological strategies to decrease pain and disability may include gentle exercise, the application of heat (thermal packs) or cold (ice packs), relaxation, and yoga (Arthritis Society, 2017b). Splints may be prescribed to rest and stabilize painful or inflamed joints.

Once an acute flare has subsided, a physiotherapist can provide valuable assistance in planning an exercise program. Therapists often recommend tai chi as a low-impact form of exercise. Tai chi can be performed by patients of all ages and may be practised in a wheelchair. The nurse should emphasize the importance of warming up before practice to prevent stretch injuries.

Patient and caregiver teaching related to OA is an important nursing responsibility. Teaching should include information about the nature and the treatment of the disease, pain management, correct posture and body mechanics, correct use of assistive devices such as a cane or walker, principles of joint protection and energy conservation (see Table 67-4), nutritional choices and weight and stress management, and an exercise program.

Patients should be assured that OA is a localized disease and that severe deforming arthritis is not the usual course. Patients can also obtain support and understanding of the disease process through community resources such as the Arthritis Self-Management Courses (Arthritis Society, 2017c).

Ambulatory and Home Care.

Home management goals should be individualized to meet the patient's needs. The caregiver, family members, and significant others should be included in goal setting and teaching. Home and work environment modification is essential for the patient's safety, accessibility, and self-care. Measures include removing scatter rugs, providing rails at the stairs and in the bathtub, using nightlights, and wearing well-fitting supportive shoes. Assistive devices such as canes, walkers, elevated toilet seats, and grab bars also reduce the load on the affected joint(s) and promote safety. Patients should be urged to continue all prescribed therapies at home and also be open to new approaches to symptom management.

Sexual counselling may help the patient and significant other enjoy physical closeness by introducing the idea of alternate positions and timing for sexual activity. Discussion also increases awareness of each

partner's needs. The nurse should encourage the patient to take analgesics or a warm bath to decrease joint stiffness before sexual activity.

Evaluation

The expected outcomes for patients with OA are as follows:

- Experience adequate amounts of rest and activity.
- Achieve satisfactory pain management.
- Maintain joint flexibility and muscle strength through joint protection and therapeutic exercise.
- Verbalize acceptance of OA as a chronic disease and collaborate with health care providers in disease management.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic, systemic autoimmune disease characterized by inflammation of connective tissue in the diarthrodial (synovial) joints, typically with periods of remission and exacerbation. RA is frequently accompanied by extra-articular manifestations.

RA occurs globally, affecting all ethnic groups. It can occur at any time of life, but the incidence increases with age, peaking between 30 and 50 years old. An estimated 300 000 Canadians are affected by RA. Women are more likely than men to have the disease (Arthritis Society, 2017d).

Etiology and Pathophysiology

Although the exact cause of RA is unknown, it probably results from a combination of genetics and environmental triggers. An autoimmune etiology that is currently the most widely accepted theory suggests that changes associated with RA begin when a genetically susceptible person has an initial immune response to an antigen. Although a bacterium or virus has been proposed as a possible antigen, to date, no infection or organism has been identified as the cause.

The antigen, which is probably not the same in all affected patients, triggers the formation of an abnormal immunoglobulin G (IgG). RA is characterized by the presence of autoantibodies against this abnormal IgG. The autoantibodies, known as *rheumatoid factor* (RF), combine with IgG to

form immune complexes that initially deposit on synovial membranes or superficial articular cartilage in the joints. Immune complex formation leads to the activation of complement, and an inflammatory response results. (Complement activation is discussed in Chapter 14, and immune complex formation is discussed in Chapter 16.)

Neutrophils are attracted to the site of inflammation, where they release proteolytic enzymes that can damage articular cartilage and cause the synovial lining to thicken (Figure 67-3). Other inflammatory cells include T helper (CD4) cells, which are the primary orchestrators of cell-mediated immune responses. Activated CD4 cells stimulate monocytes, macrophages, and synovial fibroblasts to secrete the proinflammatory cytokines interleukin-1 (IL-1), interleukin-6 (IL-6), and tumour necrosis factor (TNF). These cytokines are the primary factors that drive the inflammatory response in RA. If unarrested, the disease progresses through four stages, which are identified in Table 67-5.

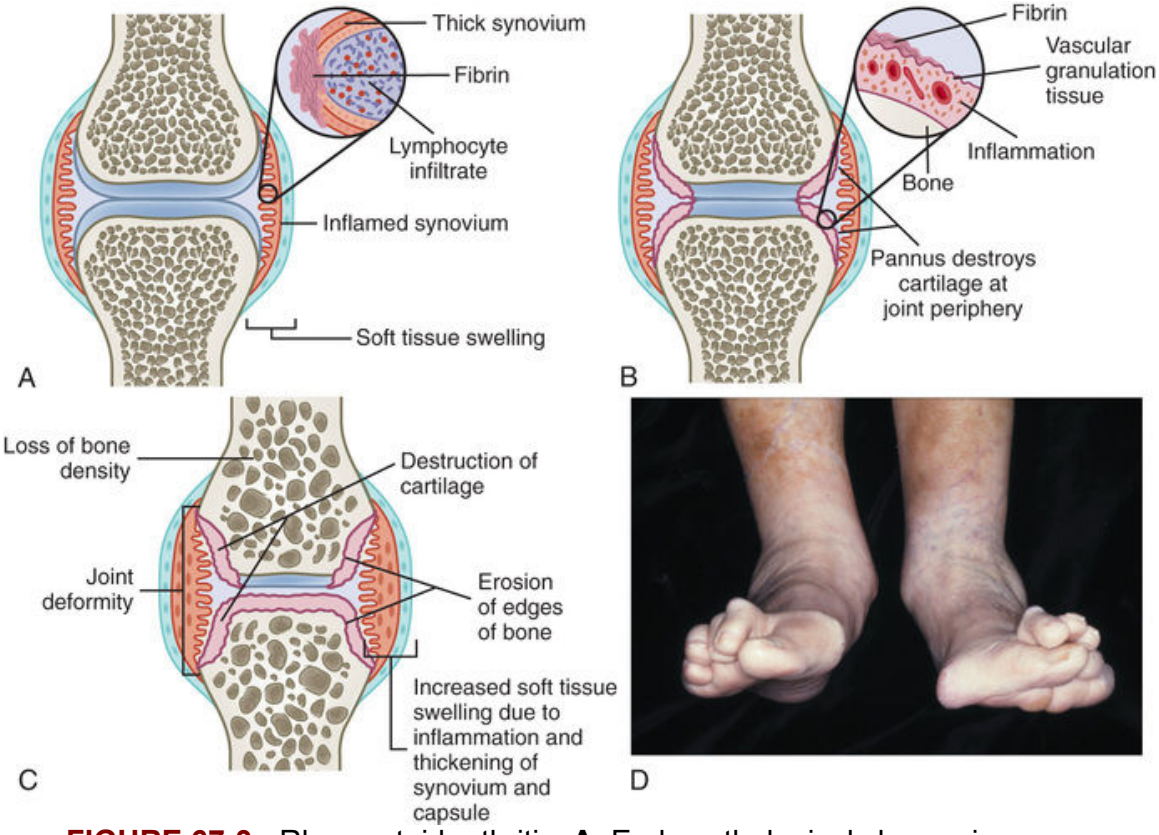

FIGURE 67-3 Rheumatoid arthritis. **A,** Early pathological change in rheumatoid arthritis is rheumatoid synovitis. The synovium is inflamed. Lymphocytes and plasma cells increase greatly. **B,** With time, articular cartilage destruction occurs, vascular granulation tissue grows across the surface of the cartilage (pannus) from the edges of the joint, and the articular surface shows loss of cartilage beneath the extending pannus, most marked at the joint margins. **C,** Inflammatory pannus causes focal destruction of bone. At the edges of the joint, there is osteolytic destruction of bone, responsible for erosions seen on radiographs. This phase is associated with joint deformity. **D,** Multiple deformities of the foot associated with rheumatoid arthritis. Source: **D,** Canale, S. T., & Beaty, J. H. (2013). *Campbell's operative orthopaedics* (12th ed.). Philadelphia: Mosby.

TABLE 67-5

ANATOMICAL STAGES OF RHEUMATOID ARTHRITIS

Stage I: Early
No destructive changes visible on radiograph; possible radiographic evidence of osteoporosis
Stage II: Moderate
Radiographic evidence of osteoporosis, with or without slight bone or cartilage destruction; no joint deformities (although possibly limited joint mobility); adjacent muscle atrophy; possible presence of extra-articular soft-tissue lesions (e.g., nodules, tenosynovitis)
Stage III: Severe
Radiographic evidence of cartilage and bone destruction in addition to osteoporosis; joint deformity, such as subluxation, ulnar deviation, or hyperextension, without fibrous or bony ankylosis; extensive muscle atrophy; possible presence of extra-articular soft-tissue lesions (e.g., nodules, tenosynovitis)
Stage IV: Terminal
Fibrous or bony ankylosis; stage III criteria

Genetic Factors.

Genetic predisposition is important in the development of RA. For example, a higher concurrence of RA has been noted in identical twins compared with fraternal twins (Firestein, 2012). The strongest evidence for a familial influence is the increased occurrence of a human leukocyte antigen (HLA) known as HLA-DR4 and HLA-DR1 antigens. Smoking increases the risk for RA for people who are genetically predisposed to the disease and makes successful treatment more difficult.

Clinical Manifestations

Joints.

The onset of RA is typically insidious. Nonspecific manifestations such as fatigue, anorexia, weight loss, and generalized stiffness may precede the onset of arthritic complaints. The stiffness becomes more localized in the following weeks to months. Some patients report a history of a precipitating stressful event such as infection, work stress, physical exertion, childbirth, surgery, or emotional upset. However, researchers have been unable to correlate such events directly with the onset of RA.

Specific articular involvement is manifested clinically by pain, stiffness, limitation of motion, and signs of inflammation such as heat, swelling, and tenderness. Joint symptoms occur symmetrically and frequently affect the small joints of the hands (PIP and MCP joints) and feet (MTP joints). Larger peripheral joints such as wrists, elbows, shoulders, knees, hips, ankles, and the jaw may also be involved. The cervical spine may be affected, but the axial skeleton (the spine and the bones connected to it) is generally spared. In Table 67-6, the manifestations of RA and OA are compared.

TABLE 67-6

COMPARISON OF RHEUMATOID ARTHRITIS AND OSTEOARTHRITIS

Parameter	Rheumatoid Arthritis	Osteoarthritis
Affected joints	Small joints first (PIP, MCP, and MTP joints), wrists, elbows, shoulders, knees; usually bilateral, symmetrical joint involvement	Weight-bearing joints (knees, hips); small joints (MCP, DIP, and PIP); cervical and lumbar spine; often asymmetrical
Age at onset	Young to middle age	Usually >40 yr of age
Disease	Systemic disease with exacerbations and remissions	Localized disease with variable, progressive course
Effusions	Common	Uncommon
Gender	Female-to-male ratio is 2 : 1 or 3 : 1; less marked difference after age 60	Before age 50, more men than women; after age 50, more women than men
Laboratory findings	RF positive in 80% of patients Elevated ESR and CRP level indicative of active inflammation	RF negative Transient elevation in ESR related to synovitis
Nodules	Present, especially on extensor surfaces	Heberden nodes (DIP joints) and Bouchard nodes (PIP joints)
Pain characteristics	Stiffness lasts from 1 hr to all day and may decrease with use; pain is variable, may disrupt sleep	Stiffness occurs on arising but usually subsides after 30 min; pain gradually worsens with joint use and disease progression, relieved with rest
Radiographs	Joint space narrowing, erosion, subluxation with advanced disease; osteoporosis related to corticosteroid use	Joint space narrowing, osteophytes, subchondral cysts, sclerosis
Synovial fluid	WBC count >2 × 10^9/L with mostly neutrophils	WBC count <2 × 10^9/L (mild leukocytosis)
Weight	Lost or maintained weight	Often overweight

CRP, C-reactive protein; *DIP*, distal interphalangeal; *ESR*, erythrocyte sedimentation rate; *MCP*, metacarpo-phalangeal; *MTP*, metatarso-phalangeal; *PIP*, proximal interphalangeal; *RF*, rheumatoid factor; *WBC*, white blood cell.

Patients characteristically experience joint stiffness after periods of inactivity. Morning stiffness may last from 60 minutes to several hours or more, depending on disease activity. MCP and PIP joints are typically swollen. In early disease, the fingers may become spindle-shaped from synovial hypertrophy and thickening of the joint capsule (see Figure 67-3). Joints become tender, painful, and warm to the touch. Joint pain increases with motion, varies in intensity, and may not be proportional to the degree

of inflammation. Tenosynovitis frequently affects the extensor and flexor tendons around the wrists, producing manifestations of carpal tunnel syndrome and making it difficult for patients to grasp objects.

As disease activity progresses, inflammation and fibrosis of the joint capsule and supporting structures may lead to deformity and disability. Atrophy of muscles and destruction of tendons around the joint cause one articular surface to slip past the other *(subluxation).* Metatarsal head dislocation and subluxation in the feet may cause pain and walking disability. Typical distortions of the hand include ulnar drift ("zigzag deformity"), swan-neck deformity, and boutonnière deformity (Figure 67-4).

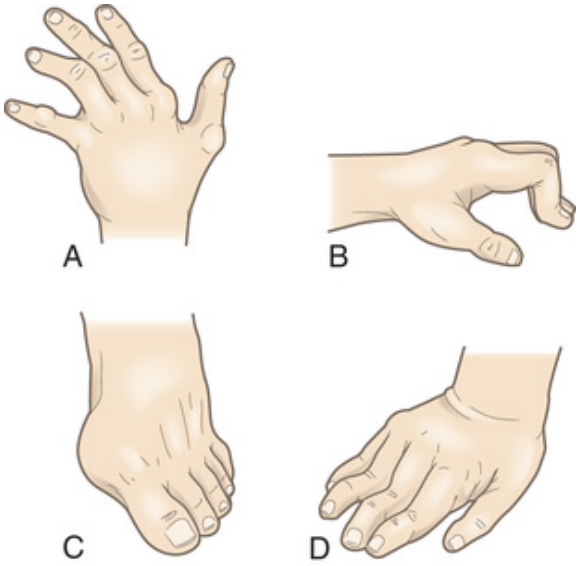

FIGURE 67-4 Typical deformities of rheumatoid arthritis. **A,** Ulnar drift. **B,** Boutonnière deformity. **C,** Hallux valgus. **D,** Swan-neck deformity.

Extra-Articular Manifestations.

RA can affect nearly every system in the body. Extra-articular manifestations of RA are depicted in Figure 67-5. Extra-articular manifestations are more likely to occur in people with high levels of biomarkers such as RF.

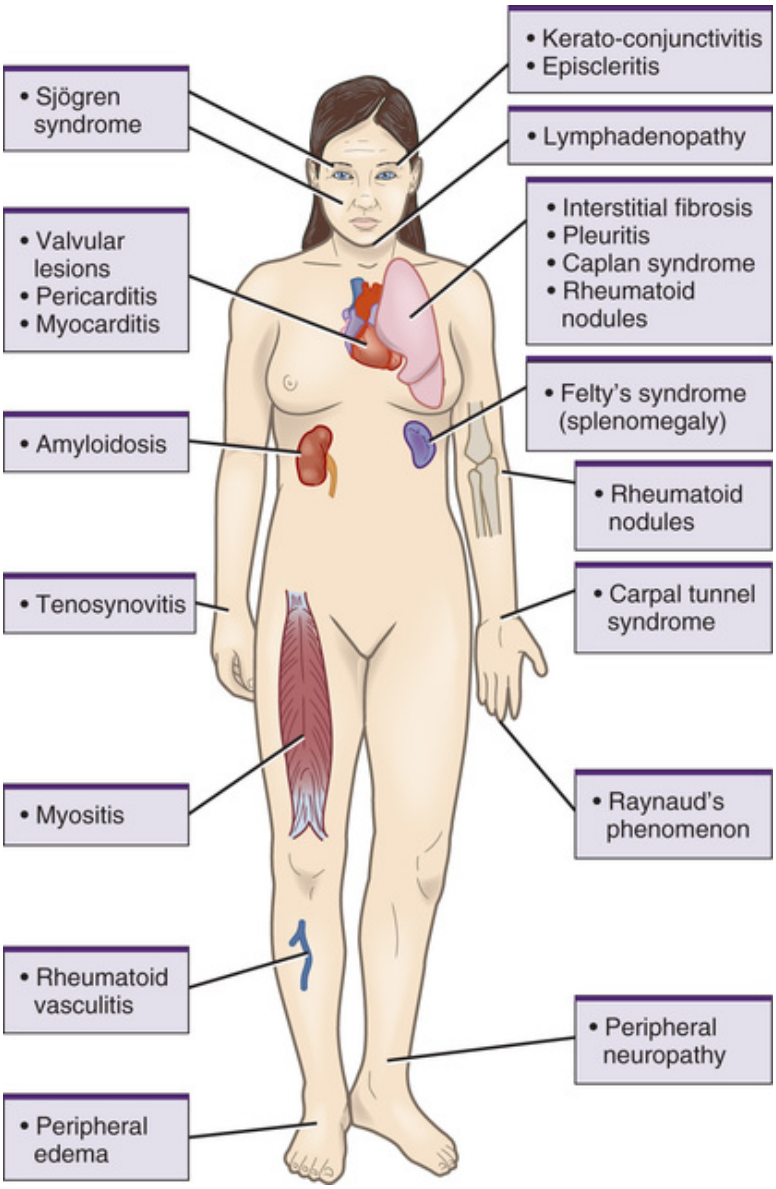

FIGURE 67-5 Extra-articular manifestations of rheumatoid arthritis.

Rheumatoid nodules develop in 20% of all patients with RA (Arthritis Society, 2017d). Those affected with nodules usually have high titres of RF. Rheumatoid nodules appear subcutaneously as firm, nontender, granuloma-type masses and are usually over the extensor surfaces of joints such as those of the fingers and elbows. Nodules at the base of the spine and the back of the head are common in older adults. On the skin, these nodules can ulcerate, similar to pressure injuries. In later disease, cardiopulmonary effects may occur. These may include pleurisy, pleural effusion, pericarditis, pericardial effusion, and cardiomyopathy.

Sjögren syndrome is seen in 10% to 15% of patients with RA. Sjögren syndrome can occur by itself or in conjunction with other arthritic disorders such as RA and systemic lupus erythematosus. Affected patients have diminished lacrimal and salivary gland secretion, leading to a dry mouth; burning, itchy eyes with decreased tearing; and photosensitivity.

Felty's syndrome occurs most commonly in patients with severe, nodule-forming RA. It is characterized by splenomegaly and leukopenia.

Flexion contractures and hand deformities cause diminished grasp strength and affect the patient's ability to perform self-care tasks. Nodular myositis and muscle fibre degeneration can lead to pain similar to that of vascular insufficiency. Cataract development and loss of vision can result from scleral nodules. Depression may occur and is often related to the chronic pain associated with RA (Durham, Fowler, Donato, et al., 2015).

Diagnostic Studies

An accurate diagnosis is essential to the initiation of appropriate treatment and the prevention of unnecessary disability. A diagnosis is often based on history and physical findings, but some laboratory tests are useful for confirmation and to monitor disease progression (see Table 67-7). Positive RF occurs in approximately 80% of adult patients, and titres rise during active disease. Elevations in ESR and C-reactive protein (CRP) levels are general indicators of active inflammation. Antinuclear antibody (ANA) titres are also present in some patients with RA. Testing for the anti-citrullinated protein antibody (ACPA) is another important diagnostic test for RA. Levels of ACPA are more specific than those of RF for RA and in some cases may allow for an earlier and more accurate diagnosis (Durham, Fowler, Donato, et al., 2015).

Synovial fluid analysis early in the course of the disease often reveals a straw-coloured fluid with many fibrin flecks. The enzyme MMP-3 is increased in the synovial fluid of patients with RA and may be a marker of progressive joint damage. The white blood cell (WBC) count of synovial fluid is elevated (up to 25×10^9/L). Inflammatory changes in the synovium can be confirmed by tissue biopsy.

Radiological studies are not specifically diagnostic of RA. The findings may be inconclusive during early stages of the disease, revealing only soft-tissue swelling and possible bone demineralization. In later stages of the disease, narrowing of the joint space, destruction of articular cartilage, erosion, subluxation, and deformity are seen. Malalignment and ankylosis are often evident in advanced disease. Baseline radiographs may be useful

in monitoring disease progression and treatment effectiveness. Bone scans are more useful in detecting early joint changes and confirming a diagnosis so that RA treatment can be initiated. Criteria for the diagnosis of RA in a newly presenting patient are described in Table 67-7.

TABLE 67-7
DIAGNOSTIC CRITERIA FOR RHEUMATOID ARTHRITIS

Patients should be tested for RA if they are initially seen with the following signs: • At least one joint with definite clinical synovitis • Synovitis not better explained by another disease	
Criterion	**Score**
A. Joint Involvement	
1 large joint	0
2–10 large joints	1
1–3 small joints (with or without involvement of large joints)	2
4–10 small joints (with or without involvement of large joints)	3
>10 joints (at least 1 small joint)	5
B. Serology (at Least One Test Result Needed)	
Negative RF and negative ACPA	0
Low-positive RF or low-positive ACPA	2
High-positive RF or high-positive ACPA	3
C. Acute-Phase Reactants (at Least One Test Result Needed)	
Normal CRP and normal ESR	0
Abnormal CRP or abnormal ESR	1
D. Duration of Symptoms	
<6 weeks	0
≥6 weeks	1

Scoring: Add score of categories A–D. Possible scores range from 0–10. A score of ≥6 indicates the definitive presence of RA.

ACPA, anti-citrullinated peptide antibodies; *CRP,* C-reactive protein; *ESR,* erythrocyte sedimentation rate; *RF,* rheumatoid factor.

Source: Aletaha, D., Neogi, T., Silman, A., et al. (2010). 2010 rheumatoid arthritis classification criteria. *Arthritis and Rheumatism, 62*(9), 2569–2581. doi:10.1002/art.27584.

Collaborative Care

Care of patients with RA begins with a comprehensive program of education and drug therapy. Education regarding drug therapy includes correct administration, reporting of adverse effects, and frequent medical and laboratory follow-up visits. Patients and caregivers should be taught about the disease process and home management strategies. NSAIDs are prescribed to promote physical comfort. Physiotherapy helps patients maintain joint motion and muscle strength. Occupational therapy helps to develop upper extremity function and encourages joint protection through

the use of splints or other assistive devices and strategies for activity pacing.

An individualized treatment plan accounts for the nature of the disease activity, joint function, age, gender, family and social roles, and response to previous treatment (Table 67-8). A caring, long-term relationship with an arthritis health care team can promote the patient's self-esteem and positive coping.

TABLE 67-8

COLLABORATIVE CARE
Rheumatoid Arthritis

Diagnostic
• History and physical examination
• Laboratory studies
  • Complete blood cell (CBC) count
  • Erythrocyte sedimentation rate (ESR)
  • Rheumatoid factor (RF)
  • Anti-citrullinated protein antibody (ACPA)
  • Antinuclear antibody (ANA)
  • C-reactive protein (CRP)
• Radiological studies of involved joints
• Analysis of synovial fluid
Collaborative Therapy
• Nutritional and weight management counselling
• Therapeutic exercise
• Psychological support
• Rest, joint protection, and use of assistive devices
	• Heat and cold applications
	• Complementary and alternative therapies
	  • Herbal products
	  • Acupuncture
	  • Movement therapies
	• Drug therapy (see Table 67-3)
	  • Disease-modifying antirheumatic drugs (DMARDs)
	  • Intra-articular or systemic corticosteroids
	  • Nonsteroidal anti-inflammatory drugs (NSAIDs)
	  • Biological and targeted therapy
	• Reconstructive surgery (e.g., arthroplasty)

Drug Therapy

Disease-Modifying Antirheumatic Drugs.

Drugs remain the cornerstone of RA treatment (see Table 67-3). Because irreversible joint changes can occur as early as the first year of RA, health care providers now aggressively prescribe disease-modifying antirheumatic drugs (DMARDs). These drugs have the potential to lessen the permanent effects of RA, such as joint erosion and deformity. The choice of drug is based on disease activity, the patient's level of function, and lifestyle considerations, such as the desire to bear children.

Treatment of early RA often involves DMARD therapy with methotrexate (Durham, Fowler, Donato, et al., 2015). The rapid anti-inflammatory effect of methotrexate reduces clinical symptoms in days to weeks. It has a lower toxicity compared to other drugs. Adverse effects include bone marrow suppression and hepatotoxicity. Methotrexate

therapy necessitates frequent laboratory monitoring, including CBC and chemistry panel.

Sulphasalazine (Salazopyrin) and the antimalarial drug hydroxychloroquine (Plaquenil) may be effective DMARDs for mild to moderate disease. They are rapidly absorbed, relatively safe, and well tolerated. The synthetic DMARD leflunomide (Arava) blocks immune cell overproduction. Its efficacy and adverse effects are similar to those of methotrexate and sulphasalazine. Because the drug is teratogenic, the possibility of pregnancy must be excluded before therapy is initiated.

Tofacitinib (Xeljanz) is a new drug used to treat moderate to severe active RA. This drug is from a new class of medications called JAK (Janus kinase) inhibitors. The drug interferes with the JAK enzymes that contribute to joint inflammation in RA.

Biological and Targeted Therapies.

Biological or targeted drug therapies are also used to slow disease progression in RA. These drugs can be categorized based on their mechanism of action (see Table 67-3). They can be used to treat patients with moderate to severe disease who have not responded to DMARDs or in combination therapy with an established DMARD such as methotrexate.

Tumour necrosis factor inhibitors include etanercept (Enbrel), infliximab (Remicade), adalimumab (Humira), certolizumab (Cimzia), and golimumab (Simponi). Etanercept is a biologically engineered copy (using recombinant deoxyribonucleic acid [DNA] technology) of the TNF cell receptor. This soluble TNF receptor binds to TNF in circulation before TNF can bind to the cell surface receptor. By inhibiting binding of TNF, etanercept inhibits the inflammatory response. This drug is given as a subcutaneous injection.

Drug Alert

Etanercept (Enbrel)

- Increased risk for serious infection and heart failure is a concern.
- Persistent fever, bruising, bleeding, or other signs of infection should be reported.

Infliximab and adalimumab are monoclonal antibodies that bind to TNF, thus preventing it from binding to TNF receptors on cells. Infliximab is given by intravenous (IV) in combination with methotrexate. Adalimumab is administered subcutaneously.

Certolizumab and golimumab are TNF inhibitors that improve symptoms in patients with moderate to severe RA. Both drugs are given in combination with methotrexate. When compared to other biological and targeted therapy, certolizumab stays in the system longer and may also show a more rapid (1 to 2 weeks) and significant reduction in RA symptoms. Certolizumab is also used in treating Crohn's disease.

Drug Alert

Tumour Necrosis Factor Inhibitors

- Tuberculin test and chest radiograph should be administered before initiation of therapy.
- The patient should be monitored for signs of infection and the drug stopped if acute infection develops.
- Patients should be instructed to avoid live vaccination while taking the drug.

Anakinra (Kineret) is a recombinant version of IL-1 receptor antagonist (IL-1Ra). It blocks the biological activity of IL-1 by competitively inhibiting the binding of IL-1 to the IL-1 receptor. It is given as a subcutaneous injection. Anakinra is used to reduce the pain and swelling associated with moderate to severe RA. It can be used in combination with DMARDs but not with TNF inhibitors. Concurrent use of anakinra and TNF inhibitors can cause serious infection and neutropenia.

Tocilizumab (Actemra) blocks the action of IL-6, a proinflammatory cytokine. It is used to treat patients who have moderate to severe RA and have not adequately responded to or cannot tolerate other drugs for RA.

Abatacept (Orencia) blocks T-cell activation. It is recommended for patients who have an inadequate response to DMARDS and TNF inhibitors. It is given IV. Like anakinra, it should not be used concomitantly with TNF inhibitors.

Rituximab (Rituxan) is a monoclonal antibody that targets B cells. It may be used in combination with methotrexate for patients with moderate to

severe RA not responding to TNF inhibitors (e.g., etanercept, infliximab). It is given IV.

Other Drug Therapy.

Additional medications used infrequently for treating RA include antibiotics (minocycline), immuno-suppressants (azathioprine [Imuran]), D-penicillamine (Cuprimine), and gold preparations (auranofin [Ridaura], gold sodium thiomalate [Myochrysine]).

Corticosteroid therapy can be used for symptom control. Intra-articular injections may temporarily reduce the pain and inflammation associated with disease flare-ups. Long-term use of oral corticosteroids should not be a mainstay of RA treatment because of the risk for complications, including osteoporosis and avascular necrosis. However, low-dose prednisone may be used for a limited time with select patients to decrease disease activity until DMARD therapy is effective.

Various NSAIDs and salicylates continue to be included in the drug regimen to treat arthritis pain and inflammation. Enteric-coated ASA (Aspirin) is often used in high dosages of 3.2 to 5.4 g/day (10 to 18 tablets). NSAIDs have anti-inflammatory, analgesic, and antipyretic properties. Some relief may be noted within days of the start of treatment with NSAIDs, but full effectiveness may take 2 to 3 weeks. NSAIDs may be used when patients cannot tolerate high doses of ASA (Aspirin). Anti-inflammatory drugs that are taken only once or twice a day may improve the patient's ability to follow the treatment regimen (see Table 67-3). The newer generation NSAIDs, the COX-2 inhibitors, are effective in RA as well as OA. Celecoxib (Celebrex) is currently the only available COX-2 inhibitor.

Nutritional Therapy.

Although there is no special diet for RA, balanced nutrition is important. Fatigue, pain, depression, limited endurance, and mobility deficits often accompany RA and may cause a loss of appetite or interfere with the patient's ability to shop for and prepare food. Weight loss may result. An occupational therapist may help the patient modify the home environment and use assistive devices to make food preparation easier.

Corticosteroid therapy or immobility secondary to pain may result in unwanted weight gain. A sensible weight loss program, consisting of balanced nutrition and exercise, reduces stress on affected joints. Corticosteroids also increase the appetite, which results in a higher caloric intake. In addition, patients may become distressed as signs and

symptoms of Cushing's syndrome—including moon facies and the redistribution of fatty tissue to the trunk—change the physical appearance. Patients must be encouraged to continue to eat a balanced diet and not to alter the corticosteroid dose or stop therapy abruptly. Weight slowly adjusts to normal several months after cessation of therapy.

Surgical Therapy.

Occasionally, surgery is needed to relieve severe pain and improve the function of severely deformed joints. Removal of the joint lining (synovectomy) is one type of surgical therapy. Total joint replacement (arthroplasty) can be done for many different joints in the body. Joint surgery is discussed in Chapter 65.

Nursing Management Rheumatoid Arthritis

Nursing Assessment

Subjective and objective data that should be obtained from patients with RA are presented in Table 67-9.

TABLE 67-9

NURSING ASSESSMENT
Rheumatoid Arthritis

Subjective Data
Important Health Information
Past health history: Recent infections; precipitating factors such as emotional upset, infections, overwork, childbirth, surgery; pattern of remissions and exacerbations *Family history:* Family history of rheumatoid arthritis or other autoimmune diseases *Medications:* Use of ASA (Aspirin), NSAIDs, corticosteroids, DMARDs *Surgery or other treatments:* Any joint surgery
Symptoms
• Symmetrical joint pain and aching that increases with motion or stress on joint; stiffness and joint swelling; muscle weakness, difficulty walking; paresthesias of hands and feet; numbness, tingling, loss of sensation • Dry mucous membranes of mouth and pharynx; anorexia, weight loss; fatigue, malaise
Objective Data
General
Lymphadenopathy, fever
Integumentary
Kerato-conjunctivitis; subcutaneous rheumatoid nodules on forearm, elbows; skin ulcers; shiny, taut skin over involved joints; peripheral edema
Cardiovascular
Symmetrical pallor and cyanosis of fingers (Raynaud's phenomenon); distant heart sounds, murmurs, dysrhythmias
Respiratory
Chronic bronchitis, tuberculosis, histoplasmosis, fibrosing alveolitis
Gastro-Intestinal
Splenomegaly (Felty's syndrome)
Musculo-Skeletal
Symmetrical joint involvement with swelling, erythema, heat, tenderness, and deformities; enlargement of proximal phalangeal and MCP joints; limitation of joint movement; muscle contractures, muscle atrophy
Possible Diagnostic Findings
Positive rheumatoid factor, ↑ ESR, anemia; ↑ WBC count in synovial fluid; evidence of joint space narrowing and of bone erosion and deformity on radiograph (osteoporosis with advanced disease)

DMARDs, disease-modifying antirheumatic drugs; *ESR*, erythrocyte sedimentation rate; *MCP*, metacarpo-phalangeal; *NSAIDs*, nonsteroidal anti-inflammatory drugs; *WBC*, white blood cell.

Nursing Diagnoses

Nursing diagnoses for patients with RA may include, but are not limited to, the following:

- *Impaired physical mobility* related to *pain* (joint pain, stiffness and deformity)
- *Chronic pain* related to *injury agent* (joint inflammation, overuse of joints, and ineffective pain or comfort measures)
- *Disturbed body image* related to *alteration in self-perception* (chronic disease activity, long term treatment, deformities, stiffness, and inability to perform usual activities)

Additional information on nursing diagnoses for the patient with RA is presented in Nursing Care Plan (NCP) 67-1, available on the Evolve website.

Planning

The overall goals are that patients with RA will (a) have satisfactory pain management, (b) have minimal loss of functional ability of the affected joints, (c) participate in planning and carrying out the therapeutic regimen, (d) maintain a positive self-image, and (e) perform self-care to the maximum extent possible.

Nursing Implementation

Health Promotion.

Prevention of RA is not possible based on the current state of knowledge. However, early treatment can help prevent further joint damage. Community education programs should focus on symptom recognition to promote early diagnosis and treatment of RA. The Arthritis Society offers many publications, classes, and support activities to assist people who are affected (see the Resources at the end of this chapter).

Acute Intervention.

The primary goals in the management of RA are reduction of inflammation, management of pain, maintenance of joint function, and prevention or minimization of joint deformity. Goals may be met through a comprehensive program of drug therapy, balance of rest and activity with joint protection, heat and cold applications, exercise, and patient and caregiver teaching. The nurse works closely with other health care providers to restore function and to help patients make appropriate lifestyle adjustments to chronic illness.

Patients who are newly diagnosed with RA are usually treated on an outpatient basis. Hospitalization may be necessary for patients with extra-articular complications or advancing disease that necessitates reconstructive surgery for disabling deformities.

Intervention begins with a careful physical assessment (e.g., joint pain, swelling, range of motion [ROM], and general health status). The nurse must also evaluate psychosocial needs (e.g., family support, sexual satisfaction, emotional stress, financial constraints, vocational and career limitations) and environmental concerns (e.g., transportation, home or work modifications). After problem identification, a carefully planned program for rehabilitation and education can be coordinated by the nurse for the interdisciplinary health care team.

Suppression of inflammation is achieved most effectively through the administration of NSAIDs, DMARDs, and biological and targeted therapies. Careful attention to timing of drug administration is crucial to sustain a therapeutic drug level and reduce early morning stiffness. The nurse should discuss the action and adverse effects of each prescribed drug and the importance of necessary laboratory monitoring. Because many patients with RA take several different drugs, the drug regimen must be as easy as possible to understand. The nurse should encourage patients to develop a method for remembering to take their medications (e.g., pill container).

Nonpharmacological management may include the use of therapeutic heat and cold, rest, relaxation techniques, joint protection (Table 67-10; see also Table 67-4), biofeedback (see Chapter 12), transcutaneous electrical nerve stimulation (TENS; see Chapter 10), and hypnosis. The nurse should help the patient and family choose therapies that promote optimal comfort within the parameters of their lifestyle.

TABLE 67-10

PATIENT & CAREGIVER TEACHING GUIDE
Protection of Small Joints

The following instructions should be included when teaching the patient with arthritis how to protect small joints.

1. Maintain joint in neutral position to minimize deformity.
    - Press water from a sponge instead of wringing.
2. Use strongest joint available for any task.
    - When rising from chair, push with palms rather than fingers.
    - Carry laundry basket in both arms rather than with fingers.
3. Distribute weight over many joints instead of stressing a few.
    - Slide objects instead of lifting them.
    - Hold packages close to body for support.
4. Change positions frequently.
    - Do not hold a book or grip a steering wheel for long periods without resting.
    - Avoid grasping pencils or cutting vegetables with a knife for extended periods.
5. Avoid repetitious movements.
    - Do not knit for long periods.
    - Rest between rooms when vacuuming.
    - Modify home environment to include faucets and doorknobs that are pushed rather than turned.
6. Modify chores to avoid stress on joints.
    - Avoid heavy lifting.
    - Sit on stool instead of standing during meal preparation.

Lightweight splints may be prescribed to rest an inflamed joint and prevent deformity from muscle spasms and contractures. Splints should be removed at regular intervals to give skin care and perform ROM exercises. After assessment has been completed and supportive care has been given, the splints should be reapplied as prescribed. The occupational therapist may help identify additional self-help devices for ADLs.

Care and procedures should be scheduled around the patient's morning stiffness. Sitting or standing in a warm shower, sitting in a tub with warm towels around the shoulders, or simply soaking the hands in a basin of warm water may help relieve joint stiffness and allow the patient to perform ADLs more comfortably.

Ambulatory and Home Care

Rest.

Alternating scheduled rest periods with activity throughout the day helps relieve fatigue and pain. The amount of rest needed varies according to the severity of the disease and the patient's limitations. Patients should rest before becoming exhausted. Total bed rest is rarely necessary and should be avoided, to prevent stiffness and other effects of immobility. However, even a patient with mild disease may require daytime rest in addition to 8

to 10 hours of sleep at night. The nurse should help patients identify ways to modify daily activities to avoid overexertion that can lead to fatigue and an exacerbation of disease activity. For example, a patient may tolerate meal preparation more easily while sitting on a high stool in front of the sink.

Good body alignment during rest can be maintained through use of a firm mattress or bed board. Positions of extension should be encouraged, and positions of flexion should be avoided. To decrease the risk for joint contracture, pillows should never be placed under the knees. A small, flat pillow may be used under the head and shoulders.

Joint Protection.

Protecting joints from stress is important. The nurse can help patients identify ways to modify tasks to put less stress on joints during routine activities (see Table 67-10). Energy conservation requires careful planning. The emphasis is on work simplification techniques. Work should be done in short periods with scheduled rest breaks to avoid fatigue (pacing). Activities should be organized to avoid going up and down stairs repeatedly. Carts should be used to carry supplies, and materials that are used often can be stored in a convenient, easily reached area. Time-saving joint protective devices (e.g., electric can opener) should be used whenever possible. Tasks can also be delegated to other family members.

The patient's independence may be increased by occupational therapy training with assistive devices that help simplify tasks, such as built-up utensils, buttonhooks, modified drawer handles, lightweight plastic dishes, and raised toilet seats. Wearing shoes with Velcro fasteners and clothing with snaps or a zipper down the front makes dressing easier. A cane or a walker offers support and relief of pain when walking.

Heat and Cold Therapy and Exercise.

Heat and cold applications can help relieve stiffness, pain, and muscle spasm. Application of ice is especially beneficial during periods of disease exacerbation, whereas moist heat appears to offer better relief of chronic stiffness. Superficial heat sources such as heating pads, moist hot packs, paraffin baths, and warm baths or showers can relieve stiffness to allow participation in therapeutic exercises. Plastic bags of frozen vegetables (peas or corn), which can easily mould around the shoulder, wrists, or knees, are an effective home treatment. Patients can also use ice cubes or small paper cups of frozen water to massage areas proximal or distal to a painful joint. Heat and cold can be used as often as desired. However, heat

application should not exceed 20 minutes at one time, and the cold application should not exceed 10 to 15 minutes at one time. The nurse should alert patients to the possibility of a burn and advise them to avoid the use of a heat-producing cream (e.g., capsaicin) with another external heat device.

Individualized exercise is an integral part of the treatment plan. Usually, a physiotherapist develops a therapeutic exercise program to improve the flexibility and strength of the affected joints and the patient's overall endurance. The nurse should reinforce program participation and ensure that the exercises are being performed correctly. Inadequate joint movement can result in progressive joint immobility and muscle weakness, and overaggressive exercise can result in increased pain, inflammation, and joint damage. It should be emphasized that participating in a recreational exercise program (e.g., walking, swimming) or performing usual daily activities does not eliminate the patient's need for therapeutic exercise to maintain adequate joint motion.

Gentle ROM exercises are usually performed daily to keep the joints functional. Patients should have the opportunity to practise the exercises with supervision. Aquatic exercises in warm water (25°C to 30°C) allow easier joint movement because of the buoyancy and warmth of the water. At the same time, although movement seems easier, water provides two-way resistance that makes muscles work harder than they would in the air. During acute inflammation, exercises should be limited to one or two repetitions.

Psychological Support.

Self-management and adherence to an individualized home treatment program can be accomplished only if the patient has a thorough understanding of RA, the nature and course of the disease, and the goals of therapy. In addition, the patient's value system and perception of the disease must be considered.

The patient is constantly challenged by problems of limited function and fatigue, loss of self-esteem, altered body image, and fear of disability and deformity. Alterations in sexuality should be discussed. Chronic pain or loss of function may make the patient vulnerable to believing the claims of false advertising and attempting unproven or even dangerous remedies. The nurse can help patients recognize fears and concerns that are faced by all people who live with chronic illness.

Evaluation of the family support system is important. Financial planning may be necessary. Community resources such as a home care

nurse, homemaker services, and vocational rehabilitation may be considered. Self-help groups are beneficial for some patients.

The presence of chronic pain may lead to depression. Strategies that may help to decrease depressive symptoms include listening to music, reading, exercising, and counselling. Hypnosis and biofeedback may also be of value.

Age-Related Considerations

Arthritis

The prevalence of arthritis among older adults is high, and the disease is accompanied by problems unique to this age group. The most problematic areas related to connective tissue disease in older adults include the following:

- Because of the high incidence of OA expected in older adults, health care providers often do not consider the presence of other types of arthritis.
- Age alone causes changes in serological profiles, which makes interpretation of laboratory values such as RF and ESR more difficult. Medications taken for comorbid conditions can also affect laboratory values.
- Polypharmacy in older adults can result in iatrogenic arthritis.
- Nonorganic musculo-skeletal pain syndromes and weakness may be related to depression and physical inactivity.
- Diseases such as systemic lupus erythematosus (SLE), which commonly occurs in younger adults, can develop in a milder form in older adults.

Aging brings many physical and metabolic changes that may increase older-adult patients' sensitivity to both the therapeutic and the toxic effects of some drugs. Older adults who take NSAIDs have an increased risk for adverse effects, particularly GI bleeding and renal toxicity. The use of NSAIDS with a shorter half-life may require more frequent dosing but may also produce fewer adverse effects in older-adult patients with altered drug metabolism.

The common occurrence of polypharmacy in the older adult makes the use of additional drugs for RA treatment particularly problematic because

of the increased likelihood of untoward drug interactions. The drug regimen should be simplified as much as possible to increase adherence (e.g., limited number of drugs with decreased frequency of administration), particularly for patients who don't receive regular assistance.

A major concern of treatment in older-adult patients relates to the use of corticosteroid therapy. Corticosteroid-induced osteopenia can add to the problem of decreased bone density related to age and inactivity. It can also increase the occurrence of pathological fractures, especially compression fractures of vertebrae. Corticosteroid-induced myopathy can be minimized or prevented by an age-appropriate exercise program. Although important for all age groups, an adequate support system for older adults is a critical factor in the ability to follow a treatment regimen that includes nutritional planning, exercise, general health maintenance, and appropriate therapy.

Gout

Gout is a type of recurring acute arthritis characterized by the accumulation of uric acid crystals in one or more joints. Characteristic deposits of sodium urate crystals occur in articular, periarticular, and subcutaneous tissues. Gout occurs more frequently in men than in women and affects up to 2% of Canadians (Arthritis Society, 2015a).

Gout may be classified as primary or secondary. In *primary gout,* a hereditary error of purine metabolism leads to the overproduction or retention of uric acid. Primary gout, which accounts for 90% of cases, occurs primarily in middle-aged men.

Secondary gout may be related to another acquired disorder or may be the result of drugs known to inhibit uric acid excretion. Secondary gout may also be caused by drugs that increase the rate of cell death, such as the chemotherapeutic agents used in treating leukemia. Hyperuricemia may also develop in patients taking thiazide diuretics, women who are postmenopausal, and organ transplant recipients who are receiving immuno-suppressive agents.

Obesity in men has been shown to increase the risk for gout. Hypertension, diuretic use, and excessive alcohol consumption are additional risk factors. A diet high in purine-rich foods (e.g., shellfish such as crab and shrimp; vegetables such as lentils, asparagus, and spinach; meats such as beef, chicken, and pork) will not cause gout but can trigger an acute attack if a person is susceptible to gout.

Etiology and Pathophysiology

Uric acid is the major end product of purine catabolism and is excreted primarily by the kidneys. Gout is caused by (1) an increase in uric acid production; (2) underexcretion of uric acid by the kidneys; or (3) increased intake of foods containing purines, which are metabolized to uric acid by the body. Underexcretion of uric acid is believed to be the major cause of hyperuricemia in 80% to 90% of people who are affected. High dietary intake of purine alone has relatively little effect on the uric acid levels. Hyperuricemia may result from prolonged fasting or excessive alcohol drinking because of the increased production of keto acids, which then inhibit uric acid excretion.

Clinical Manifestations and Complications

In the acute phase, gouty arthritis may occur in one or more joints but usually fewer than four. Affected joints may appear dusky or cyanotic and are extremely tender. Inflammation of the great toe *(podagra)* is the most common initial problem. Other affected joints may include the midtarsal area of the foot, the ankle, the knee, and the wrist. Olecranon (bony tip of the elbow) bursae may also be involved. Acute gouty arthritis is usually precipitated by trigger events such as trauma, surgery, alcohol ingestion, or systemic infection. Symptoms typically begin at night, with sudden swelling and excruciating pain; peak within several hours; and are often accompanied by low-grade fever. Individual attacks usually subside, treated or untreated, in 2 to 10 days. The affected joint returns entirely to normal, and patients are often free of symptoms between attacks.

Chronic gout is characterized by multiple joint involvement and visible deposits of sodium urate crystals, called *tophi.* These are typically noted in the synovium, the subchondral bone, the olecranon bursae, and the vertebrae; along tendons; and in the skin and cartilage (Figure 67-6). Tophi are rarely present at the time of the initial attack and are generally noted only many years after the onset of disease.

FIGURE 67-6 Tophi associated with chronic gout. Nodules are painless and filed with uric acid crystals. Source: Courtesy of John Cook, MD. From Goldstein, B. G., & Goldstein, A. E. (1997). *Practical dermatology.* (2nd ed.). St Louis: Mosby.

The severity of gouty arthritis varies. The clinical course may consist of infrequent mild attacks or multiple severe episodes (up to 12 per year) associated with a slowly progressive disability. In general, the higher the serum uric acid level, the earlier the appearance of tophi and the greater the tendency toward more frequent, severe episodes of acute gout. Chronic inflammation may result in joint deformity, and cartilage destruction may predispose the joint to secondary OA. Large and unsightly tophaceous deposits may perforate overlying skin, producing draining sinuses that often become infected.

Excessive uric acid excretion may lead to kidney or urinary tract stone formation. Pyelonephritis associated with intrarenal sodium urate deposits and obstruction may contribute to renal disease.

Diagnostic Studies

In gout, serum uric acid levels are usually elevated as high as 0.51 mmol/L. However, hyperuricemia is not specifically diagnostic of gout because increased levels may be related to a variety of drugs or may exist as an asymptomatic abnormality in the general population. Specimens for 24-hour urine uric acid values may be obtained to determine if the disease is caused by decreased renal excretion or overproduction of uric acid.

Synovial fluid aspiration is a controversial part of patient evaluation because an accurate diagnosis of gout is possible in 80% of patients on the basis of clinical symptoms alone. However, aspiration may have therapeutic value by decompressing a swollen joint capsule. Joint aspiration is also the only reliable method to distinguish gout from septic

arthritis and *pseudogout* (calcium phosphate crystals are formed). Affected fluid characteristically contains needle-like monosodium urate crystals (Saccomano & Ferrera, 2015). Radiographic studies appear normal in the early stages of gout. In chronic disease, tophi may appear as eroded areas in the bone.

Collaborative Care

Goals for care of patients with gout (Table 67-11) include termination of an acute attack through use of an anti-inflammatory agent such as colchicine. Drug therapy is the primary therapy used in treating acute and chronic gout. In addition, weight reduction (as needed) and possible avoidance of alcohol and foods high in purine (red and organ meats) are recommended.

TABLE 67-11

COLLABORATIVE CARE
Gout

Diagnostic
• History and physical examination
• Elevated serum uric acid levels
• Elevated uric acid levels in 24-hr urine collection
• Family history of gout
• Presence of sodium urate crystals in synovial fluid
• Radiographic studies
Collaborative Therapy
• Dietary avoidance of food and fluids with high purine content (e.g., anchovies, liver, wine, beer)
• Joint aspiration and intra-articular corticosteroids
	• Drug therapy
	  • Adrenocorticotrophic hormone (ACTH)
	  • Allopurinol (Zyloprim)
	  • Colchicine
	  • Corticosteroids (prednisone)
	  • Febuxostat (Uloric)
	  • Intra-articular corticosteroids (methylprednisolone acetate)
	  • Nonsteroidal anti-inflammatory drugs (e.g., naproxen [Naprosyn])
	  • Probenecid (Benuryl)
	• Joint immobilization
	• Local application of heat or cold

Drug Therapy.

Acute gout is treated with colchicine and NSAIDs. Because colchicine has anti-inflammatory effects but no analgesic properties, an NSAID is added to the treatment regimen for pain management. Oral administration of colchicine generally produces dramatic pain relief when given within 12 to 24 hours of an attack (Hardy, 2011). Colchicine also has diagnostic merit in that a good response to this drug offers further evidence for the diagnosis of gout.

Future attacks of gout are prevented in part by a maintenance dose of urate-lowering drugs such as a xanthine oxidase inhibitor (allopurinol [Zyloprim]) or a uricosuric drug (probenecid [Benuryl]). Febuxostat

(Uloric), a selective inhibitor of xanthine oxidase, is given for long-term management of hyperuricemia in people with chronic gout.

Corticosteroids, given either orally or by intra-articular injection, can be helpful in treating acute attacks of gout. Systemic corticosteroids may be used only if routine therapies are contraindicated or ineffective. Adrenocorticotrophic hormone (ACTH) may also be used for treating acute gout.

For many years, the standard therapy for hyperuricemia caused by urate underexcretion has been uricosuric drugs such as probenecid, which inhibit renal tubular reabsorption of urates. However, these drugs are ineffective when creatinine clearance is reduced, as can occur in patients older than 60 years and those with renal impairment. ASA (Aspirin) inactivates the effect of uricosurics, resulting in urate retention, and should be avoided while patients are taking uricosuric drugs. Acetaminophen can be used safely if analgesia is required.

Adequate urine volume with normal renal function (2 to 3 L/day) must be maintained to prevent precipitation of uric acid in the renal tubules. Allopurinol, which blocks the production of uric acid, is particularly useful in patients with uric acid stones or renal impairment, in whom uricosuric drugs may be ineffective or dangerous. The angiotensin II receptor antagonist losartan (Cozaar) may be especially useful in the treatment of older-adult patients with both gout and hypertension. Losartan promotes urate diuresis and may normalize serum urate levels. Combination therapy with losartan and allopurinol may also be given. Regardless of which drugs are prescribed, serum uric acid levels must be checked regularly to monitor treatment effectiveness.

Nutritional Therapy.

Dietary restrictions that limit alcohol and foods high in purine help minimize uric acid production (see Chapter 48, Table 48-13). Patients who are obese should be instructed to follow a carefully planned weight-reduction program.

Nursing Management Gout

Nursing interventions for patients with an acute episode of gout include supportive care for the inflamed joints. The nurse must avoid causing pain to an inflamed joint by careless handling. Bed rest may be appropriate, with affected joints properly immobilized. Involvement of a lower extremity may require use of a cradle or footboard to protect the painful area from the weight of bed linens. The nurse should assess the limitation of motion and degree of pain and document treatment effectiveness.

The nurse should help patients and their families understand that hyperuricemia and gouty arthritis are chronic problems that can be controlled with careful adherence to a treatment program (Saccomano & Ferrera, 2015). The importance of drug therapy and the need for periodic determination of serum uric acid levels should be explained thoroughly. Patients should be able to demonstrate knowledge of precipitating factors that may cause an attack, including excessive caloric intake or overindulgence in purine-containing foods and alcohol; starvation (fasting); drug use (e.g., niacin, ASA [Aspirin], diuretics); and major medical events (e.g., surgery, myocardial infarction).

Lyme Disease

Lyme disease is a spirochetal infection caused by *Borrelia burgdorferi* and transmitted by the bite of an infected deer tick. It was first identified in 1975 in Lyme, Connecticut, after an unusual clustering of arthritis in children. The tick typically feeds on mice, dogs, cats, cows, horses, deer, and humans. Wild animals do not exhibit the illness, but clinical Lyme disease does occur in domestic animals. Person-to-person transmission does not occur.

The peak season for infection in humans is from spring and summer. The number of infected ticks continues to rise in Canada. The most prevalent areas in Canada include southern British Columbia; southeastern and south-central Manitoba; southern, eastern, and northwestern Ontario; southern Quebec; southern New Brunswick and Grand Manan Island; and parts of Nova Scotia (Public Health Agency of Canada, 2016).

Symptoms of Lyme disease can mimic those of other diseases, such as multiple sclerosis, mononucleosis, and meningitis. The most characteristic clinical symptom of early localized disease is erythema migrans (EM), a

skin lesion at the site of the tick bite that occurs in 70% to 80% of people who are infected, within 3 to 30 days after exposure (Figure 67-7). The lesion begins as a red macule or papule that slowly expands to form a large round lesion of up to 30 cm with a bright red border and central clearing ("bull's eye rash"). The EM lesion is often accompanied by acute flulike symptoms, such as low-grade fever, chills, headache, stiff neck, fatigue, swollen lymph nodes, and migratory joint and muscle pain. Of note, loss of tone in facial muscles can manifest as Bell's palsy. Symptoms usually occur within a week but may be delayed for up to 30 days. The flulike symptoms generally resolve over a period of weeks or months, even if untreated.

FIGURE 67-7 Erythema migrans of Lyme disease. Source: Swartz, M. H. (2010). Textbook of physical diagnosis: History and examination (6th ed., p. 186, Figure 8-112). Philadelphia: W. B. Saunders.

If not treated, the spirochete can disseminate within several weeks or months to the heart, joints, and central nervous system (CNS). Carditis may occur (Bockenstedt, 2012). About 60% of people with untreated infection develop chronic arthritic pain and swelling in the large joints. Nervous system problems may include severe headaches or poor motor coordination. One neurological condition, tertiary neuroborreliosis, results in confusion and forgetfulness.

A diagnosis of Lyme disease is often based on clinical manifestations, particularly the EM lesion, and a history of exposure in an endemic area. CBC count and ESR are usually normal. A two-step laboratory testing process is recommended to confirm diagnosis (Government of Canada, 2015). The first step is the enzyme immunoassay (EIA), a test that yields positive results for most people with Lyme disease. If the EIA result is

positive or inconclusive, a Western blot test is done to confirm the infection. Cerebro-spinal fluid should be examined in individuals with neurological involvement.

Active lesions can be treated with oral antibiotic therapy. Doxycycline, cefuroxime (Ceftin), and amoxicillin are often effective in early stages of infection and in prevention of later stages of the disease. Doxycycline prevents Lyme disease when given within 3 days after the bite of a deer tick. Short-term therapy for 2 to 3 weeks is usually effective for solitary EM, but patients with neurological or cardiac complications may require IV therapy with ceftriaxone or penicillin. In most cases, people with Lyme disease are treated successfully with antibiotics. Approximately 10% to 20% of people treated with antibiotics for Lyme disease may experience lingering fatigue or joint and muscle pain. This condition, known as post–Lyme disease syndrome, may result from residual damage to tissues and the immune system (Bockenstedt, 2012).

Reducing exposure to ticks is the best way to prevent Lyme disease. Teaching of patients and caregivers who live in endemic areas is outlined in Table 67-12. No vaccine is available for Lyme disease.

TABLE 67-12

PATIENT & CAREGIVER TEACHING GUIDE
Prevention and Early Treatment of Lyme Disease

The following instructions should be included when teaching patients and caregivers how to prevent Lyme disease.

- Avoid walking through tall grasses and low brush and sitting on logs.
- Mow grass. Remove brush around paths, buildings, and campsites to create "tick-safe zones."
- Move woodpiles and bird feeders away from house. Discourage deer (main source of food for adult ticks) from being in the area.
- Wear long pants or nylon tights of tightly woven, light-coloured fabric so that ticks can be easily seen.
- Tuck pants into boots or long socks, tuck long-sleeved shirts into pants, and wear closed shoes when hiking.
- Check often for ticks crawling from pant legs to open skin.
- Thoroughly inspect and wash clothes. Placing clothing in dryer on high heat effectively kills ticks.
- Spray insect repellent containing DEET sparingly on skin or apply permethrin to boots and clothes (especially on lower extremities) and camping gear.
- Have pets wear tick collars, inspect them often, and do not allow pets on furniture or beds.

The following instructions should be included when teaching patients and caregivers living in endemic areas.

- Remove attached ticks with tweezers (not fingers). Grasp tick's mouth parts as close to skin as possible and gently pull straight out. Do not twist or jerk. Avoid folk solutions such as painting the tick with nail polish or petroleum jelly.
- Wash bitten area with soap and water and apply antiseptic. Wash hands.
- See a health care provider immediately if flulike symptoms or a bull's eye rash appears within 3 to 30 days after removal of tick.

DEET, diethyltoluamide.

Septic Arthritis

Septic arthritis (infectious or bacterial arthritis) is caused by microorganisms invading the joint cavity. Bacteria can travel through the bloodstream from another site of active infection, resulting in hematogenous seeding of the joint. Organisms can also be introduced directly through trauma or surgical incision.

Any bacteria can cause the infection, including nonpathogenic bacteria in patients who are immuno-compromised. *Staphylococcus aureus* and *Streptococcus hemolyticus* are the most common causative organisms. *Neisseria gonorrhoeae* is the most common cause in sexually active young adults. Factors that increase the risk for infection include diseases in which host resistance is decreased (e.g., leukemia, diabetes mellitus); treatment with corticosteroids or immuno-suppressive drugs; and debilitating chronic illness.

Large joints such as the knee and the hip are most frequently involved. Inflammation of the joint cavity causes severe pain, erythema, and swelling. Because infection has often spread from a primary site elsewhere in the body, fever or shaking chills often accompany articular manifestations. A diagnosis may be made by aspiration of the joint (arthrocentesis) and culture of the synovial fluid. However, WBC counts may be low early in the infectious process, and diagnosis is not possible based solely on WBC counts. Blood cultures for aerobic and anaerobic organisms should also be obtained.

Septic arthritis requires prompt treatment to prevent joint destruction and bone loss. Broad-spectrum antibiotics against Gram-negative organisms, pneumococci, and staphylococci are often started before the causative organism is identified. Once the organism is determined, the treatment can become specific. Infections may respond to treatment within 2 weeks or may take as long as 4 to 8 weeks, depending on the causative organism. Local aspiration and surgical drainage may be required. If diagnosis and treatment are delayed, destruction of articular cartilage can occur, followed by loss of joint function. Chronic infection can also develop. Septic arthritis of the hip can contribute to development of avascular necrosis.

Nursing intervention includes assessment and monitoring of joint inflammation, pain, and fever. To control pain, use resting splints or traction to immobilize affected joints. Local hot compresses can also help relieve pain. Gentle ROM exercises should be initiated as soon as tolerated to prevent muscle atrophy and joint contractures. The nurse should explain the need for antibiotics and the importance of their continued use until the infection is resolved. The nurse should offer support to a patient who requires arthrocentesis or operative drainage. Strict aseptic technique should be used in assisting with joint aspiration procedures.

Spondyloarthropathies

The **spondyloarthropathies** are a group of interrelated multisystem inflammatory disorders that affect the spine, the peripheral joints, and periarticular structures. These disorders are all negative for rheumatoid factor (RF) and thus are often referred to as seronegative arthropathies.

Inheritance of HLA-B27 is strongly associated with these diseases. Both genetic and environmental factors play a role in the development of this group of diseases, which includes ankylosing spondylitis, psoriatic arthritis, and reactive arthritis. (HLAs and their relationship to autoimmune diseases are discussed in Chapter 16.)

The spondyloarthropathies share clinical and laboratory characteristics that make it difficult to distinguish among them in early stages of disease. These characteristics include absence of antibodies in the serum, inflammatory arthritis of the spine, peripheral joint involvement predominantly of the lower extremities, sacroiliitis, uveitis, enteric mucosal lesions, and skin lesions (Robinson & Benham, 2015).

Ankylosing Spondylitis

Ankylosing spondylitis (AS) is a chronic inflammatory disease that affects primarily the axial skeleton, including the sacroiliac joints, the intervertebral disc spaces, and the costovertebral articulations. HLA-B27 antigen is found in approximately 90% of people with AS. Individuals with the antigen have a significantly greater risk of developing a spondyloarthropathy than those who do not. As many as 150 000 to 300 000 Canadians are affected by AS (Arthritis Society, 2015b). The usual age at onset is 15 to 30 years, and three times more men than women develop AS (Arthritis Society, 2015b).

Etiology and Pathophysiology

Genetic predisposition appears to play an important role in the disease pathogenesis, but the precise mechanisms are unknown. Aseptic synovial inflammation in joints and adjacent tissue causes the formation of granulation tissue *(pannus)* and dense fibrous scars that lead to fusion of articular tissues. Extra-articular inflammation can affect the eyes, the lungs, the heart, the kidneys, and the peripheral nervous system.

Clinical Manifestations and Complications

AS is characterized by symmetrical sacroiliitis and progressive inflammatory arthritis of the axial skeleton. Symptoms of inflammatory spine pain are the first clues to the diagnosis. Affected patients typically complain of low back pain, stiffness, and limitation of motion that is worse during the night and in the morning but improves with mild activity. In affected women, early symptoms of disease may be pain and stiffness in the neck rather than the lower back. General symptoms such as fever, fatigue, anorexia, and weight loss are rarely present. Uveitis (intraocular inflammation) is the most common nonskeletal symptom. It can appear as an initial manifestation of the disease years before arthritic symptoms develop. Patients with AS may also experience chest pain and sternal or costal cartilage tenderness that can be distressing.

Severe postural abnormalities and deformity can lead to significant disability for patients with AS (Figure 67-8). Impaired spinal ROM and fixed kyphosis contribute to altered visual function, which raises concerns about safe ambulation. Aortic insufficiency and pulmonary fibrosis are frequent complications. Cauda equina syndrome can also result, contributing to lower extremity weakness and bladder dysfunction. In addition, affected patients are at risk for spinal fracture because of associated osteoporosis.

FIGURE 67-8 Advanced ankylosing spondylitis. Kyphotic posture causes many patients to have a protuberant abdomen secondary to pulmonary restriction. Source: Kim, D. H., Henn, J., Vaccaro, A. R., et al. (Eds.). (2006). *Surgical anatomy and techniques to the spine.* Philadelphia: W. B. Saunders.

Diagnostic Studies

Radiological studies are essential for the diagnosis and follow-up of AS. However, radiographs are limited in detecting early sacroiliitis or subtle changes in posterior vertebrae. MRI can be useful in assessing early cartilage abnormalities, while CT scan is appropriate in specific situations (e.g., cases with subtle radiographic changes). Changes on later spinal radiographs include the appearance of "bamboo spine," which is the result of calcifications *(syndesmophytes)* that bridge from one vertebra to another.

Laboratory testing is not specific, but ESR may be elevated and mild anemia may be present. When the suspicion of AS is high, the presence of HLA-B27 antigen increases the likelihood of this diagnosis.

Genetics in Clinical Practice

Ankylosing Spondylitis

Genetic Basis

Inheritance of human leukocyte antigen HLA-B27 increases susceptibility to development of ankylosing spondylitis (AS).

Incidence

- About 80% to 90% of White patients with ankylosing spondylitis (AS) have HLA-B27 antigen.
- Inheriting HLA-B27 does not mean that a person will develop the disease. Of children who inherit HLA-B27 from a parent with AS, 80% do not develop the disease.
- AS is three times more common in men than in women.
- It occurs more often in White people than in other ethnic groups.
- It affects 7 per 100 000 people.

Genetic Testing

- Testing for HLA-B27 antigen is available.

Clinical Implications

- Diagnosis of AS usually occurs between ages 18 and 30.
- Multiple genetic and environmental factors play a role in the pathogenesis of the disease.
- It is not known how HLA-B27 increases the risk for AS.
- AS is present in about 3% to 10% of patients with inflammatory bowel disease (IBD).
- About 50% to 70% of patients with both AS and IBD have the HLA-B27 antigen.

HLA, human leukocyte antigen.

Collaborative Care

Prevention of AS is not possible. However, families with other diagnosed HLA-B27–positive rheumatic diseases (e.g., acute anterior uveitis, juvenile

spondyloarthritis) should be alert to signs of low back pain for early identification and treatment of AS.

Care of the patient with AS is aimed at maintaining maximal skeletal mobility while decreasing pain and inflammation. Heat applications can help in the relief of local symptoms. NSAIDs and salicylates are commonly prescribed. DMARDs such as sulphasalazine (Salazopyrin) or methotrexate have little effect on spinal disease but may help with peripheral joint disease. Local corticosteroid injections may be beneficial in relieving symptoms.

TNF, which promotes inflammation, is found in elevated levels in the blood and certain tissues of patients with AS. Etanercept (Enbrel), a biological and targeted therapy drug, binds TNF and inhibits its action. Etanercept reduces active inflammation and improves spinal mobility. Additional anti-TNF inhibitors (infliximab, adalimumab, golimumab) may also be effective.

Once pain and stiffness are managed, exercise is essential. Postural control is important for minimizing spinal deformity. The exercise regimen should include back, neck, and chest stretches. Hydrotherapy has also been shown to decrease pain and facilitate spinal extension. Surgery may be indicated for severe deformity and mobility impairment. Spinal osteotomy and total joint replacement are the most commonly performed procedures (see Chapter 65).

Nursing Management Ankylosing Spondylitis

The key nursing responsibility for patients with AS is education about the disease and principles of therapy. The home management program should include regular exercise and attention to posture, local moist heat applications, and knowledgeable use of drugs.

The nurse's baseline ROM assessment should include chest expansion (using breathing exercises). Smoking cessation must be encouraged to decrease the risk for lung complications in patients with reduced chest expansion. Ongoing physiotherapy includes gentle, graded stretching and strengthening exercises to preserve ROM and improve thoracolumbar flexion and extension.

The nurse should discourage excessive physical exertion during flare-ups of the disease. Proper positioning at rest is essential. The mattress should be firm, and patients should sleep on the back with a flat pillow, avoiding positions that encourage flexion deformity. Postural training emphasizes avoiding spinal flexion (e.g., leaning over a desk); heavy lifting; and prolonged walking, standing, or sitting. Participation in sports that facilitate natural stretching, such as swimming and racquet games, should be encouraged. Family counselling and vocational rehabilitation are important.

Psoriatic Arthritis

Psoriatic arthritis (PsA) is a progressive inflammatory disease that affects approximately 10% to 30% of people with psoriasis (Arthritis Society, 2017e). *Psoriasis* is a common, benign, inflammatory skin disorder characterized by red, irritated, and scaly patches. Both PsA and psoriasis appear to have a genetic link with the HLA antigens in many patients. Although the exact cause of PsA is unknown, a combination of immune, genetic, and environmental factors is suspected.

PsA can occur in different forms. These include (1) arthritis involving primarily the small joints of the hands and feet (DIP), (2) asymmetric arthritis involving joints of the extremities, (3) symmetric polyarthritis resembling RA, and (4) arthritis of the sacroiliac joints and spine (psoriatic spondylitis) (Arthritis Society, 2017e).

On radiographs, the cartilage loss and erosion resemble those of RA. Many patients with advanced cases of PsA have widened joint spaces. A "pencil-in-cup" deformity is common at the DIP joints as a result of osteolysis. In this deformity, the narrowed end(s) of the metacarpals or phalanges insert into the expanded end of the other (adjacent) bone sharing the joint. Elevated ESR, mild anemia, and elevated blood uric acid levels are present in some patients; therefore, gout must be ruled out.

Treatment includes splinting, joint protection, and physiotherapy. NSAIDs given early in the course of the disease may help with inflammation. Drug therapy also includes DMARDs such as methotrexate, which are effective for both cutaneous and articular manifestations. Sulphasalazine (Salazopyrin) and cyclosporin may be used for treating PsA. In addition, biological and targeted therapy, such as etanercept, golimumab, adalimumab, and infliximab, may also be used.

Reactive Arthritis

Reactive arthritis *(Reiter's syndrome)* occurs more commonly in young men than in young women. It is associated with a symptom complex that includes urethritis, conjunctivitis, and mucocutaneous lesions. Although the exact etiology is unknown, reactive arthritis appears to occur after exposure to specific genito-urinary or GI tract infections. *Chlamydia trachomatis* is most often implicated in sexually transmitted reactive arthritis (Arthritis Society, 2017f). Reactive arthritis is also associated with GI infections with *Shigella, Salmonella, Campylobacter,* or *Yersinia* species and other microorganisms.

Individuals who are positive for HLA-B27 are at increased risk of developing reactive arthritis after sexual contact or exposure to certain enteric pathogens. This finding supports the likelihood of a genetic predisposition.

Urethritis develops within 1 to 2 weeks after sexual contact or GI infection. In women, symptoms include cervicitis. Low-grade fever, conjunctivitis, and arthritis may occur over the next several weeks. This type of arthritis tends to be asymmetrical, frequently involving the large joints of the lower extremities and the toes. Lower back pain may occur with severe disease. Mucocutaneous lesions commonly manifest as small, painless, superficial ulcerations on the tongue, the oral mucosa, and the glans penis. Soft-tissue manifestations commonly include Achilles tendinitis or plantar fasciitis. Few laboratory findings are abnormal, although the ESR may be elevated.

Prognosis is favourable; most patients recover after 2 to 16 weeks. Because reactive arthritis is often associated with *C. trachomatis* infection, treatment of patients and their sexual partners with doxycycline is widely recommended. Conjunctivitis and lesions require no treatment, but topical ophthalmic corticosteroids are typically prescribed for treatment of uveitis. Drug therapy may also include NSAIDs, methotrexate, and sulphasalazine. Physiotherapy may be helpful during disease recovery.

Most patients have complete remission with restoration of full joint function. Up to 30% may develop chronic or recurring disease, which can result in major disability (Hill, 2012). Radiographic changes in chronic disease closely resemble those of AS. Treatment of chronic reactive arthritis is based on symptoms.

Other Connective Tissue Disorders

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a multisystem, inflammatory, autoimmune disease. It is a complex disorder of multifactorial origin resulting from interactions among genetic, hormonal, environmental, and immunological factors. SLE typically affects the skin, the joints, and serous membranes (pleura, pericardium), along with the renal, hematological, and neurological systems. SLE is characterized by a chronic, unpredictable course marked by alternating periods of exacerbation and remission.

The overall incidence of SLE in Canada is approximately 1 per 2 000 people. Most cases occur in women during their child-bearing years. Approximately 90% of people with SLE are women (Arthritis Society, 2017g).

Etiology and Pathophysiology

The etiology of the abnormal immune response in SLE is unknown. Because of the high prevalence of SLE among family members, a genetic influence is suspected. Multiple susceptibility genes from the HLA complex, including HLA-DR3, show associations with SLE.

Hormones are also known to play a role in the etiology of SLE. Onset or exacerbation of disease symptoms sometimes occurs after the onset of menarche, with the use of oral contraceptives, and during and after pregnancy. The disease tends to worsen in the immediate postpartum period.

Environmental factors are believed to contribute to the occurrence of SLE; sun exposure and burns are the most common environmental triggers. Infectious agents may serve as a stimulus for immune hyperactivity. SLE may also be precipitated or aggravated by certain drugs, such as procainamide, hydralazine (Apresoline), and a number of anticonvulsant agents.

SLE is characterized by the production of a large variety of autoantibodies against nucleic acids (e.g., single- and double-stranded DNA), erythrocytes, coagulation proteins, lymphocytes, platelets, and many other self-proteins. Autoimmune reactions characteristically are directed against constituents of the cell nucleus (antinuclear antibodies [ANAs]), particularly DNA.

Circulating immune complexes containing antibodies against DNA are deposited in the basement membranes of capillaries in the kidneys, the heart, the skin, the brain, and the joints. Complement is activated and inflammation occurs. The overaggressive antibody response is also related to activation of B and T cells. The specific manifestations of SLE depend on which cell types or organs are involved. (SLE is a type III hypersensitivity response [see Chapter 16].)

Clinical Manifestations and Complications

The severity of SLE is extremely variable, ranging from relatively mild to rapidly progressive and affecting many organ systems (Figure 67-9). The progressive organ involvement of SLE has no characteristic pattern. Any organ can be affected by an accumulation of circulating immune complexes. The most commonly affected tissues are the skin and muscle, the lining of the lungs, the heart, nervous tissue, and the kidneys. Generalized complaints such as fever, weight loss, arthralgia, and excessive fatigue may precede an exacerbation of disease activity.

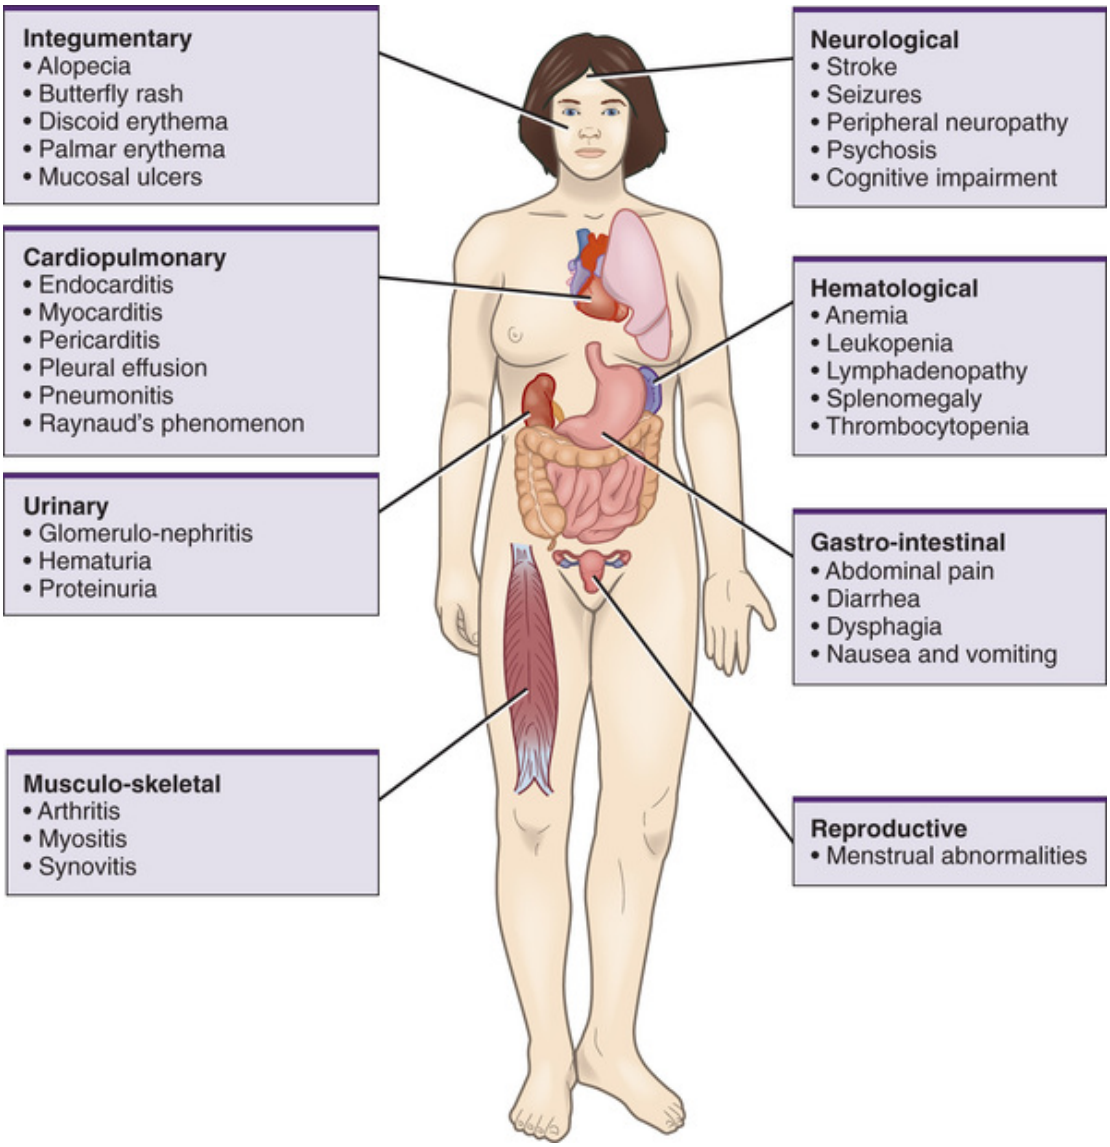

FIGURE 67-9 Multisystem involvement in systemic lupus erythematosus.

Dermatological Manifestations.

Cutaneous vascular lesions can appear in any location but are most likely to develop in sun-exposed areas. Severe skin reactions can occur in people who are photosensitive. The classic "butterfly rash" over the cheeks and bridge of the nose occurs in 50% of patients with SLE (Figure 67-10). About 20% of patients have *discoid* (round, coin-shaped) lesions. A small number of patients have persistent lesions, photosensitivity, and mild systemic disease, in a syndrome referred to as *subacute cutaneous lupus.*

FIGURE 67-10 Butterfly rash manifestation of systemic lupus erythematosus. Source: Kliegman, R. M., Stanton, B. F., St. Geme III, J. W., et al. (Eds.). (2011). *Nelson textbook of pediatrics* (19th ed., Figure 152-1, A). Philadelphia: W. B. Saunders.

Ulcers of the oral or the nasopharyngeal membranes occur in up to one-third of patients with SLE. Alopecia is also common, with or without underlying scalp lesions. The hair may grow back during remission, but hair loss may be permanent over lesions. The scalp becomes dry and scaly and atrophied.

Musculo-Skeletal Problems.

Arthritis occurs in more than 90% of patients with SLE. Polyarthralgia with morning stiffness is often the patient's first complaint and may precede the onset of multisystem disease by many years. Diffuse swelling is accompanied by joint and muscle pain, and some stiffness may be experienced. Lupus-related arthritis is generally nonerosive, but it may cause deformities such as swan-neck appearance of the fingers (see Figure 67-4, *D*), ulnar deviation, and subluxation with hyperlaxity of the joints. Patients with SLE have an increased risk for bone loss and fracture.

Cardiopulmonary Problems.

Tachypnea and cough in patients with SLE are suggestive of lung disease. Pleurisy is also possible. Cardiac involvement may include dysrhythmias that result from fibrosis of the sinoatrial and atrioventricular nodes. This is an ominous sign of advanced disease, contributing significantly to the morbidity and mortality seen in SLE. Pericarditis can also occur. Clinical factors such as hypertension and hypercholesterolemia require aggressive

therapy and careful monitoring. In addition, people with SLE are at risk for secondary antiphospholipid syndrome (APS), a disorder of coagulation that leads to clots in the arteries and veins, with associated risk for stroke, gangrene, and heart attack.

Renal Problems.

Lupus nephritis (LN) occurs in approximately 40% of patients with SLE. Renal involvement is usually evident within 5 years after symptoms of SLE appear. Manifestations of renal involvement vary from mild proteinuria to rapid, progressive glomerulo-nephritis. Scarring and permanent damage can lead to end-stage renal disease.

The primary goal in treating LN is to slow the progression of nephropathy and preserve renal function by managing the underlying disease. The importance of obtaining a renal biopsy is controversial, but findings can help guide treatment. Although LN may be one of the more serious complications of SLE, effective treatments are available. These typically include corticosteroids, cytotoxic agents (cyclophosphamide [Procytox]), and immuno-suppressive agents (azathioprine [Imuran], cyclosporin [Neoral], mycophenolate mofetil [CellCept]). Rituximab and eculizumab (Soliris) are being studied as possible treatments. Oral prednisone or pulsed IV methylprednisolone may also be used as an intervention for LN, especially in the initial treatment period, when cytotoxic agents have not had time to take effect.

Nervous System Problems.

Along with renal involvement, neuro-psychiatric manifestations are prevalent in SLE. Generalized or focal seizures are the most common manifestation involving the CNS and occur in as many as 15% of patients with SLE by the time of diagnosis. Seizures are generally controlled by corticosteroids or anticonvulsant drugs. Peripheral neuropathy can also occur, leading to sensory and motor deficits.

Cognitive dysfunction, recognized as a CNS manifestation of SLE, may result from the deposition of immune complexes within brain tissue. It is characterized by disordered thought processes, disorientation, memory deficits, and psychiatric symptoms such as severe depression and psychosis. Occasionally, a stroke or aseptic meningitis may be attributable to SLE. Headaches are also common and can become severe during exacerbation of the disease.

Hematological Problems.

The formation of antibodies against blood cells, such as erythrocytes, leukocytes, and thrombocytes, and against coagulation factors, is also a common feature of SLE (Tsokos, 2011). Anemia, mild leukopenia, and thrombo-cytopenia are often present in SLE. Some patients develop a tendency toward coagulopathy, involving either excessive bleeding or blood clot development. A manifestation of antiphospholipid antibody syndrome is a common cause of hypercoagulability in patients with SLE, many of whom benefit from high-intensity treatment with warfarin (Coumadin).

Infection.

Patients with SLE appear to have increased susceptibility to infections, possibly in relation to defects in the ability to phagocytize invading bacteria, deficiencies in production of antibodies, and the immuno-suppressive effect of many anti-inflammatory drugs. Infection is a major cause of death, with pneumonia being the most common infection. Fever may indicate an underlying infectious process rather than lupus activity alone. Vaccinations are generally safe for patients with SLE. The exception is the need to avoid live virus vaccines in patients who are being treated with corticosteroids or cytotoxic agents.

Diagnostic Studies

The diagnosis of SLE is based on the presence of distinct criteria revealed through patient history, physical examination, and laboratory findings (Table 67-13). No specific test is diagnostic for SLE, but a variety of abnormalities may be present in the blood. SLE is marked by the presence of ANA in 97% of people with the disease.

TABLE 67-13

CRITERIA FOR DIAGNOSIS OF SYSTEMIC LUPUS ERYTHEMATOSUS*

• Antinuclear antibodies • Arthritis: nonerosive, involvement of two or more joints characterized by tenderness, swelling, and effusion • Discoid rash • Hematological disorder: hemolytic anemia, leukopenia, lymphopenia, or thrombo-cytopenia • Immunological disorder: positive result of LE preparation; anti-DNA antibody or antibody to Sm nuclear antigen; or false-positive result of serological tests for syphilis • Malar rash • Neurological disorder: seizures or psychosis • Oral ulcers • Photosensitivity • Renal disorder: persistent proteinuria or cellular casts in urine • Serositis: pleuritis or pericarditis

*SLE is diagnosed if four or more of the criteria are present, serially or simultaneously, during any interval of observation. Revised criteria by a subcommittee of the American College of Rheumatology are used for the purpose of classification in population surveys, not for the diagnosis in individual patients.

LE, lupus erythematosus; *Sm,* Smith.

Sources: Tan, E. M., Cohen, A. S., Fries, J. F., et al. (1982). The 1982 revised criteria for the classification of systemic lupus erythematosus. *Arthritis and Rheumatism, 25*(11), 1271–1277. doi:10.1002/art.1780251101; and Hochberg, M. C. (1997). Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus [Letter]. *Arthritis and Rheumatism, 40*(9), 1725. doi:10.1002/art.1780400928.

Other antibodies include anti-DNA, antineuronal, anticoagulant, anti-WBC, anti–red blood cell (RBC), antiplatelet, antiphospholipid, and anti–basement membrane antibodies. Anti-double-stranded DNA antibodies are found in half of all people with SLE. The anti-Smith (Sm) antibodies are found in 30% to 40% of people with lupus and are almost always considered diagnostic. The lupus erythematosus (LE) cell prep test is a nonspecific test for SLE and is positive in other rheumatic diseases. ESR and CRP levels are not diagnostic of SLE but may be used to monitor disease activity and effectiveness of therapy.

Collaborative Care

A major challenge in the treatment of SLE is to manage the active phase of the disease while preventing complications of treatments. Survival is influenced by several factors, including age, race, sex, socioeconomic status, comorbid conditions, and the severity of disease. The prognosis of

SLE can be improved with early diagnosis, prompt recognition of serious organ involvement, and effective therapeutic regimens.

Drug Therapy.

NSAIDs continue to be an important intervention, especially for patients with mild polyarthralgias or polyarthritis. Because prolonged therapy is likely, patients must be monitored carefully for GI and renal effects from NSAID use.

Antimalarial agents such as hydroxychloroquine (Plaquenil) and chloroquine are often used to treat fatigue and moderate skin and joint problems. Unlike the rapid response noted with corticosteroids, effects of antimalarial therapy may not be noticed for several months. Flares may also be prevented with these drugs. Funduscopic and visual field examinations must be performed by an ophthalmologist every 6 to 12 months when patients are on hydroxychloroquine. Retinopathy can develop with high-dosage use of these drugs, but it generally reverses when they are discontinued. If patients cannot tolerate an antimalarial agent, an antileprosy drug such as dapsone may be used.

The use of corticosteroids should be limited. However, tapering doses of IV methylprednisolone may be useful in controlling severe exacerbations of polyarthritis. Steroid-sparing immuno-suppressants such as methotrexate can serve as an alternative treatment and are prescribed in combination with folic acid to decrease the adverse effects of corticosteroids. However, high doses of corticosteroids may be especially appropriate for patients with very severe cutaneous SLE.

Immuno-suppressive drugs such as azathioprine (Imuran) and cyclophosphamide (Procytox) may be prescribed to reduce the need for long-term corticosteroid therapy. Close monitoring is necessary to minimize drug toxicity and other adverse effects. Azathioprine or cyclophosphamide is also appropriate for treatment of severe organ-system disease, especially LN. Close monitoring is necessary to minimize drug toxicity and adverse effects. Because blood clots can be a life-threatening complication of SLE, anticoagulants such as warfarin or heparin may be prescribed.

Clinical trials are currently investigating the effect of various medications on SLE management. These include biological and targeted therapy agents that interfere with the immune response, such as abatacept (Orencia). Thalidomide as a second-line therapy has been shown to improve cutaneous lupus even in people who have not responded to other therapies.

When teaching patients about their prescribed drugs, the nurse should include the indications for use, proper administration, and possible adverse effects. Patients should understand that abrupt cessation may exacerbate disease activity.

Disease management is most appropriately monitored by serial anti-DNA titres and serum complement levels (Table 67-14). Simpler and less costly tests such as ESR or CRP measurement may also help in monitoring treatment effectiveness.

TABLE 67-14

COLLABORATIVE CARE
Systemic Lupus Erythematosus

Diagnostic
• History and physical examination • Antibody titres (e.g., anti-DNA, anti-Sm, ANA) • Chest radiograph • Complete blood cell count • ECG to determine extra-articular involvement • LE cell prep • Radiographic examination of affected joints • Serum complement levels • Urinalysis
Collaborative Therapy
• Antimalarials (e.g., hydroxychloroquine [Plaquenil]) • Corticosteroids for exacerbations and severe disease • Immuno-suppressive drugs (e.g., cyclophosphamide [Procytox], mycophenolate [CellCept]) • NSAIDs for mild disease • Steroid-sparing drugs (e.g., methotrexate)

ANA, antinuclear antibody; *DNA,* Deoxyribonucleic acid; *ECG,* electrocardiogram; *LE,* lupus erythematosus; *NSAIDs,* nonsteroidal anti-inflammatory drugs; *Sm,* Smith.

Nursing Management Systemic Lupus Erythematosus

Nursing Assessment

Subjective and objective data that should be obtained from patients with SLE are presented in Table 67-15. In particular, the extent to which pain and fatigue influence ADLs must be evaluated.

TABLE 67-15

NURSING ASSESSMENT
Systemic Lupus Erythematosus

Subjective Data
Important Health Information
Past health history: Exposure to ultraviolet radiation, drugs, chemicals, viral infections; stress (physical or psychological); states of increased estrogen activity (including early onset of menarche; pregnancy and postpartum period); pattern of remissions and exacerbations *Medications:* Oral contraceptives, procainamide, hydralazine (Apresoline), isoniazid (INH), anticonvulsant drugs, antibiotics (possibly precipitating symptoms of SLE), corticosteroids, NSAIDs
Symptoms
• Weight loss; nausea and vomiting; xerostomia (salivary gland dryness); oral and nasal ulcers; dysphagia; diarrhea or constipation; decreased urine output. • Morning stiffness; joint swelling and deformity; polyarthralgia; painful, throbbing cold fingers with numbness and tingling; photosensitivity with rash; chest pain (pericardial, pleuritic); abdominal pain; shortness of breath, dyspnea • Visual disturbances: vertigo; headache; excessive fatigue, insomnia • Amennorrhea; irregular menstrual periods; frequent infections • Depression; withdrawal
Objective Data
General
Fever, lymphadenopathy, periorbital edema
Integumentary
Alopecia; dry, scaly scalp; kerato-conjunctivitis, malar "butterfly" rash, palmar or discoid erythema, urticaria, periungual erythema, purpura, or petechiae; leg ulcers
Respiratory
Pleural friction rub, decreased breath sounds
Cardiovascular
Vasculitis; pericardial friction rub; hypertension, edema, dysrhythmias, murmurs; bilateral, symmetrical pallor and cyanosis of fingers (Raynaud's phenomenon)
Gastro-Intestinal
Oral and pharyngeal ulcers; splenomegaly
Neurological
Facial weakness, peripheral neuropathies, papilledema, dysarthria, confusion, hallucination, disorientation, psychosis, seizures, aphasia, hemiparesis
Musculo-Skeletal
Myopathy, myositis, arthritis
Urinary
Proteinuria
Possible Findings
Presence of anti-DNA, anti-Sm, and antinuclear antibodies; anemia, leukopenia, thrombo-cytopenia; ↑ ESR; positive result of LE cell prep; ↑ serum creatinine; microscopic hematuria, cellular casts in urine; pericarditis or pleural effusion evident on chest radiograph

DNA, deoxyribonucleic acid; *ESR*, erythrocyte sedimentation rate; *LE*, lupus erythematosus; *NSAIDs*, nonsteroidal anti-inflammatory drugs; *SLE*, systemic lupus erythematosus; *Sm*, Smith.

Nursing Diagnoses

Nursing diagnoses for the patient with SLE may include, but are not limited to, the following:

- *Fatigue* related to *physical deconditioning* (chronic inflammation and altered immunity)
- *Impaired comfort* related to *insufficient situational control* (symptoms of illness, treatment adverse effects, variable and unpredictable disease progression)

Additional information on nursing diagnoses for patients with SLE is presented in NCP 67-2, available on the Evolve website.

Planning

The overall goals are that patients with SLE will (1) have satisfactory pain management, (2) adhere to the therapeutic regimen to achieve maximum symptom management, (3) demonstrate awareness of and avoid activities that cause disease exacerbation, and (4) maintain optimal role function and a positive self-image.

Nursing Implementation

Health Promotion.

Prevention of SLE is not possible at this time. However, education of health care providers and the community should promote a clear understanding of the disease and the need for early diagnosis and treatment.

Acute Intervention.

As in the majority of rheumatic diseases, the unpredictable nature of SLE presents many challenges to the patient and caregiver. The physical, psychological, and sociocultural problems associated with the long-term management of SLE require the varied approaches and skills of the multidisciplinary health care team.

During an exacerbation of SLE, a patient may become abruptly and dramatically ill. Nursing interventions include accurately recording the severity of symptoms and documenting the response to therapy. The nurse should assess fever pattern, joint inflammation, limitation of motion, location and degree of discomfort, and fatigue. The nurse should also monitor the patient's weight and fluid intake and output if corticosteroids are prescribed because of the fluid-retention effect of these drugs and the

possibility of acute kidney injury. Collection of 24-hour urine samples for protein and creatinine clearance may be ordered. The nurse should observe for signs of bleeding that result from drug therapy, such as pallor, skin bruising, petechiae, or tarry stools.

Careful assessment of neurological status includes observation for visual disturbances, headaches, personality changes, seizures, and forgetfulness. Psychosis may indicate CNS disease or may be an adverse effect of corticosteroid therapy. Irritation of the nerves of the extremities (peripheral neuropathy) may produce numbness, tingling sensation, and weakness of the hands and feet.

The nurse should also explain the nature of the disease, modes of therapy, and all diagnostic procedures. Emotional support for the patient and family is essential, especially during an exacerbation.

Ambulatory and Home Care.

Nursing interventions must emphasize the importance of patient cooperation for successful home management. The nurse should help patients understand that even strong adherence to the treatment plan is not a guarantee against exacerbation because the course of the disease is unpredictable. A variety of factors may increase disease activity, such as fatigue, sun exposure, emotional stress, infection, drugs, and surgery. Nursing interventions should be directed toward assisting patients and their families in eliminating or minimizing exposure to precipitating factors (Table 67-16).

TABLE 67-16

PATIENT & CAREGIVER TEACHING GUIDE
Systemic Lupus Erythematosus

The following instructions should be included in the teaching plan for a patient with systemic lupus erythematosus and the caregiver.

- Avoidance of drying soaps, powders, household chemicals
- Avoidance of exposure to individuals with infection
- Avoidance of physical and emotional stress
- Community resources and health care agencies
- Disease process
- Energy conservation and pacing techniques
- Marital and pregnancy counselling as needed
- Names of drugs, actions, adverse effects, dosage, administration
- Pain management strategies
- Regular medical and laboratory follow-up
- Therapeutic exercise, use of heat therapy (for arthralgia)
- Use of sunscreen protection (at least SPF 15), with minimal sun exposure between the hours of 1100 and 1500

SPF, sun protection factor.

Lupus and Pregnancy.

Because SLE is most common in women of child-bearing age, treatment during pregnancy must be considered. The woman's primary health care provider (or rheumatologist) and obstetrician should thoroughly discuss with the woman her desire to become pregnant. Infertility may have already resulted from renal involvement and the use of high-dose corticosteroid and chemotherapy drugs. Patients with SLE should understand that spontaneous abortion, stillbirth, and intrauterine growth retardation are common problems during pregnancy. They occur because of deposits of immune complexes in the placenta and because of inflammatory responses in the placental blood vessels.

The renal, cardiovascular, and pulmonary systems and the CNS may be especially affected during pregnancy. Women who already demonstrate serious SLE involvement in these systems should be counselled against pregnancy. For the best outcome, pregnancy should be planned at a time when the disease activity is minimal. Exacerbation is common during the postpartum period. Therapeutic abortion offers the same risk for postdelivery exacerbation as does carrying the fetus to term.

Psychosocial Issues.

Patients with SLE confront many psychosocial issues. Disease onset and symptoms may be vague, and SLE may remain undiagnosed for a long period. Supportive therapies may become as important as medical treatment in helping patients cope with the disease. The nurse should

inform patients and their families that the prognosis for the majority of people with SLE is good.

Families worry about hereditary aspects, and patients with SLE want to know whether their children will also have SLE. Many couples require pregnancy and sexual counselling. Individuals making decisions about marriage and careers worry about how SLE will interfere with their plans. The nurse may have to educate teachers, employers, and co-workers.

The obvious physical effects of skin rashes, discoid lesions, and alopecia may cause social isolation for a patient with SLE, affecting the individual's self-esteem and body image (Jolly, Pickard, Mikolaitis, et al., 2012). Consultation with a dermatologist may be recommended for appropriate treatment and cosmetic products to conceal the rash.

Pain and fatigue may interfere with quality of life. Pacing techniques and relaxation therapy can help the patient remain involved in day-to-day activities. The nurse should stress the importance of planning both recreational and occupational activities. Young adults may find physical limitations and restrictions of sun exposure particularly difficult to follow. Nursing interventions should assist patients in developing and accomplishing reasonable goals for improving or maintaining mobility, energy levels, and self-esteem.

Evaluation

Following are the expected outcomes for the patient with SLE:

- Use energy conservation techniques
- Adapt lifestyle to energy level
- Maintain skin integrity with the use of topical treatments
- Prevent exacerbations with the use of sunscreens and limited sun exposure

Additional information on expected outcomes for patients with SLE is presented in NCP 67-2 on the Evolve website.

Scleroderma

Scleroderma, or *systemic sclerosis,* is a disorder of connective tissue characterized by fibrotic, degenerative, and occasionally inflammatory

changes in skin, blood vessels, synovium, skeletal muscle, and internal organs.

Although symptoms may begin at any time, the usual age at onset is between 30 and 50 years. Scleroderma affects up to five times more women than men (Arthritis Society, 2017h).

Two types of disease exist: limited cutaneous scleroderma, which is the more common type (80%), and diffuse scleroderma. Both forms are systemic, with distinct degrees and types of organ involvement and disease progression. The prognosis for patients with limited disease is generally better than for those with diffuse disease.

Etiology and Pathophysiology

The exact cause of scleroderma is unknown. Immunological dysfunction and vascular abnormalities are believed to play a role in the development of widespread systemic disease. Other risk factors associated with skin thickening include environmental occupational exposure to coal, plastics, and silica dust.

In scleroderma, collagen—the protein that gives normal skin its strength and elasticity—is overproduced (Figure 67-11). Excessive production of collagen leads to progressive tissue fibrosis and occlusion of blood vessels. Proliferation of collagen disrupts the normal functioning of internal organs, such as the lungs, the kidneys, the heart, and the GI tract.

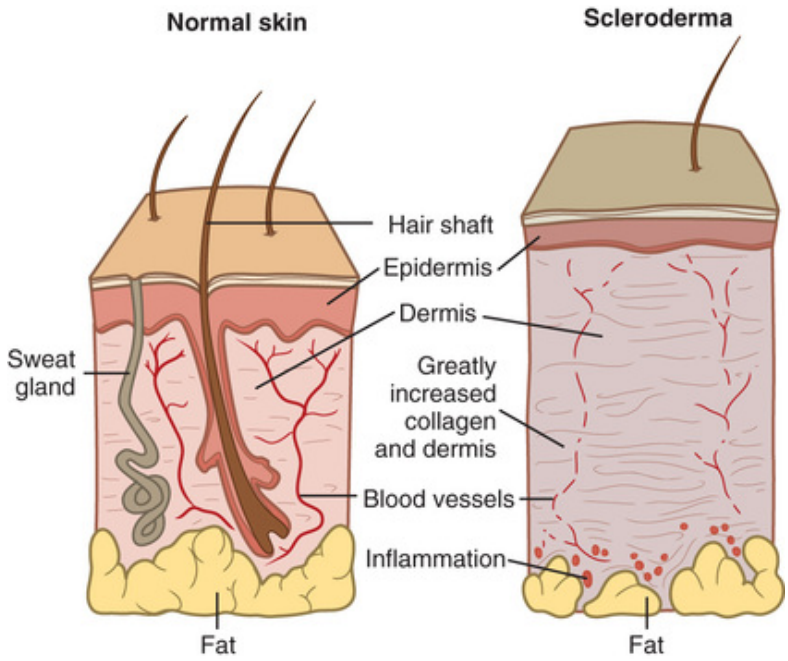

FIGURE 67-11 Skin changes in scleroderma.

The vascular alterations, which primarily involve the small arteries and arterioles, are almost always present in scleroderma. These changes are some of the earliest alterations in scleroderma.

Clinical Manifestations

Manifestations of scleroderma range from a diffuse cutaneous thickening with rapidly progressive and widespread organ involvement to the more benign limited cutaneous form. The signs of limited disease appear on the face and the hands, whereas diffuse disease initially involves the trunk and extremities. Clinical manifestations can be described by the acronym **CREST:**

Calcinosis: painful deposits of calcium in the skin
Raynaud's phenomenon: abnormal blood flow in response to cold or stress
Esophageal dysfunction: difficulty with swallowing, caused by internal scarring
Sclerodactyly: tightening of the skin on the fingers and toes
Telangiectasia: red spots on the hands, the forearms, the palms, the face, and the lips

Raynaud's Phenomenon.

Raynaud's phenomenon (an episodic vasospastic disorder of small cutaneous arteries, most frequently involving the fingers and toes) is the most common initial complaint in limited scleroderma. Blood flow to these extremities is diminished on exposure to cold (blanching or white phase), followed by cyanosis as hemoglobin releases oxygen to the tissues (blue phase) and then erythema during rewarming (red phase). The colour changes are often accompanied by numbness and tingling. Raynaud's phenomenon may precede the onset of systemic disease by months, years, or even decades. (Raynaud's phenomenon is described in more detail in Chapter 40.)

Skin and Joint Changes.

Symmetrical, painless swelling or thickening of the skin of the fingers and hands may progress to diffuse scleroderma of the trunk. In limited disease, skin thickening does not generally extend above the elbow or above the knee, although in some individuals the face is affected. In more diffuse disease, the skin loses elasticity and becomes taut and shiny, producing the typical expressionless facies with tightly pursed lips. Skin changes in the face may also contribute to reduction in ROM in the temporomandibular joint. The hands may be affected by *sclerodactyly*, in which the fingers are in a semiflexed position, with tightened skin up to the wrist. Reduced peripheral joint function may occur as an early symptom of polyarthritis.

Internal Organ Involvement.

About 20% of people with scleroderma develop secondary Sjögren syndrome, a condition associated with dry eyes and mouth. Dysphagia, gum disease, and dental caries can result. Frequent reflux of gastric acid can result from esophageal fibrosis. If swallowing becomes difficult, patients often decrease food intake and lose weight. Additional GI effects include constipation, which results from colonic hypomotility, and diarrhea, caused by malabsorption from bacterial overgrowth.

Lung involvement includes pleural thickening, pulmonary fibrosis, and pulmonary function abnormalities. Affected patients develop a cough and dyspnea. Pulmonary hypertension and interstitial lung disease can occur. Pulmonary hypertension is treated with medications such as extended-release nifedipine (Adalat), bosentan, and ambrisentan. (Pulmonary hypertension is discussed in Chapter 30.) Lung disease is the main cause of death in patients with scleroderma.

Primary heart disease consists of pericarditis, pericardial effusion, and cardiac dysrhythmias. Myocardial fibrosis that results in heart failure occurs most frequently in patients with diffuse disease.

Renal disease was previously a major cause of death in diffuse scleroderma. Because malignant hypertension in association with rapidly progressive and irreversible renal insufficiency may occur, early recognition of renal involvement and initiation of therapy are critical. Improvements in dialysis, bilateral nephrectomy in patients with uncontrollable hypertension, and kidney transplantation have offered some hope to patients with renal failure. In particular, use of angiotensin-converting enzyme (ACE) inhibitors (e.g., lisinopril [Prinivil]) has markedly improved the treatment of renal disease.

Diagnostic Studies

Laboratory findings in scleroderma are relatively normal. Blood studies may reveal a mildly elevated ESR and mild hemolytic anemia as a result of RBC damage from diseased small vessels. ANAs are found in most patients (Varga, 2011). The scleroderma antibody SCL-70 is found in about 30% of patients with diffuse disease, and serum RF is found in 30% of affected patients. An anticentromere antibody is seen in many patients with CREST. If renal involvement is present, urinalysis may reveal proteinuria, microscopic hematuria, and casts. Serum levels of creatinine may be elevated. Radiographic evidence of subcutaneous calcification, distal esophageal hypomotility, or bilateral pulmonary fibrosis is diagnostic of scleroderma. Pulmonary function studies reveal decreased vital capacity and lung compliance.

Collaborative Care

The collaborative care of scleroderma (Table 67-17) offers no specific long-term treatment. Supportive care is directed toward attempts to prevent or treat secondary complications of involved organs. Physiotherapy helps maintain joint mobility and preserve muscle strength. Occupational therapy assists patients in maintaining functional abilities.

TABLE 67-17

COLLABORATIVE CARE
Scleroderma

Diagnostic	Collaborative Therapy

• History and physical examination
• Anticentromere antibody titre
• Antinuclear antibody titre
• Electrocardiography
• Microscopic study of nail bed capillaries
• Pulmonary function test
• Radiographic studies of chest and hands
• Skin or visceral biopsy
• Urinalysis (proteinuria, hematuria, casts)
	• Physiotherapy and occupational therapy
	• Drug therapy
	  • Angiotensin-converting enzyme (ACE) inhibitors (lisinopril [Prinivil])
	  • Calcium channel blockers (diltiazem [Cardizem], nifedipine [Adalat])
	  • Immuno-suppressive drugs (e.g., cyclophosphamide [Procytox]; mycophenolate mofetil [CellCept])
	  • Vasoactive agents: bosentan (Tracleer); epoprostenol (Flolan)

Drug Therapy.

No specific drug or combination of drugs has been proven effective in the treatment of scleroderma. Vasoactive agents are often prescribed for early stages of the disease, and calcium channel blockers (nifedipine [Adalat] and diltiazem) are now a common treatment choice for Raynaud's phenomenon. Prazosin, an α-adrenergic blocking agent, increases blood flow to the fingers. Bosentan (Tracleer), an endothelin-receptor antagonist, and epoprostenol (Flolan), a vasodilator, may assist in preventing and treating digital ulcers while improving exercise capacity and heart and lung dynamics. Losartan (Cozaar), an angiotensin II blocker, may also be used to treat Raynaud's phenomenon.

Corticosteroids may have little effect on scleroderma. Topical agents may provide some relief from joint pain. Capsaicin cream may be useful, not only as a local analgesic, but also as a vasodilator. Other therapies are prescribed to address specific systemic problems, such as tetracycline for diarrhea caused by bacterial overgrowth, histamine H_2-receptor blockers (e.g., cimetidine) and proton pump inhibitors (e.g., omeprazole [Losec]) for esophageal symptoms, antihypertensive agents (e.g., captopril, propranolol [Inderal]), methyldopa for hypertension with renal involvement, and immuno-suppressive drugs (e.g., cyclophosphamide [Procytox]; mycophenolate mofetil [CellCept]).

Nursing Management Scleroderma

Prevention of scleroderma is not possible. Nursing intervention often begins during a hospitalization for diagnostic purposes. The nurse assesses vital signs, weight, intake and output, respiratory and bowel function, and joint ROM at regular intervals, as indicated by specific symptoms, to plan appropriate care. Emotional stress and cold ambient temperatures may aggravate Raynaud's phenomenon. Patients with scleroderma should not undergo finger-stick blood testing because of compromised circulation and poor healing of the fingers.

Health teaching is an important nursing intervention as patients and their families begin to live with this disease. Obvious changes in the face and the hands often lead to poor self-image and the loss of mobility and function. Patients must actively complete therapeutic exercises at home to prevent skin retraction and promote vascularization. Mouth excursion (opening the mouth widely, as in yawning) is a good exercise to help with temporo-mandibular joint function. Isometric exercises are most appropriate if the patient has arthropathy (disease of the joint) because no joint movement occurs. The nurse should encourage the use of moist heat applications or paraffin baths to promote skin flexibility in the hands and feet. Patients should use assistive devices as appropriate and organize activities to preserve strength and reduce disability.

Hands and feet should be protected from cold exposure and possible burns or cuts that might heal slowly. Smoking should be avoided because of its vasoconstricting effect. Signs of infection should be promptly reported. Lotions may help alleviate skin dryness and cracking, but they must be rubbed in for an unusually long time because of the thickness of the skin.

Dysphagia may be reduced by eating small, frequent meals, chewing carefully and slowly, and drinking fluids with food. Heartburn may be minimized with the use of antacids 45 to 60 minutes after each meal and by sitting upright for at least 2 hours after eating. Using additional pillows or raising the head of the bed on blocks may help reduce nocturnal gastro-esophageal reflux.

Job modifications are often necessary because stair climbing, using a computer, writing, and cold exposure may pose particular problems. Patients may become socially withdrawn as skin tightening alters the appearance of the face and the hands. Dining out may become a socially embarrassing event because of the patient's restricted opening of the

mouth, difficulty swallowing, and reflux. Some individuals with scleroderma wear gloves to protect fingertip ulcers and to provide extra warmth. Daily oral hygiene must be emphasized; neglect may lead to increased tooth and gingival problems. Patients need a dentist who is familiar with scleroderma and can deal with a small mouth opening.

Psychological support, biofeedback training, and relaxation techniques can reduce stress and improve sleeping habits. Sexual dysfunction resulting from body changes, pain, muscular weakness, limited mobility, decreased self-esteem, erectile dysfunction, and decreased vaginal secretions may necessitate sensitive counselling.

Polymyositis and Dermatomyositis

Polymyositis (PM) refers to diffuse, idiopathic, inflammatory myopathies of the connective tissues, especially striated muscle, that produce bilateral weakness, usually most severe in the proximal or limb-girdle muscles. When muscle changes associated with PM are accompanied by characteristic skin changes, the disorder is called **dermatomyositis** (DM) (Arthritis Society, 2017i).

Although these relatively rare disorders can be similar in signs, symptoms, and treatment, PM and DM are two distinct diseases. They are most common in children and adults over 50 years. (Arthritis Society, 2017i). Both diseases occur twice as often in women as in men. Patients with PM generally have more severe disease than those with DM.

Etiology and Pathophysiology

The exact cause of PM and DM is unknown. Theories include an infectious agent, neoplasms, drugs or vaccinations, and stress. Because T cytotoxic cells and macrophages have been found near the damaged muscle fibres of patients with PM, this disease is believed to be caused by cell-mediated injury. In contrast, DM has been associated with B cells (humoral immunity) and destruction of the muscle microvasculature. An autoimmune response to nuclear and cytoplasm self-antigens has also been noted in many people with these disorders (von Mühlen & Nakamura, 2011).

Clinical Manifestations and Complications

Muscular.

Patients with DM and PM experience weight loss and increasing fatigue, with gradually developing weakness of the muscles, that leads to difficulty in performing routine activities. The muscles most commonly affected are those of the shoulders, the legs, the arms, and the pelvic girdle. Patients may have difficulty rising from a chair or bathtub, climbing stairs, combing the hair, or reaching into a high cupboard. Neck muscles may become so weak that patients are unable to raise the head from the pillow. Muscle discomfort or tenderness is uncommon. Muscle examination reveals an inability to move against resistance or even gravity. Weakness of the pharyngeal muscles may result in dysphagia and dysphonia (nasal or hoarse voice).

Dermal.

Skin changes of DM include a classic violet-coloured, cyanotic, or erythematous symmetrical rash *(heliotrope rash)* with edema around the eyelids. Violet-coloured or erythematous papules (Gottron papules) and small plaques develop over the DIP or MCP areas and at elbow or knee joints in about 70% of patients with DM (Figure 67-12). Because of these early skin changes, DM is usually recognized earlier than PM, in which a rash does not appear. Reddened, smooth, or scaly patches appear with the same symmetrical distribution but sparing the interphalangeal spaces (Gottron sign); they can be confused with psoriasis or seborrheic dermatitis. An erythematous scaling rash (poikiloderma) may develop as a late finding on the back, buttocks, and a V-shaped area of the anterior neck and chest. Hyperemia and telangiectasias are often present at the nail beds. Calcium nodules (calcinosis cutis), which can develop throughout the skin, are especially common in long-standing DM.

FIGURE 67-12 Dermatomyositis skin changes. Gottron papules.
Source: Firestein, G. S., Budd, R. C., Gabriel, S. E. et al. (2012). *Kelley's textbook of rheumatology.* (9th ed.). Philadelphia: Saunders.

Other Manifestations.

Joint redness, pain, and inflammation often occur and contribute to limitations in joint ROM in DM and PM. Contractures and muscle atrophy may occur with advanced disease. Weakening of the pharyngeal muscles can lead to a poor cough effort, difficulty swallowing, and increased risk for aspiration pneumonia in both disorders. Interstitial lung disease occurs in up to 65% of all affected patients. People with DM also have an increased risk for cancer, which may be present at time of diagnosis. Both diseases may be associated with other connective tissue disorders (e.g., scleroderma).

Diagnostic Studies

Diagnosis of DM or PM is confirmed by MRI, electromyographic (EMG) findings, muscle biopsy, and serum enzyme levels. An EMG suggestive of PM shows bizarre, high-frequency dis-charges and spontaneous fibrillation, with positive spikes at rest. Muscle biopsy reveals necrosis, degeneration, regeneration, and fibrosis with pathological findings distinct for DM or PM. Markers such as creatinine kinase and myoglobin are elevated. Elevation of the ESR or CRP is also expected with active disease. In addition, more than 50% of people with PM have positive RF. The skin rash typical of DM is not commonly found with other disorders.

Nursing and Collaborative Management Polymyositis and Dermatomyositis

PM and DM are initially treated with high-dose corticosteroids. Improvement is generally achieved if corticosteroid therapy is promptly instituted, and the dosage can typically be reduced as improvement is noted. Long-term corticosteroid therapy may often be required because relapses are common when the drug is withdrawn. If corticosteroids are ineffective after 4 weeks of treatment or organ involvement is occurring (or both), immuno-suppressive drugs (methotrexate, azathioprine [Imuran], cyclophosphamide [Procytox]) may be administered.

DM has been shown to improve with high doses of IV immunoglobulin. Topical corticosteroids and hydroxychloroquine (Plaquenil) may also be prescribed to treat the skin rash.

The role of newer medications such as TNF inhibitors remains unclear, although their use in refractory cases has shown some success.

Physiotherapy can be helpful and should be tailored to the activity of the disease. Massage and passive movement are appropriate during active disease. More aggressive exercises should be reserved for periods when disease activity is minimal, as evidenced by low serum enzyme levels.

Nursing interventions should include a thorough explanation of the disease, the prescribed therapies, all diagnostic tests, and the importance of regular medical care. It is important for patients to understand that the benefits of therapy are often delayed. For example, weakness may increase during the first few weeks of corticosteroid therapy. Special attention is paid to patient safety. Use of assistive devices should be encouraged as a fall prevention strategy. To prevent aspiration, patients should be encouraged to rest before meals, maintain an upright position when eating, and choose a diet of easily swallowed foods.

The nurse should assist patients in organizing activities and using pacing techniques to conserve energy. The nurse should encourage the patient to perform daily ROM exercises to prevent contractures. When active inflammation is not evident, muscle-strengthening (repetitive) exercises may be started. Home care and bed rest may become necessary during the acute phase of PM because profound muscle weakness renders patients unable to carry out ADLs.

Mixed (Overlapping) Forms of Connective Tissue Disease

Patients with a combination of clinical features of several rheumatic diseases are described as having *mixed* or *overlapping connective tissue disease.* The term is used to describe a disorder with features of SLE, Sjögren syndrome, and PM. Approximately 80% of people with this disease are women.

Sjögren Syndrome

Sjögren syndrome is a relatively common autoimmune disease that targets moisture-producing exocrine glands, leading to the common symptoms of *xerostomia* (dry mouth) and *kerato-conjunctivitis sicca* (dry eyes) (Jonsson, Vogelsang, Volchenkov, et al., 2011). The nose, the throat, the airways, and the skin can also become dry. The disease can affect other glands as well, including those in the stomach, the pancreas, and the intestines (extraglandular involvement). The disease is usually diagnosed in people older than 40, and 90% of them are women.

In primary Sjögren syndrome, symptoms can be traced to problems with the lacrimal and the salivary glands. Patients with primary disease are likely to have antibodies against the cytoplasmic antigens SS-A (or Ro) and SS-B (or La), as well as ANA. Patients with secondary Sjögren syndrome typically had another autoimmune disease (e.g., RA, SLE) before Sjögren syndrome developed.

Sjögren syndrome appears to be caused by genetic and environmental factors. Several genes seem to be involved. The trigger may be a viral or bacterial infection that adversely stimulates the immune system. In Sjögren syndrome, lymphocytes attack and damage the lacrimal and salivary glands.

Dry eyes are characterized by decreased tearing, which leads to a "gritty" sensation in the eyes, burning sensation, blurred vision, and photosensitivity. Dry mouth leads to buccal membrane fissures, altered sense of taste, dysphagia, and increased frequency of mouth infections or dental caries. Dry skin and rashes, joint and muscle pain, and thyroid problems may also be present. Other exocrine glands can be affected. For example, vaginal dryness may lead to dyspareunia (painful intercourse).

Autoimmune thyroid disorders, including Graves' disease and Hashimoto thyroiditis, are common with Sjögren syndrome. Histological study reveals lymphocyte infiltration of salivary and lacrimal glands. The disease may become more generalized and involve the lymph nodes, the bone marrow, and the visceral organs (pseudolymphoma). Lymphoma

develops in about 5% of patients with Sjögren syndrome (Covelli, Lanciano, Tartaglia, et al., 2012).

Ophthalmological examination (Schirmer test for tear production), measures of salivary gland function, and lower lip biopsy of minor salivary glands aid in the diagnosis. The treatment for Sjögren syndrome is based on symptoms, including (a) instillation of preservative-free artificial tears as necessary to maintain adequate hydration and lubrication, (b) surgical punctal occlusion, and (c) increased fluids with meals. Dental hygiene is also important.

Pilocarpine (Salagen) can be used to treat symptoms of dry mouth. Increased humidity in the home may reduce respiratory infections. Vaginal lubrication with a water-soluble product may increase comfort during intercourse.

Soft-Tissue Rheumatic Syndromes

Myofascial Pain Syndrome

Myofascial pain syndrome is a chronic form of muscle pain. It is characterized by musculo-skeletal pain and tenderness, typically in the chest, neck, shoulders, hips, and lower back. Referred pain from these muscle groups can also travel to the head, causing severe headaches, as well as to the buttocks and hands.

Temporo-mandibular joint pain may also originate in myofascial pain. Regions of pain are often within the taut bands and fascia of skeletal muscles. When activated by pressure, trigger points are thought to activate a characteristic pattern of pain that can worsen with activity or stress.

Myofascial pain syndrome occurs most often in middle-aged adults and more often in women than in men. Affected patients describe the pain as deep and aching, accompanied by a sensation of burning, stinging, and stiffness. Examples of this syndrome include fibromyalgia, myalgia, and myositis (Belden, DeFriez, & Huether, 2012).

Physiotherapy is one treatment used for myofascial pain syndrome. A typical exercise is the "spray and stretch" method, in which the painful area is iced or sprayed with a coolant such as ethyl chloride and then stretched. Positive results have been achieved by injection of the trigger points with a local anaesthetic (e.g., 1% lidocaine). Massage, acupuncture, biofeedback, and ultrasound therapy have also been shown to benefit some patients.

Fibromyalgia

Fibromyalgia syndrome (FMS) is a chronic disorder characterized by widespread, nonarticular musculo-skeletal pain and fatigue with multiple tender points. People with fibromyalgia also typically experience nonrestorative sleep, morning stiffness, irritable bowel syndrome, and anxiety. Fibromyalgia is a commonly diagnosed musculo-skeletal disorder and a major cause of disability that affects approximately 2% of Canadians, with 80% to 90% being women (Arthritis Society, 2017j). Fibromyalgia and systemic exertion intolerance disease (SEID) share many commonalities (Table 67-18).

TABLE 67-18

COMMONALITIES BETWEEN FIBROMYALGIA AND SYSTEMIC EXERTION INTOLERANCE DISEASE

Commonality	Description
Clinical manifestations	Generalized musculo-skeletal pain, malaise and fatigue, cognitive dysfunction, headaches, sleep disturbances, depression, anxiety, fever.
Collaborative therapy	Treatment is symptomatic and may include antidepressant drugs such as amitriptyline (Elavil) and fluoxetine (Prozac). Other measures are heat, massage, regular stretching, biofeedback, stress management, and relaxation training. Patient and caregiver teaching is essential.
Course of disease	Variable intensity of symptoms; fluctuates over time.
Diagnosis	No definitive laboratory tests or joint and muscle examinations; mainly a diagnosis of exclusion.
Etiology (theories)	Infectious trigger, dysfunction in HPA axis, alteration in CNS.
Occurrence	Previously healthy, young, and middle-aged women.

HPA, hypothalamic-pituitary-adrenal; *CNS*, central nervous system.

Etiology and Pathophysiology

Research continues to focus on identifying the underlying causes and the pathophysiological mechanisms of fibromyalgia. There is general agreement that fibromyalgia is a disorder involving neuroendocrine or neurotransmitter dysregulation. The pain amplification experienced by the affected patient is caused by abnormal sensory processing in the CNS.

Multiple physiological abnormalities have been found. They include increased levels of substance P in the spinal fluid, low levels of blood flow to the thalamus, dysfunction of the hypothalamic-pituitary-adrenal (HPA) axis, low levels of serotonin and tryptophan, and abnormalities in cytokine function. Serotonin and substance P play a role in mood regulation, sleep, and pain perception. Changes in the HPA axis can also negatively affect a person's physical and mental health, leading to an increased incidence of depression and a decreased response to stress. Genetic factors also contribute to the etiology of fibromyalgia, as a familial tendency exists. A recent illness or trauma may serve as a trigger in susceptible people.

Clinical Manifestations and Complications

Patients with fibromyalgia experience a widespread burning pain that worsens and improves through the course of a day. It is often difficult for patients to discriminate whether pain occurs in the muscles, the joints, or soft tissues. Head or facial pain often results from stiff or painful neck and shoulder muscles. The pain can accompany temporo-mandibular joint

dysfunction, which affects an estimated one-third of patients with fibromyalgia.

Physical examination characteristically reveals point tenderness at 11 or more of 18 identified sites (Figure 67-13). Patients with fibromyalgia are sensitive to painful stimuli throughout the body and not merely at the identified tender sites. In addition, point tenderness can vary from day to day. On some occasions, the patient may respond to fewer than 11 tender points. At other times, palpation of all sites may elicit pain.

Cognitive effects range from difficulty concentrating to memory lapses and a feeling of being overwhelmed when dealing with multiple tasks. Many individuals report migraine headaches. Depression and anxiety often occur and may necessitate drug therapy. Stiffness, nonrefreshing sleep, fatigue, and numbness or tingling sensation in the hands or feet (paresthesia) often accompanies fibromyalgia. Restless legs syndrome is also typical, with patients describing an irresistible urge to move the legs when at rest or lying down.

Irritable bowel syndrome with manifestations of constipation, diarrhea, or both; abdominal pain; and bloating is common. Patients with fibromyalgia may also experience difficulty swallowing, perhaps because of abnormalities in esophageal smooth-muscle function. Increased frequency of urination and urinary urgency, in the absence of a bladder infection, are typical complaints. Women with fibromyalgia may experience more difficult menstruation, with a worsening of disease symptoms during this time.

Diagnostic Studies

A definitive diagnosis of fibromyalgia is often difficult to establish. Lack of knowledge among health care providers may also cause delays in diagnosis and treatment.

Laboratory results in most cases serve to rule out other disorders suspected on the basis of the patient's history and physical examination. On occasion, a low ANA titre is present, but it is not considered diagnostic. Muscle biopsy may reveal a nonspecific moth-eaten appearance or fibre atrophy. The American College of Rheumatology classifies an individual as having fibromyalgia if the following two criteria are met: (a) pain is experienced in 11 of the 18 tender points on palpation (see Figure 67-13) and (b) a history of widespread pain for at least 3 months is documented (Wolfe, Clauw, Fitzcharles, et al., 2010). *Widespread pain* is defined as occurring on both sides of the body and above and below

the waist. In addition, fatigue, cognitive symptoms, and extensive somatic symptoms are considered in establishing a diagnosis.

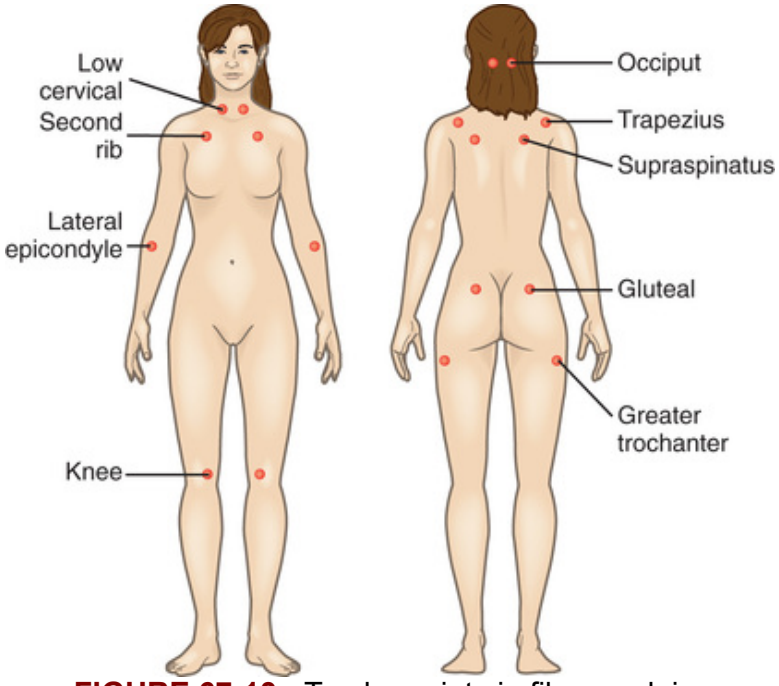

FIGURE 67-13 Tender points in fibromyalgia.

Collaborative Care

The treatment of fibromyalgia is symptomatic and requires a high level of patient motivation. The nurse can play a key role in teaching patients to be active participants in the therapeutic regimen. Rest can help pain, aching, and tenderness.

Drug treatment for the chronic widespread pain associated with fibromyalgia includes pregabalin (Lyrica) and duloxetine (Cymbalta). Low-dose tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), or benzodiazepines (e.g., diazepam [Valium]) may also be prescribed. If the tricyclic antidepressant amitriptyline (Elavil) is not well tolerated, similar drugs can be substituted (e.g., doxepin [Sinequan], imipramine, trazodone). SSRI antidepressants (e.g., sertraline [Zoloft], paroxetine [Paxil]) tend to be reserved for affected patients who also have depression. SSRIs may need to be prescribed at higher doses than when used to treat depression. Both antidepressants and muscle relaxants have

sedative effects that can help in improving nighttime rest for patients with fibromyalgia.

Long-acting opioids are generally not recommended unless fibromyalgia is refractory to other therapies. In some patients, pain may be managed with OTC analgesics such as acetaminophen (Tylenol), ibuprofen (Motrin, Advil), or naproxen (Aleve).

Nursing Management Fibromyalgia

Because of the chronic nature of fibromyalgia, patients need consistent support from the nurse and other members of the health care team. Massage is often combined with ultrasound therapy or the application of alternating heat and cold packs to soothe tense, sore muscles and increase blood circulation. Gentle stretching can be performed by a physiotherapist or practised by the patient at home to relieve muscle tension and spasm. Yoga and tai chi are often appropriate. Low-impact aerobic exercise, such as walking, can help prevent muscle atrophy.

Often, dietitians urge patients with fibromyalgia to limit their consumption of sugar, caffeine, and alcohol because these substances have been shown to be muscle irritants. Vitamin and mineral supplements may be appropriate to combat stress, correct deficiencies, and support the immune system. However, unproven "miracle diets" or supplements should be carefully investigated by patients and discussed with the health care provider before any of them is used. Patients should understand that some foods and supplements may cause serious and even dangerous adverse effects when taken along with certain drugs.

Pain and the related symptoms of fibromyalgia can cause significant stress. Patients with fibromyalgia may not deal effectively with stress. Effective relaxation strategies include biofeedback, mindfulness meditation, and cognitive behavioural therapy. Patients need to receive initial training for these interventions, but they can then continue to practise them on their own. Psychological counselling (individual or group) may also prove beneficial for patients. (Stress and stress management are discussed in Chapter 8.)

Systemic Exertion Intolerance Disease

Systemic exertion intolerance disease (SEID), also known as *chronic fatigue syndrome (CFS) or myalgic encephalomyelitis,* is a serious, complex, multisystem disease in which exertion of any sort (physical, emotional, cognitive) can adversely affect multiple organs in a person (Institute of Medicine, 2015). SEID is a poorly understood condition that can have a devastating effect on the lives of patients and their families. More women are affected than men. SEID occurs in all ethnic and socioeconomic groups. The true prevalence of SEID is unknown because many people with the disease have not been diagnosed.

Etiology and Pathophysiology

Despite efforts to determine the etiology and the pathology of SEID, the precise mechanisms remain unknown. However, there are many theories about the cause of SEID. Neuroendocrine abnormalities that have been implicated involve a hypofunction of the HPA axis and the hypothalamic-pituitary-gonadal (HPG) axis, which together regulate the stress response and reproductive hormone levels. Several microorganisms have been investigated as etiological agents, including herpes viruses (e.g., Epstein Barr virus [EBV], cytomegalovirus [CMV]), retroviruses, enteroviruses, *Candida albicans,* and mycoplasma. Because many patients with the disease have cognitive deficits (e.g., decreased memory, attention, concentration), changes in the CNS have been suggested as the cause of SEID.

Clinical Manifestations

Diagnosis of SEID requires that the patient have the following three symptoms:

1. Profound fatigue lasting at least 6 months
2. Postexertional malaise: total exhaustion after even minor physical or mental exertion that patients sometimes describe as a "crash"
3. Unrefreshing sleep

At least one of the following two manifestations is also required:

1. Cognitive impairment ("brain fog")
2. Worsening of symptoms upon standing (orthostatic intolerance)

SEID is often difficult to distinguish from fibromyalgia because many clinical features are similar (Table 67-18). In about half the cases, SEID develops insidiously, or patients may have intermittent episodes that gradually become chronic. Severe fatigue is the most common symptom of SEID and causes patients to seek health care.

In other situations, SEID arises suddenly in a previously active, healthy individual. An unremarkable influenza-like illness or other acute stress is often identified as a triggering event. Associated symptoms may fluctuate in intensity over time.

Patients may become angry and frustrated with the inability of health care providers to diagnose a problem. The disorder may have a major

effect on work and family responsibilities. Some patients may need help with ADLs.

Diagnostic Studies

Physical examination and diagnostic studies can be used to rule out other possible causes of a patient's symptoms. No laboratory test can diagnose SEID or measure its severity. SEID generally remains a diagnosis of exclusion.

Nursing and Collaborative Management SEID

Because there is no definitive treatment for SEID, supportive management is essential. Patients should be informed about what is known about the disease, and all complaints should be taken seriously.

NSAIDs can be used to treat headaches, muscle and joint aches, and fever. Because many patients with SEID also have allergies and sinusitis, antihistamines and decongestants can be used to treat allergic symptoms. Tricyclic antidepressants (e.g., doxepin [Sinequan], amitriptyline [Elavil]) and SSRIs (e.g., fluoxetine [Prozac], paroxetine [Paxil]) can improve mood and sleep problems. Clonazepam (Rivotril) can also be used to treat sleep disturbances and panic disorders. The use of low-dose hydrocortisone to decrease fatigue and disability is being studied.

Total rest is not advised because it can potentiate the self-image of being an invalid. On the other hand, strenuous exertion can exacerbate the exhaustion. Therefore, it is important to plan a carefully graduated exercise program. A well-balanced diet that includes fibre and fresh, dark-coloured fruits and vegetables for antioxidant action is essential in treatment. Behavioural therapy may be used to promote a positive outlook, as well as improve overall disability, fatigue, and other symptoms.

One of the major problems facing many patients with SEID is loss of livelihood and economic security. When the illness strikes, they cannot work or must decrease the amount of time working. Obtaining disability benefits can be frustrating because of the difficulty in establishing a diagnosis of SEID. Patients with SEID may experience substantial occupational and psychosocial impairments and loss, including the social pressure and isolation from being characterized as lazy or having a mental illness.

SEID does not appear to progress. Although most patients recover or experience at least gradual improvement over time, some do not show substantial improvement. Recovery is more common in individuals with a sudden onset of SEID.

Case Study

Rheumatoid Arthritis

Source: Blend Images/Shutterstock.com.

Patient Profile

Grace Kim, a 42-year-old married woman, is seen at the rheumatology clinic because she is experiencing swelling and stiffness in the small joints of her hands.

Subjective Data

- Is a concert pianist
- Experiencing joint pain and stiffness in both hands for the past 6 weeks
- Experiencing fatigue, anorexia, and morning stiffness
- Gave birth to her first child 2 months ago

Objective Data

Physical Examination

- Swelling and tenderness of third and fourth MCP joints of both hands
- Mild pain with neck motion

Diagnostic Studies

- Elevated ESR, positive RF and ACPA
- Evidence of moderate bone demineralization on bilateral hand radiographs

Collaborative Care

- Diagnosis: RA
- Therapy: started on methotrexate, 7.5 mg PO once per week; etanercept (Enbrel), 50 mg subcutaneously once per week; and prednisone, 10 mg daily

Discussion Questions

1. How might the nurse explain the pathophysiology of RA to Ms. Kim?
2. How might the recent childbirth have influenced the symptoms that she is currently experiencing?
3. What are some home and work modifications that the nurse can suggest to Ms. Kim that will reduce her symptoms?
4. What suggestions can the nurse make to Ms. Kim about coping with fatigue?
5. ***Priority decision:*** On the basis of the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
6. ***Evidence-informed practice:*** Why is an exercise program important in the treatment plan for Ms. Kim?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Which of the following would the nurse understand as causing damage to the joints of a client with rheumatoid arthritis?
   a. The development of Heberden nodes in the joint capsule
   b. The deterioration of cartilage by the enzyme hyaluronidase
   c. Invasion of pannus into the joint capsule and subchondral bone
   d. Bony ankylosis after inflammation of the joints in HLA-B27–positive individuals
2. A client with rheumatoid arthritis is experiencing articular involvement of the joints. The nurse recognizes that these characteristic changes include which of the following? *(Select all that apply)*
   a. Bamboo-shaped fingers
   b. Metatarsal head dislocation in feet
   c. Noninflammatory pain in large joints
   d. Asymmetric involvement of small joints
   e. Morning stiffness lasting 60 minutes or more
3. Which of the following would the nurse teach to a client with ankylosing spondylitis?
   a. Avoid extremes in environmental temperatures.
   b. Continue with physical activity during flare-ups.
   c. Apply cool compresses for relief of local symptoms.
   d. Maintain proper posture and engage in regular exercise.
4. When the nurse administers medications to clients with gout, which of the following would the nurse recognize as a treatment for acute disease?
   a. Colchicine
   b. Sulphasalazine
   c. Allopurinol
   d. Cyclosporin
5. The nurse is teaching a client with SLE about the disorder. The nurse understands that the pathophysiology of SLE includes which of the

following?

a. Circulating immune complexes formed from IgG autoantibodies reacting with IgG

b. An autoimmune T-cell reaction that results in destruction of the deep dermal skin layer

c. Immunological dysfunction leading to chronic inflammation in the cartilage and bones

d. The production of a variety of autoantibodies directed against constituents of the cell nucleus

6. The nurse is caring for a client with Sjögren syndrome. Which of the following autoimmune disorders may the client also develop?

a. Uveitis

b. Ulcerative colitis

c. Glomerulo-nephritis

d. Hashimoto thyroiditis

7. Which of the following should be considered in the management of systemic exertion intolerance disease (SEID)? *(Select all that apply)*

a. Dark green vegetables in diet

b. DMARDs to reduce symptoms

c. Total rest during acute exacerbations

d. SSRIs or tricyclic antidepressants

e. Behavioural therapy

1. c; 2. b, e; 3. d; 4. a; 5. d; 6. d; 7. a, d, e.

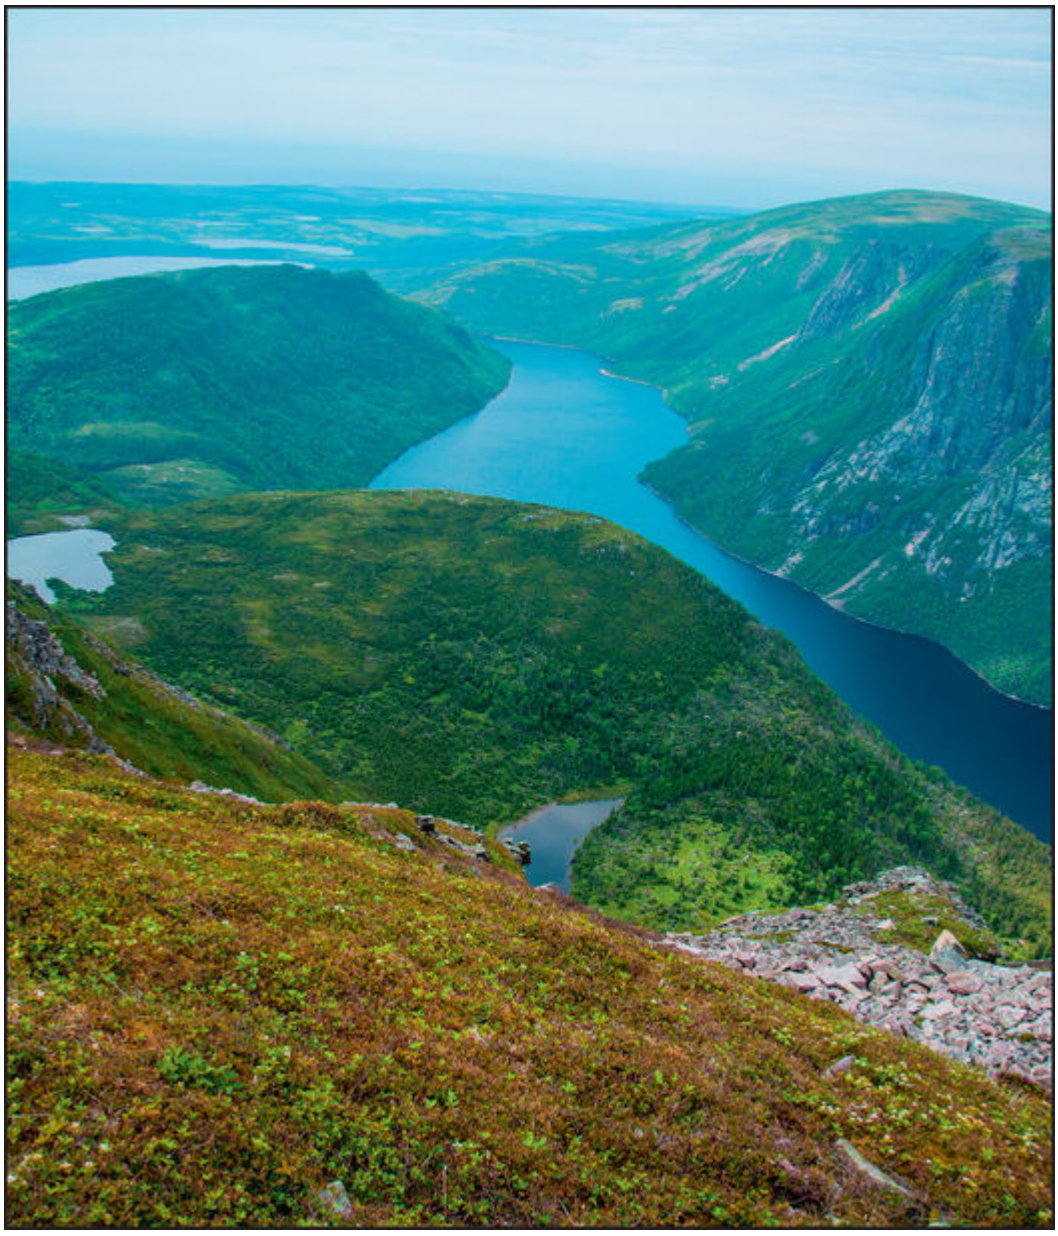
SECTION 12

Nursing Care in Specialized Settings

OUTLINE

Introduction



Source: RuthChoi/Shutterstock.com.

CHAPTER 68

Nursing Management

Critical Care Environment

Written by, Maureen A. Seckel, Linda Bucher

Adapted by, Sandra Goldsworthy

LEARNING OBJECTIVES

1. Describe the critical care certification process available to critical care nurses in Canada as well as advanced-practice roles such as the clinical nurse specialist and the acute care nurse practitioner.
2. Select appropriate nursing interventions to manage common problems and needs of critically ill patients.
3. Develop effective strategies to manage issues related to the families and caregivers of critically ill patients.
4. Apply the principles of hemodynamic monitoring and the collaborative care and nursing management of the patient receiving this intervention.
5. Differentiate the purpose of, indications for, and function of circulatory assist devices and related collaborative care and nursing management.
6. Differentiate the indications for and contrast the modes of mechanical ventilation.
7. Select appropriate nursing interventions related to the care of an intubated patient.
8. Relate the principles of mechanical ventilation to the collaborative care and nursing management of patients receiving this intervention.

KEY TERMS

arterial pressure–based cardiac output (APCO), p. 1735
assist-control ventilation (ACV), p. 1748
circulatory assist devices (CADs), p. 1739
continuous positive airway pressure (CPAP), p. 1750

endotracheal (ET) intubation, p. 1742
hemodynamic monitoring, p. 1731
high-frequency oscillatory ventilation (HFOV), p. 1750
intra-aortic balloon pump, p. 1739
mechanical ventilation, p. 1747
negative-pressure ventilation, p. 1747
phlebostatic axis, p. 1733
positive end-expiratory pressure (PEEP), p. 1749
positive-pressure ventilation (PPV), p. 1747
pressure-support ventilation (PSV), p. 1749
ventricular assist device (VAD), p. 1741
volume ventilation, p. 1747
weaning, p. 1753

Critical Care Nursing

Critical Care Units

According to the Canadian Association of Critical Care Nurses (CACCN, 2017), critical care nursing is "a specialty which exists to care for patients who are experiencing life-threatening health crises within a patient-/family-centred model of care." Critical care nurses care for patients with acute and unstable physiological problems, as well as their caregivers. Their role involves assessing life-threatening conditions, initiating appropriate interventions, and evaluating the outcomes of the interventions.

Critical care units, also called *intensive care units (ICUs)*, are designed to meet the special needs of critically ill patients. In many acute care settings, the concept of critical care has expanded from delivering care in a standard unit to bringing critical care to patients wherever they might be. The electronic or virtual ICU is designed to augment the bedside critical care team by monitoring the patient from a remote location (Figure 68-1). Similarly, a rapid response team provides advanced care by specialized health care providers, usually including a critical care nurse, a respiratory therapist, and a critical care physician. The team ensures immediate care to unstable patients in noncritical units. Patients often exhibit subtle early signs of deterioration (e.g., mild confusion) 6 to 8 hours before cardiac or respiratory arrest, and early critical care intervention has made significant contributions to reducing mortality rates in these patients (Maharaj, Raffaele, & Wendon, 2015).

FIGURE 68-1 Electronic intensive care unit control room. Source: Frownfelter, D., & Dean, E. (2012). *Cardiovascular and pulmonary physical therapy: Evidence and practice* (5th ed., p. 562, Figure 34-2). St. Louis: Mosby Elsevier.

The technology available in the ICU is extensive and always evolving. It is possible to continuously monitor the electrocardiogram (ECG), blood pressure (BP), oxygen (O_2) saturation, cardiac output (CO), intracranial pressure, and temperature. More advanced monitoring devices measure cardiac index (CI), stroke volume (SV), stroke volume variation (SVV), ejection fraction, end-tidal carbon dioxide (CO_2), and tissue O_2 consumption. Patients may receive ongoing support from mechanical ventilators, intra-aortic balloon pumps (IABPs), circulatory assist devices (CADs), or dialysis machines. Figure 68-2 shows a typical ICU.

FIGURE 68-2 Typical critical care unit. Source: Amélie Benoist/Science Source.

Progressive-care units (PCUs), also called *intermediate-care units* or *step-down units,* provide a transition between the ICU and the general care unit or discharge (Prin & Wunsch, 2014). Generally, PCU patients are at risk for serious complications, but their risk is lower than that of ICU patients. Examples of patients found in PCUs include those scheduled for interventional cardiac procedures (e.g., stent placement), awaiting heart transplant, receiving stable doses of vasoactive intravenous (IV) drugs, or being weaned from prolonged mechanical ventilation. Monitoring capabilities in these units include continuous ECG, arterial BP, O_2 saturation, and end-tidal CO_2. PCUs provide critical care nursing for an at-risk population in a more cost-effective environment.

Critical Care Nurse

A critical care nurse has in-depth knowledge of anatomy, physiology, pathophysiology, pharmacology, and advanced assessment skills as well as the ability to use advanced technology. Critical care nurses perform frequent assessments to monitor trends (patterns) in the patient's physiological parameters (e.g., BP, ECG). This level of observation allows the nurse to rapidly recognize and manage complications while fostering healing and recovery. The nurse also provides psychological support to the patient and caregiver(s). To be effective, the critical care nurse must be able to communicate and collaborate with all members of the multidisciplinary health care team (e.g., physician, dietitian, social worker, respiratory therapist, and occupational therapist).

Critical care nurses face ethical dilemmas related to the care of patients. Moral distress over perceived issues of delivering futile or nonbeneficial care can lead to emotional exhaustion or burnout. Consequently, it is important that all members of the health care team coexist in a healthy work environment.

Specialization in critical care nursing usually initially requires comprehensive theoretical preparation and a preceptored orientation or internship. New innovations for preparing nurses to practise in critical care settings include educational opportunities to participate in cases that mimic the critical care environment in the human simulation laboratory (Alberta Health Services, 2016).

The Canadian Nurses Association offers critical care certification (CNCC[C]) in critical care nursing. The designation requires that a registered nurse have practice experience in critical care nursing and successfully complete a comprehensive written examination set to national standards. Continued critical care practice and retesting or continuing education is required for recertification at 5-year intervals. CNCC(C) certification validates knowledge of critical care nursing. In Canada, registered nurses may also choose to complete a critical care certificate through classroom or online education, typically combined with preceptored clinical experience.

Advanced-practice critical care nurses have a graduate degree (master's or doctorate). These nurses are employed in a variety of roles: patient and staff educators, consultants, administrators, researchers, or expert practitioners. The advanced-practice critical care nurse who is a clinical nurse specialist typically functions in one or more of these roles. Typically, a clinical nurse specialist has graduate preparation as well as expertise in critical care. Another advanced-practice role is the acute care nurse practitioner (ACNP). ACNPs provide comprehensive care to select critically ill patients and their families. They conduct comprehensive assessments, order and interpret diagnostic tests, manage health problems and disease-related symptoms, prescribe treatments, and coordinate care during transitions in settings. ACNPs may practise independently (e.g., providing comprehensive care to the chronically critically ill) or collaboratively (e.g., providing symptom management in conjunction with physicians). In Canada, ACNPs are prepared at the graduate level.

Critical Care Patient

A patient is generally admitted to the ICU for one of three reasons. First, the patient may be physiologically unstable, requiring advanced and sophisticated clinical judgements by a nurse or physician. Second, the patient may be at risk for serious complications and require frequent and often invasive interventions. Third, the patient may require intensive and complicated nursing support related to the use of IV polypharmacy (e.g., neuro-muscular blockade, thrombolytics, drugs requiring titration) and advanced technology (e.g., mechanical ventilation, intracranial pressure monitoring, continuous renal replacement therapy, hemodynamic monitoring).

ICU patients can be clustered by disease condition (e.g., neurology, pulmonary) or age group (e.g., neonatal, pediatrics). ICU patients are sometimes clustered by acuity (e.g., acute and unstable as opposed to technology-dependent but stable). Patients commonly treated in the ICU include those with respiratory distress, myocardial ischemia or infarction, or acute neurological impairment or those receiving care after cardiac surgery or major organ transplantation. The care of critically injured patients is provided in trauma and burn ICUs. Patients with medical emergencies (e.g., septic shock, drug overdoses, or diabetic ketoacidosis) are often treated in a medical ICU. Patients who are not expected to recover from an illness are usually not admitted to an ICU. For example, the ICU is not used to manage a patient in a persistent coma or to prolong the natural process of death.

Common Problems of Critical Care Patients.

Patients admitted to the ICU are at risk for numerous complications and special problems. Critically ill patients are usually immobile and at risk for venous thromboembolism and skin problems (see Chapter 26). The use of multiple invasive devices predisposes patients to health care–associated infections (HAIs). Sepsis and multiple-organ dysfunction syndrome may follow (see Chapter 69).

Nutrition.

Patients are often admitted to ICUs with conditions that result in either hypermetabolic states (e.g., burns, trauma, sepsis) or catabolic states (e.g., acute kidney injury). Other times, patients may be admitted in severely malnourished states (e.g., chronic heart, pulmonary, or liver disease). In general, malnutrition has been linked to increases in mortality and morbidity.

Whom to feed, what to feed, when to feed, and how to feed (e.g., route of administration) are crucial questions that the nurse must ask when caring for a critically ill patient. The nurse must collaborate with the physician and the dietitian to determine how best to meet the nutritional needs of ICU patients.

The primary goal of nutritional support is to prevent or correct nutritional deficiencies. This is usually accomplished by the early provision of enteral nutrition (i.e., delivery of calories via the gastro-intestinal [GI] tract) or parenteral nutrition (i.e., delivery of calories intravenously). Enteral nutrition preserves the structure and function of the gut mucosa and prevents the movement of gut bacteria across the intestinal wall and into the bloodstream. In addition, early enteral nutrition is associated with fewer complications and shorter hospital stays and is less expensive than parenteral nutrition (McClave, Taylor, Martindale, et al., 2016). (Enteral and parenteral nutrition are discussed in Chapter 42.)

Parenteral nutrition is used when the enteral route cannot provide adequate nutrition or is contraindicated. Examples of these conditions include paralytic ileus, diffuse peritonitis, intestinal obstruction, pancreatitis, GI ischemia, intractable vomiting, and severe diarrhea.

Anxiety.

Anxiety is a common problem for ICU patients. The primary sources of anxiety include the perceived or anticipated threat to physical health, actual loss of control of body functions, and placement in a foreign environment. Many patients and caregivers feel uncomfortable in the ICU environment with its complex equipment, high noise and light levels, isolation from family, and intense pace of activity. Pain and sleeplessness enhance anxiety, as do immobilization, loss of control, and impaired communication.

To help reduce anxiety, the nurse should encourage patients and caregivers to express concerns, ask questions, and state their needs. Patients and caregivers should be included in all conversations and have the purpose of equipment and procedures explained to them. The nurse should structure the patient's environment in such a way as to decrease anxiety if possible and encourage caregivers to bring in photographs and personal items. Appropriate use of antianxiety drugs (e.g.,

lorazepam [Ativan]) and relaxation techniques (e.g., music therapy) may reduce the stress response that can be triggered by anxiety (Chlan, Weinert, Heiderscheit, et al., 2013).

Pain.

The control of pain in an ICU patient is paramount. Pain management is a significant issue among critically ill patients and with poor assessment can result in serious physical and psychological consequences (Georgiou, Hadjibalassi, Lambrinou, et al., 2015). Inadequate pain control is often linked to agitation and anxiety and is known to contribute to the stress response. Critically ill patients at high risk for pain include patients who (a) have medical conditions that include ischemic, infectious, or inflammatory processes; (b) are immobilized; (c) have invasive monitoring devices, including endotracheal (ET) tubes; and (d) are scheduled for any invasive or noninvasive procedures.

For some critically ill patients, continuous IV sedation (e.g., propofol [Diprivan]) and an analgesic agent (e.g., fentanyl) are a practical and effective strategy for sedation and pain control. However, patients receiving deep sedation are unresponsive, which prevents the nurse and other health care providers from properly assessing the patient's neurological status. To address this limitation, guidelines that include a daily, scheduled interruption of sedation, or "drug holiday," have been developed. Daily sedative interruption allows the patient to awaken and the health care provider to conduct a neurological examination and assess readiness for weaning from the mechanical ventilator (Safer Health Care Now, 2012). (Chapter 10 has more detailed information on pain management.) The most current guidelines for pain, agitation, and delirium in the ICU include an analgesia-first approach, with lighter sedation so that patients can report their pain scale (Barr, Fraser, Puntillo, et al., 2013).

Informatics in Practice

Smart Infusion Pumps

Smart infusion pumps, with preprogrammed drug libraries and wireless technology, calculate medication dose and delivery rates to help prevent IV medication errors and reduce the risk for patient harm.

Smart pumps provide information used in ensuring safe practices, such as how many infusions were programmed using the drug library, how many times pumps were manually overridden, and how often an alert resulted in reprogramming an infusion.

Remember, if a nurse enters incorrect data, there will be incorrect results. Some drugs (e.g., heparin) require that a second nurse confirm the pump settings. Nurses must use their best judgement when using smart infusion pumps or any other technology and follow employer policy.

Impaired Communication.

Inability to communicate is a distressing problem for patients who are unable to speak because of the use of sedative or paralyzing drugs or an ET tube. As part of any procedure, the nurse should explain what will happen or is happening to the patient. When the patient cannot speak, the nurse should explore alternative methods of communication, including the use of devices such as picture boards, notepads, magic slates, tablets, cellphones (instant messaging applications), or computer keyboards. When speaking with the patient, the nurse should look directly at the patient and use hand gestures when appropriate. For patients who do not speak English, an approved interpreter must be used (see Chapter 2, Tables 2-5 and 2-6).

Nonverbal communication is also important. A large amount of procedure-related touch and much less comfort-related touch often characterize the ICU environment. Patients have different levels of tolerance for being touched, usually related to cultural background and personal history. It may be appropriate to provide comforting touch with ongoing evaluation of the patient's response. If appropriate, the nurse can encourage caregivers to touch and talk with the patient even if the patient is unresponsive or comatose.

Sensory-Perceptual Problems.

Acute and reversible sensory-perceptual changes are common in ICU patients. The combination of alterations in mentation (e.g., delusions, short attention span, loss of recent memory), psychomotor behaviour (e.g., restlessness, lethargy), and sleep–wake cycle (e.g., daytime sleepiness, nighttime agitation) has been inappropriately labelled *ICU psychosis.* The patient experiencing these alterations is not psychotic but is suffering from delirium. Delirium has been found to be common in mechanically ventilated patients in the ICU and can lead to increased length of hospital stay and increased length of mechanical ventilation (Mehta, Cook, Devlin, et al., 2015).

Demographic factors predisposing the patient to delirium include advanced age, pre-existing cognitive impairment (e.g., dementia), vision or hearing impairments, and a history of drug or alcohol use. Environmental factors that can contribute to delirium include sleep deprivation, anxiety, sensory overload, and immobilization. Physical conditions such as hemodynamic instability, hypoxemia, hypercarbia, electrolyte disturbances, and severe infections can precipitate delirium. As well, certain drugs (e.g., sedatives [benzodiazepines], furosemide [Lasix], antimicrobials [aminoglycosides]) have been associated with the development of delirium (Barr, Fraser, Puntillo, et al., 2013). (Delirium is discussed in Chapter 62.)

The nurse should monitor the patient for delirium and mental clarity. Tools to assess for delirium include the Confusion Assessment Method (CAM) for the ICU and the Intensive Care Delirium Screening Checklist (ICDSC) (see the Resources at the end of the chapter). It is critical that physiological factors be addressed (e.g., correction of oxygenation, perfusion, and electrolyte problems). The use of clocks and calendars can help orient the patient. In addition, the presence of a caregiver may help orient the patient and reduce agitation.

Sensory overload can also result in patient distress and anxiety. Environmental noise levels are particularly high in the ICU. One study in the United Kingdom found that sounds in the five ICUs studied peaked above 85 dBA and that all sites consistently had noise levels greater than the limit of 35 dB recommended by the World Health Organization (WHO; Darbyshire & Young, 2013). The nurse can limit noise and assist the patient in understanding noises that cannot be prevented. Conversation is a particularly stressful noise, especially when the discussion concerns the patient and is held in the presence of, but without participation from, the patient. The nurse can eliminate this source of stress by finding suitable places for patient-related discussions and, when possible, including the patient in the discussion.

The nurse can also limit noise levels directly by muting phones, setting alarms appropriate to the patient's condition, and eliminating unnecessary alarms. For example, the nurse can silence the BP alarms when manipulating invasive lines and then reactivate the alarms when done. Similarly, the nurse can silence ventilator alarms during ET suctioning. Finally, the nurse can limit overhead paging and all unnecessary noise in patient care areas.

Sleep Problems.

Nearly all ICU patients experience sleep disturbances. Patients may have difficulty falling asleep or have disrupted sleep because of noise, anxiety, pain, frequent monitoring, or treatment procedures. Sleep disturbance is a significant stressor in the ICU, contributing to delirium and possibly affecting recovery (Delaney, Van Haren, & Lopez, 2015). The nurse can structure the environment to promote the patient's sleep–wake cycle. Strategies for achieving this include clustering activities, scheduling rest periods, dimming lights at nighttime, opening curtains during the daytime, obtaining physiological measurements without disturbing the patient, limiting noise, and providing comfort measures (e.g., back rubs). If necessary, pharmacological therapy may be needed to induce and maintain sleep. (Sleep and sleep disorders are discussed in Chapter 9.)

Issues Related to Caregivers.

When a person becomes critically ill, care extends beyond the patient to the patient's caregivers because they are intimately involved. Caregivers play a valuable role in the patient's recovery and are members of the health care team. They contribute to the patient's well-being by:

- Providing a link to the patient's personal life (e.g., news of family, job)
- Advising the patient in health care decisions or functioning as the decision maker when the patient cannot
- Helping with activities of daily living (e.g., bathing, oral suctioning)

- Providing positive, loving, and caring support

To be effective in caring for their loved one, caregivers need the nurse's guidance and support. The experience of having a friend or family member as a patient in the ICU is physically and emotionally difficult, often to the point of exhaustion. Anxiety regarding the patient's condition and prognosis and concerns regarding the patient's pain and other discomforts are some of the issues caregivers confront. In addition, it is common for caregivers to experience anxiety regarding the financial issues related to the provision of care during a critical illness. Consulting with the case manager or social worker is helpful in these instances.

Caregivers typically experience disruption of their daily routines to support the patient. They may be far from their own home and supportive friends and family members. Ultimately, caregivers of the critically ill are considered to be in crisis, and family-centred care is essential. To provide family-centred care effectively, the nurse must be skilled in crisis intervention. The nurse should conduct a family assessment and intervene as necessary. Interventions can include active listening, reduction of anxiety, and support of those who become upset or angry (Davidson, 2016).

The nurse should acknowledge the caregivers' feelings and accept and support their decisions. The nurse should consult other health care team members (e.g., chaplains, psychologists, patient representatives) as necessary to assist caregivers to adjust. The extent to which family-centred care is provided can affect the patient's clinical course in the ICU. The nurse can identify a spokesperson for the family so that information between the health care team and the family is coordinated.

The caregiver needs reassurance regarding the way in which the patient's care is managed and decisions are made. To this end, the nurse can invite the caregiver to meet the health care team members and also evaluate the appropriateness of including caregivers in multidisciplinary rounds and patient care conferences. The nurse should provide the caregiver with the opportunity to participate in decision making. When patients are incapable of making their own health care decisions, they may have designated a durable power of attorney for health care, and this person also should be involved in the patient's plan of care. If the patient has an advance directive or a living will, the caregiver will need to see that the patient's wishes are followed.

Caregivers are better able to accept and cope with problems if they observe that the health care team is hopeful, caring, and competent; decisions are deliberate; and their input is valued. Caregivers of critically ill patients need the convenience of access to the patient. Limiting visitation does not protect the patient from adverse physiological consequences (Davidson, 2016). In addition, flexible visiting hours for family align with a family-centred approach. The first time that caregivers visit, it is important for the nurse to prepare them for the experience by briefly describing the patient's appearance and the physical environment (e.g., equipment, noise). The nurse should accompany the caregivers as they enter the room and observe the responses of both the patient and the caregivers and invite the caregivers to participate in the patient's care if they desire. In some ICUs, visitation includes animal-assisted therapy or pet visitation. The positive benefits of these interventions

(e.g., decreases in BP and anxiety) far outweigh the risks (e.g., transmission of infection from animal to patient), and they should be a part of the visitation policy.

In addition to traditional visiting, research has shown that caregivers of patients undergoing invasive procedures (e.g., central line insertion) and cardiopulmonary resuscitation want the option of being present at the bedside during these events. Even when the outcomes were not favourable, being present helped caregivers remove doubts about the patient's condition, decreased their anxiety and fear, facilitated the need to be together and to support their loved one, and facilitated the grief process when death occurred. The Canadian Critical Care Society encourages ICUs to develop policies and procedures that provide for the option of family presence during invasive procedures and cardiopulmonary resuscitation (Oczkowski, Mazzetti, Cupido, et al., 2015).

Culturally Competent Care

Critical Care Patients

Providing culturally competent care to critically ill patients and families is challenging. Often, the nurse is focused on meeting the physiological needs of the patient and may not appreciate the influence of the patient's culture on the illness experience. However, the cultural dimensions of the meaning of sickness and health, pain, dying and death, and grief need to be considered when caring for critically ill patients and their families. (Chapter 2 discusses cultural issues.)

Cultural perspectives on dying and death are complex. For example, telling some patients that they are dying as a way of letting them prepare for death may be considered an infringement on the role of the family. Others view a discussion about advance directives as a legal device to deny care. Customs surrounding dying and death vary widely, from leaving a window open to allow the spirit of the dead person to leave to providing the final bath for the deceased. The nurse caring for the dying patient must make every attempt to understand and accommodate the family's cultural traditions.

The expressions of grief that follow the loss of a loved one are highly individualized and influenced by several variables. These include the relationship between the grieving person and the deceased, whether the loss is sudden or anticipated, the support systems available to the grieving person, the person's past experiences with loss, and the person's religious and cultural beliefs. It is of utmost importance that the critical care nurse proceed cautiously with patients facing death and their families. Asking patients “What do you want to know?” and “Who do you want with you when discussing options?” is a good starting point (CACCN, 2011). (Chapter 13 provides additional information about end-of-life care.)

Hemodynamic Monitoring

Hemodynamic monitoring is the measurement of pressure, flow, and oxygenation within the cardiovascular system. Both invasive (internally placed devices) and noninvasive (external devices) hemodynamic measurements are made in the ICU. Values commonly measured include systemic arterial pressure and pulmonary artery pressure (PAP), central venous pressure (CVP), pulmonary artery occlusive pressure (PAOP), CO and CI, SV/stroke volume index (SVI), and oxygen saturation of the hemoglobin of arterial blood (SaO_2) and mixed venous blood (SvO_2). From these measurements, the clinician calculates several values, including the resistance of the systemic and pulmonary arterial vasculature as well as oxygen content, delivery, and consumption. When these data are integrated with clinical assessment data, the nurse can derive a picture of the patient's hemodynamic status and the effect of therapy. All measures need to be made with attention to technical accuracy. False or inaccurate data can result in unnecessary and inappropriate treatment.

Hemodynamic Terminology

Cardiac Output and Cardiac Index.

Cardiac output (CO) is the volume of blood pumped by the heart in 1 minute. *Cardiac index* (CI) is the measurement of the CO adjusted for body size, and it is a more precise measurement of the efficiency of the pumping action of the heart. Although minor beat-to-beat changes may occur, generally the left and right ventricles pump the same volume. The volume pumped with each heartbeat is the SV. Like CI, SVI is the measurement of SV adjusted for body size. CO and the forces opposing blood flow determine BP, the force exerted by blood on the vessel wall. The opposition to blood flow offered by the vessels is called *systemic vascular resistance* (SVR) or *pulmonary vascular resistance.* Preload, afterload, and contractility (see Chapter 34) determine SV (and thus CO and BP). Understanding these concepts and relationships is essential for the critical care nurse. In addition, the nurse must understand the effects of manipulation of each of these variables. The formulas and normal values for common hemodynamic parameters are given in Table 68-1.

TABLE 68-1
Resting Hemodynamic Parameters

Indicators	Normal Range
Preload	
Right atrial pressure (RAP) or central venous pressure (CVP)	2–8 mm Hg
Pulmonary artery wedge pressure (PAWP) or left atrial pressure (LAP)	6–12 mm Hg
Pulmonary artery diastolic pressure (PADP)	4–12 mm Hg
$\text{Right ventricular end-diastolic volume (RVEDV)} = \frac{\text{Stroke volume (SV)}}{\text{Right ventricular ejection fraction (RVEF)}}$	100–160 mL
Afterload	
$\text{Pulmonary vascular resistance (PVR)} = \frac{(\text{Pulmonary artery mean pressure [PAMP]} - \text{PAWP}) \times 80}{\text{Cardiac output (CO)}}$	<250 dynes/sec/cm^{-5}
$\text{Pulmonary vascular resistance index (PVRI)} = \frac{(\text{PAMP} - \text{PAWP}) \times 80}{\text{Cardiac index (CI)}}$	160–380 dynes/sec/cm^{-5}/m^2
$\text{Systemic vascular resistance (SVR)} = \frac{(\text{Mean arterial pressure [MAP]} - \text{CVP}) \times 80}{\text{CO}}$	800–1 200 dynes/sec/cm^{-5}
$\text{Systemic vascular resistance index (SVRI)} = \frac{(\text{MAP} - \text{CVP}) \times 80}{\text{CI}}$	1 970–2 390 dynes/sec/cm^{-5}/m^2
$*\text{MAP} = \frac{\text{Systolic blood pressure} + 2\ (\text{Diastolic blood pressure})}{3}$	70–105 mm Hg
$*\text{PAMP} = \frac{\text{Pulmonary artery systolic pressure (PASP)} + 2\ \text{PADP}}{3}$	10–20 mm Hg
Other	
$\text{Stroke volume} = \frac{\text{CO}}{\text{Heart rate}}$	60–150 mL/beat
$\text{Stroke volume index (SVI)} = \frac{\text{CI}}{\text{Heart rate}}$	30–65 mL/beat/m^2
$\text{Stroke volume variation (SVV)} = \frac{\text{SV}_{\text{max}} - \text{SV}_{\text{min}}}{\text{SV}_{\text{mean}}}$	<13%
Heart rate (HR)	60–100 beats/min

Indicators	Normal Range
$CO = SV \times HR$	4–8 L/min
$CI = \frac{CO}{\text{Body surface area (BSA)}}$	2.2–4 L/min/m^2
$RVEF = \frac{SV}{RVEDV \times 100}$	40%–60%
Arterial hemoglobin O_2 saturation	95%–100%
Mixed venous hemoglobin O_2 saturation	60%–80%
Venous hemoglobin O_2 saturation	70%

*These formulas are approximations because they do not take into consideration the heart rate. The monitor looks at the area under the pressure curve, as well as the heart rate, to calculate MAP and PAMP.

Preload.

Preload is the volume within a cardiac chamber at the end of diastole. Unfortunately, chamber volume measurements are difficult to obtain. Instead, various pressures are used to estimate volume. Left ventricular preload is called *left ventricular end-diastolic pressure.* PAOP, a measure of pulmonary occlusive pressure, reflects left ventricular end-diastolic pressure under normal conditions (i.e., when there is no mitral valve pathological condition, intracardiac defect, or dysrhythmia). CVP, measured in the right atrium or in the vena cava close to the heart, is the right ventricular preload or right ventricular end-diastolic pressure when there is no tricuspid valve pathological condition, intracardiac defect, or dysrhythmia.

The effects of preload are explained by *Starling's law,* which states that the more a myocardial fibre is stretched during filling, the more it shortens during systole and the greater the force of the contraction to a physiological limit. As preload increases, force generated in the following contraction increases; thus, SV and CO increase. The greater the preload, the greater the myocardial (heart muscle) stretch and the greater the oxygen requirement of the myocardium. Hence, increases in CO via increased preload require increased delivery of oxygen to the myocardium. It should be remembered that the change in SV with preload comes about because of stretching of the heart muscle. However, the clinical measurement made is not a direct measurement of the muscle length; the measurement made is pressure at the time of the peak stretch (end diastole) (see Table 68-1). This pressure indirectly indicates the amount of stretch and the volume. This pressure is also important because it indicates pressure in the blood vessels of the lung or in the blood returning to the heart. Preload can be increased by fluid administration and decreased by diuresis.

Afterload.

Afterload refers to the forces opposing ventricular ejection. These forces include systemic arterial pressure, the resistance offered by the aortic valve, and the mass and density of the blood to be moved. Clinically, although the measures fail to include all the components of afterload, SVR and arterial pressure are indexes of left ventricular afterload. Similarly, pulmonary vascular resistance and PAP are indexes of right ventricular afterload. Increased afterload often results in a decreased CO. CO can be restored by decreasing afterload (i.e., decreasing forces opposing contraction). When afterload is reduced, myocardial oxygen needs are decreased. Thus, when CO is increased, myocardial oxygen requirements are decreased. Drug therapy directed at reducing afterload (e.g., nitroglycerine or nitroprusside) is often used in the management of heart failure (see Chapter 37).

Vascular Resistance.

Systemic vascular resistance (SVR) is the resistance of the systemic vascular bed. *Pulmonary vascular resistance* is the resistance of the pulmonary vascular bed. Both of these measures reflect afterload as described earlier and can be adjusted for body size (see Table 68-1).

Contractility.

Contractility describes the strength of contraction. Contractility is said to increase when preload is not changed yet the heart contracts more forcefully. Epinephrine, norepinephrine, isoproterenol, dopamine, dobutamine, digitalis-like drugs, calcium, and milrinone (Primacor) increase contractility. These agents are termed *positive inotropes*. Contractility is diminished by *negative inotropes*, such as acidosis and certain drugs (e.g., barbiturates, alcohol, procainamide, calcium channel blockers, β-adrenergic blockers). Increased contractility results in increased SV and increased myocardial oxygen requirements. There are no direct clinical measures of cardiac contractility. To indirectly determine contractility, the nurse measures the patient's preload (PAOP or wedge) and CO and graphs the results. If preload, heart rate, and afterload remain constant yet CO changes, contractility is altered. Contractility diminishes in the failing heart.

Principles of Invasive Pressure Monitoring

Invasive lines are commonly used in the ICU to measure systemic and pulmonary BPs. Components of a typical invasive arterial pressure monitoring system are illustrated in Figure 68-3. The catheter, pressure tubing, flush system, and usually the transducer are disposable.

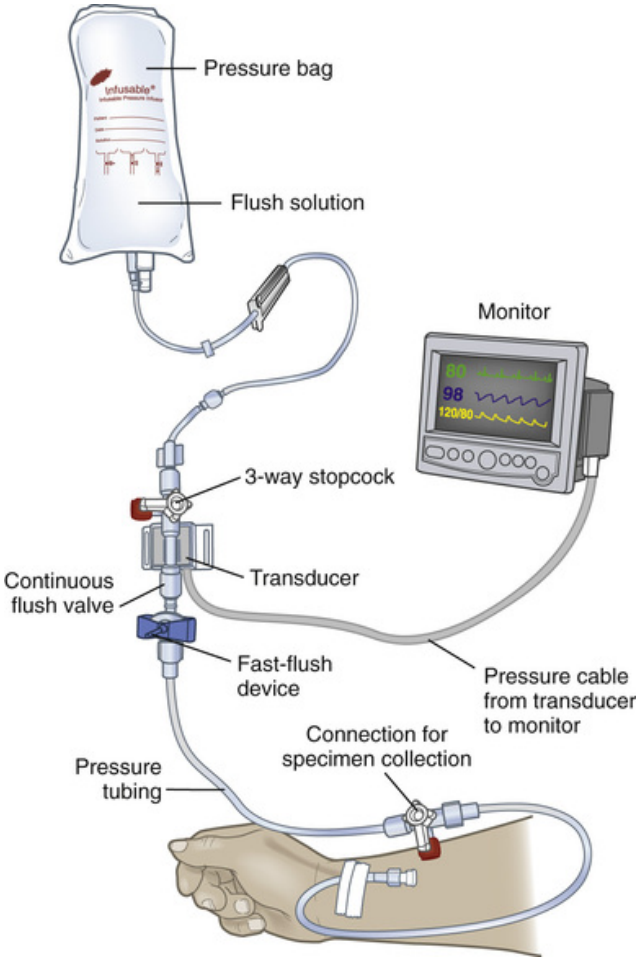


FIGURE 68-3 Components of a pressure monitoring system. The cannula, shown entering the radial artery, is connected via pressure (nondistensible) tubing to the transducer. The transducer converts the pressure wave into an electronic signal. The transducer is wired to the electronic monitoring system, which amplifies, conditions, displays, and records the signal. Stopcocks are inserted into the line for specimen withdrawal and for referencing and zero-balancing procedures. A flush system, consisting of a pressurized bag of intravenous fluid, tubing, and a flush device, is connected to the system. The flush system provides continuous slow (≈3 mL/hr) flushing and provides a mechanism for fast flushing of lines.

To accurately measure pressure, equipment must be referenced and zero-balanced, and dynamic response characteristics optimized. *Levelling* means positioning the transducer so that the zero reference point is at the level of the atria of the heart. The stopcock nearest the transducer is usually the zero reference for the transducer. To place this level with the atria, the nurse uses an external landmark, the phlebostatic axis. To identify the **phlebostatic axis,** two imaginary lines are drawn with the patient supine (Figure 68-4, *A*). The first line, a horizontal line, is drawn through the midchest, halfway between the outermost anterior and the outermost posterior surfaces. The second line, a vertical line, is drawn through the fourth intercostal space at the sternum. The phlebostatic axis is the intersection of the

two imaginary lines. Once the phlebostatic axis is identified, it should be marked on the patient's chest with a permanent marker. The port of the stopcock nearest the transducer must be positioned level with the phlebostatic axis.

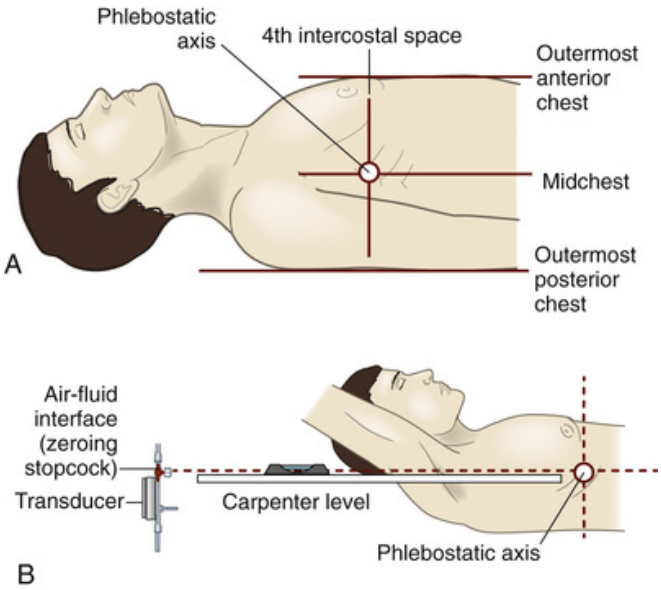

FIGURE 68-4 Identification of the phlebostatic axis. **A,** Phlebostatic axis is an external landmark used to identify the level of the atria in the supine patient. It is defined as the intersection of two imaginary lines: one drawn horizontally from the midchest, midway between the anterior and posterior chest walls, and the other drawn vertically through the fourth intercostal space along the lateral chest wall. **B,** Air–fluid interface (zeroing the stopcock) is level with the phlebostatic axis using a carpenter's or laser level.

Zeroing confirms that when pressure within the system is zero, the equipment reads zero. This is accomplished by opening the reference stopcock to room air and observing the monitor for a reading of zero. Most transducers in current use are disposable and have little zero drift. Zeroing the transducer is recommended during initial setup, immediately after insertion of the arterial line, when the transducer has been disconnected from the pressure cable or the pressure cable has been disconnected from the monitor, and when the accuracy of the measurements is questioned, and it should be done according to the manufacturer's guidelines. Optimizing dynamic response characteristics involves checking that the equipment reproduces without distortion a signal that changes rapidly. A *dynamic response test (square wave test)* is performed every 8 to 12 hours and when the system is opened to air, or if the accuracy of the measurements is questioned. It involves checking that the equipment reproduces a distortion-free signal (Figure 68-5).

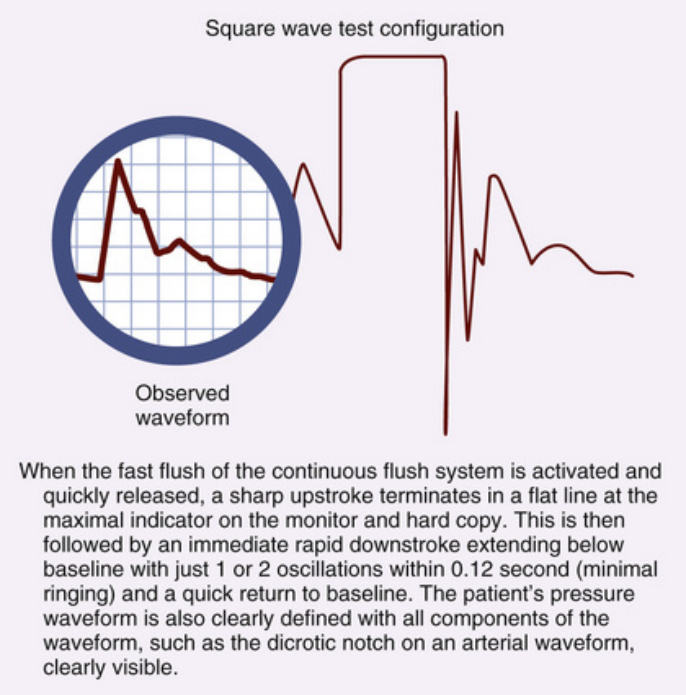

FIGURE 68-5 Optimally damped system. Dynamic response test (square wave test) using the fast-flush system: normal response. No adjustment in the monitoring system is required. Source: Darovic, G. O. (1995). *Hemodynamic monitoring* (2nd ed.). Philadelphia: Saunders.

Steps in obtaining BP measurements with an invasive line are given in Table 68-2. Pressure measurements can be obtained from both digital and printed analogue outputs, but accurate readings are best obtained from a printed pressure tracing at the end of expiration. Initial readings are made with the patient flat. Unless the patient's BP is extremely sensitive to orthostatic changes, values at modest degrees of backrest elevation (≤45 degrees) are generally equivalent to measurements with the patient flat. Studies have not demonstrated the accuracy of readings obtained for patients in the lateral position but do support the accuracy of readings in the prone position. It is not necessary to reposition the patient for each pressure reading. However, it is necessary to move the zero reference stopcock to keep it positioned at the phlebostatic axis (see Figure 68-4, *B*).

TABLE 68-2

Measurement of Blood Pressure With Invasive Lines

1. The nurse explains the procedure to the patient.
2. The nurse positions the patient supine and flat or, if appropriate, with the head of the bed elevated up to 45 degrees.
3. The nurse confirms that the zero reference (port of the stopcock nearest the transducer) is placed at the level of the phlebostatic axis (see Figure 68-4). If the reference stopcock is not taped to the patient's chest, a carpenter's level should be used to position the stopcock on a bedside pole at the point level with the phlebostatic axis.
4. The nurse observes the monitor tracing, assesses the quality of the tracing, and performs a dynamic response test (see Figure 68-5).
5. The nurse obtains an analogue printout, if available, and measures the systolic and diastolic pressures at end-expiration (see Figure 68-6). If no printout is available, the nurse freezes the tracing on the oscilloscope screen and uses the cursor to measure the pressures at end-expiration.
6. The nurse records the pressure measurements promptly, including (if available) the printout marked to identify the points read.

Types of Invasive Pressure Monitoring

Arterial Blood Pressure.

Continuous arterial pressure monitoring is indicated for patients in many situations, including acute hypertension and hypotension, respiratory failure, shock, neurological injury, coronary interventional procedures, continuous infusion of vasoactive drugs, and frequent arterial blood gas (ABG) sampling. A 20-gauge, 5.1-cm, nontapered Teflon over-the-needle cannula is typically used to cannulate a peripheral artery, such as the radial, brachial, or femoral, using a percutaneous approach. It is important that the insertion site be immobilized so that the catheter line is not dislodged and lines do not become kinked.

Measurements.

The nurse can use the arterial line to obtain systolic, diastolic, and mean BPs (Figure 68-6). High- and low-pressure alarms should be set, based on the patient's current status, and activated. Measurements are obtained at end-expiration to limit the effect of the respiratory cycle on arterial pressure (Shaffer, 2011). In patients with heart failure, the systolic upstroke may be slower. In patients with volume depletion, systolic pressure varies greatly with mechanical ventilation, diminishing during inspiration. In the case of severe heart failure, systolic amplitude does not vary with ventilation. With dysrhythmias, it is useful to observe simultaneous ECG and pressure tracings. Dysrhythmias that significantly diminish arterial pressure are more urgent than those that cause only a slight decrease in systolic amplitude.

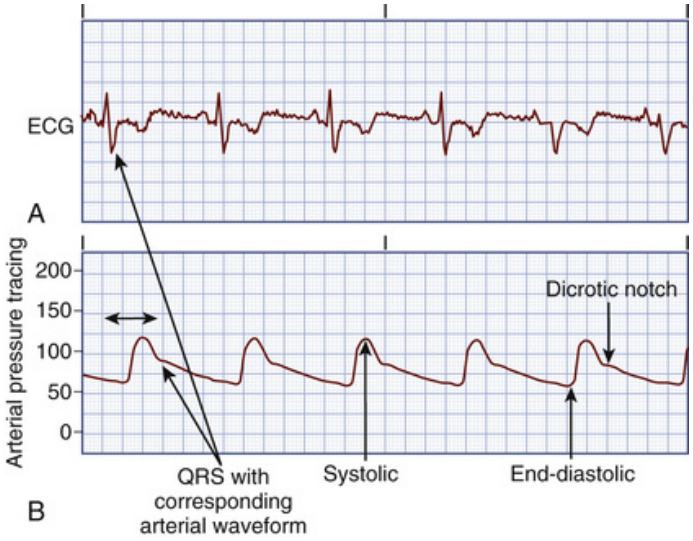

FIGURE 68-6 **A,** Simultaneously recorded electrocardiogram (ECG) tracing. **B,** Systemic arterial pressure tracing. Systolic pressure is the peak pressure. The dicrotic notch indicates aortic valve closure. Diastolic pressure is the lowest value before contraction. Mean pressure is the average pressure over time calculated by the monitoring equipment. Source: Adapted from Urden, L. D., Stacy, K. M., & Lough, M. E. (2010). *Critical care nursing*: *Diagnosis and management* (6th ed., p. 333, Figure 18-8). St. Louis: Mosby.

Complications.

Arterial lines carry a risk for hemorrhage, infection, thrombus formation, and neurovascular impairment. Hemorrhage is most likely to occur when the catheter becomes dislodged or the line becomes disconnected. To avoid this serious complication, the nurse uses Luer-Lok connections and always checks the arterial waveform and ensures that the alarms are activated. If the pressure in the line falls (e.g., when the line is disconnected), the low-pressure alarm sounds immediately, allowing prompt correction of the problem. Pressure is always monitored when an arterial line is in place, even if the line was placed for ABG sampling.

Infection is a risk with any invasive line. The nurse should inspect the insertion site for local signs of inflammation and monitor the patient for signs of systemic infection. To limit the risk for contamination and catheter-related infection, the pressure tubing and transducer should be changed every 72 hours. As well, the pressure bag should be changed every 24 hours.

Circulatory impairment can result from formation of a thrombus around the catheter, release of an embolus, spasm, or occlusion of the circulation by the catheter. Before inserting a line into the radial artery, an Allen test should be performed to confirm that ulnar circulation is sufficient to sustain the hand. In this test, pressure is applied to the radial and ulnar arteries simultaneously. The patient is instructed to open and close the hand repeatedly. The hand should blanch. The nurse then releases the pressure on the ulnar artery while compressing the radial artery. If pinkness fails to return within 6 seconds, the ulnar artery is insufficient, indicating that the radial artery should not be used for line insertion.

To maintain line patency and limit thrombus formation, assess the continuous flush system every 1 to 4 hours to determine that (a) the pressure bag is inflated to 300 mm Hg, (b) the flush bag contains fluid, and (c) the system is delivering 3 to 6 mL/hr. Because of the risk for heparin-induced thrombo-cytopenia, heparinized saline should not be routinely used for the flush solution (Shaffer, 2011). Once the catheter is inserted, the nurse should evaluate the neuro-vascular status distal to the arterial insertion site hourly. The limb with compromised arterial flow will be cool and pale, with capillary refill time longer than 3 seconds. There may be symptoms of neurological impairment (e.g., paresthesia, pain, paralysis). Neuro-vascular impairment can result in loss of a limb and is an emergency.

Arterial Pressure–Based Cardiac Output.

Arterial pressure–based cardiac output (APCO) monitoring is a minimally invasive technique to determine *continuous CO* (CCO)/*continuous CI* (CCI), in order to assess a patient's ability to respond to fluids by increasing stroke volume *(preload responsiveness)*. This assessment is determined by using SVV or by measuring the percentage of increase in SV after a fluid bolus (Edwards Lifesciences, 2006; see Table 68-1). This technology uses a specialized sensor that attaches to a standard arterial pressure line and a monitor (Figure 68-7).

FIGURE 68-7 FloTrac sensor and Vigileo monitor. Source: Courtesy Edwards Lifesciences LLC, Irvine, CA. FloTrac, Vigileo and Swan Ganz are trademarks of Edwards Lifesciences.

SVV is the variation of the arterial pulsation caused by the heart–lung interaction. It is a sensitive indicator of preload responsiveness when used on select patients. SVV is used only for patients on controlled mechanical ventilation with a fixed respiratory rate and a fixed tidal volume (V_T) of 8 mL/kg. Also, the APCO monitor may not be able to filter certain dysrhythmias—specifically atrial fibrillation—

limiting the use of SVV in these patients. These limitations apply only to SVV, not to the use of APCO for CO monitoring.

Measurements.

Arterial pressure is the force generated by the ejection of blood from the left ventricle into the arterial circulation. Pulsatile pressure waves are produced by the heart's contractions (systole). The specialized sensor measures the arterial pulse pressure, which is proportional to SV. APCO monitoring uses the arterial waveform characteristics along with patient demographic data (i.e., gender, age, height, and weight) to calculate SV and pulse rate (PR) to calculate CCO/CCI and SV/SVI every 20 seconds. CO is calculated by multiplying the PR and SV and is displayed on a continuous basis (Kern, 2011). APCO monitoring is frequently used in conjunction with a central venous oximetry catheter. Together, these allow for continuous monitoring of central venous oxygen saturation ($ScvO_2$) and SVR that is derived from the CVP.

APCO is indicated only in adult patients and cannot be used in patients who are on IABP therapy (Kern, 2011).

Pulmonary Artery Flow-Directed Catheter.

PAP monitoring is used to guide acute-phase management of patients with complicated cardiac, pulmonary, or intravascular volume problems (Table 68-3). Pulmonary artery (PA) diastolic pressure and PAOP are sensitive indicators of fluid volume status and cardiac function. PA diastolic pressure and PAOP are increased in patients with fluid volume overload and heart failure and are decreased in patients with volume deficit. Fluid therapy based on PAP allows restoration of fluid balance while avoiding overcorrection of the problem. Monitoring PAPs can allow precise therapeutic manipulation of preload, which allows CO to be maintained without placing the patient at risk for pulmonary edema.

TABLE 68-3

Clinical Indications for Pulmonary Artery Catheterization

• Acute respiratory distress syndrome
• Acute respiratory failure in patients with chronic obstructive pulmonary disease
• Cardiac tamponade
• Complex fluid imbalance (e.g., trauma, burns, sepsis)
• Evaluation of circulatory syndromes (e.g., heart failure, mitral valve regurgitation, intraventricular shunts)
• Intra-aortic balloon pump therapy
• Myocardial infarction with complications (e.g., left ventricular failure, cardiogenic shock, ventricular septal rupture)
• Perioperative fluid imbalance in high-risk patients (e.g., cardiac history)
• Shock states (e.g., cardiogenic, septic, hypovolemic)
• Vasoactive drug therapy support

A PA flow-directed catheter is used to measure PAPs, including PAOP. The standard PA catheter is number 7.5 French, 110 cm long, with four or five lumens (Figure 68-8). When properly positioned, the distal lumen port (catheter tip) is within the PA (Figure 68-9). This port is used to monitor PAPs and withdraw mixed venous blood specimens (e.g., to evaluate oxygen saturation). A balloon connected to

an external valve via the second lumen surrounds the distal lumen port. Balloon inflation has two purposes: (a) to allow moving blood to float the catheter forward and (b) to allow PAOP measurement. There will be one or two proximal lumens, with exit ports in the right atrium (if only one) or the right atrium and the right ventricle (if two). The right atrium port is used for measurement of CVP, injection of fluid for CO determination, and withdrawal of blood specimens. If a second proximal port is available, it is used for infusion of fluids and drugs or blood sampling. A thermistor lumen port located near the distal tip is wired to an external connector. This port is used for monitoring blood or core temperature and for measuring CO using the thermodilution method.

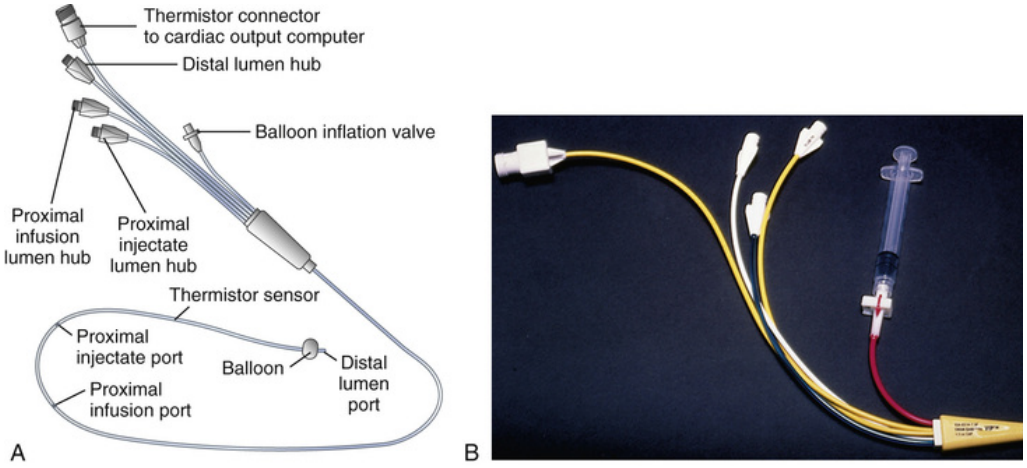

FIGURE 68-8 Pulmonary artery (PA) catheter. **A,** Illustrated catheter has five lumens. When properly positioned, the distal lumen port is in the PA, and the proximal lumen ports are in the right atrium and the right ventricle. The distal port and one of the proximal ports are used to measure PA and central venous pressures, respectively. A balloon surrounds the catheter near the distal end. The balloon inflation valve is used to inflate the balloon with air to allow reading of the pulmonary artery wedge pressure. A thermistor located near the distal tip senses PA temperature and is used to measure thermodilution cardiac output when solution cooler than body temperature is injected into a proximal port. **B,** Photograph of a catheter. FIGURE 68-9 Position of the pulmonary artery flow-directed catheter during progressive stages of insertion with corresponding pressure waveforms. Source: Adapted from Urden, L. D., Stacy, K. M., & Lough, M. E. (2010). *Critical care nursing: Diagnosis and management* (6th ed., p. 348, Figure 18-18). St. Louis: Mosby.

In addition to these standard features, PA catheters with specialized features are available. One modification is the inclusion of an atrial electrode, useful in recording the atrial ECG or pacing the heart. Another common modification is inclusion of a fibre-optic sensor in the distal tip that detects SvO_2. Another type of PA catheter provides continuous measurement of right ventricular volume and ejection fraction, and some catheters provide continuous CO monitoring. The PA catheter sheath (introducer) usually has a side port that serves as a large-bore IV line. Most catheters have a plastic "sleeve" connected to the sheath, which allows the catheter to be advanced or pulled back while maintaining sterility. The physician or other qualified health care provider (e.g., ACNP) usually manipulates the PA catheter, but this practice varies by institution.

Pulmonary Artery Catheter Insertion.

Before PA catheter insertion, the nurse should note the patient's electrolyte, acid–base, oxygenation, and coagulation status. Imbalances such as hypokalemia, hypomagnesemia, hypoxemia, or acidosis can make the heart more irritable and increase the risk for ventricular dysrhythmia during catheter insertion. Coagulopathy increases the risk for hemorrhage.

Preparation for the procedure includes arranging the monitor, cables, and infusion and pressurized flush solutions. The system is zero-referenced to the phlebostatic axis. The physician or other health care provider explains the procedure to the patient and obtains informed consent. The patient is positioned supine and flat. The

PA catheter is inserted through a sheath percutaneously into the internal jugular, subclavian, antecubital, or femoral vein using surgical asepsis. Venous cutdown is rarely required. The catheter is advanced through the venous system to the right side of the heart.

The nurse must continuously observe the characteristic waveforms on the monitor as the catheter is moved through the heart to the PA (see Figure 68-9). When the tip reaches the right atrium, the balloon is inflated. Inflation of the balloon should not exceed the balloon's capacity (usually 1–1.5 mL of air). The catheter is then "floated" through the tricuspid valve into the right ventricle and then through the pulmonic valve to the PA. It is necessary to monitor the ECG continuously during insertion because of the risk for dysrhythmias, particularly when the catheter reaches the right ventricle. Once a typical PAOP tracing is observed, the balloon is deflated, and the PA waveform should return on the monitor. Following insertion, a chest radiograph confirms the catheter's position. To maintain the catheter in its proper position, it is secured at the point of entry into the skin. The nurse should note and record the measurement at the exit point. At the procedure's end, an occlusive dressing is applied and then is changed according to institution policy.

Recently, the use of PA catheters has decreased dramatically. This decrease is due in part to the risks associated with the technology (e.g., infection, PA rupture, and infarction) and the development of less invasive techniques (e.g., APCO monitoring).

Central Venous or Right Atrial Pressure Measurement.

CVP is a measurement of right ventricular preload. It can be measured with a PA catheter using one of the proximal lumens or with a central venous catheter placed in the internal jugular or subclavian vein. CVP is measured as a mean pressure at the end of expiration. CVP waveforms (Figure 68-10) are similar to PAOP waveforms. Although the PA diastolic pressure and the wedge pressure are more sensitive indicators of fluid volume status, CVP also reflects fluid volume problems. An elevated CVP indicates right ventricular failure or volume overload. A low CVP indicates hypovolemia.

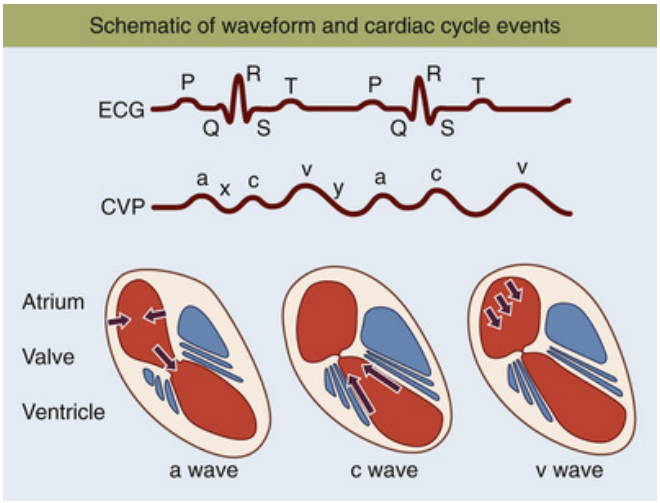

FIGURE 68-10 Cardiac events that produce the central venous pressure (CVP) waveform with *a*, *c*, and *v* waves. *a* wave represents atrial contraction. *x* descent represents atrial relaxation. *c* wave represents the bulging of the closed tricuspid valve into the right atrium during ventricular systole. *v* wave represents atrial filling. *y* descent represents opening of the tricuspid valve and filling of the ventricle. *ECG*, electrocardiogram. Source: Adapted from Urden, L. D., Stacy, K. M., & Lough, M. E. (2010). *Critical care nursing: Diagnosis and management* (6th ed., p. 338, Figure 18-11). St. Louis: Mosby.

Noninvasive Hemodynamic Monitoring: Impedance Cardiography.

Impedance cardiography (ICG) is a continuous or intermittent, noninvasive method of obtaining CO and assessing thoracic fluid status. Based on the concepts of impedance (the resistance to the flow of electric current [Ω]), ICG uses four sets of external electrodes to deliver a high-frequency, low-amplitude current similar to that used in apnea monitors. Blood is an excellent conductor of electricity (lower impedance), and pulsatile blood flow generates electrical impedance changes. ICG measures the change in impedance (dΩ) in the ascending aorta and left ventricle over time (dt) and is represented as dΩ/dt. Ωo is the measurement of the average impedance of the fluid in the thorax. Impedance-based hemodynamic parameters (CO, SV, and SVR) are calculated from Ωo, dΩ/dt, mean arterial pressure, CVP, and the ECG.

Major indications for ICG include early signs and symptoms of pulmonary or cardiac dysfunction, differentiation of cardiac or pulmonary cause of shortness of breath, evaluation of etiology and management of hypotension, monitoring after discontinuing a PA catheter or justification for insertion of a PA catheter, evaluation of pharmacotherapy, and diagnosis of rejection following cardiac transplantation. ICG is not recommended in patients who have generalized edema or third spacing because the excess volume interferes with accurate signals.

Venous Oxygen Saturation.

Both CVP and PA catheters can include sensors to measure O_2 saturation of hemoglobin of venous blood. Either $ScVO_2$ (O_2 saturation of venous blood from the

CVP catheter) or SvO_2 (O_2 saturation from the PA catheter) is useful in determining the adequacy of tissue oxygenation. $ScvO_2/SvO_2$ reflects the dynamic balance between oxygenation of the arterial blood, tissue perfusion, and tissue oxygen consumption. $ScvO_2/SvO_2$ is useful in assessing hemodynamic status and response to treatments or activities when considered in conjunction with arterial O_2 saturation (Table 68-4). Normal $ScvO_2/SvO_2$ at rest is 60% to 80%.

TABLE 68-4
Clinical Interpretation of SvO_2 Measurements

SvO_2 Measurement	Physiological Basis for Change in SvO_2	Clinical Diagnosis and Rationale
High SvO_2 (80%–95%)	Increased oxygen supply Decreased oxygen demand	• Patient receiving more oxygen than required by clinical condition • Anaesthesia, which causes sedation and decreased muscle movement • Hypothermia, which lowers metabolic demand (e.g., with cardiopulmonary bypass) • Sepsis caused by decreased ability of tissues to use oxygen at the cellular level • False high-positive because pulmonary artery catheter is wedged in a pulmonary capillary
Normal SvO_2 (60%–80%)	Normal oxygen supply and metabolic demand	• Balanced oxygen supply and demand
Low SvO_2 (<60%)	Decreased oxygen supply caused by: • Low hemoglobin • Low arterial saturation (SaO_2) • Low cardiac output • Increased oxygen consumption (VO_2)	• Anemia or bleeding with compromised cardiopulmonary system • Hypoxemia resulting from decreased oxygen supply or lung disease • Cardiogenic shock caused by left ventricular pump failure • Metabolic demand exceeds oxygen supply in conditions increasing metabolic rate, including physiological states such as shivering, seizures, and hyperthermia and nursing interventions that increase muscle movement, such as obtaining bed scale weight and repositioning

Source: Urden, L. D., Stacy, K. M., & Lough, M. E. (2010). *Critical care nursing: Diagnosis and management* (6th ed., p. 362, Table 18-8). St. Louis: Mosby.

Sustained decreases and increases in $ScvO_2/SvO_2$ must be analyzed carefully. Decreased SvO_2 may indicate (a) decreased arterial oxygenation, (b) low CO, (c) low hemoglobin, or (d) increased O_2 consumption. If the $ScvO_2/SvO_2$ falls, the nurse determines which of these four factors has changed. The nurse observes for changes in arterial oxygenation by monitoring pulse oximetry results or ABGs. By noting any changes in level of consciousness, strength and quality of peripheral pulses, urine output, and skin colour and temperature, the nurse can grossly assess CO and tissue perfusion. If arterial oxygenation, CO, and hemoglobin are unchanged, a fall in SvO_2 indicates increased O_2 consumption, which could result from an increased metabolic rate, pain, movement, or fever. If O_2 consumption increases without a comparable increase in O_2 delivery, more O_2 is extracted from the blood, and $ScvO_2/SvO_2$ will continue to fall.

Increased $ScvO_2/SvO_2$ is also clinically significant and may indicate a clinical improvement (e.g., increased SaO_2, improved perfusion, decreased metabolic rate) or problems (e.g., sepsis, ventricular septal defect). In sepsis, O_2 may not be extracted properly at the tissue level, resulting in increased mixed venous O_2 saturation.

Nursing interventions may be guided by changes in $ScvO_2/SvO_2$. The nurse might note that the patient's heart rate increased moderately during repositioning but that the $ScvO_2/SvO_2$ remained stable. In this case, the nurse might conclude that the position change was tolerated. A drop in the $ScvO_2/SvO_2$ would be an indication to stop the activity until the SvO_2 returns to the previous level.

In many cases, as activity or metabolism increases, heart rate and CO increase, and SvO_2 remains constant or varies slightly. However, it is not uncommon for critically ill patients to have conditions that prevent substantial increases in CO. For example, such an increase could occur in the patient with heart failure, shock, dysrhythmias, or cardiac transplantation. In these cases, $ScvO_2/SvO_2$ can provide a useful indicator of the balance between O_2 delivery and consumption.

Noninvasive Arterial Oxygenation Monitoring.

Pulse oximetry is a noninvasive and continuous method of determining arterial oxygenation (SpO_2), and monitoring SpO_2 may reduce how often ABG sampling is needed (see Chapter 28). SpO_2 is normally 95% to 100%. A common use for pulse oximetry is to evaluate the effectiveness of O_2 therapy. Decreased SpO_2 indicates inadequate oxygenation of the blood in the pulmonary capillaries. This may be corrected by increasing the fraction of inspired oxygen (FiO_2) and evaluating the patient's response. Similarly, the nurse uses SpO_2 to monitor how the patient tolerates decreases in FiO_2 and responds to changes in position and treatments. For example, the nurse might note that SpO_2 falls when the patient is positioned in a left lateral recumbent position. The nurse could then plan position changes that pose less risk for the patient.

Accurate SpO_2 measurements may be difficult to obtain on patients who are hypothermic, receiving IV vasopressor therapy (e.g., norepinephrine [Levophed]), or experiencing hypoperfusion (e.g., shock). The usual location for placement of the oximetry probe is a finger; alternative locations for probe placement may have to be considered (e.g., forehead, earlobe) during periods of hypoperfusion.

Nursing Management Hemodynamic Monitoring

Assessment of hemodynamic status requires integration of data from many sources and comparison of the data over time. Thorough, basic nursing observations provide important clues about the patient's hemodynamic status. The nurse should begin by obtaining baseline data regarding the patient's general appearance, level of consciousness, skin colour and temperature, vital signs, peripheral pulses, and urine output. Does the patient appear tired, weak, exhausted? There may be too little cardiac reserve to sustain even minimal activity. Pallor, cool skin, and diminished pulses may indicate decreased CO. Changes in mental clarity may reflect problems with cerebral perfusion or oxygenation. Monitoring urine output reflects the adequacy of perfusion to the kidneys. The patient with diminished perfusion to the GI tract may develop hypoactive or absent bowel sounds. If the patient is bleeding and developing shock, BP might initially be relatively stable, yet the patient may become increasingly pale and cool from peripheral vasoconstriction. Conversely, the patient experiencing septic shock may remain warm and pink yet develop tachycardia and BP instability. Although heart rates of 100 beats per minute are common among stressed, compromised, critically ill patients, sustained tachycardia greatly increases myocardial oxygen demand and may result in diminished CO.

The critical care nurse correlates observational data with data obtained from biotechnology (e.g., ECG; arterial pressure, PAP, PAOP; SvO_2). Single hemodynamic values are rarely significant. The nurse must evaluate the whole clinical picture with the goals of recognizing early clues and intervening before problems escalate.

Circulatory Assist Devices

Mechanical **circulatory assist devices (CADs),** such as the IABP and the left ventricular assist device (VAD), are used to decrease cardiac work and improve organ perfusion in patients with heart failure when conventional drug therapy is no longer adequate. The type of device used depends on the extent and the nature of the myocardial problem and the capabilities of the institution and staff. CADs provide interim support in three types of situations: (a) the left ventricle requires support while recovering from acute injury; (b) the heart requires surgical repair (e.g., a ruptured septum), but the patient's condition must be stabilized; and (c) the heart has failed, and the patient is awaiting cardiac transplantation. All CADs decrease left ventricular workload, increase myocardial perfusion, and augment circulation. The most commonly used CAD is the IABP. Several types of VADs are available, and additional devices are under development.

Intra-Aortic Balloon Pump

The **intra-aortic balloon pump (IABP)** provides temporary circulatory assistance to the compromised heart by reducing afterload (via reduction in systolic pressure) and augmenting the aortic diastolic pressure. Table 68-5 lists clinical conditions for which the IABP is used. The IABP consists of a sausage-shaped balloon, a pump that inflates and deflates the balloon, control devices for synchronizing the balloon inflation to the cardiac cycle, and fail-safe devices (Figure 68-11). Under strict aseptic technique, the balloon is inserted percutaneously or surgically into the femoral artery, advanced toward the heart, and positioned in the descending thoracic aorta just below the left subclavian artery (Figure 68-12). Following placement of the balloon, the position is confirmed radiologically. A pneumatic device cyclically fills the balloon with helium at the start of diastole (immediately after aortic valve closure) and deflates it just before systole. The ECG is the primary trigger used to initiate the deflation on the R wave (of the QRS) and the inflation on the T wave, and the dicrotic notch of the arterial pressure tracing is used to refine timing. IABP support is referred to as *counter-pulsation* because the timing of balloon inflation is opposite to ventricular contraction. The IAPB assist ratio is 1 : 1 in the acute phase of treatment, that is, one IABP cycle of inflation and deflation for every heartbeat.

TABLE 68-5
Indications and Contraindications for the Intra-Aortic Balloon Pump

Indications
• Acute myocardial infarction with any of the following:*
• Acute mitral valve dysfunction
• Acute ventricular septal defect
• Cardiogenic shock
• High-risk interventional cardiology procedures
• Preoperative, intraoperative, and postoperative cardiac surgery (e.g., prophylaxis before surgery, failure to be weaned from cardiopulmonary bypass, left ventricular failure after cardiopulmonary bypass)
• Recurrent chest pain with or without ventricular dysrhythmias
• Ventricular aneurysm accompanied by ventricular dysrhythmias
• Refractory unstable angina (when drugs have failed)
• Short-term bridge to cardiac transplantation
Contraindications
• Abdominal aortic and thoracic aneurysms
• Generalized peripheral vascular disease†
• Irreversible brain damage
• Moderate to severe aortic insufficiency
• Terminal or untreatable diseases of any major organ system

*Allows time for emergent angiography and corrective cardiac surgery to be performed.

†May inhibit placement of balloon and is considered a relative contraindication; sheathless insertion may be used.

FIGURE 68-11 Intra-aortic balloon pump machine. Source: © Ivan Stojanovic/Dreamstime.

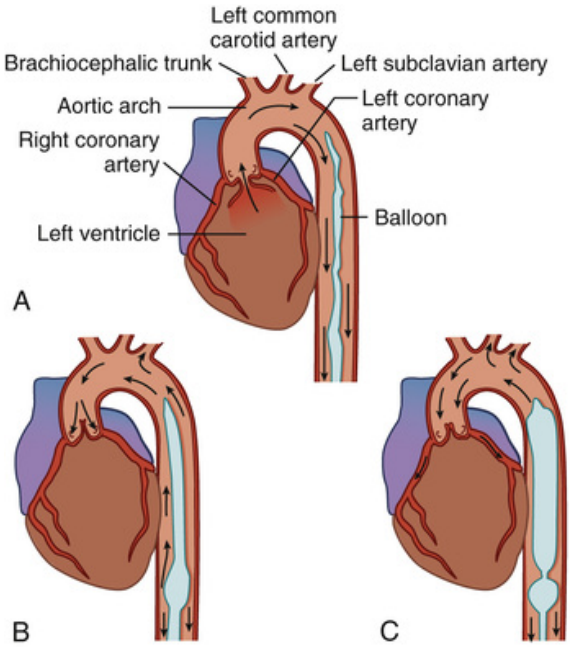

FIGURE 68-12 Intra-aortic balloon pump. **A,** During systole, the balloon is deflated, which facilitates ejection of the blood into the periphery. **B,** In early diastole, the balloon begins to inflate. **C,** In late diastole, the balloon is totally inflated, which augments aortic pressure and increases the coronary perfusion pressure, with the end result of increased coronary and cerebral blood flow.

Effects of Counter-Pulsation.

In late diastole, when the balloon is totally inflated, blood is forcibly displaced distally to the extremities and proximally to the coronary arteries and the main branches of the aortic arch. Diastolic arterial pressure rises (diastolic augmentation), increasing coronary artery perfusion pressure and perfusion of vital organs. The rise in coronary artery perfusion pressure causes an increase in blood flow to the myocardium. The balloon is rapidly deflated just before systole. The suddenly created vacuum causes aortic pressure to drop. With aortic resistance to left ventricular ejection reduced (reduced afterload), the left ventricle empties more easily and completely. As with other types of afterload reduction, the SV increases, yet the myocardial oxygen consumption decreases. Hemodynamic effects of the IABP are summarized in Table 68-6.

TABLE 68-6
Hemodynamic Effects of Intra-Aortic Balloon Pumps

Effects of Inflation During Diastole

• Improved oxygen delivery to the myocardium
  • Decreased angina pain
  • Decreased electrocardiographic evidence of ischemia
  • Decreased ventricular ectopy
• Increased diastolic pressure (may exceed systolic pressure)
• Increased pressure in the aortic root during diastole
• Increased coronary perfusion pressure

Effects of Deflation During Systole

• Decreased afterload
• Decreased myocardial oxygen consumption
• Decreased peak systolic pressure
• Increased forward flow of blood, decreasing preload
  • Decreased crackles
  • Decreased PA pressures, including PAOP
• Increased stroke volume, possibly associated with the following:
  • Decreased heart rate
  • Improved sensorium
  • Increased urine output
  • Warmed skin

PA, pulmonary artery; *PAOP*, pulmonary artery occlusive pressure.

Complications With IABP Therapy.

Vascular injuries such as dislodgment of plaque, aortic dissection, and compromised distal circulation are common with IABP therapy. Thrombus and embolus formation add to the risk for circulatory compromise to the extremity. The action of the IABP can also destroy platelets and cause thrombo-cytopenia. Peripheral nerve damage can occur, particularly when a cutdown is performed for insertion. Movement of the balloon can block the left subclavian, renal, or mesenteric arteries, in turn resulting in a weak or absent radial pulse, decreased urine output, and reduced or absent bowel sounds. Patients receiving IABP therapy are prone to infection. Local or systemic signs of infection require catheter removal (Castellucci, 2011). To reduce these complications, the nurse should perform cardiovascular, neuro-vascular, and hemodynamic assessments every 15 to 60 minutes, depending on the patient's status (Table 68-7).

TABLE 68-7

Nursing Management: Potential Complications of the Intra-Aortic Balloon Pump

Potential Complication	Nursing Management
Site infection from invasive lines	• Use strict aseptic technique for insertion and dressing changes for all lines. • Cover all insertion sites with occlusive dressings. • Administer prescribed prophylactic antibiotic for entire course of therapy.
Pneumonia associated with immobilization	• Reposition patient q2h, being careful not to displace balloon. • If patient with pneumonia requires physiotherapy of the chest, avoid introducing an ECG artifact.
Arterial trauma caused by insertion or displacement of balloon	• Evaluate and mark peripheral pulses before insertion of balloon to use as baseline for assessing pulses after insertion. • After insertion of balloon, evaluate perfusion to both extremities at least every hour. • Measure urine output at least every hour (occlusion of renal arteries causes severe decrease in urine output). • Observe arterial waveforms for sudden changes. • Keep head of bed <45 degrees. • Do not flex cannulated leg at the hip. • Immobilize cannulated leg to prevent flexion using a draw sheet tucked under the mattress, a soft ankle restraint, or a knee immobilizer.
Thrombo-embolism caused by trauma, balloon obstruction of blood flow distal to catheter	• Administer prophylactic heparin if ordered. • Evaluate pulses, urine output, and level of consciousness at least every hour. • Check circulation, sensation, and movement in both legs at least every hour.
Hemorrhage from insertion site	• Check site for bleeding at least every hour. • Observe vital signs for hypovolemia.

ECG, electrocardiogram.

Mechanical complications from IABP are rare but can occur. Improper timing of balloon inflation may cause increased afterload, decreased CO, myocardial ischemia, and increased myocardial O_2 demand. These complications must be recognized immediately. If the balloon develops a leak, the pump will automatically stop. The catheter must be promptly removed to avoid an embolus. Signs of a leak include less effective augmentation, repeated alarms for gas loss, and blood backing up into the catheter. A malfunction of the balloon or console triggers fail-safe alarms and automatically shuts down the unit.

The patient with an IABP is relatively immobile, limited to side-lying or supine positions with the head of the bed (HOB) elevated less than 45 degrees. The patient may be receiving ventilatory support and will likely have multiple invasive lines that increase the challenge of comfortable positioning. The patient may experience sleeplessness and anxiety. Adequate sedation, pain relief, skin care, and comfort measures are essential.

As the patient improves, circulatory support provided by the IABP is gradually reduced. Weaning involves reducing the IABP assist ratio from 1 : 1 to 1 : 2 and assessing the patient's response. If hemodynamic parameters remain stable, the ratio can be changed from 1 : 2 to 1 : 3 until the IABP catheter is removed. Pumping is continued until the line is removed even if the patient is stable. This reduces the risk for thrombus formation around the catheter.

Ventricular Assist Devices

The **ventricular assist device (VAD)** provides short- and long-term support for the failing heart and allows more mobility than the IABP. VADs are inserted into the path of flowing blood to augment or replace the action of the ventricle. Some VADs are implanted internally (e.g., peritoneum), and others are positioned externally. A typical VAD shunts blood from the left atrium or ventricle to the device and then to the aorta. Some VADs provide right ventricular or biventricular support (Figure 68-13).

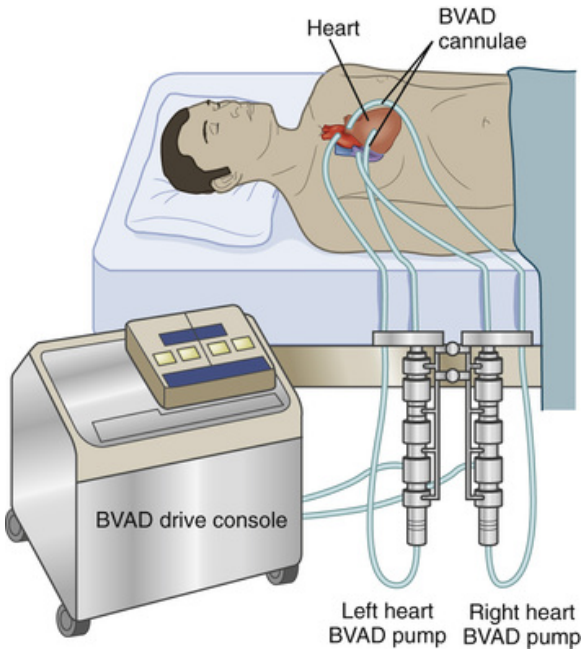

FIGURE 68-13 Schematic diagram of a biventricular assist device (BVAD).

Failure to wean a patient from cardiopulmonary bypass (CPB) after surgery is a primary indicator for VAD support. VADs are also used to support patients with ventricular failure caused by myocardial infarction and patients awaiting heart transplantation. A VAD is a temporary device that can partially or totally support circulation until the heart recovers or a donor heart is obtained. Cannula sites depend on the type of device used. For support of the right side of the heart, the right atrium and PA are cannulated. The left ventricular apex can be cannulated for left VADs. Direct cannulation of the atria and great vessels occurs in the operating room through a sternotomy.

Appropriate patient selection for VAD therapy is critical. Indications include (a) failure to be weaned from CPB or postcardiotomy cardiogenic shock, (b) a bridge to recovery or heart transplantation, and (c) patients with New York Heart Association class IV heart disease (see Table 37-4 in Chapter 37) who have failed medical therapy. Relative contraindications for VAD therapy include (a) body surface area less than manufacturer's limit (i.e., 1.3 m^2), (b) renal or liver failure unrelated to a cardiac event, and (c) comorbidities that would limit life expectancy to less than 3 years (Puhlman & Fleck, 2011).

Implantable Artificial Heart

In 2013, 142 patients in Canada received cardiac transplants (Canadian Institute for Health Information, 2017), yet the demand for donor hearts far exceeds the supply. Research on mechanical CADs has led to the development of a fully implantable artificial heart that can sustain the body's circulatory system. This device is used to replace the hearts of patients who are not eligible for a transplantation and have no other treatment alternative. One major advantage of the artificial heart compared with heart transplantation is decreased costs for implantation and drug therapies.

Nursing Management Circulatory Assist Devices

The patient with an IABP requires highly skilled nursing care. The nurse must perform frequent and thorough cardiovascular assessments. These include measurement of hemodynamic parameters (e.g., arterial BP, CO/CI, SVR), auscultation of the heart and lungs, and evaluation of the ECG (e.g., rate, rhythm). The nurse must also assess for adequate tissue perfusion (e.g., skin colour and temperature, mental status, capillary refill, peripheral pulses, urine output, bowel sounds) at regular intervals. It is expected that IABP therapy will improve these findings.

Nursing care of the patient with a VAD is similar to that of the patient with an IABP. The nurse must observe the patient for bleeding, cardiac tamponade, ventricular failure, infection, dysrhythmias, renal failure, hemolysis, and thrombo-embolism. Unlike the patient with an IABP, who must remain in bed with limited position changes, the patient with VAD may be mobile and require an activity plan. In some cases, patients with VADs may go home. Preparation for discharge is complex and requires in-depth teaching about the device and support equipment (e.g., battery chargers). A competent caregiver must be present at all times once the patient is discharged home.

Ideally, patients with CADs will recover through ventricular improvement, heart transplantation, or artificial heart implantation. However, many patients die, or the decision to terminate the device is made, and death follows. Both the patient and caregiver require emotional support. Other members of the health care team, such as social workers or clergy, should be consulted as appropriate.

Artificial Airways

Patients in the ICU often need mechanical assistance to maintain airway patency. Inserting a tube into the trachea, bypassing upper airway and laryngeal structures, creates an artificial airway. The tube is placed into the trachea via the mouth or nose past the larynx **(endotracheal [ET] intubation)** or through a stoma in the neck *(tracheostomy).* ET intubation is more common than a tracheostomy in ICU patients. It is performed quickly and safely at the bedside. Indications for ET intubation include (a) upper airway obstruction (e.g., secondary to burns, tumour, bleeding), (b) apnea, (c) high risk for aspiration, (d) ineffective clearance of secretions, and (e) respiratory distress. Figure 68-14 shows the parts of an ET tube.

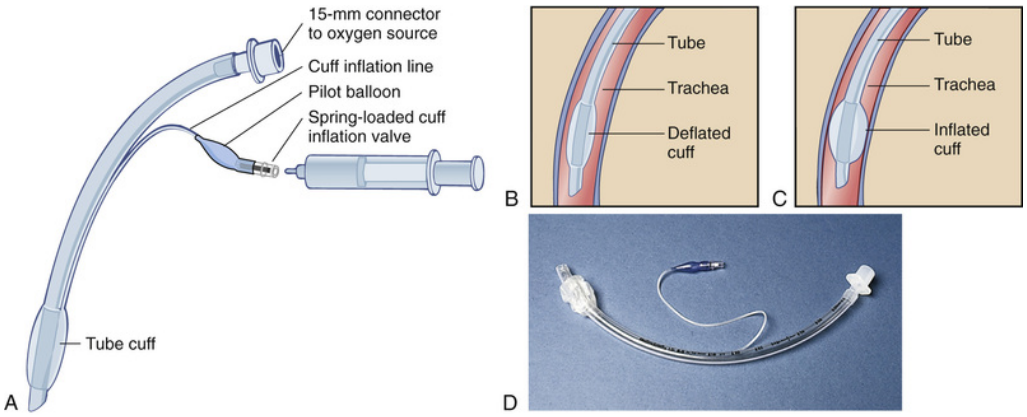

FIGURE 68-14 Endotracheal tube. **A,** Parts of an endotracheal tube. **B,** Tube in place with the cuff deflated. **C,** Tube in place with the cuff inflated. **D,** Photograph of the tube before placement. Source: *A,* Beare, P. G., & Myers, J. L. (1998). *Adult health nursing* (3rd ed.). St. Louis: Mosby.

A *tracheotomy* is a surgical procedure that is performed when the need for an artificial airway is expected to be long term. There is ongoing debate regarding the timing of a tracheotomy in the patient requiring an ET tube. Research suggests that early tracheotomy (2 to 10 days) may have advantages over delayed tracheotomy, particularly when mechanical ventilation is predicted to be needed for longer than 10 to 14 days (Villwock & Jones, 2014). The situation varies with the patient, physician, and institution. Chapter 29 discusses tracheostomy tubes and related nursing management.

Evidence-Informed Practice

Research Highlight

Does Timing of Tracheotomy Affect Critically Ill Patient Outcomes?

Clinical Question

In critically ill patients (P), what is the effect of an early tracheotomy (I) versus late tracheotomy (C) on short-term mortality and incidence of ventilator-assisted pneumonia (O)?

Best Available Evidence

Systematic review of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence

- In seven RCTs (n = 1 044) of critically ill adult patients requiring prolonged mechanical ventilation, early tracheotomy was compared with either late tracheotomy or prolonged endotracheal intubation.
- Primary outcomes were short-term mortality and ventilator-assisted pneumonia (VAP).
- Secondary outcomes were long-term mortality, duration of ventilation and sedation, length of stay in ICU and hospital, and complications.
- Early tracheotomy did not significantly reduce short-term or long-term mortality or rate of VAP. Tracheotomy timing was not related to reductions in duration of mechanical ventilation or sedation, shorter stays in ICU or hospital, or more complications.

Conclusion

- Clinically significant outcomes are not affected by timing of a tracheotomy.

Implications for Nursing Practice

- The optimal tracheotomy timing (early vs. late) for patients on prolonged mechanical ventilation is not really known.
- Benefits of tracheotomy (e.g., increased patient comfort, improved oral hygiene) and the risks and complications (e.g., bleeding, wound infection, tracheal stenosis) need to be considered and weighed against the risks and benefits of prolonged endotracheal intubation.

P, Patient population of interest; *I,* intervention or area of interest; *C,* comparison of interest or comparison group; *O,* outcomes of interest (see Chapter 1).

Wang F, Wu Y, Bo L, et al. The timing of tracheotomy in critically ill patients undergoing mechanical ventilation: A systematic review and meta-analysis of randomized controlled trials. *Chest*. 2011;*140*(6):1456–1465.

Endotracheal Tubes

In *oral intubation,* the ET tube is passed through the mouth and vocal cords and into the trachea with the aid of a laryngoscope or a bronchoscope. In *nasal ET intubation,* the ET is placed blindly (i.e., without seeing the larynx) through the nose, nasopharynx, and vocal cords. Oral ET intubation is preferred for most emergencies because the airway can be secured rapidly and a larger-diameter tube is used. A larger-bore ET tube reduces the *work of breathing* (WOB) because of less airway resistance. It is easier to remove secretions and perform fibre-optic bronchoscopy if needed. Nasal ET intubation is rarely used but may be needed when head and neck movement is risky.

There are risks associated with oral ET intubation. It is difficult to place an oral tube if head and neck mobility is limited (e.g., suspected spinal cord injury). Teeth can be chipped or accidentally removed during the procedure. Salivation is increased and swallowing is difficult. Patients can obstruct the ET tube by biting down on it. Sedation along with a bite block or oropharyngeal airway may be used to avoid this. The ET tube and bite block (if used) should be secured (separately) to the face. Mouth care is a challenge because of limited space in the oral cavity. Using smaller or pediatric-sized oral products for tooth brushing, cleaning, and suctioning may be necessary.

Nasal intubation is contraindicated in patients with facial fractures or suspected fractures at the base of the skull and postoperatively after cranial surgeries. The WOB is greater because the longer, narrower tube offers more airflow resistance and may kink. Suctioning and secretion removal are more difficult.

Endotracheal Intubation Procedure

Unless ET intubation is emergent, consent for the procedure is obtained. The patient and caregiver must be told the reason for ET intubation, the steps in the procedure, and the patient's role in the procedure (if indicated). It should also be explained that, while intubated, the patient will not be able to speak but that other means of communication will be provided. The patient should also be informed that his or her hands may briefly be restrained for safety purposes.

A self-inflating *bag–valve–mask* (BVM) (e.g., Ambu bag) should be available and attached to O_2, suctioning equipment ready at the bedside, and IV access. The BVM contains a reservoir that is filled with O_2 so that concentrations of 90% to 95% are delivered. The slower the bag is deflated and inflated, the higher the O_2 concentration that is delivered. The nurse should assemble and check the equipment

to be used, remove the patient's dentures or partial plates (for oral intubation), and administer medications as ordered. Premedication varies depending on the patient's level of consciousness (e.g., awake, obtunded) and the nature of the procedure (e.g., emergent, nonemergent).

Rapid-sequence intubation (RSI) is the rapid, concurrent administration of both a sedative and a paralytic agent during emergency airway management to decrease the risks for aspiration and injury to the patient. RSI is not indicated in patients who are in cardiac arrest or are known to have a difficult airway (Stollings, Diedrich, Oyen, et al., 2014). A sedative–hypnotic–amnesic (e.g., midazolam, etomidate) is used to induce unconsciousness, along with a rapid-onset opioid (e.g., fentanyl) to blunt the pain of the procedure. A paralytic drug (e.g., succinylcholine) is then given to produce skeletal muscle paralysis. The patient's oxygenation status must be monitored during the procedure using pulse oximetry.

For oral intubation, place the patient supine with the head extended and the neck flexed ("sniffing position"). This position permits visualization of the vocal cords. For nasal intubation, the nasal passages may be sprayed with a local anaesthetic and vasoconstrictor (e.g., lidocaine [Xylocaine] with epinephrine) to reduce trauma and bleeding. Before intubation is started, the patient should be preoxygenated using the BVM and 100% O_2 for 3 to 5 minutes. Each intubation attempt is limited to less than 30 seconds, and the patient should be ventilated between successive attempts using the BVM and 100% O_2.

After intubation, the cuff should be inflated and the placement of the ET tube confirmed while the patient is manually ventilated using the BVM with 100% O_2. An end-tidal CO_2 detector is used to confirm proper placement by noting the presence of exhaled CO_2 from the lungs. The detector should be placed between the BVM and the ET tube, and the nurse should observe for either a colour change (indicating the presence of CO_2) or a number. If no CO_2 is detected, the tube is in the esophagus and needs to be reinserted (Walsh, Crotwell, & Restrepo, 2011) The lungs must be auscultated for bilateral breath sounds, and the epigastrium for the absence of air sounds. The nurse should observe the chest for symmetric chest wall movement. In addition, SpO_2 should be stable or improved.

If the findings support proper ET tube placement, the tube is then connected to an O_2 source and secured per employer policy (Figure 68-15). The nurse should suction the ET tube and pharynx and insert a bite block as needed. A chest radiograph is done immediately to confirm tube location (2 to 6 cm above the carina in the adult). This position allows the patient to move the neck without moving the tube or causing it to enter the right mainstem bronchus. Once proper positioning is confirmed with radiography, the nurse should record and mark the position of the tube at the lip or teeth (usually 21 cm for women and 23 cm for men) or nose. Excess tubing is cut to reduce dead air space.

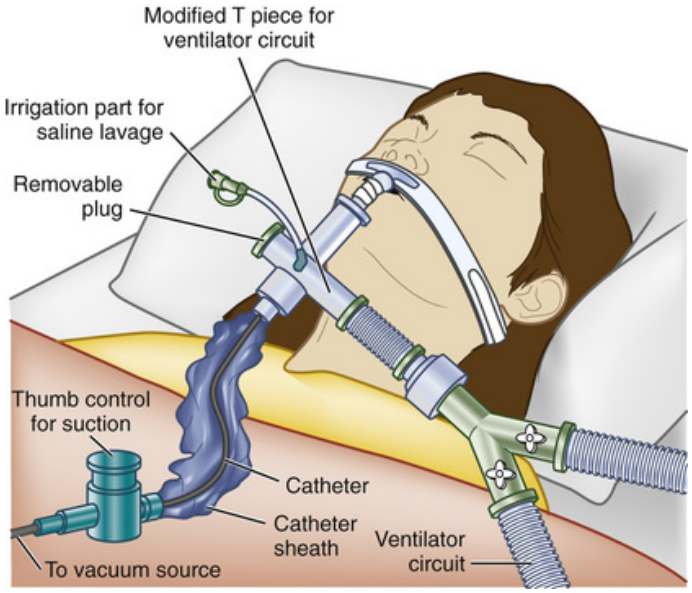

FIGURE 68-15 Closed tracheal suction system.

The ET tube is connected to either humidified air, O_2, or a mechanical ventilator. ABGs are obtained immediately after intubation to determine baseline oxygenation and ventilation status. ABG values are reviewed and used to guide oxygenation and ventilation changes. Continuous pulse oximetry and end-tidal CO_2 monitoring provide valuable data related to arterial oxygenation and ventilation.

Nursing Management Artificial Airway

Management of a patient with an artificial airway is often a shared responsibility between the nurse and the respiratory therapist, with specific management tasks determined by employer policy. Nursing responsibilities for the patient with an artificial airway may include some or all of the following: (a) maintaining correct tube placement, (b) maintaining proper cuff inflation, (c) monitoring oxygenation and ventilation, (d) maintaining tube patency, (e) assessing for complications, (f) providing oral care and maintaining skin integrity, and (g) fostering comfort and communication.

Maintaining Correct Tube Placement

The patient with an ET tube should be continuously monitored to ensure the tube remains in place. A tube that is dislodged could end up in the pharynx or enter the esophagus or the right mainstem bronchus (thus ventilating only the right lung).

Safety Alert

Endotracheal Tube Placement

- Proper ET tube position can be maintained by placing an "exit mark" on the tube.
- The mark must remain constant while the patient is at rest and during patient care, repositioning, and transport.

The chest wall must be observed for symmetrical movement and auscultated to confirm bilateral breath sounds. If the ET tube is not positioned properly, it is an emergency. The nurse should stay with the patient, maintain the airway, support ventilation, and call for the appropriate help to immediately reposition the tube. It may be necessary to ventilate the patient with a BVM and 100% O_2. If a dislodged tube is not repositioned, minimal or no O_2 is delivered to the lungs or the entire V_T is delivered to one lung. This places the patient at risk for pneumothorax.

Maintaining Proper Cuff Inflation

The cuff is an inflatable, pliable sleeve encircling the outer wall of the ET tube (see Figure 68-14). The high-volume, low-pressure cuff stabilizes and "seals" the ET tube within the trachea and prevents escape of ventilating gases. However, excess volume in the cuff can damage the tracheal mucosa. To avoid this, once the cuff is inflated with air, the cuff pressure should be measured and monitored. To ensure adequate tracheal perfusion, cuff pressure should be maintained at 20 to 25 cm H_2O (Lorente,

Lecuona, Jiménez, et al., 2014). It will need to be measured and recorded after intubation and on a routine basis (e.g., every 8 hours) using the *minimal occluding volume* (MOV) *technique* or *the minimal leak technique* (MLT).

The steps in the MOV technique for cuff inflation are as follows: (a) for the mechanically ventilated patient, a stethoscope is placed over the trachea and the cuff inflated to MOV by adding air until no air leak is heard at peak inspiratory pressure (end of ventilator inspiration); (b) for the spontaneously breathing patient, the cuff is inflated until no sound is heard after a deep breath or after inhalation with a BVM; (c) a manometer is used to verify that cuff pressure is between 20 and 25 cm H_2O; and (d) cuff pressure is recorded in the chart. If adequate cuff pressure cannot be maintained or larger volumes of air are needed to keep the cuff inflated, there could be a leak in the cuff or tracheal dilation at the cuff site. In these situations, the nurse should notify the physician to reposition or change the ET tube.

The procedure for MLT is similar with one exception: a small amount of air is removed from the cuff until a slight air leak is auscultated at peak inflation. Both techniques aim to prevent the risk for tracheal damage from high cuff pressures. The use of continuous cuff measurement is being studied (Sole, Su, Talbert, et al., 2011).

Monitoring Oxygenation and Ventilation

The patient with an ET tube is vigilantly monitored for adequate oxygenation through assessments of clinical findings, ABGs, SpO_2, and, if available, $ScvO_2/SvO_2$. The nurse should assess for signs of hypoxemia such as a change in mental status (e.g., confusion), anxiety, dusky skin, and dysrhythmias. Periodic ABGs (specifically partial pressure of oxygen in arterial blood [PaO_2]) and continuous SpO_2 provide objective data regarding oxygenation. Lower values are expected in patients with some disease states, such as chronic obstructive pulmonary disease (COPD).

Indicators of ventilation include clinical findings, partial pressure of carbon dioxide in arterial blood ($PaCO_2$), and continuous partial pressure of end-tidal CO_2 ($PETCO_2$). The nurse should assess the patient's respirations for rate, rhythm, and use of accessory muscles. The patient who is hyperventilating will be breathing rapidly and deeply and may experience circumoral and peripheral numbness and tingling. The patient who is hypoventilating will be breathing shallowly or slowly and may appear dusky. $PaCO_2$ is the best indicator of alveolar hyperventilation (e.g., decreased $PaCO_2$, increased pH indicate respiratory alkalosis) or hypoventilation (e.g., increased $PaCO_2$, decreased pH indicate respiratory acidosis).

$PETCO_2$ monitoring *(capnography)* is done by analyzing exhaled gas directly at the ventilator circuit *(mainstream sampling)* or by transporting a sample of gas via small-bore tubing to a bedside monitor *(sidestream sampling).* Continuous $PETCO_2$ monitoring can assess the patency of the airway and the presence of breathing. In addition, gradual changes in $PETCO_2$ values may accompany an increase in CO_2 production (e.g., sepsis, hypoventilation, neuro-muscular blockade) or a decrease in CO_2 production (e.g., hypothermia, decreased CO, metabolic acidosis). In patients

with normal ventilation-to-perfusion ratios (see Chapter 70), $PETCO_2$ can be used as an estimate of $PaCO_2$, with $PETCO_2$ generally 1 to 5 mm Hg lower than $PaCO_2$.

Maintaining Tube Patency

A patient should not be routinely suctioned; rather, the nurse should assess the patient regularly to determine if suctioning is needed. Indications for suctioning include (a) visible secretions in the ET tube, (b) sudden onset of respiratory distress, (c) suspected aspiration of secretions, (d) increase in peak airway pressures, (e) auscultation of adventitious breath sounds over the trachea or bronchi, (f) increase in respiratory rate or sustained coughing, and (g) sudden or gradual decrease in PaO_2 or SpO_2.

Table 68-8 describes two recommended suctioning methods: the closed-suction technique (CST) and the open-suction technique (OST). The CST uses a suction catheter that is enclosed in a plastic sleeve connected directly to the ventilator circuit (see Figure 68-15). With the CST, oxygenation and ventilation are maintained during suctioning, and exposure to the patient's secretions is reduced. The CST should be used for patients who (a) require high levels of positive end-expiratory pressure (PEEP) (greater than 10 cm H_2O), (b) have high levels of FiO_2, (c) have bloody or infected pulmonary secretions, (d) require frequent suctioning, or (e) experience clinical instability with the OST (Seckel, 2017).

TABLE 68-8
Suctioning Procedures for a Patient on a Mechanical Ventilator

General Measures
1. Gather all equipment. 2. Wash hands and don personal protective equipment. 3. Explain procedure and patient's role in assisting with secretion removal by coughing. 4. Monitor patient's cardiopulmonary status (e.g., vital signs, SpO_2, SvO_2, $ScvO_2$, ECG, level of consciousness) before, during, and after the procedure. 5. Turn on suction and set vacuum to 100 to 120 mm Hg. 6. Pause ventilator alarms.
Open-Suction Technique
1. Open sterile catheter package using the inside of the package as a sterile field. *Note:* Suction catheter should be no wider than half the diameter of the ET tube (e.g., for a 7-mm ET tube, select a 10-French suction catheter). 2. Fill the sterile solution container with sterile normal saline or water. 3. Don sterile gloves. 4. Pick up sterile suction catheter with the dominant hand. Using the nondominant hand, secure the connecting tube (to suction) to the suction catheter. 5. Check equipment for proper functioning by suctioning a small volume of sterile saline solution from the container. (Go to step 7.)
Closed-Suction Technique
6. Connect the suction tubing to the closed-suction port. 7. Hyperoxygenate the patient for 30 sec using one of the following methods: • Activate the suction hyperoxygenation setting on the ventilator using the nondominant hand. • Increase FiO_2 to 100%. *Note:* FiO_2 must be returned to baseline level at the completion of the procedure if not done automatically after preset time by ventilator. • Disconnect the ventilator tubing from the ET tube and manually ventilate the patient with 100% O_2 using a BVM device.* Administer 5 or 6 breaths over 30 sec. *Note*: Use of a second person to deliver the manual breaths will significantly increase the tidal volume delivered. 8. With suction off, gently and quickly insert the catheter using the dominant hand. When resistance is met, pull back 1 cm. 9. Apply continuous or intermittent suction using the nondominant thumb. Withdraw the catheter within 10 sec or less. 10. Hyperoxygenate for 30 sec as described in step 7. 11. If secretions remain and the patient has tolerated the procedure, perform two to three suction passes as described in steps 8 and 9. *Note:* Rinse the suction catheter with sterile saline solution between suctioning passes as needed. 12. Reconnect patient to ventilator (open-suction technique). 13. At the completion of ET tube suctioning, rinse the catheter and connecting tubing with the sterile saline solution. 14. Suction oral pharynx. *Note:* A separate catheter must be used for this step when using the closed-suction technique. 15. Discard the suction catheter, and rinse the connecting tubing with the sterile saline solution (open-suction technique). 16. Reset FiO_2 (if necessary) and ventilator alarms. 17. Reassess patient for signs of effective suctioning.

*Attach a PEEP valve to the BVM for patients on >5 cm H_2O PEEP.

BVM, bag–valve–mask; *ECG*, electrocardiogram; *ET*, endotracheal; *FiO_2*, fraction of inspired oxygen; *PEEP*, positive end-expiratory pressure; *$ScvO_2$*, central venous oxygen saturation; *SpO_2*, oxygen saturation; *SvO_2*, venous oxygen saturation.

Source: Adapted from Seckel, M. A. (2017). Suctioning: Endotracheal or tracheostomy tube. In D. L. Wiegand (Ed.), *AACN procedure manual for critical care* (7th ed.). St. Louis: Elsevier.

Potential complications associated with suctioning include hypoxemia, bronchospasm, increased intracranial pressure, dysrhythmias, hypertension, hypotension, mucosal damage, pulmonary bleeding, pain, and infection. The patient must be assessed closely before, during, and after the suctioning procedure. If the patient does not tolerate suctioning (e.g., decreased SpO_2, increased or decreased BP, sustained coughing, development of dysrhythmias), the procedure should be stopped and the patient hyperoxygenated until equilibration occurs before attempting another suction pass. Hypoxemia can be prevented by hyperoxygenating the patient before and after each suctioning pass and limiting each pass to 10

seconds or less (see Table 68-8). Both the ECG and SpO_2 should be assessed before, during, and after the suctioning procedure.

Causes of dysrhythmias during suctioning include (a) hypoxemia resulting in myocardial ischemia; (b) vagal stimulation caused by tracheal irritation; and (c) sympathetic nervous system stimulation caused by anxiety, discomfort, or pain. Dysrhythmias include tachydysrhythmias and bradydysrhythmias, premature beats, and asystole. If any new dysrhythmias develop, suctioning should be stopped. Excessive suctioning must be avoided in patients with severe hypoxemia or bradycardia.

Tracheal mucosal damage may occur because of excessive suction pressures (greater than 120 mm Hg), overly vigorous catheter insertion, or the characteristics of the suction catheter itself. Blood streaks or tissue shreds in aspirated secretions may indicate that mucosal damage has occurred. Mucosal damage increases the risk for infection and bleeding, particularly if the patient is receiving anticoagulants (Seckel, 2017). Trauma to the mucosa can be prevented by following the steps described in Table 68-8.

Secretions may be thick and difficult to suction because of inadequate hydration, inadequate humidification, infection, or inaccessibility of the left mainstem bronchus or lower airways. Adequately hydrating the patient (e.g., oral or IV fluids) and providing supplemental humidification of inspired gases may assist in thinning secretions. Instillation of normal saline into the ET tube is discouraged and may be harmful. If infection is the cause of thick secretions, the patient must receive appropriate antibiotics. Mobilization, postural drainage, percussion, and turning of the patient every 2 hours may help move secretions into larger airways.

Providing Oral Care and Maintaining Skin Integrity

When an oral ET tube is in place, the patient's mouth is always open. The nurse should moisten the lips, tongue, and gums with saline or water swabs to prevent mucosal drying. Proper oral care provides comfort and prevents injury to the gums and plaque formation (Table 68-9). Meticulous care is required to prevent skin breakdown on the face, lips, tongue, and nares because of pressure from the ET tube or bite block or the method used to secure the ET tube to the patient's face. The ET tube should be repositioned and retaped every 24 hours and as needed. This practice may be shared between the nurse and respiratory therapist or limited to the respiratory therapist.

TABLE 68-9

Oral Care Procedures for a Patient on a Mechanical Ventilator—General Measures

1. Gather all equipment.
2. Wash hands and don personal protective equipment.
3. Explain procedure to the patient and the family, if present.
4. Perform oral care using pediatric or adult soft toothbrushes at least twice a day by gently brushing to clean and remove plaque.
5. Use oral swabs with a 1.5% hydrogen peroxide solution q2–4h.

Note: Postoperative cardiac surgery patients are the only population in which use of 2% chlorhexidine gluconate is recommended twice a day.

6. Apply a mouth moisturizer to oral mucosa and lips with each cleaning.
7. Suction oral cavity and pharynx frequently. See Figure 68-16 for an example of an endotracheal tube that can provide continuous subglottic suctioning.

FIGURE 68-16 Continuous subglottal suctioning can be provided by the Hi-Lo Evac Tube. A dorsal lumen above the cuff allows for suctioning of secretions from the subglottic area. Source: © 2017 Medtronic. All rights reserved. Used with the permission of Medtronic.

Note

- All oral suction equipment and suction tubing should be changed q24h.
- The nondisposable oral suction apparatus should be rinsed with sterile normal saline after each use and placed on a dry paper towel.

Source: Adapted from Vollman, K. M., & Sole, M. L. (2011). Endotracheal tube and oral care. In D. L. Wiegand (Ed.), *AACN procedure manual for critical care* (6th ed., pp. 33–37). St. Louis: Elsevier.

For the nasally intubated patient, the nurse should remove the old tape or ties and clean the skin around the ET tube with saline-soaked gauze or cotton swabs. For the orally intubated patient, the nurse should remove the bite block (if present) and the old tape or ties. After providing oral hygiene, the nurse repositions the ET tube to the opposite side of the mouth, replaces the bite block (if appropriate), and reconfirms proper cuff inflation and tube placement. The ET tube is then secured again per employer policy. If a manufactured tube holder is used, the straps should be loosened, the area under the straps massaged, and then the straps reapplied. Two staff members should perform the repositioning procedure to prevent accidental

dislodgement. The patient must be monitored for any signs of respiratory distress throughout the procedure.

Fostering Comfort and Communication

Intubation is a major stressor for the patient (Wade, Hardy, Howell, et al., 2013). The intubated patient may experience anxiety from not being able to talk or not knowing what to expect.

The physical discomfort associated with ET intubation and mechanical ventilation often requires sedating the patient and giving an analgesic until the ET tube is no longer required. The patient may need morphine, lorazepam, propofol, or other sedatives to blunt the anxiety and discomfort related to intubation. The nurse should evaluate the drugs' effectiveness in achieving an acceptable level of patient comfort. In addition, relaxation techniques (e.g., music therapy) should be considered to complement drug therapy.

Complications of Endotracheal Intubation

Two major complications of ET intubation are unplanned extubation and aspiration. Unplanned *extubation* (i.e., removal of the ET tube from the trachea) can be a catastrophic event and usually complicates the patient's recovery. Unplanned extubations can be due to patient removal of the ET tube or accidental removal during movement or a procedure. Usually the unplanned extubation is obvious (the patient is holding the ET tube). Other times, the tip of the ET tube is in the hypopharynx or esophagus and the extubation is not so obvious.

Safety Alert—

Unplanned Extubation

The nurse should observe for signs of unplanned extubation, which can be a life-threatening event:

- Patient talking
- Activation of the low-pressure ventilator alarm
- Diminished or absent breath sounds
- Respiratory distress
- Gastric distension

The nurse is responsible for preventing unplanned extubation by ensuring that the ET tube is secured and observing and supporting the ET tube during repositioning, procedures, and patient transfers.

Should an unplanned extubation occur, the nurse should stay with the patient and call for help. Interventions are aimed at maintaining the patient's airway, supporting

ventilation (e.g., manually ventilating the patient with a BVM and 100% O_2), securing the appropriate assistance to immediately reintubate the patient (if necessary), and providing psychological support to the patient.

Aspiration is another potential hazard for the patient with an ET tube. The ET tube passes through the epiglottis, splinting it in an open position. Thus the intubated patient cannot protect the airway from aspiration. The high-volume, low-pressure ET or tracheal cuff cannot totally prevent the trickle of oral or gastric secretions into the trachea. Further, secretions collect above the cuff. When the cuff is deflated, those secretions can move into the lungs. Some ET tubes provide continuous suctioning of secretions above the cuff.

Oral intubation increases salivation, yet swallowing is difficult, so the nurse should suction the patient's mouth frequently using a tonsil-tip (Yankauer) suction catheter or a sterile single-use catheter. Other factors contributing to aspiration include improper cuff inflation, patient positioning, and tracheo-esophageal fistula. Patients with an ET tube are at risk for aspiration of gastric contents. Even when the cuff is properly inflated, precautions should be taken to prevent vomiting, which can lead to aspiration. Often, a nasogastric (NG) or an orogastric (OG) tube is inserted and connected to low, intermittent suction when a patient is first intubated. An OG tube is preferred over an NG tube to reduce the risk for sinusitis. All patients who are intubated or receiving enteral feedings must have the HOB elevated a minimum of 30 to 45 degrees unless medically contraindicated.

Mechanical Ventilation

Mechanical ventilation is the process by which the FiO_2 (21% [room air] or more) is moved in and out of the lungs by a machine. Mechanical ventilation is not curative. It is a means of supporting patients until they recover the ability to breathe independently. It can also serve as a bridge to long-term mechanical ventilation or to a decision being made to withdraw ventilatory support.

Indications for mechanical ventilation include (a) apnea or impending inability to breathe or protect the airway, (b) acute respiratory failure (see Chapter 70), (c) severe hypoxia, and (d) respiratory muscle fatigue (Burns, 2011a). Patients with chronic pulmonary disease and their caregivers should be given the opportunity to discuss mechanical ventilation before end-stage respiratory disease develops. The nurse should encourage all patients, particularly those with chronic illnesses, to discuss the subject with their families and health care providers. Patients should then record and place the results of these discussions in an advance directive. The decision to use, withhold, or withdraw mechanical ventilation must be made carefully, respecting the wishes of the patient and caregiver. When the health care team, patient, and caregiver disagree over the plan of care, the employer's ethics committee must be consulted for assistance.

Types of Mechanical Ventilation

The two major types of mechanical ventilation are negative-pressure and positive-pressure ventilation.

Negative-Pressure Ventilation.

Negative-pressure ventilation involves the use of chambers that encase the chest or body and surround it with intermittent subatmospheric (or negative) pressure. The "iron lung," developed during the polio epidemic, was the first form of negative-pressure ventilation. Intermittent negative pressure around the chest wall causes the chest to be pulled outward, reducing intrathoracic pressure. Air rushes in via the upper airway, which is outside the sealed chamber. Expiration is passive. The machine cycles off, allowing chest retraction. This type of ventilation is similar to normal ventilation in that decreased intrathoracic pressures produce inspiration, and expiration is passive. Negative-pressure ventilation is delivered by noninvasive ventilation and does not require an artificial airway.

Positive-Pressure Ventilation.

Positive-pressure ventilation (PPV) is the primary method used with acutely ill patients (Figure 68-17). During inspiration, the ventilator pushes air into the lungs under positive pressure. Unlike spontaneous ventilation, intrathoracic pressure is raised during lung inflation rather than lowered. Expiration occurs passively as in

normal expiration. Modes of PPV are categorized into two groups: volume and pressure ventilation (Goldsworthy & Graham, 2014).

FIGURE 68-17 Patient receiving mechanical ventilation. Source: Courtesy Draeger Medical.

Volume Ventilation.

With **volume ventilation,** a predetermined V_T is delivered with each inspiration, and the amount of pressure needed to deliver the breath varies based on compliance and resistance factors of the patient–ventilator system. Consequently, the V_T is consistent from breath to breath, but airway pressures vary.

Pressure Ventilation.

With *pressure ventilation*, the peak inspiratory pressure is predetermined, and the V_T delivered to the patient varies based on the selected pressure and compliance and resistance factors of the patient–ventilator system. With this understanding, careful attention must be given to the V_T to prevent unplanned hyperventilation or hypoventilation. For example, when the patient breathes out of synchrony with the ventilator, the pressure limit may be reached quickly, and the volume of gas delivered may be small. Initially, pressure ventilation was used only in stable patients being weaned from the ventilator. Today, pressure ventilation is frequently used to treat critically ill patients.

Settings of Mechanical Ventilators

Mechanical ventilator settings regulate rate, depth, and other characteristics of ventilation (Table 68-10). Settings are based on the patient's status (e.g., ABGs, ideal body weight, level of consciousness, muscle strength). The ventilator is tuned as finely as possible to match the patient's ventilatory pattern. Settings are evaluated and adjusted frequently until the patient achieves optimal ventilation. Some settings serve as a fail-safe mechanism, alerting staff to problems with ventilation. It is

important that the nurse check that all ventilator alarms are always on. Alarms alert the staff to potentially dangerous situations such as mechanical malfunction, apnea, unplanned extubation, or patient asynchrony with the ventilator (Table 68-11). On many ventilators, the alarms can be temporarily suspended or silenced for up to 2 minutes for suctioning or testing while a staff member is in the room. After that time, the alarm system automatically becomes functional again.

TABLE 68-10

Settings of Mechanical Ventilation

Parameter	Description
High-pressure limit	Regulates the maximal pressure the ventilator can generate to deliver the V_T; when the pressure limit is reached, the ventilator terminates the breath and spills the undelivered volume into the atmosphere; usual setting is 10–20 cm H_2O above peak inspiratory pressure
I : E ratio	Duration of inspiration (I) to duration of expiration (E); usual setting is 1 : 2 to 1 : 1.5 unless IRV is desired
Inspiratory flow rate and time	Speed with which the V_T is delivered; usual setting is 40–80 L/min and time is 0.8–1.2 sec
Oxygen concentration	Fraction of inspired oxygen (FiO_2) delivered to patient; may be set between 21% (essentially room air) and 100%; usually adjusted to maintain PaO_2 level >60 mm Hg or SpO_2 level >90%
Positive end-expiratory pressure (PEEP)	Positive pressure applied at the end of expiration of ventilator breaths; usual setting is 5 cm H_2O
Pressure support	Positive pressure used to augment patient's inspiratory pressure; usual setting is 6–18 cm H_2O
Respiratory rate (f)	Number of breaths the ventilator delivers per minute; usual setting is 6–20 breaths/min
Sensitivity	Determines the amount of effort the patient must generate to initiate a ventilator breath; it may be set for pressure triggering or flow triggering; usual setting for a pressure trigger is 0.5–1.5 cm H_2O below baseline pressure and for a flow trigger is 1–3 L/min below baseline flow
Tidal volume (V_T)	Volume of gas delivered to patient during each ventilator breath; usual volume is 6–10 mL/kg

IRV, inverse ratio ventilation; *PaO_2,* partial pressure of oxygen in arterial blood; *SpO_2,* oxygen saturation value obtained by pulse oximetry.

TABLE 68-11

Modes of Mechanical Ventilation

Volume Modes

Controlled Mandatory Ventilation (CMV) or Control Ventilation (CV)

In this mode, the ventilator provides all of the patient's minute ventilation. The clinician sets rate, tidal volume (V_T), inspiratory time, and positive end-expiratory pressure (PEEP). Generally, *PEEP* is used to describe those situations in which the patient is chemically relaxed or is paralyzed from a spinal cord or neuro-muscular disease and is therefore unable to initiate spontaneous breaths. The ventilator may be set on CMV, assist-control (AC), or synchronized intermittent mandatory ventilation (SIMV)—all these options provide volume breaths at the clinician-selected rate.

Assist-Control (ACV) or Assisted Mandatory Ventilation (AMV)

This option requires that a rate, V_T, inspiratory time, and PEEP be set for the patient. The ventilator sensitivity is also set, and when the patient initiates a spontaneous breath, a full-volume breath is delivered.

Intermittent Mandatory Ventilation (IMV) and Synchronized Intermittent Mandatory Ventilation (SIMV)

This mode requires that rate, V_T, inspiratory time, sensitivity, and PEEP be set by the clinician. In between "mandatory breaths," patients can spontaneously breathe at their own rates and V_T. With SIMV, the ventilator synchronizes the mandatory breaths with the patient's own inspirations.

Pressure Modes

Pressure-Support Ventilation (PSV)

This mode provides an augmented inspiration to a spontaneously breathing patient. With PSV, the clinician selects an inspiratory pressure level, PEEP, and sensitivity. When the patient initiates a breath, a high flow of gas is delivered to the preselected pressure level, and pressure is maintained throughout inspiration. The patient determines the parameters of V_T, rate, and inspiratory time.

Pressure-Controlled Inverse Ratio Ventilation (PC-IRV)

This mode combines pressure-limited ventilation with an inverse ratio of inspiration to expiration. The clinician selects the pressure level, the rate, the inspiratory time (1 : 1, 2 : 1, 3 : 1, 4 : 1), and the PEEP level. With the prolonged inspiratory times, auto-PEEP may result. The auto-PEEP may be a desirable outcome of the inverse ratios. Some clinicians use PC without IRV. Conventional inspiratory times are used, and rate, pressure level, and PEEP are selected.

Positive End-Expiratory Pressure (PEEP) and Continuous Positive Airway Pressure (CPAP)

PEEP

This ventilatory option creates positive pressure at end-exhalation. PEEP restores functional residual capacity (FRC). The term *PEEP* is used when end-expiratory pressure is provided during ventilator positive-pressure breaths.

CPAP

Similar to PEEP, CPAP restores FRC. This pressure is continuous during spontaneous breathing; no positive-pressure breaths are present.

Source: Modified from Burns, S. M. (2011). Ventilatory management: Volume and pressure modes. In D. L. Wiegand (Ed.), *AACN procedure manual for critical care* (6th ed., p. 266, Table 35-2). St. Louis: Mosby.

Modes of Volume Ventilation

The variable methods by which the patient and ventilator interact to deliver effective ventilation are called *ventilator modes.* The selected ventilator mode is based on how much WOB the patient should or can perform. *WOB* refers to inspiratory effort needed to overcome the elasticity and viscosity of the lungs along with the airway resistance. The mode is determined by the patient's ventilatory status, respiratory drive, and ABGs. Generally, ventilator modes are controlled or assisted.

With controlled ventilatory support, the ventilator does all of the WOB. With assisted ventilatory support, the ventilator and patient share the WOB. Historically, volume modes such as controlled mandatory ventilation (CMV), assist-control ventilation (ACV), and synchronized intermittent mandatory ventilation (SIMV)

have been used to treat critically ill patients. More recently, pressure modes such as pressure-support ventilation (PSV) and pressure-control inverse ratio ventilation (PC-IRV) have become more widespread (Burns, 2011a). Table 68-11 describes these ventilator modes.

Assist-Control Ventilation.

With **assist-control ventilation (ACV),** the ventilator delivers a preset V_T at a preset frequency. When the patient initiates a spontaneous breath, the ventilator senses a decrease in intrathoracic pressure and then delivers the preset V_T. The patient can breathe faster than the preset rate but not slower. This mode has the advantage of allowing the patient some control over ventilation while providing some assistance. ACV is used in patients with a variety of conditions, including neuro-muscular disorders (e.g., Guillain-Barré syndrome), pulmonary edema, and acute respiratory failure.

In the ACV mode, the patient has the potential for hypoventilation and hyperventilation. The spontaneously breathing patient can easily be overventilated, resulting in hyperventilation. If the volume or minimum rate is set low and the patient is apneic or weak, the patient will be hypoventilated. Thus these patients require vigilant assessment and monitoring of ventilatory status, including respiratory rate, ABGs, SpO_2, and $ScvO_2/SvO_2$. It is also important that the sensitivity or amount of negative pressure required to initiate a breath is appropriate to the patient's condition. For example, if it is too difficult for the patient to initiate a breath, the WOB is increased and the patient may tire or develop ventilator asynchrony (i.e., the patient "fights" the ventilator).

Synchronized Intermittent Mandatory Ventilation.

With *synchronized intermittent mandatory ventilation* (SIMV), the ventilator delivers a preset V_T at a preset frequency in synchrony with the patient's spontaneous breathing. Between ventilator-delivered breaths, the patient is able to breathe spontaneously through the ventilator circuit. Thus the patient receives the preset FiO_2 during the spontaneous breaths but self-regulates the rate and volume of those breaths. This mode of ventilation differs from ACV, in which all breaths are of the same preset volume. It is used during continuous ventilation and during weaning from the ventilator. SIMV may also be combined with PSV (described below). Potential benefits of SIMV include improved patient–ventilator synchrony, lower mean airway pressure, and prevention of muscle atrophy, as the patient takes on more of the WOB.

SIMV also has disadvantages. If spontaneous breathing decreases when the preset rate is low, ventilation might not be adequately supported. Only patients with regular, spontaneous breathing should use low-rate SIMV. Weaning with SIMV demands close monitoring and may take longer because the rate of breathing is gradually reduced. Patients being weaned from SIMV may also have increased muscle fatigue associated with spontaneous breathing efforts.

Modes of Pressure Ventilation

Pressure-Support Ventilation.

With **pressure-support ventilation (PSV),** positive pressure is applied to the airway only during inspiration and is used in conjunction with the patient's spontaneous respirations. The patient must be able to initiate a breath for this modality to be used. The level of positive airway pressure is preset so that the gas flow rate is greater than the patient's inspiratory flow rate. As the patient initiates a breath, the machine senses the spontaneous effort and supplies a rapid flow of gas at the initiation of the breath and variable flow throughout the breath. With PSV, the patient determines inspiratory length, V_T, and respiratory rate. V_T depends on the pressure level and airway compliance.

PSV is used with continuous ventilation and during weaning. PSV may also be used with SIMV during weaning. PSV is not used as a sole ventilatory support during acute respiratory failure because of the risk for hypoventilation. Advantages of PSV include increased patient comfort, decreased WOB (because inspiratory efforts are augmented), decreased O_2 consumption (because inspiratory work is reduced), and increased endurance conditioning (because the patient is exercising respiratory muscles).

Pressure-Control Inverse Ratio Ventilation.

Pressure-control inverse ratio ventilation (PC-IRV) combines pressure-limited ventilation with an inverse ratio of inspiration (I) to expiration (E). Some clinicians use PC without IRV. The I/E ratio is the ratio of duration of inspiration to the duration of expiration. This value is normally a ratio of 1 : 2. With IRV, the I/E ratio begins at 1 : 1 and may progress to 4 : 1. Prolonged positive pressure is applied, increasing inspiratory time. IRV progressively expands collapsed alveoli. The short expiratory time has a PEEP-like effect, preventing alveolar collapse. Because IRV imposes a nonphysiological breathing pattern, the patient requires sedation with or without paralysis. PC-IRV is indicated for patients with acute respiratory distress syndrome (ARDS) who continue to have refractory hypoxemia despite high levels of PEEP. Not all patients with poor oxygenation respond to PC-IRV.

Airway Pressure Release Ventilation.

Airway pressure release ventilation (APRV) permits spontaneous breathing at any point during the respiratory cycle with a preset continuous positive airway pressure (CPAP) with short timed pressure releases. The CPAP level (pressure high, pressure low) is adjusted to maintain oxygenation goals while the timed releases (time high, time low) are increased or decreased to meet ventilation goals. V_T is not a set variable and depends on the CPAP level, the patient's compliance and resistance, and spontaneous breathing effort. The mode is designed for patients with ARDS who need high pressure levels for alveolar recruitment (open collapsed alveoli). One

advantage of this mode is the ability to permit spontaneous respirations, which may reduce the need for deep sedation or paralytics.

Other Modes.

Improvements in ventilator technology have led to the development of additional pressure modes. However, because of the nonstandardization of these options, the names and features are manufacturer specific. The superiority of these modes has not been established. Some examples include *volume-assured pressure ventilation* and *adaptive support ventilation.*

Other Ventilatory Manoeuvres

Positive End-Expiratory Pressure.

Positive end-expiratory pressure (PEEP) is a ventilatory manoeuvre in which positive pressure is applied to the airway during exhalation. Normally during exhalation, airway pressure drops to zero, and exhalation occurs passively. With PEEP, exhalation remains passive, but pressure falls to a preset level, often 3 to 20 cm H_2O. Lung volume during expiration and between breaths is greater than normal with PEEP. This increases functional residual capacity (FRC) and often improves oxygenation with restoration of lung volume that normally remains at the end of passive exhalation. The mechanisms by which PEEP increases FRC and oxygenation include increased aeration of patent alveoli, aeration of previously collapsed alveoli, and prevention of alveolar collapse throughout the respiratory cycle.

PEEP is titrated to the point that oxygenation improves without compromising hemodynamics. This setting is termed *best* or *optimal PEEP.* Often, 5 cm H_2O PEEP (referred to as *physiological PEEP*) is used prophylactically to replace the glottic mechanism, help maintain a normal FRC, and prevent alveolar collapse. PEEP of 5 cm H_2O is also used for patients with a history of alveolar collapse during weaning. PEEP improves gas exchange, vital capacity, and inspiratory force when used during weaning.

In contrast, *auto-PEEP* is not purposely set on the ventilator but is a result of inadequate exhalation time. Auto-PEEP is additional PEEP over what is set by the health care provider. This additional PEEP may result in increased WOB, barotrauma, and hemodynamic instability. However, during some ventilator modes (e.g., PC-IRV), auto-PEEP may be desirable. Interventions to limit auto-PEEP include sedation and analgesia, large-diameter ET tube, bronchodilators, short inspiratory times, and decreased respiratory rates. Reducing water accumulation in the ventilator circuit by frequent emptying or use of heated circuits also limits auto-PEEP. In patients with short exhalation times and early airway closure (e.g., asthma), setting PEEP can offset auto-PEEP by splinting the airway open during exhalation and preventing "air trapping."

In general, the major purpose of PEEP is to maintain or improve oxygenation while limiting risk for O_2 toxicity. FiO_2 can often be reduced when PEEP is used. PEEP is indicated in lungs with diffuse disease, severe hypoxemia unresponsive to

FiO_2 greater than 50%, and loss of compliance or stiffness. It is used in pulmonary edema to provide a counter-pressure opposing fluid extravasation. The classic indication for PEEP therapy is ARDS (see Chapter 70). PEEP is contraindicated or used with extreme caution in patients with highly compliant lungs (e.g., COPD), unilateral or nonuniform disease, hypovolemia, and low CO. In these cases, the adverse effects of PEEP may outweigh any benefits.

Continuous Positive Airway Pressure.

Continuous positive airway pressure (CPAP) restores FRC and is similar to PEEP. However, the pressure in CPAP is delivered continuously during spontaneous breathing, thus preventing the patient's airway pressure from falling to zero. For example, if CPAP is 5 cm H_2O, airway pressure during expiration is 5 cm H_2O. During inspiration, 1 to 2 cm H_2O of negative pressure is generated, thus reducing airway pressure to 3 or 4 cm H_2O. The patient receiving SIMV with PEEP receives CPAP when breathing spontaneously. CPAP is commonly used in the treatment of severe obstructive sleep apnea or hypopnea (Burns, 2011b). A nasal mask attached to a high-flow blower is applied to maintain pressure in the airway and prevent airway collapse. An ET or tracheal tube can be used in place of the nasal mask. CPAP increases WOB because the patient must forcibly exhale against the CPAP. Therefore, it must be used with caution in patients with myocardial compromise.

Bilevel Positive Airway Pressure.

In addition to O_2, *bilevel positive airway pressure* (BiPAP) provides two levels of positive-pressure support: higher inspiratory positive airway pressure and lower expiratory positive airway pressure. It is a noninvasive modality and is delivered through a tight-fitting face mask, nasal mask, or nasal pillows. As with PSV delivered through an artificial airway, the patient must be able to spontaneously breathe and cooperate with this treatment (Burns, 2011b). BiPAP is used for COPD patients with heart failure and acute respiratory failure and for patients with sleep apnea. BiPAP may also be used after extubation to prevent reintubation. Patients with shock, altered mental status, or increased airway secretions are not candidates for BiPAP because of the risk for aspiration and the inability to remove the mask.

High-Frequency Oscillatory Ventilation.

High-frequency oscillatory ventilation (HFOV) involves delivery of a small V_T (usually 1 to 5 mL/kg of body weight) at a rapid respiratory rate (100 to 300 breaths/min) in an effort to recruit and maintain lung volume and reduce intrapulmonary shunting. One benefit of HFOV is the ability to support gas exchange at a fixed mean airway pressure while limiting the risk for ventilator-induced lung injury. HFOV has been widely accepted in neonatal and pediatric ICUs. It is used in adults for the treatment of refractory hypoxemia and ARDS (Ali & Ferguson, 2011). Patients receiving HFOV must be sedated and may be paralyzed to

suppress spontaneous respiration. All patients must receive concurrent sedation and analgesia if using a paralytic drug.

Nitric Oxide.

Nitric oxide (NO) is a gaseous molecule that is made intravascularly and participates in the regulation of pulmonary vascular tone. Inhibition of NO production results in pulmonary vasoconstriction, and administration of continuous inhaled NO results in pulmonary vasodilation. NO may be administered via an ET tube, a tracheostomy, or a face mask. Currently, NO is used in ARDS, as a diagnostic screening tool for pulmonary hypertension during a cardiac catheterization, and during or after cardiac surgery.

Prone Positioning.

Prone positioning is the repositioning of a patient from a supine or lateral position to a prone position (on the stomach, face down). This repositioning improves lung recruitment (re-expansion) through various mechanisms. Gravity reverses the effects of fluid in the dependent parts of the lungs as the patient is moved from supine to prone. The heart rests on the sternum, away from the lungs, contributing to an overall uniformity of pleural pressures. The prone position is a relatively safe (although nurse-intensive), supportive therapy used to improve oxygenation in critically ill patients with acute lung injury or ARDS (Henderson, Griesdale, Dominelli, et al., 2014).

Extracorporeal Membrane Oxygenation.

Extracorporeal membrane oxygenation (ECMO) is an alternative form of pulmonary support for the patient with severe respiratory failure. It is used more frequently in the pediatric and neonatal populations but is increasingly being used in adults. ECMO is a modification of cardiac bypass and involves partially removing blood from a patient with large-bore catheters, infusing O_2, removing CO_2, and returning the blood to the patient. This intensive therapy requires systemic anticoagulation and is a time-limited intervention. A skilled team of specialists, including a perfusionist, is required continuously at the bedside (Combes, Brodie, Bartlett, et al., 2014).

Complications of Positive-Pressure Ventilation

Although PPV may be essential to maintain ventilation and oxygenation, it can cause adverse effects. It is often difficult to distinguish complications of mechanical ventilation from the underlying disease.

Cardiovascular System.

PPV can affect circulation because of the transmission of increased mean airway pressure to the thoracic cavity. With increased intrathoracic pressure, thoracic

vessels are compressed. This compression results in decreased venous return to the heart, decreased left ventricular end-diastolic volume (preload), decreased CO, and hypotension. Mean airway pressure is further increased if titrating PEEP (greater than 5 cm H_2O) to improve oxygenation.

If the lungs are noncompliant (e.g., ARDS), airway pressures are not as easily transmitted to the heart and blood vessels. Thus effects of PPV on CO are reduced. Conversely, with compliant lungs (e.g., emphysema), there is increased danger of transmission of high airway pressures and negative effects on hemodynamics.

Compromised venous return by PPV is worsened by hypovolemia (e.g., hemorrhage) and decreased venous tone (e.g., sepsis, spinal shock). Restoration and maintenance of the circulating blood volume are important in minimizing cardiovascular complications.

Pulmonary System.

Complications of PPV affecting the pulmonary system include barotrauma, volutrauma, alveolar hypoventilation and hyperventilation, and ventilator-associated pneumonia.

Barotrauma.

As lung inflation pressures increase, risk of *barotrauma* increases. Patients with compliant lungs (e.g., COPD) are at greater risk for barotrauma, which results when the increased airway pressure distends the lungs and possibly ruptures fragile alveoli or emphysematous blebs. Patients with stiff lungs (e.g., ARDS) who are given high inspiratory pressures and high levels of PEEP (greater than 5 cm H_2O) and patients with lung abscesses resulting from necrotizing organisms (e.g., staphylococci) are also susceptible to barotrauma.

Air can escape into the pleural space from alveoli or interstitium and become trapped. Pleural pressure increases and collapses the lung, causing pneumothorax. (Chapter 30 discusses the clinical manifestations of pneumothorax.) The lungs receive air during inspiration but cannot expel it during expiration. Respiratory bronchioles are larger on inspiration than expiration. They may close on expiration, and air becomes trapped. With PPV, a simple pneumothorax can become a life-threatening tension pneumothorax. The mediastinum and contralateral lung are compressed, reducing CO. Immediate treatment of the pneumothorax is required. For some patients, chest tubes are placed prophylactically.

Pneumomediastinum usually begins with rupture of alveoli into the lung interstitium. Progressive air movement occurs into the mediastinum and subcutaneous neck tissue, and a pneumothorax often follows. New, unexplained subcutaneous emphysema is an indication for immediate chest radiography. Pneumomediastinum and subcutaneous emphysema may be too small to detect on a radiograph or to appear clinically before the development of a pneumothorax.

Volutrauma.

The concept of *volutrauma* in PPV relates to the lung injury that occurs when a large V_T is used to ventilate noncompliant lungs. Volutrauma results in alveolar fractures and movement of fluids and proteins into the alveolar spaces. Low-volume ventilation rather than pressure ventilation should be used in ARDS patients to protect the lungs.

Alveolar Hypoventilation.

Alveolar hypoventilation can be caused by inappropriate ventilator settings, leakage of air from the ventilator tubing or around the ET tube or tracheostomy cuff, lung secretions or obstruction, and low ventilation/perfusion ratio. A low V_T or respiratory rate decreases minute ventilation. This decrease results in hypoventilation and leads to respiratory acidosis. A leaking cuff or tubing that is not secured may cause air leakage, lowering the delivered V_T. Excess lung secretions can cause hypoventilation. Mobilizing the patient, turning the patient every 1 to 2 hours, providing chest physiotherapy to lung areas with increased secretions, encouraging deep breathing and coughing, and suctioning (as needed) may limit hypoventilation. Atelectasis may develop. Increasing the V_T, adding small increments of PEEP, and adding a preset number of sighs to the ventilator settings reduce the risk for atelectasis.

Alveolar Hyperventilation.

Respiratory alkalosis can occur if the respiratory rate or V_T is set too high *(mechanical overventilation)* or if the patient receiving assisted ventilation is *hyperventilating*. It is easy to overventilate a patient on PPV. Particularly at risk are patients with chronic alveolar hypoventilation and CO_2 retention. For example, the patient with COPD may have a chronic $PaCO_2$ elevation (acidosis) and compensatory bicarbonate retention by the kidneys. When the patient is ventilated, the patient's "normal baseline" rather than the standard normal values is the therapeutic goal. If the COPD patient is returned to a standard normal $PaCO_2$, the patient will develop alkalosis because of the retained bicarbonate. Such a patient could move from compensated respiratory acidosis to serious metabolic alkalosis. The presence of alkalosis makes weaning from the ventilator difficult. Alkalosis, especially if the onset is abrupt, can have additional serious consequences, including hypokalemia, hypocalcemia, and dysrhythmias. Neuro-muscular irritability, seizures, coma, and death can occur. Usually the patient with COPD who is supported on the ventilator does better with a short inspiratory and longer expiratory time.

If hyperventilation is spontaneous, it is important to determine the cause and treat it. Possible causes include hypoxemia, pain, fear, anxiety, or compensation for metabolic acidosis. Patients who fight the ventilator or breathe out of synchrony may be anxious or in pain. If the patient is anxious and fearful, the nurse can help by sitting with the patient and verbally coaching the patient to breathe with the ventilator. If these measures fail, manually ventilating the patient slowly with a BVM and 100% O_2 may slow breathing enough to bring it in synchrony with the ventilator.

Ventilator-Associated Pneumonia.

The risk for health care–associated pneumonia is highest in patients requiring mechanical ventilation because the ET or tracheostomy tube bypasses normal upper airway defences. In addition, a poor nutritional state, immobility, and the underlying disease process (e.g., immuno-suppression, organ failure) make the patient more prone to infection. *Ventilator-associated pneumonia* (VAP) is pneumonia that occurs 48 hours or more after ET intubation (Safer Healthcare Now, 2012). It occurs in 9% to 27% of all intubated patients, with half of the cases developing within the first 4 days of mechanical ventilation. In addition, patients who develop VAP have significantly longer hospital stays and higher mortality rates than those who do not.

In patients with early VAP (within 96 hours of mechanical ventilation), sputum cultures often grow Gram-negative bacteria (e.g., *Escherichia coli, Klebsiella, Streptococcus pneumoniae, Haemophilus influenzae*). Organisms associated with late VAP include antibiotic-resistant organisms such as *Pseudomonas aeruginosa* and oxacillin-resistant *Staphylococcus aureus.* These organisms are abundant in the hospital environment. They can spread in a number of ways, including contaminated respiratory equipment, inadequate handwashing, adverse environmental factors such as poor room ventilation and high traffic flow, and decreased patient ability to cough and clear secretions. Colonization of the oropharynx tract by Gram-negative organisms predisposes the patient to Gram-negative pneumonia.

Clinical evidence suggesting VAP includes fever, elevated white blood cell count, purulent or odorous sputum, crackles or rhonchi on auscultation, and pulmonary infiltrates noted on chest radiograph. The patient is treated with antibiotics after appropriate cultures are taken by tracheal suctioning or bronchoscopy and when infection is evident.

Guidelines on VAP prevention include (a) elevating the HOB a minimum of 30 to 45 degrees unless medically contraindicated, (b) avoiding routine changes of the patient's ventilator circuit tubing, and (c) using an ET tube with a dorsal lumen above the cuff to allow continuous suctioning of secretions in the subglottic area (Canadian Patient Safety Institute, 2016; Safer Healthcare Now, 2012). Prevention also includes strict handwashing before and after suctioning, after touching ventilator equipment, and after contact with any respiratory secretions (see "Nursing Management: Artificial Airway," earlier in this chapter). Always wear gloves when in contact with the patient and change gloves between activities (e.g., emptying urinary catheter drainage, hanging an IV drug). Finally, always drain the water as it collects in the ventilator tubing, keeping it away from the patient.

Sodium and Water Imbalance.

Progressive fluid retention often occurs after 48 to 72 hours of PPV, especially PPV with PEEP. Fluid retention is associated with decreased urine output and increased sodium retention. Fluid balance changes may be due to decreased CO, which in turn results in diminished renal perfusion. Consequently, renin release is stimulated with subsequent production of angiotensin and aldosterone (see Chapter 47, Figure 47-6).

This process results in sodium and water retention. It is also possible that pressure changes within the thorax are associated with decreased release of atrial natriuretic peptide, which also causes sodium retention. Mild water retention is also associated with PPV. Less insensible water loss occurs via the airway because ventilated delivered gases are humidified with body-temperature water. In addition, as a part of the stress response, the release of antidiuretic hormone and cortisol contributes to sodium and water retention.

Neurological System.

In patients with head injury, PPV (especially with PEEP) can impair cerebral blood flow. The increased intrathoracic positive pressure impedes venous drainage from the head, resulting in jugular venous distension. The patient may exhibit increases in intracranial pressure because of the impaired venous return and increase in cerebral volume. Elevating the HOB and keeping the patient's head in alignment may decrease the harmful effects of PPV on intracranial pressure.

Gastro-Intestinal System.

Patients receiving PPV are stressed because of the serious illness, immobility, or discomforts associated with the ventilator. This places the ventilated patient at risk for developing stress ulcers and GI bleeding. Patients with a pre-existing ulcer or those receiving corticosteroids are at an increased risk. Any kind of circulatory compromise, including reduction of CO caused by PPV, may contribute to ischemia of the gastric and intestinal mucosa and possibly increase the risk for translocation of GI bacteria.

To decrease the risk for VAP, guidelines support the use of routine peptic ulcer prophylaxis in mechanically ventilated patients (Plummer, Blaser, & Deane, 2014). Peptic ulcer prophylaxis includes the administration of histamine (H_2)-receptor blockers (e.g., ranitidine [Zantac]), proton pump inhibitors (PPIs) (e.g., esomeprazole [Nexium]), and enteral nutrition to decrease gastric acidity and diminish the risk for stress ulcer and hemorrhage.

Gastric and bowel dilation may occur because of gas accumulation in the GI tract from swallowed air. The irritation of an artificial airway may cause excessive air swallowing and subsequent gastric dilation. Gastric or bowel dilation may put pressure on the vena cava, decrease CO, and prohibit adequate diaphragmatic excursion during spontaneous breathing. Elevation of the diaphragm as a result of paralytic ileus or bowel dilation leads to compression of the lower lobes of the lungs. This compression may cause atelectasis and compromise respiratory function. Decompression of the stomach is done by inserting an OG or NG tube (Plummer, Blaser, & Deane, 2014).

Immobility, sedation, circulatory impairment, decreased oral intake, use of opioid pain medications, and stress contribute to decreased peristalsis. The patient's inability to exhale against a closed glottis may make defecation difficult. As a result, the ventilated patient is at risk for constipation, so a bowel regimen should be initiated.

Musculo-Skeletal System.

Maintenance of muscle strength and prevention of the problems associated with immobility are important. Adequate analgesia and nutrition can enhance exercise tolerance. Plans should be made for early and progressive mobility of appropriate patients receiving PPV. In collaboration with physiotherapists and occupational therapists, the nurse should perform passive and active exercises to maintain muscle tone in the upper and lower extremities. Simple manoeuvres such as leg lifts, knee bends, quadriceps setting, or arm circles are appropriate. Contractures, pressure ulcers, foot drop, and external rotation of the hip and legs can be prevented by proper positioning and the use of specialized mattresses or beds. For ventilating the patient during ambulation, a portable ventilator or manual ventilation with a BVM and 100% O_2 is appropriate.

Psychosocial Needs.

The patient receiving mechanical ventilation often experiences physical and emotional stress. In addition to the problems related to critical care patients discussed at the beginning of this chapter, the patient supported by a mechanical ventilator is unable to speak, eat, move, or breathe normally. Tubes and machines cause pain, fear, and anxiety. Usual activities of daily living such as eating, elimination, and coughing are extremely complicated. The nurse should involve patients and caregivers in decision making as much as possible.

Patients receiving PPV usually require sedation (e.g., propofol), analgesia (e.g., fentanyl), or both to facilitate optimal ventilation. Before initiating sedation or analgesia in the mechanically ventilated patient who is agitated or anxious, the nurse should identify the cause of distress. Common problems that can result in patient agitation or anxiety include PPV, nutritional deficits, pain, hypoxemia, hypercapnia, drugs, and environmental stressors (e.g., sleep deprivation). Delirium is an acute change in mental status. It is a marker of cerebral insufficiency and is associated with longer hospital stays and higher mortality rates. ICU patients are particularly vulnerable to delirium, and the nurse must make every effort to assess and treat it (Barr, Fraser, Puntillo, et al., 2013).

In some situations, the decision is made to paralyze the patient with a neuro-muscular blocking agent (e.g., cisatracurium) to provide more effective synchrony with the ventilator and improve oxygenation. Health care providers should remember that the paralyzed patient can hear, see, think, and feel. It is important to administer IV sedation and analgesia concurrently when the patient is paralyzed. Monitoring patients receiving these medications is challenging. Assessment of the patient should include train-of-four (TOF) testing, clinical assessment for physiological signs of pain or anxiety (changes in heart rate and BP), and ventilator synchrony. The TOF assessment involves using a peripheral nerve stimulator to deliver four successive stimulating currents to elicit muscle twitches (Figure 68-18). The number of twitches varies with the percentage of neuro-muscular blockade. The usual goal is one or two twitches out of four. Noninvasive electroencephalogram-based technology can also help guide sedative and analgesic therapy in these

patients. Excessive administration of neuro-muscular blocking agents may predispose the patient to prolonged paralysis and muscle weakness even after these agents are stopped.

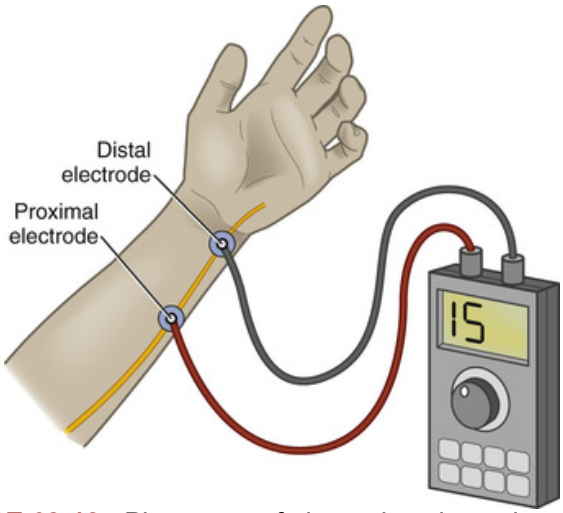

FIGURE 68-18 Placement of electrodes along ulnar nerve.

Many patients have few memories of their time in the ICU, whereas others remember vivid details. Although appearing to be asleep, sedated, or paralyzed, patients may be aware of their surroundings, so health care providers should always address them as if they were awake and alert (Desai, Law, & Needham, 2011).

Machine Disconnection or Malfunction.

Mechanical ventilators may become disconnected or malfunction. When turned on and operative, alarms alert the nurse to problems (Table 68-12). Most deaths from accidental ventilator disconnection occur while the alarm is off, and most accidental disconnections in critical care settings are discovered by low-pressure alarms. The most frequent site for disconnection is between the tracheal tube and the adapter. Connections should be pushed together and then twisted to ensure they are secure. Alarms should be set at all times, and the nurse should chart that this is the case. Alarms can be paused (not inactivated) during suctioning or removal from the ventilator but must be reactivated before the nurse leaves the patient's bedside.

TABLE 68-12
Interpreting Mechanical Ventilation Alarms

Alarm	Possible Causes
Apnea	Change in patient condition Loss of airway (e.g., total or partial extubation) Oversedation Respiratory arrest
High tidal volume, minute ventilation, or respiratory rate	Change in patient condition Excess condensate (water) in tubing (i.e., false reading) Pain, anxiety
High-pressure limit	Condensate in tubing Decreased compliance (e.g., pulmonary edema, pneumothorax) Increased resistance (e.g., bronchospasm) Kinked or compressed tubing (e.g., patient biting on ET tube) Patient fighting ventilator (ventilator asynchrony) Secretions, coughing, or gagging
Low tidal volume or minute ventilation	Change in patient's breathing efforts (e.g., rate and volume) ET tube or tracheal cuff leak (e.g., patient speaking, grunting) Insufficient gas flow Patient disconnection, loose connection, or leak in circuit
Low-pressure limit	ET tube or tracheal cuff leak (e.g., patient speaking, grunting) Loss of airway (e.g., total or partial extubation) Total or partial ventilator disconnect
Ventilator inoperative or low battery	Machine malfunction Unplugged, power failure, or internal battery not charged

ET, endotracheal.

Source: Adapted from Pierce, L.N. (2007). *Management of the mechanically ventilated patient* (2nd ed.). St. Louis: Saunders.

Ventilator malfunction may occur due to several factors. Although most institutions have emergency generators in the event of a power failure and newer ventilators may have battery backup, power failure is always a possibility. A plan should be in place for manually ventilating all patients who depend on a ventilator. If, at any time, the ventilator is determined to be malfunctioning (e.g., failure of O_2 supply), the patient should be disconnected from the machine and manually ventilated with a BVM and 100% O_2 until the ventilator is fixed or replaced.

Weaning From Positive-Pressure Ventilation and Extubation

Weaning is the process of reducing ventilator support and resuming spontaneous ventilation. The weaning process differs for patients requiring short-term ventilation (up to 3 days) than for those requiring long-term ventilation (longer than 3 days). Patients requiring short-term ventilation (e.g., after cardiac surgery) experience a linear weaning process. Patients likely to require prolonged PPV (e.g., patients with COPD who develop respiratory failure) often experience a weaning process that consists of peaks and valleys. Preparation for weaning begins when PPV is initiated and involves a team approach (e.g., nurse, physician, patient, caregiver, dietitian, respiratory therapist, physiotherapist).

Weaning generally consists of three phases: the *preweaning phase*, the *weaning process*, and the *outcome phase*. The preweaning, or assessment, phase determines the patient's ability to breathe spontaneously. Assessment in this phase depends on a combination of respiratory (Table 68-13) and nonrespiratory factors. Weaning

assessment parameters should include criteria to assess muscle strength (negative inspiratory force) and endurance (spontaneous V_T, vital capacity, minute ventilation, and rapid shallow breathing index). In addition, the patient's lungs should be reasonably clear on auscultation and chest radiograph. Nonrespiratory factors include the patient's neurological status; hemodynamics; fluid, electrolytes, and acid–base balance; nutrition; and hemoglobin. It is important to have an alert, well-rested, and well-informed patient relatively free from pain and anxiety who can cooperate with the weaning plan. This does not mean complete withdrawal from sedatives or analgesics. Instead, drugs should be titrated to achieve comfort without causing excessive drowsiness.

TABLE 68-13
Indicators for Weaning

Weaning Readiness

Patients receiving mechanical ventilation for respiratory failure should undergo a formal assessment of weaning potential if the following are satisfied:*

1. Reversal of the underlying cause of respiratory failure
2. Adequate oxygenation:
   PaO_2 >80–100
   FiO_2 ≤40%–50%
   PEEP ≤5–8 cm H_2O
   pH ≥7.25
3. Hemodynamic stability:
   Absence of clinically significant hypotension (low-dose or no vasopressor therapy)
   Absence of myocardial ischemia
4. Patient ability to initiate an inspiratory effort

Weaning Assessment

Measurement	Significance	Normal Values	Indices for Weaning
Compliance, rate, oxygenation, and pressure (CROP) index	Combined index that is complex to calculate C_{Dyn} = Compliance C_{Dyn} × NIF × (PaO_2/PAO_2)/f PaO_2/PAO_2 = Oxygenation ratio of arterial O_2/alveolar O_2	Not applicable	>13
Minute ventilation (V_E)	Tidal volume (V_T) multiplied by respiratory rate over 1 min For example: 0.350 (V_T) × 28 (f) = 8.8 L/min	5–10 L/min	≤10 L/min
Negative inspiratory force (NIF) or pressure (NIP)	Amount of negative pressure that a patient is able to generate to initiate spontaneous respirations Measured by clinician: After complete occlusion of inspiratory valve, a pressure manometer is attached to airway or mouth for 10–20 sec while negative inspiratory efforts are noted	−75 to −100 cm H_2O	>−20 cm H_2O The more negative the number, the better indication for weaning.
Positive expiratory pressure (PEP)	Measure of expiratory muscle strength and ability to cough. Measured by clinician: After complete occlusion of expiratory valve, a pressure manometer is attached to the airway or mouth for 10–20 sec while positive expiratory efforts are noted	60–85 cm H_2O	≥30 cm H_2O
Rapid shallow breathing index (f/V_T)	Spontaneous respiratory rate over 1 min divided by tidal volume (in L) Easier calculation and more widely used For example: 30 (f)/0.400 (V_T) = 75/L	60–105/L	<105/L
Spontaneous respiratory rate (f)	Respiratory rate and frequency >1 min	12–20 min	<38 min
Spontaneous tidal volume (V_T)	Amount of air exchanged during normal breathing at rest; measure of muscle endurance	7–9 mL/kg	≥5 mL/kg
Vital capacity (VC)	Maximum inspiration and then measurement of air during maximal forced expiration; measure of respiratory muscle endurance or reserve or both; requires patient cooperation	65–75 mL/kg	≥10–15 mL/kg

*The decision to use these criteria must be individualized to the patient.

C_{Dyn}, dynamic compliance; *(f),* spontaneous respiratory rate; *FiO_2,* fraction of inspired oxygen; *NIF,* negative inspiratory force; *PaO_2,* partial pressure of oxygen in arterial blood; *PAO_2*; *PEEP,* positive end-expiratory pressure.

Evidence-based guidelines for weaning and discontinuing ventilatory support. *Chest, 120*(6 Suppl), 375S–395S; and Burns, S. M. (2011). Weaning process. In D. L. Wiegand (Ed.), *AACN procedure manual for critical care* (6th ed., pp. 291–300). St. Louis: Elsevier.

A *spontaneous breathing trial* (SBT) is recommended for patients who demonstrate weaning readiness (Burns, 2011c). An SBT should be at least 30 minutes but no more than 120 minutes. It may be done with low levels of CPAP, low levels of PSV, or a T-

piece. Tolerance of the trial may lead to extubation. Failure to tolerate an SBT should prompt a search for reversible or complicating factors and a return to a nonfatiguing ventilator modality for the patient. The SBT should be reattempted the next day.

The use of a weaning protocol decreases ventilator days. The parts of a protocol are not as important as the use of a protocol to prevent delays in weaning. Patients receiving SIMV can have the ventilator breaths gradually reduced as their ventilatory status permits. CPAP or PSV can be added to SIMV. PSV is thought to provide gentle, slow respiratory muscle conditioning. It may be especially beneficial for patients who are deconditioned or have heart problems. Some patients may be weaned by simply providing humidified oxygen (T-piece or flow-by method).

Weaning may be tried at any time of day, although it is usually done during the day, with the patient ventilated at night in a rest mode. The rest mode should be a stable, nonfatiguing, and comfortable form of support for the patient. Regardless of the weaning mode selected, all health care team members should be familiar with the weaning plan. Additionally, it is important to permit the patient's respiratory muscles to rest between weaning trials. Once the respiratory muscles become fatigued, they may require 12 to 24 hours to recover.

The patient being weaned and the caregiver need ongoing emotional support. The nurse should explain the weaning process to them and keep them informed of progress. For the weaning trial, the patient should be in a comfortable sitting or semirecumbent position. Baseline vital signs and respiratory parameters are obtained, and, during the trial, the nurse closely monitors the patient for signs and symptoms that may signal intolerance and a need to end the trial (e.g., tachypnea, dyspnea, tachycardia, dysrhythmias, sustained desaturation [SpO_2 less than 91%], hypertension or hypotension, agitation, diaphoresis, anxiety, sustained V_T less than 5 mL/kg, changes in mentation). The patient's tolerance throughout the weaning process should be documented, including statements regarding the patient's and the caregiver's perceptions.

The *weaning outcome phase* is the period when the patient is extubated or weaning is stopped because no further progress is being made. The patient who is ready for extubation should receive hyperoxygenation and suctioning (e.g., oropharynx, ET tube). For extubation, the nurse instructs the patient to take a deep breath and, at the peak of inspiration, deflates the cuff and removes the tube in one motion. After the tube has been removed, the nurse encourages the patient to deep-breathe and cough and suctions the oropharynx as needed. Supplemental O_2 should be administered, and naso-oral care provided. The patient's vital signs, respiratory status, and oxygenation must be carefully monitored immediately after extubation, within 1 hour, and per institution policy. If the patient does not tolerate extubation, immediate reintubation or a trial of noninvasive ventilation may be necessary.

Chronic Mechanical Ventilation

Mechanical ventilators are no longer limited to the ICU but are now a part of long-term and home care. In some instances, terminally ill, ventilated patients may be

discharged to hospice. The success of home mechanical ventilation depends, in part, on careful predischarge assessment and planning for both the patient and caregivers.

Both negative-pressure and positive-pressure ventilators are used in the home. Negative-pressure ventilators do not require an artificial airway and are less complicated to use. Several types of small, portable (battery-powered) positive-pressure ventilators are available and can be attached to a wheelchair or placed on a bedside table. Settings and alarms on these ventilators are simpler to use than on standard ICU ventilators.

Home mechanical ventilation has advantages and disadvantages. Having the patient in the home eliminates the strain that the hospital setting imposes on family dynamics. Caregivers' feelings of helplessness when they first hear about the necessity for long-term mechanical ventilation is frequently balanced by the opportunity to participate in the patient's care in the home setting. At home, the patient may be able to take part in more activities of daily living around an individualized schedule and, because of the smaller size of the home ventilator, be more mobile. Another advantage of home mechanical ventilation is the reduced risk for HAIs.

Disadvantages of home mechanical ventilation include problems related to equipment, reimbursement, caregiver stress and fatigue, and the patient's complex needs. Ventilated patients are usually dependent, requiring extensive nursing care, at least initially. Disposable products may not be reimbursable. Financial resources must be carefully assessed when arranging home mechanical ventilation. A meeting with the discharge team should be scheduled before a teaching plan for discharge is initiated.

Another disadvantage of home mechanical ventilation is its potential impact on the family. Caregivers may seem enthusiastic about caring for their loved one in the home but may be motivated by numerous, complex factors. They may not understand the sacrifices they may have to make financially and in personal time and commitment. Caregivers should be encouraged to consider respite care to periodically relieve their stress and fatigue.

Nursing Management Mechanical Ventilation

Nursing Care Plan (NCP) 68-1 for the patient receiving mechanical ventilation is available on the Evolve website for this chapter.

Other Critical Care Content

Table 68-14 lists additional critical care content presented in other chapters of this book.

Case Study

Critical Care and Mechanical Ventilation

Source: Kulniz/Shutterstock.com.

Patient Profile

Richard Kincaid is a 72-year-old man who collapsed on the street. He was unresponsive on admission and remains in the same state. He has an oral ET tube in place and is receiving mechanical ventilation. He weighs 90 kg. A subclavian central line was placed to monitor CVP and administer fluids.

Subjective Data

None; patient is unresponsive to painful stimuli.

Objective Data

Physical Examination

- Noninvasive BP is 100/75 mm Hg; heart rate is 128 (atrial fibrillation with a rapid ventricular response); temperature is 38.8°C; SpO_2 is 98%.
- Purulent secretions from ET tube.
- Breath sounds: rhonchi bilaterally, decreased breath sounds on the right.

Diagnostic Studies

- Chest radiography reveals right lower lung consolidation.
- ABGs: pH 7.48; PaO_2: 94 mm Hg; $PaCO_2$: 30 mm Hg; bicarbonate (HCO_3) 34 mmol/L.
- Computed tomography (CT) scan is positive for massive cerebro-vascular accident.

Collaborative Care

- Positive-pressure ventilation settings: assist-control mode
- Settings: FiO_2 70%, V_T 700 mL, respiratory rate 16 breaths/min, PEEP 5 cm H_2O
- Enteral feeding at 25 mL/hr via small-bore feeding tube
- In-dwelling urinary catheter to bedside drainage
- HOB elevated at 40 degrees

- Position change every 2 hours
- Chest physical therapy performed every 2 to 4 hours
- Azithromycin (Zithromax) 500 mg intravenously q24h
- Cefotaxime (Claforan) 2 g intravenously q6h
- 5% dextrose in normal saline (D5NS) with potassium chloride (KCl) 20 mmol/L at 100 mL/hr

Discussion Questions

1. Identify two reasons for intubating and providing mechanical ventilation for Mr. Kincaid.
2. What do Mr. Kincaid's ABGs indicate, and which ventilator setting(s) should be changed?
3. What is his PaO_2/FiO_2 ratio and what does it signify?
4. Mr. Kincaid's BP drops to 80 mm Hg, and he remains in atrial fibrillation with a ventricular rate of 158. A PA catheter is inserted for further hemodynamic monitoring. What would be the purpose of hemodynamic monitoring (in addition to CVP monitoring) in this patient?
5. ***Priority decision:*** What are the two priority nursing considerations for a patient with a PA catheter?
6. Mr. Kincaid's initial PAOP is 14 mm Hg, CI is 2 L/min/m^2, and systemic vascular resistance index (SVRI) is 2 667 dynes/sec/cm^{-5}/m^2. How would the nurse interpret these values? What medical interventions would the nurse anticipate?
7. Mr. Kincaid's pulmonary condition deteriorates. PaO_2 drops to 70 mm Hg, and SpO_2 is 89%. PEEP is increased to 7.5 cm H_2O. What implications does this have for Mr. Kincaid given his hemodynamic status?
8. Based on the data presented, what are the actual and potential problems that the nurse can identify with this patient?
9. ***Evidence-informed practice:*** Mr. Kincaid's family wants to know why he is getting tube feedings. What should the nurse tell the family? What is the evidence to support the use of tube feedings?
10. After 4 days, Mr. Kincaid remains unresponsive and has developed renal failure. The physician believes the patient will not recover and wishes to discuss goals of care with the patient's caregiver. What would be the nurse's role in this meeting?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. What does a certification in critical care by the Canadian Nurses Association indicate?
   a. Has earned a master's degree in the field of providing advanced critical care nursing
   b. Is an advanced-practice nurse in the care of acutely ill clients
   c. May practise independently to provide symptom management for the critically ill
   d. Has practised in critical care and successfully completed a test of critical care knowledge
2. What are the appropriate nursing interventions for the client with delirium in the ICU? *(Select all that apply)*
   a. Use clocks and calendars to maintain orientation.
   b. Encourage round-the-clock presence of caregivers at the bedside.
   c. Sedate the client with appropriate drugs to protect the client from harmful behaviours.
   d. Silence all alarms, reduce overhead paging, and avoid conversations around the client.
   e. Identify physiological factors that may be contributing to the client's confusion and irritability.
3. What is the most ideal plan for family involvement in the ICU?
   a. Having a family member at the bedside at all times
   b. Allowing family at the bedside at brief intervals
   c. Devising an individual plan with family involved with care and comfort measures
   d. Restricting visitation in the ICU because the environment is overwhelming to visitors
4. In hemodynamic monitoring, what does zeroing refer to, and which one of the following does the nurse zero to?
   a. Cardiac output (CO) monitoring system to the level of the left ventricle
   b. Pressure monitoring system to the level of the catheter tip located in the client
   c. Pressure monitoring system to the level of the atrium, identified as the midaxillary line
   d. Pressure monitoring system to the level of the atrium, identified as the phlebostatic axis
5. What hemodynamic changes should the nurse expect to find after successful initiation of intra-aortic balloon pump use in a client in cardiogenic shock?

a. Decreased wedge and increased CO

b. Decreased systemic vascular resistance and decreased stroke volume

c. Increased diastolic blood pressure (BP) and decreased systolic BP

d. Decreased central venous pressure and increased right atrial pressure

6. What nursing management should be included for the client with an artificial airway?

a. Routine suctioning of the tube at least every 2 hours

b. Observing for cardiac dysrhythmias during suctioning

c. Maintaining endotracheal tube cuff pressure at 30 cm H_2O

d. Preventing tube dislodgement by limiting mouth care to lubrication of the lips

7. What is the purpose of adding positive end-expiratory pressure to positive-pressure ventilation?

a. To increase functional residual capacity and improve oxygenation

b. To increase fraction of inspired oxygen in an attempt to wean the client and avoid oxygen toxicity

c. To determine whether the client is able to be weaned and avoid the risk of pneumomediastinum

d. To determine whether the client is in synchrony with the ventilator or needs to be paralyzed

8. For what should the nurse monitor the client with positive-pressure mechanical ventilation?

a. Paralytic ileus because pressure on the abdominal contents affects bowel motility

b. Diuresis and sodium depletion because of increased release of atrial natriuretic peptide

c. Signs of cardiovascular insufficiency because pressure in the chest impedes venous return

d. Respiratory acidosis in a client with chronic obstructive pulmonary disease because of alveolar hyperventilation and increased arterial partial pressure of oxygen levels

1. d; 2. a, c, e; 3. c; 4. d; 5. a; 6. b; 7. a; 8. c.

CHAPTER 69

Nursing Management

Shock, Systemic Inflammatory Response Syndrome, and Multiple-Organ Dysfunction Syndrome

Written by, Maureen A. Seckel

Adapted by, Janet A. Piper

LEARNING OBJECTIVES

1. Relate the pathophysiology to the clinical manifestations of the different types of shock: cardiogenic, hypovolemic, distributive, and obstructive.
2. Compare the effects of shock, systemic inflammatory response syndrome (SIRS), and multiple-organ dysfunction syndrome (MODS) on the major body systems.
3. Compare the collaborative care, drug therapy, and nursing management of patients experiencing different types of shock.
4. Describe the nursing management of a patient experiencing multiple-organ dysfunction syndrome (MODS).

KEY TERMS

anaphylactic shock, p. 1764
cardiogenic shock, p. 1760

hypovolemic shock, p. 1760

multiple-organ dysfunction syndrome (MODS), p. 1777

neurogenic shock, p. 1763

sepsis, p. 1764

septic shock, p. 1764

severe sepsis, p. 1764

shock, p. 1759

systemic inflammatory response syndrome (SIRS), p. 1777

Shock, systemic inflammatory response syndrome (SIRS), and multiple-organ dysfunction syndrome (MODS) are serious and interrelated problems. Figure 69-1 shows the relationship of how shock can lead to the development of SIRS and then MODS. This chapter provides an overview and related management of shock, SIRS, and MODS.

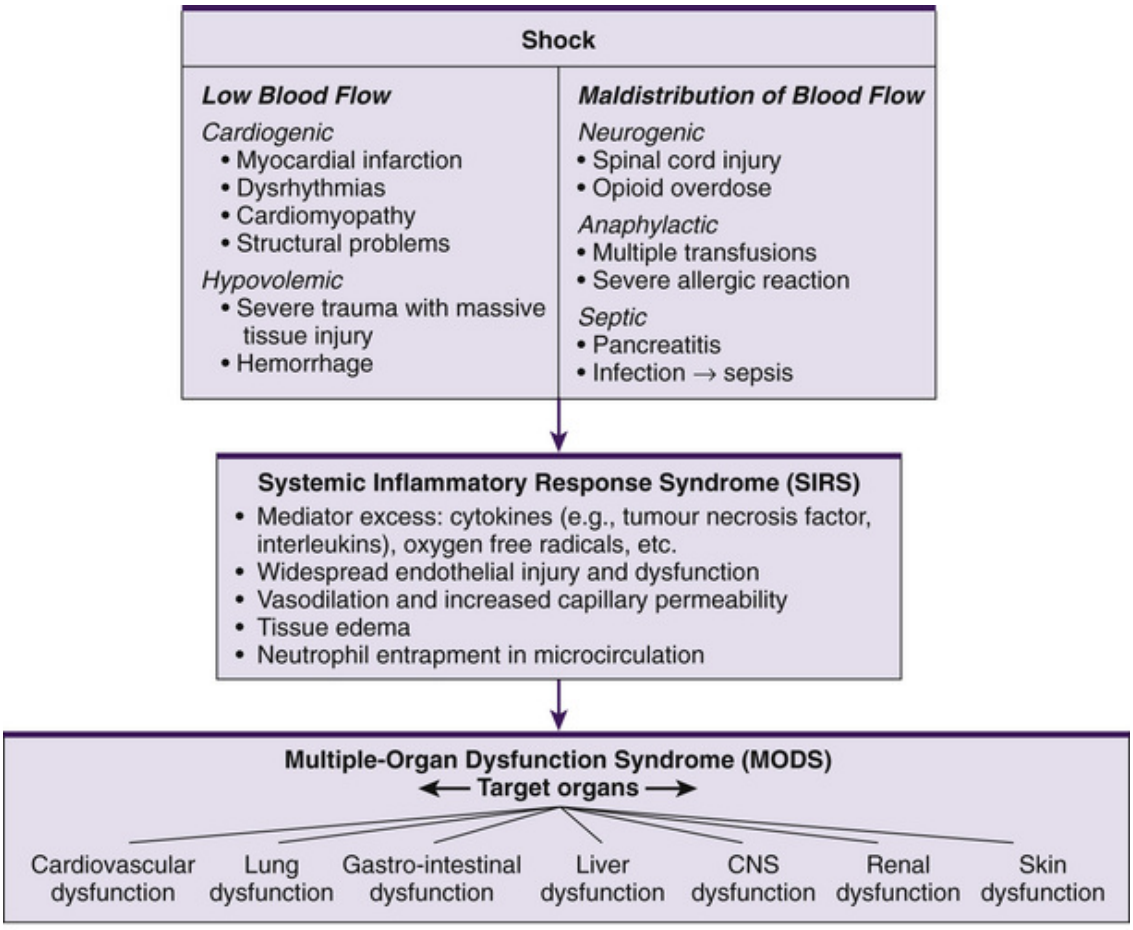

FIGURE 69-1 Relationship of shock, systemic inflammatory response syndrome, and multiple-organ dysfunction syndrome. *CNS,* central nervous system.

Shock

Shock is a syndrome characterized by decreased tissue perfusion and impaired cellular metabolism. This condition results in an imbalance between the supply of and the demand for oxygen and nutrients. The exchange of oxygen and nutrients at the cellular level is essential for life. When cells experience hypoperfusion, the demand for oxygen and nutrients exceeds the supply at the microcirculatory level.

Classification of Shock

Although the cause, the initial presentation, and the management strategies of the various types of shock differ, the physiological responses of the cell to hypoperfusion are similar. Shock may be classified as *low flow*—cardiogenic and hypovolemic shock—or *distributive*—neurogenic, anaphylactic, and septic shock (Lawrence, 2011). Classification details are listed in Table 69-1.

TABLE 69-1
CLASSIFICATION OF SHOCK STATES

Types and Causes	Examples
Cardiogenic Shock	
Diastolic dysfunction: inability of the heart to fill	Cardiac tamponade, ventricular hypertrophy, cardiomyopathy
Dysrhythmias	Bradydysrhythmias, tachydysrhythmias
Structural factors	Valvular stenosis or regurgitation, ventricular septal rupture, tension pneumothorax
Systolic dysfunction: inability of the heart to pump blood forward	Myocardial infarction, cardiomyopathy, blunt cardiac injury, severe systemic or pulmonary hypertension, myocardial depression from metabolic problems
Hypovolemic Shock	
Absolute Hypovolemia	
External loss of whole blood	Hemorrhage from trauma, surgery, gastro-intestinal bleeding
Loss of other body fluids	Vomiting, diarrhea, excessive diuresis, diabetes insipidus, diabetes mellitus
Relative Hypovolemia	
Fluid shifts	Burn injuries, ascites
Internal bleeding	Fracture of long bones, ruptured spleen, hemothorax, severe pancreatitis
Massive vasodilation	Sepsis
Pooling of blood or fluids	Bowel obstruction
Distributive Shock	
Neurogenic Shock	
Hemodynamic consequence of spinal cord injury or disease at or above T5 Spinal anaesthesia Vasomotor centre depression	Severe pain, drugs, hypoglycemia, injury
Anaphylactic Shock	
Hypersensitivity (allergic) reaction to a sensitizing substance	Contrast media, blood or blood products, drugs, insect bites, anaesthetic agents, food or food additives, vaccines, environmental agents, latex
Septic Shock	
At-risk patients	Older adults, patients with chronic diseases (e.g., diabetes mellitus, chronic kidney disease, heart failure), patients receiving immuno-suppressive therapy or who are malnourished or debilitated
Infection	Pneumonia, peritonitis, urinary tract, invasive procedures, indwelling lines and catheters

Shock Caused by Low Blood Flow

Cardiogenic Shock.

Cardiogenic shock occurs when either systolic or diastolic dysfunction of the pumping action of the heart results in compromised cardiac output (CO). Causes of cardiogenic shock are listed in Table 69-1. Mortality rates for patients with cardiogenic shock approach 60% (Patel & Hollenberg, 2011).

The heart's inability to pump the blood forward is classified as *systolic dysfunction*. Systolic dysfunction affects primarily the left ventricle because systolic pressure and tension are greater in the left chambers of the heart. When systolic dysfunction affects the right chambers of the heart, blood flow through the pulmonary circulation is compromised. Extensive left ventricular infarction and subsequent ventricular failure account for more than 75% of all cases of cardiogenic shock, and the prognosis is extremely poor. *Diastolic dysfunction* impairs the ability of the right or left ventricle to fill during diastole. Decreased filling of the ventricle results in decreased stroke volume (McAtee, 2011).

Figure 69-2 describes the pathophysiology of cardiogenic shock. Whether the initiating event is myocardial dysfunction, a structural problem (e.g., valvular abnormality, ventricular septal rupture, tension pneumothorax), or dysrhythmias, the physiological responses are similar —both tissue perfusion and cellular metabolism are impaired.

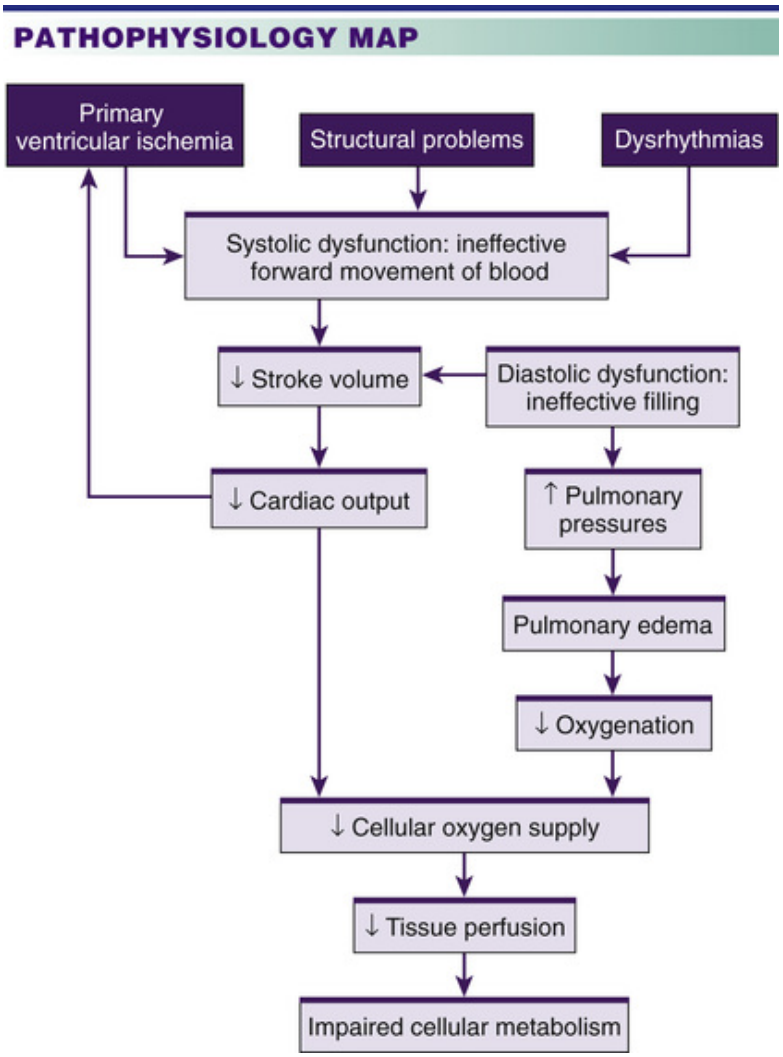

FIGURE 69-2 The pathophysiology of cardiogenic shock. Source: Urden, L. D., Stacy, K. M., & Lough, M. E. (2010). *Critical care nursing: Diagnosis and management* (6th ed., p. 984, Figure 39-2). St. Louis: Mosby.

The early clinical presentation of cardiogenic shock is similar to that of a patient with acute decompensated heart failure (see Chapter 37). An increase in systemic vascular resistance (SVR) increases the workload of the heart, thus increasing the myocardial oxygen consumption. The heart's inability to pump blood forward results in low CO (<4 L/min) and low cardiac index (<2.1 L/min/m^2). On examination, the patient may exhibit tachycardia, hypotension, and narrowed pulse pressure. Pulmonary congestion may be present, as evidenced by tachypnea and lung crackles. The hemodynamic profile demonstrates increases in the pulmonary artery occlusive (or wedge) pressure (PAOP) and pulmonary vascular resistance (Table 69-2). Signs of peripheral hypoperfusion (e.g., cyanosis, pallor, cool and clammy skin, decreased capillary refill time) are apparent. Decreased

renal blood flow results in sodium and water retention and decreased urine output. Anxiety, confusion, and agitation may develop as cerebral perfusion is impaired. Diagnostic workup for cardiogenic shock will include laboratory studies, electrocardiography (ECG), chest radiography, and echocardiography (Table 69-3). The overall clinical presentation of a patient with cardiogenic shock is described in Table 69-4.

TABLE 69-2
EFFECTS OF SHOCK ON HEMODYNAMIC PARAMETERS*

Type	HR	Pulse Pressure	BP	SVR	PVR	CVP	PAP	PAOP	CO	$S_VO_2/S_{CV}O_2$
Low Blood Flow

TABLE 69-3

DIAGNOSTIC STUDIES
Laboratory Abnormalities in Shock

Laboratory Study	Finding	Significance of Finding
Blood, Serum and Whole Blood Chemistries		
Arterial blood gases	Respiratory alkalosis	In early shock, occurs secondary to hyperventilation
	Metabolic acidosis	In later shock, occurs when organic acids, such as lactic acid, accumulate in blood as a result of anaerobic metabolism
Base deficit	≥6	Indicates acid production secondary to hypoxia
Blood cultures	Growth of organisms	May occur in patients who are in septic shock
BUN	Increased	Indicates impaired kidney function as a result of hypoperfusion caused by severe vasoconstriction, or occurs secondary to catabolism of cells (e.g., in trauma, infection)
Creatinine	Increased	Indicates impaired kidney function as a result of hypoperfusion caused by severe vasoconstriction; is more sensitive indicator of renal function than BUN
Creatine kinase	Increased	In trauma and MI, increases in response to cellular damage or hypoxia
DIC screen		Acute DIC can develop within hours to days after an initial assault on the body (e.g., shock)
D-dimer	Increased	
Fibrin split products	Increased	
Fibrinogen level	Decreased	
Platelet count	Decreased	
PTT and INR	Prolonged	
Thrombin time	Increased	
Glucose	Increased	In early shock, increases because of release of liver glycogen stores in response to SNS stimulation and cortisol; insulin insensitivity develops
	Decreased	Decreases because of depleted glycogen stores, with hepatocellular dysfunction as shock progresses
Lactic acid	Increased	Usually increases once significant hypoperfusion and impaired oxygen use at the cellular level have occurred; by-product of anaerobic metabolism
Liver enzymes (ALT, AST, GGT)	Increased	Elevations indicate liver cell destruction in progressive stage of shock
Potassium	Increased	Increases when cellular death liberates intracellular potassium; in AKI; and in the presence of acidosis
	Decreased	In early shock, decreases because of increased secretion of aldosterone, which causes renal excretion of potassium
RBC count, hematocrit, hemoglobin	Normal	Remains within normal limits (a) in shock because of relative hypovolemia and pump failure and (b) in hemorrhagic shock before fluid resuscitation
	Decreased	In hemorrhagic shock, decreases after fluid resuscitation when fluids other than blood are used
	Increased	In nonhemorrhagic shock, increases as a result of actual hypovolemia because fluid lost does not contain erythrocytes
Sodium	Increased	In early shock, increases because of increased secretion of aldosterone, causing renal retention of sodium
	Decreased	May occur iatrogenically when excessive hypotonic fluid is administered after fluid loss
Troponin	Increased	In MI
Urine		
Specific gravity	Increased	Occurs secondary to the action of ADH
	Fixed at 1.010	Occurs in renal failure

ADH, antidiuretic hormone; *AKI,* acute kidney injury; *ALT,* alanine aminotransferase; *AST,* aspartate aminotransferase; *BUN,* blood urea nitrogen; *DIC,* disseminated intravascular coagulation; *GGT,* γ-glutamyl transferase; *INR,* international normalized ratio; *MI,* myocardial infarction; *PTT,* partial thromboplastin time; *RBC,* red blood cell; *SNS,* sympathetic nervous system.

TABLE 69-4
CLINICAL PRESENTATION IN THE MAJOR TYPES OF SHOCK

Low Blood Flow		Maldistribution of Blood Flow		
Cardiogenic Shock	**Hypovolemic Shock**	**Neurogenic Shock**	**Anaphylactic Shock**	**Septic Shock**
Cardiovascular System (see Table 69-2 for complete hemodynamic profile)				
↓ Capillary refill time Chest pain may or may not be present ↑ MVO_2	↓ Capillary refill time ↓ Preload ↓ Stroke volume	Bradycardia ↓ or ↑ Temperature	Chest pain Third spacing of fluid	Biventricular dilation: ↓ ejection fraction ↓ or ↑ Temperature
Gastro-Intestinal System				
↓ Bowel sounds Nausea and vomiting	Absence of bowel sounds	Bowel dysfunction	Abdominal pain Cramping Diarrhea Nausea Vomiting	GI bleeding Paralytic ileus
Neurological System				
↓ Cerebral perfusion: anxiety, confusion, agitation	Agitation Anxiety Confusion	Flaccid paralysis below level of lesion Loss of reflex activity	Anxiety Confusion ↓ LOC Metallic taste Sensation of impending doom	Agitation Alteration in mental status (e.g., confusion) Coma (late)
Pulmonary System				
Crackles Cyanosis Tachypnea Wheezes	Tachypnea, progressing to bradypnea (late)	Dysfunction related to level of injury	Edema of larynx and epiglottis Rhinitis Shortness of breath Stridor Swelling of lips and tongue Wheezing	ARDS Crackles Hyperventilation Hypoxemia Pulmonary hypertension Respiratory alkalosis, progressing to respiratory acidosis Respiratory failure
Renal System				
↑ Na^+ and H_2O retention ↓ Renal blood flow ↓ Urine output	↓ Urine output	Bladder dysfunction		↓ Urine output
Skin				
Cool, clammy Pallor	Cool, clammy Pallor	Cool or warm Dry ↓ Skin perfusion	Angioedema Flushing Pruritus Urticaria	Warm and flushed (early), becoming cool and mottled (late)
Other Diagnostic Findings (also see Table 69-3)				

Low Blood Flow		Maldistribution of Blood Flow		
Cardiogenic Shock	**Hypovolemic Shock**	**Neurogenic Shock**	**Anaphylactic Shock**	**Septic Shock**
↑ Blood glucose ↑ BUN ↑ Cardiac markers Chest radiographic (e.g., pulmonary infiltrates) Echocardiographic (e.g., left ventricular dysfunction) Electrocardiographic (e.g., dysrhythmias)	↓ Hematocrit ↓ Hemoglobin ↑ Lactate ↑ Urine specific gravity Changes in electrolytes		History of allergies History of exposure to contrast media Sudden onset	↑ Glucose ↑ Lactate ↓ Platelets Positive blood cultures ↓ Urine Na^+ ↑ Urine specific gravity ↑ or ↓ WBC count

ARDS, acute respiratory distress syndrome; *BUN,* blood urea nitrogen; *GI,* gastrointestinal; *LOC,* level of consciousness; *MVO_2,* myocardial oxygen consumption; *WBC,* white blood cell.

Hypovolemic Shock.

Hypovolemic shock occurs when intravascular fluid volume is lost and the remaining volume is inadequate to fill the vascular space. The volume loss may be either an absolute or a relative volume loss. *Absolute hypovolemia* results when fluid is lost through hemorrhage, gastrointestinal (GI) loss (e.g., through vomiting, diarrhea), fistula drainage, diabetes insipidus, hyperglycemia, or diuresis. *Relative hypovolemia* develops when fluid volume moves out of the vascular space into the extravascular space (e.g., interstitial or intracavitary space). This type of fluid shift is called *third spacing*. One mechanism of relative volume loss is leakage of fluid from the vascular space to the interstitial space from increased capillary permeability, as occurs in sepsis or burns (see Chapter 27). Table 69-1 provides other examples of hypovolemic shock.

In hypovolemic shock, the size of the vascular compartment remains unchanged, but the volume of blood or plasma decreases. Whether the loss of intravascular volume is absolute or relative, the physiological consequences are similar. A reduction in intravascular volume results in a decreased venous return to the heart, decreased preload, decreased stroke volume, and decreased CO (see Table 69-2). A cascade of events results in decreased tissue perfusion and impaired cellular metabolism, the hallmarks of shock (Figure 69-3).

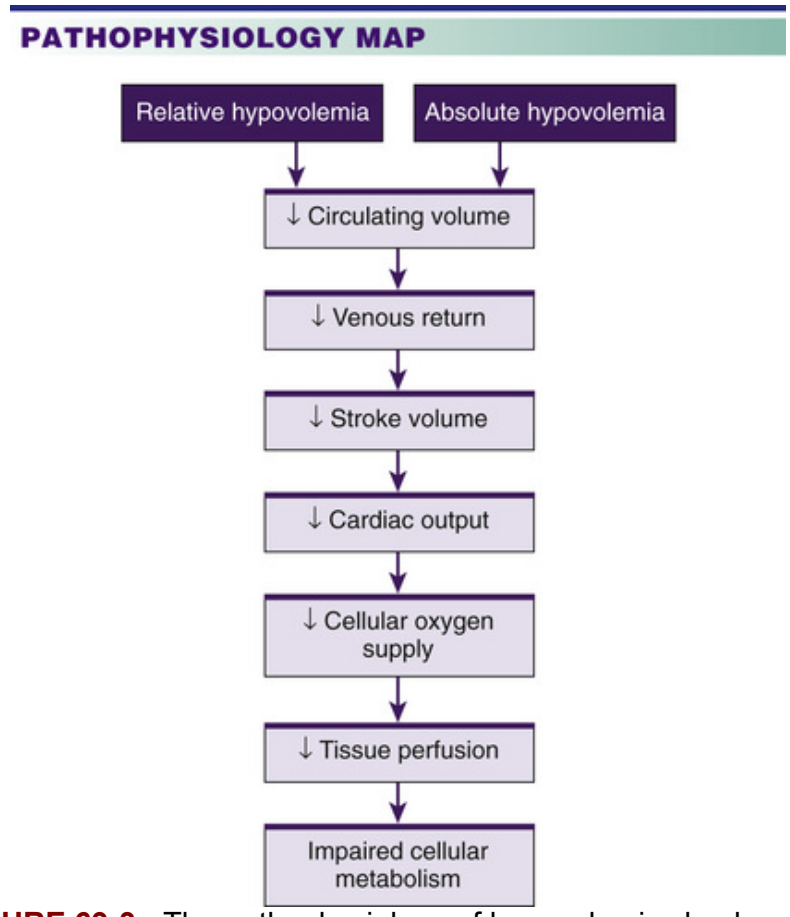

FIGURE 69-3 The pathophysiology of hypovolemic shock. Source: Urden, L. D., Stacy, K. M., & Lough, M. E. (2010). *Critical care nursing: Diagnosis and management* (6th ed., p. 982, Figure 39-1). St. Louis: Mosby.

The patient's response to low blood flow as a result of acute volume loss is dependent on a number of factors, including the extent of the injury or insult, the patient's age, and the patient's general state of health; however, the clinical presentations of hypovolemic shock are similar (see Table 69-4). An overall assessment of physiological reserves may indicate the patient's ability to compensate. A patient may compensate for a loss of up to 15% of the total blood volume (approximately 750 mL). Further loss of volume (15% to 30%) results in a sympathetic nervous system (SNS)–mediated response. This response results in increases in heart rate, CO, and respiratory rate and depth. The stroke volume and PAOP are decreased because of the decreased circulating blood volume.

The patient may appear anxious, and urine output begins to decrease. If hypovolemia is corrected by crystalloid fluid replacement at this time, tissue dysfunction is generally reversible. If volume loss is greater than 30%, compensatory mechanisms may begin to fail, and replacement with

blood or blood products should be initiated immediately. With loss of more than 40% of the total blood volume, autoregulation in the microcirculation is lost, and irreversible tissue destruction occurs (Hall, 2016). Laboratory studies that may be helpful include serial measurements of hemoglobin and hematocrit levels, urine specific gravity, serum electrolytes, blood gases, and lactic acid (see Table 69-3).

Distributive Shock: Shock Caused by Maldistribution of Blood Flow

Neurogenic Shock.

Neurogenic shock is a hemodynamic phenomenon that can occur within 30 minutes of a spinal cord injury at the fifth thoracic (T5) vertebra or above and lasts up to 6 weeks. The injury results in a massive vasodilation without compensation that is caused by the loss of SNS vasoconstrictor tone. This massive vasodilation leads to a pooling of blood in the blood vessels, tissue hypoperfusion, and, ultimately, impairment of cellular metabolism (Figure 69-4).

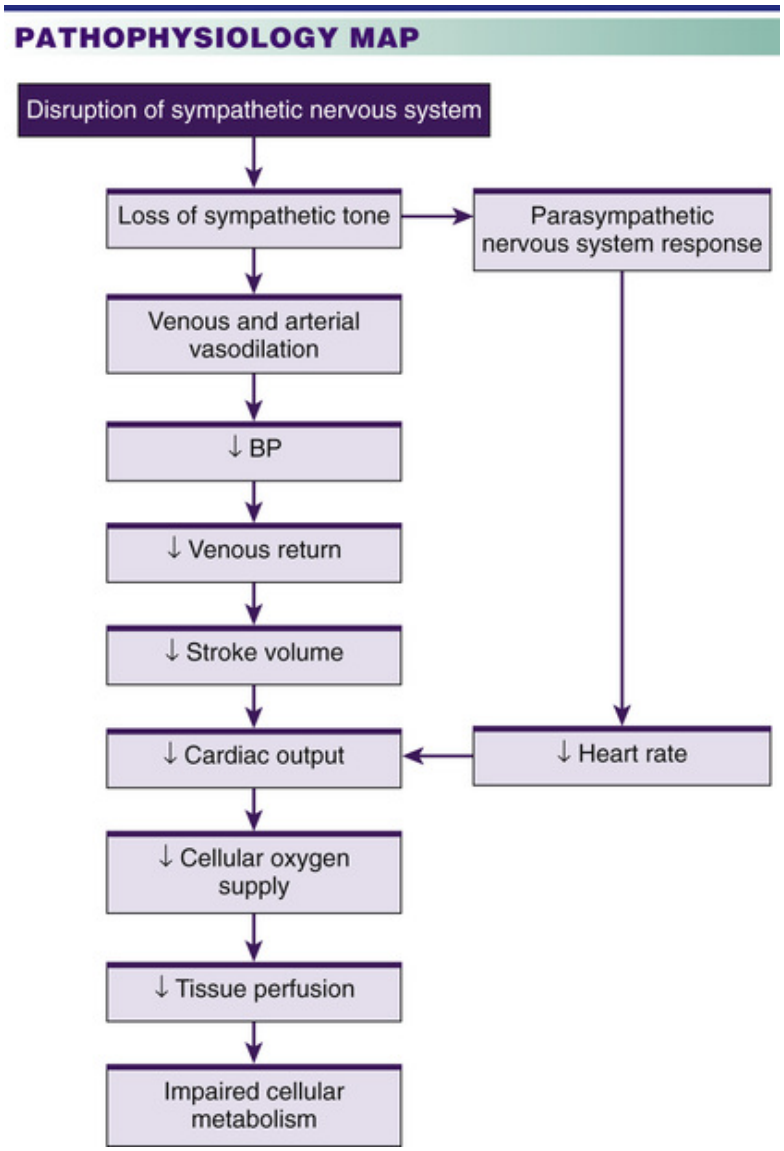

FIGURE 69-4 The pathophysiology of neurogenic shock. *BP,* blood pressure. Source: Urden, L. D., Stacy, K. M., & Lough, M. E. (2010). *Critical care nursing: Diagnosis and management* (6th ed., p. 990, Figure 39-4). St. Louis: Mosby.

In addition to spinal cord injury, spinal anaesthesia can block transmission of impulses from the SNS. Depression of the vasomotor centre of the medulla from drugs (e.g., benzodiazepines, opioids) also can result in decreased vasoconstrictor tone of the peripheral blood vessels, which leads to neurogenic shock (see Table 69-1).

Classic clinical manifestations in neurogenic shock are hypotension (from the massive vasodilation) and bradycardia (from unopposed parasympathetic stimulation) (Casha & Christie, 2011). A patient in neurogenic shock may be unable to regulate temperature, and in

combination with massive vasodilation, severe heat loss can result. Initially, the patient's skin is warm as a result of the massive dilation without compensation. As the heat dissipates, the risk for hypothermia escalates. Later, the patient's skin may be cool or warm, depending on the ambient temperature (*poikilothermia,* the taking on of the temperature of the environment). In either case, the skin is usually dry. Tables 69-2, 69-3, and 69-4 further describe the clinical presentation of a patient with neurogenic shock.

Although spinal shock and neurogenic shock often occur in the same patient, they are not the same disorder. *Spinal shock* is a transient condition that is present after an acute spinal cord injury (see Chapter 63). A patient with spinal shock experiences the absence of all voluntary and reflex neurological activity below the level of the injury (Casha & Christie, 2011).

Anaphylactic Shock.

Anaphylactic shock is an acute, life-threatening hypersensitivity (allergic) reaction to a sensitizing substance (e.g., drug, chemical, vaccine, food, insect venom). Usually an immediate reaction causes massive vasodilation, release of vasoactive mediators, and an increase in capillary permeability. As capillary permeability increases, fluid leaks from the vascular space into the interstitial space. Anaphylactic shock can lead to airway swelling (pharyngeal and laryngeal edema, stridor, hoarse voice), breathing problems (shortness of breath, increased respirations, fatigue, confusion as a result of hypoxia), and circulation problems (hypotension; tachycardia; pale, clammy skin; faintness; and even loss of consciousness). The patient becomes anxious and experiences a sense of impending doom. Without prompt treatment, respiratory or cardiac arrest may develop.

A patient can develop a severe allergic reaction, which possibly leads to anaphylactic shock, after contact, inhalation, ingestion, or injection of an antigen (allergen) to which the person has previously been sensitized (see Table 69-1). Parenteral administration of the antigen (allergen) is the route most likely to cause anaphylaxis; however, oral, topical, and inhalation routes can also cause anaphylactic reactions. Tables 69-2, 69-3, and 69-4 describe the clinical presentation of anaphylactic shock. Quick and decisive action by the nurse is crucial for preventing the progression of an anaphylactic reaction to anaphylactic shock. (Anaphylaxis is discussed in Chapter 16.)

Septic Shock.

Sepsis is a systemic inflammatory response to a documented or suspected infection. **Severe sepsis** is defined as sepsis complicated by organ dysfunction, hypoperfusion, or hypotension. **Septic shock** develops when hypotension cannot be reversed with fluid resuscitation and tissue perfusion abnormalities are present (Dellinger, Levy, Rhodes, et al., 2013). Recent statistics indicate that, in 2011, 1 in 18 deaths involved sepsis, and it was the 12th leading cause of all deaths in Canada (Navaneelan, Alam, Peters, et al., 2016).

In Canada, mortality rates in the period 2008 to 2009 were 30% among patients with sepsis, 45.2% among patients with severe sepsis, and 20.9% among patients in whom sepsis did not worsen from the initial state (Canadian Institute for Health Information [CIHI], 2009). In as many as 30% of patients with sepsis, the causative organism is not identified (CIHI, 2009). The primary organisms that do cause sepsis are Gram-negative and Gram-positive bacteria. The morbidity and mortality rates from infections with Gram-negative organisms are higher than those with Gram-positive organisms. Parasites, fungi, and viruses can also lead to the development of sepsis and septic shock (CIHI, 2009). The pathogenesis of septic shock is complex (Figure 69-5).

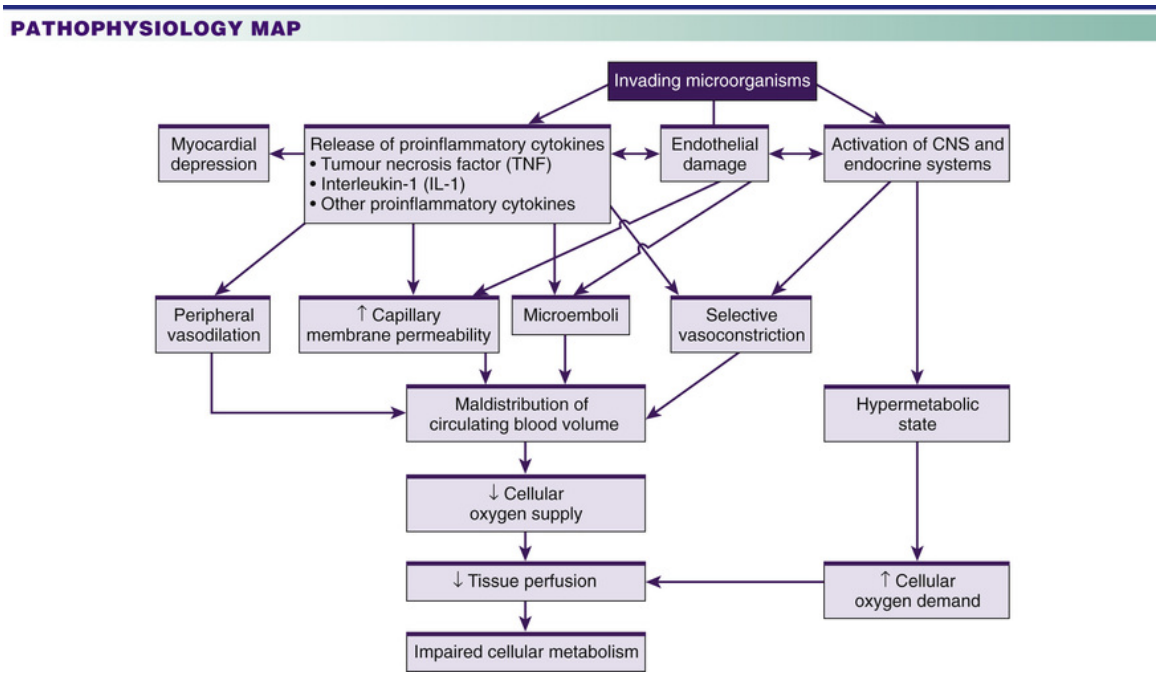

FIGURE 69-5 The pathophysiology of septic shock. *CNS*, central nervous system. Source: Urden, L. D., Stacy, K. M., & Lough, M. E. (2010). *Critical care nursing: Diagnosis and management* (6th ed., p. 992, Figure 39-5). St. Louis: Mosby.

When an antigen (microorganism) enters the body, the normal immune or inflammatory cascade responses are initiated and work together to destroy the antigen; however, in severe sepsis and septic shock, the response initiated by the body to an antigen is exaggerated. Inflammation and coagulation are increased, and fibrinolysis is decreased. Endotoxins from the microorganism cell wall stimulate the release of cytokines, including tumour necrosis factor (TNF) and interleukin-1 (IL-1), as well as other proinflammatory mediators that act through secondary mediators such as platelet-activating factor XII and interleukin-6 (Fry, 2012). (See Chapter 14 for a discussion of the inflammatory response.) The release of platelet-activating factor XII results in the formation of microthrombi and obstruction of the microvasculature. The combined effects of the mediators result in damage to the endothelium due to neutrophils and aggregated platelets adhering to the endothelium (Lawrence, 2011). With increased capillary permeability to fluid, the intravascular volume leaks into the interstitial space, further reducing SVR. This response results in vasodilation. If CO cannot increase further to compensate, septic shock develops (Lawrence, 2011).

The clinical presentation of sepsis is complex, and no single symptom or group of symptoms is specific to the diagnosis (Table 69-5). Affected patients usually experience an initial hyperdynamic state, characterized by

increased CO and decreased SVR, which stresses the myocardium, causing tachycardia and tachypnea (Fry, 2012). Initially, the skin is warm and flushed. Persistence of high CO and low SVR beyond 24 hours is an ominous finding and is often associated with an increased development of hypotension leading to MODS. Skin then becomes cool and clammy.

TABLE 69-5
DIAGNOSTIC CRITERIA FOR SEPSIS

Infection, documented or suspected, as well as one or more of the following:
General Variables
• Altered mental status • Fever (temperature >38.3°C) • Heart rate >90 beats/min • Hyperglycemia (blood glucose >7.77 mmol/L) in the absence of diabetes • Hypothermia (core temperature <36°C) • Significant edema or positive fluid balance (>20 mL/kg over 24 hr) • Tachypnea
Inflammatory Variables
• Elevated C-reactive protein • Elevated procalcitonin • Leukocytosis (WBC count >12 × 10^9/L) • Leukopenia (WBC count <4 × 10^9/L) • Normal WBC count with >10% immature forms
Hemodynamic Variables
• Arterial hypotension (SBP <90 mm Hg, MAP <70 mm Hg, or a decrease in SBP >40 mm Hg)
Organ Dysfunction Variables
• Acute oliguria (urine output <0.5 mL/kg/hr for at least 2 hr despite adequate fluid resuscitation) • Arterial hypoxemia (PaO_2/FIO_2 <300) • Coagulation abnormalities (INR >1.5 or PTT >60 sec) • Hyperbilirubinemia (total bilirubin >68.4 mcmol/L) • Ileus (absent bowel sounds) • Serum creatinine increase >44.2 mcmol/L • Thrombo-cytopenia (platelet count <100 × 10^9/L)
Tissue Perfusion Variables
• Decreased capillary refill or mottling • Hyperlactatemia (>1 mmol/L)

FIO_2, fraction of inspired oxygen; *INR,* international normalized ratio; *MAP,* mean arterial pressure; *PaO_2,* partial pressure of arterial oxygen; *PTT,* partial thromboplastin time; *SBP,* systolic blood pressure.

Source: Dellinger, R. P., Levy, M. M., Rhodes, A., et al. Surviving Sepsis Campaign guidelines committee including the pediatric subgroup. (2013). Surviving sepsis campaign: International guidelines for management of severe sepsis and septic shock, 2012. *Critical Care Medicine 41*(2), 580.

In addition to the cardiovascular dysfunction that accompanies sepsis, respiratory failure is common. Affected patients initially hyperventilate as a compensatory mechanism, which results in respiratory alkalosis. Once the patient can no longer compensate, respiratory acidosis develops.

Respiratory failure develops in 85% of patients with sepsis, and acute respiratory distress syndrome (ARDS) develops in 40%. Other clinical signs of septic shock include alteration in neurological status, decreased urine output, and GI dysfunction, such as GI bleeding and paralytic ileus. Tables 69-2 and 69-4 further delineate the clinical presentation of septic shock.

Stages of Shock

The health care provider must understand the underlying pathogenesis of the type of shock the patient is experiencing, but monitoring and management are also guided by knowing which stage of the shock "continuum" the patient is in. This continuum begins with the initial stage of shock, which occurs at a cellular level and is usually not clinically apparent. Metabolism changes at the cellular level from aerobic to anaerobic, causing lactic acid build-up. Lactic acid is a waste product and must be removed by the liver. However, this process requires oxygen, which is unavailable because of the decrease in tissue perfusion. This stage is followed by the three clinically apparent but overlapping stages of shock: the compensatory stage, the progressive stage, and the refractory (irreversible) stage (Hall, 2016).

Compensatory Stage.

In the *compensatory stage,* the body activates neural, hormonal, and biochemical compensatory mechanisms in an attempt to overcome the increasing consequences of anaerobic metabolism and to maintain homeostasis. The clinical presentation begins to reflect the body's responses to the imbalance in oxygen supply and demand (Table 69-6).

TABLE 69-6
CLINICAL MANIFESTATIONS OF THE STAGES OF SHOCK

Compensatory Stage	Progressive Stage	Refractory Stage
Cardiovascular System		
BP adequate to perfuse vital organs (heart, brain) Coronary artery dilation Narrowed pulse pressure SNS response: • Release of epinephrine and norepinephrine, which promotes vasoconstriction • ↑ Contractility • ↑ HR • ↑ MVO_2	↑ Capillary permeability → systemic interstitial edema ↓ CO → ↓ BP and ↑ HR Loss of autoregulation in microcirculation MAP <60 mm Hg (or 40 mm Hg drop in BP from baseline) ↓ Coronary perfusion → • Dysrhythmias • Myocardial ischemia • MI • Myocardial dysfunction → impaired CO ↓ Peripheral perfusion → ischemia of distal extremities, diminished pulses, ↓ capillary refill	↓ BP inadequate to perfuse vital organs Bradycardia; irregular rhythm ↓ CO Profound hypotension
Gastro-Intestinal System		
↓ Blood supply Hypoactive bowel sounds Possible ileus	Vasoconstriction and ↓ perfusion → ischemic gut (e.g., stomach, small and large intestines, gallbladder, pancreas) • Erosive ulcers • GI bleeding • Translocation of GI bacteria • Impaired absorption of nutrients	Ischemic gut
Hematological System	DIC • Thrombin clots in microcirculation • Consumption of clots in microcirculation	DIC
Hepatic System	Failure to metabolize drugs and waste products Jaundice (decreased clearance of bilirubin) ↑ NH_3 and lactate	Metabolic changes from accumulation of waste products (e.g., NH_3, lactate, CO_2)
Neurological System		
Change in level of consciousness Changes in Glasgow Coma Scale score Oriented to person, place, time Restless, apprehensive, confused	↓ Cerebral blood flow ↓ Cerebral perfusion pressure Listless or agitated ↓ Responsiveness to stimuli	Unresponsive Areflexia (loss of reflexes) Pupils unreactive and dilated
Renal System		
↑ Aldosterone level, resulting in Na^+ and H_2O reabsorption ↑ ADH level, resulting in H_2O reabsorption ↓ Renal blood flow ↑ Renin level, resulting in release of angiotensin II (vasoconstrictor)	↑ BUN/creatinine ratio Metabolic acidosis Renal tubules become ischemic → ATN ↓ Urine output ↑ Urine Na^+ ↓ Urine osmolarity and specific gravity ↓ Urine K^+	Anuria
Respiratory System		

Compensatory Stage	Progressive Stage	Refractory Stage
↓ Blood flow to the lungs Hyperventilation ↑ Minute ventilation (V_E) ↑ Physiological dead space ↑ Ventilation–perfusion mismatch	Acute respiratory distress syndrome (ARDS) • ↑ Capillary permeability • Pulmonary vasoconstriction • Pulmonary interstitial edema • Alveolar edema • ↓ Compliance • Diffuse infiltrates • ↑ Respiratory rate Moist crackles	Respiratory failure Severe refractory hypoxemia
Skin		
Warm and flushed	Cold and clammy	Mottled, cyanotic
Temperature		
Normal or abnormal	Hypothermia Sepsis: hypothermia or hyperthermia	Hypothermia
Key Laboratory Findings		
↑ Blood glucose ↓ PaO_2 ↓ $PaCO_2$ ↑ pH	↑ Bleeding times ↑ Liver enzymes: ALT, AST, GGT Thrombo-cytopenia	↓ Blood glucose Metabolic acidosis ↑ NH_3, lactate, and K^+

ADH, antidiuretic hormone; *ALT,* alanine aminotransferase; *AST,* aspartate aminotransferase; *ATN,* acute tubular necrosis; *BP,* blood pressure; *BUN,* blood urea nitrogen; *CO,* cardiac output; *DIC,* disseminated intravascular coagulation; *GGT,* γ-glutamyl transferase; *GI,* gastro-intestinal; *HR,* heart rate; K^+, potassium ions; *MAP,* mean arterial pressure; *MI,* myocardial infarction; MVO_2, myocardial oxygen consumption; Na^+, sodium ions; NH_3, ammonia; $PaCO_2$, partial pressure of arterial carbon dioxide; PaO_2, partial pressure of arterial oxygen; *SNS,* sympathetic nervous system.

One of the first clinical signs of shock is hypotension, which occurs because of a decrease in CO and a narrowing of the pulse pressure. The baroreceptors in the carotid and aortic bodies immediately respond by activating the SNS. The SNS stimulates vasoconstriction and the release of the potent vasoconstrictors epinephrine and norepinephrine. Blood flow to the most vital organs (the heart and the brain) is maintained, whereas blood flow to the nonvital organs, such as the kidneys, the GI tract, the skin, and the lungs, is diverted or shunted (Hall, 2016).

Decrease in blood flow to the kidneys activates the renin–angiotensin system. Renin is released, which activates angiotensinogen to produce angiotensin I, which is then converted to angiotensin II (see Chapter 47, Figure 47-6). Angiotensin II is a potent vasoconstrictor that causes both arterial and venous vasoconstriction. The net result is an increase in venous return to the heart and an increase in blood pressure (BP). Angiotensin II also stimulates the adrenal cortex to release aldosterone, which results in sodium and water reabsorption and in potassium excretion by the kidneys. The increase in sodium reabsorption raises the serum osmolality and stimulates the release of antidiuretic hormone (ADH) from the posterior pituitary gland. ADH works by increasing water

reabsorption by the kidneys, thus further increasing blood volume. The increase in total circulating volume results in increases in CO and BP (Hall, 2016).

Shunting of blood from the GI tract leads to decreased motility and paralytic ileus. The skin is then cold and clammy from low distribution of blood flow.

Shunting blood away from the lungs increases the patient's physiological dead space—the amount of air that does not reach gas-exchanging units and any inspired air that cannot participate in gas exchange. The clinical result of an increase in dead space is a ventilation–perfusion mismatch. Some areas of the lungs participating in ventilation are not perfused because of the decrease in blood flow to the lungs. Arterial oxygen levels decrease, and the rate and depth of respirations increase to compensate.

The myocardium responds to the SNS stimulation and the increase in oxygen demand by increasing the heart rate and contractility. However, increased contractility increases myocardial oxygen consumption (MVO_2). The coronary arteries dilate in an attempt to meet the increased oxygen demands of the myocardium.

A multisystem response to decreasing tissue perfusion is initiated in the compensatory stage of shock. At this stage, the body is able to compensate for the changes in tissue perfusion. If the perfusion deficit is corrected, the patient recovers with few or no residual consequences. If the perfusion deficit is not corrected and the body is unable to compensate, the patient enters the progressive stage of shock.

Progressive Stage.

The *progressive stage* of shock begins as compensatory mechanisms fail. In this stage, aggressive interventions are necessary to prevent the development of MODS. Continued decreased cellular perfusion and resulting altered capillary permeability are the distinguishing features of this stage. As a result of altered capillary permeability, fluid and protein leak out of the vascular space into the surrounding interstitial space. In addition to the decrease in circulating volume, systemic interstitial edema increases. The patient may have *anasarca* (diffuse, profound edema). Fluid leakage from the vascular space also affects the solid organs (e.g., liver, spleen, GI tract, lungs) and peripheral tissues by further decreasing perfusion.

The pulmonary system is often the first to display signs of critical dysfunction as blood flow to the lungs is already reduced. In response to the decreased blood flow and the SNS stimulation, the pulmonary arterioles constrict, resulting in increased pulmonary artery (PA) pressure. As the pressure within the pulmonary vasculature increases, blood flow to the pulmonary capillaries decreases, and ventilation–perfusion mismatch worsens. Another key response in the lungs is the movement of fluid from the pulmonary vasculature into the interstitial space. As capillary permeability increases, the movement of fluid to the interstitial spaces results in interstitial edema, bronchoconstriction, and a decrease in functional residual capacity. With further increases in capillary permeability, the fluid moves to the alveoli, with resultant alveolar edema and a decrease in surfactant production. The combined effects of pulmonary vasoconstriction and bronchoconstriction are impaired gas exchange, decreased compliance, and worsening ventilation–perfusion mismatch. Clinical manifestations are tachypnea, crackles, and overall increased work of breathing.

The cardiovascular system is profoundly affected. CO begins to fall, resulting in hypotension and markedly decreased coronary artery, cerebral artery, and peripheral artery perfusion. Changes in the patient's mental status become apparent in this stage. Capillary permeability continues to increase, enhancing the movement of fluid from the vascular space into the interstitial space. Sustained hypoperfusion results in weakening of peripheral pulses and ischemia of the distal extremities. Myocardial dysfunction from decreased perfusion results in dysrhythmias, myocardial ischemia, and potentially myocardial infarction (MI). The effect of prolonged hypoperfusion on the kidneys is renal tubular ischemia. The resulting acute tubular necrosis (ATN) may lead to the development of acute kidney injury (AKI), which can be worsened by nephrotoxic drugs, including certain antibiotics, anaesthetics, and diuretics (see Chapter 49). Renal function is markedly impaired during the progressive stage of shock. The urine output is decreased, and blood urea nitrogen (BUN) and serum creatinine (Cr) levels are elevated. Metabolic acidosis results from an inability to excrete acids and reabsorb bicarbonate.

The GI system is also affected as the blood supply to the GI tract is decreased. The normally protective mucosal barrier becomes ischemic. This ischemia predisposes the patient to erosive ulcers and GI bleeding (see Chapter 44), thus increasing the potential risk for bacterial translocation from the GI tract to the blood. The decrease in perfusion to

the GI tract also leads to a decrease in the ability to absorb nutrients (Miller, Kiraly, Lowen, et al., 2011).

Other systems are also affected by the sustained hypoperfusion in the progressive stage of shock. The loss of the functional ability of the liver leads to a failure of the liver to metabolize drugs and waste products such as ammonia (NH_3) and lactate. Jaundice results from an accumulation of bilirubin. As the liver cells die, enzyme levels become elevated, particularly alanine aminotransferase (ALT), aspartate aminotransferase (AST), and γ-glutamyl transferase (GGT). The liver also loses its ability to function as an immune organ. Bacteria that may translocate from the GI system cannot be scavenged by Kupffer cells. Instead, they are released into the bloodstream, which increases the possibility of the development of bacteremia.

Dysfunction of the hematological system adds to the complexity of the clinical picture. The patient is at risk for the development of disseminated intravascular coagulation (DIC). In DIC, the platelets and the clotting factors are consumed, and secondary fibrinolysis develops. This situation results in clinically significant bleeding from many orifices, including, but not limited to, the GI tract, the lungs, and puncture sites (see Chapter 33). Numerous blood laboratory values are altered (see Chapter 33, Table 33-21; Table 69-3; Table 69-6).

Refractory Stage.

In the final stage of shock, the *refractory stage,* decreased perfusion from peripheral vasoconstriction and decreased CO exacerbate anaerobic metabolism. The accumulation of lactic acid contributes to an increased capillary permeability and dilation of the capillaries. Because capillary permeability is increased, fluid and plasma proteins leave the vascular space and move to the interstitial space. Blood pools in the capillary beds as a result of constriction of the venules and dilation of the arterioles. The loss of intravascular volume worsens hypotension and tachycardia and decreases coronary blood flow. Decreases in coronary blood flow lead to worsening myocardial depression and a further decline in CO. Cerebral blood flow cannot be maintained, and cerebral ischemia results.

Patients in this stage of shock demonstrate profound hypotension and hypoxemia. The failure of the liver, the lungs, and the kidneys results in an accumulation of waste products, such as lactate, urea, ammonia, and carbon dioxide. The failure of one organ system has an effect on several other organ systems. In this final stage, recovery is unlikely. The organs

are in failure, and the body's compensatory mechanisms are overwhelmed (see Table 69-6).

Diagnostic Studies

Prompt and accurate diagnosis is crucial. Establishing a diagnosis begins with a physical examination, a thorough medical and surgical history, and findings of recent events (e.g., upper respiratory tract infection, surgery, chest pain, trauma). Numerous laboratory studies must be collected initially and serially.

Decreased tissue perfusion in shock initially leads to an elevation of lactate levels (>4 mmol/L) and a high base deficit (the amount needed to bring the pH back to normal). These laboratory changes reflect an undesirable increase in anaerobic metabolism. Other laboratory values found in shock are summarized in Table 69-3.

Additional diagnostic studies include 12-lead ECG, continuous cardiac monitoring, chest radiography, continuous pulse oximetry, and hemodynamic monitoring (e.g., arterial pressure monitoring, central venous or PA pressure monitoring). (Chapter 68 discusses hemodynamic monitoring.)

Collaborative Care: General Measures

Critical factors in the successful management of a patient experiencing shock are early recognition and prompt intervention. Astute assessment skills and urgent communication with a rapid response team may prevent the decline to the progressive or the refractory stage. Successful management likely requires quick transfer to a critical care unit; however, nurses in non–critical care settings should institute physician's orders and bundles, even before transfer to the critical care unit (Aitken, Williams, Harvey, et al., 2011). *Bundles* are collections of, generally, three to five evidence-informed practices that, when combined, improve patient outcomes [Institute for Healthcare Improvement (IHI), 2017]. Table 69-7 provides the international guidelines for the 3-hour Resuscitation Bundle and the 6-hour Septic Shock Bundle.

TABLE 69-7
SURVIVING SEPSIS CAMPAIGN CARE BUNDLES

To Be Completed Within 3 Hours
1. Measure lactate level. 2. Obtain blood cultures before administering antibiotics. 3. Administer broad-spectrum antibiotics. 4. Administer 30 mL/kg crystalloid for hypotension or lactate level ≥4 mmol/L.
To Be Completed Within 6 Hours
5. Apply vasopressors (for hypotension that does not respond to initial fluid resuscitation) to maintain a mean arterial pressure (MAP) ≥65 mm Hg. 6. In the event of persistent arterial hypotension despite volume resuscitation (septic shock) or initial lactate level ≥4 mmol/L (36 mg/dL): • Measure central venous pressure (CVP).* • Measure central venous oxygen saturation ($S_{cv}O_2$).* 7. Remeasure lactate level if initial lactate level was elevated.*

*Targets for quantitative resuscitation included in the guidelines are CVP of ≥8 mm Hg, $S_{cv}O_2$ of ≥70%, and normalization of lactate.

Source: Dellinger, R. P., Levy, M. M., Rhodes, A., et al. (2013). Surviving Sepsis Campaign guidelines committee including the pediatric subgroup. Surviving sepsis campaign: International guidelines for management of severe sepsis and septic shock, 2012, *Critical Care Medicine 41*(2), 580.

Table 69-8 provides an overview of the initial assessment findings and interventions for the emergency care of patients in shock. The nurse must ensure that the patient's airway is patent. Once the airway is established, either as a natural airway or with an endotracheal tube, oxygen should be delivered to maintain an arterial oxygen saturation (SaO_2) of 90% or higher (partial pressure of arterial oxygen [PaO_2] >60 mm Hg) to avoid hypoxemia (see Chapter 68). Mechanical ventilation may be necessary. The mean arterial pressure (MAP) and the circulating blood volume are optimized with fluid replacement and drug therapy.

TABLE 69-8

EMERGENCY MANAGEMENT
Shock

Etiology*	Assessment Findings	Interventions
Surgical • Aortic dissection • Gastro-intestinal bleeding • Postoperative bleeding • Rupture from ectopic pregnancy or of ovarian cyst • Rupture of organ or vessel • Vaginal bleeding **Medical** • Addisonian crisis • Dehydration • Diabetes insipidus • Diabetes mellitus • MI • Pulmonary embolus • Sepsis **Trauma** • Burns • Fractures, spinal injury • Multisystem or multiorgan injury • Rupture or laceration of vessel or organ (e.g., spleen)	• Anxiety • Chills • Confusion • Cool, clammy skin (warm skin in early stages of septic and neurogenic shock) • Cyanosis • Decreased level of consciousness • Decreased O_2 saturation • Dysrhythmias • Extreme thirst • Hypotension • Narrowed pulse pressure • Nausea and vomiting • Obvious hemorrhage or injury • Pallor • Rapid, weak, thready pulses • Restlessness • Sensation of impending doom • Tachypnea, dyspnea, or shallow, irregular respirations • Temperature dysregulation • Weakness	**Initial** • Administer humidified, high-flow oxygen (100%) by nonrebreather mask or bag–valve–mask device. • Anticipate need for intubation and mechanical ventilation. • Assess for life-threatening injuries (e.g., pericardial tamponade, liver laceration, tension pneumothorax). • Collect blood for laboratory studies (e.g., blood cultures, lactate measurement, WBC count). • Consider vasopressor therapy only after hypovolemia has been corrected. • Control any external bleeding with direct pressure or pressure dressing. • Establish and maintain patency of airway. • Establish IV access with two large-bore catheters, and begin fluid resuscitation with isotonic or hypertonic crystalloids (e.g., normal saline solution). • Insert an indwelling bladder catheter and nasogastric tube. • Institute antibiotic therapy if sepsis is suspected. • Stabilize cervical spine as appropriate. • Treat dysrhythmias. **Ongoing Monitoring** • Cardiac rhythm • Level of consciousness • Respiratory status • Urine output • Vital signs, including pulse oximetry, peripheral pulses, capillary refill

*See Table 69-1 for additional causes of shock.

IV, intravenous; *MI*, myocardial infarction; *WBC*, white blood cell.

Oxygen and Ventilation.

Oxygen delivery is dependent on CO, available hemoglobin, and SaO_2. Methods to optimize oxygen delivery are directed at increasing supply and decreasing demand. Supply can be increased by (a) optimizing CO with drug therapy or fluid replacement, (b) increasing hemoglobin by the transfusion of blood or packed red blood cells (RBCs), (c) increasing the SaO_2 with supplemental oxygen and mechanical ventilation, or some combination of these.

Care should be planned to avoid disrupting the balance of oxygen supply and demand. Activities that increase oxygen consumption (e.g., endotracheal suctioning, position changes) should be appropriately spaced for oxygen conservation. Continuous monitoring of central venous oxygen saturation ($ScvO_2$) by a central venous catheter or of mixed venous oxygen saturation (SvO_2) by a PA catheter is helpful. Both values reflect the dynamic balance between oxygen supply and demand. These values are considered in conjunction with the SaO_2, CO, hemoglobin, and oxygen consumption to evaluate the patient's response to treatments or activities (see Chapter 68).

Fluid Resuscitation.

The cornerstone of therapy for septic, hypovolemic, and anaphylactic shock is volume expansion with prompt and aggressive fluid resuscitation to restore tissue perfusion and improve hemodynamic status. However, fluid is given cautiously for cardiogenic and neurogenic shock. Before fluid resuscitation begins, two large-bore intravenous (IV) catheters must be inserted peripherally, or preferably, a central venous catheter. Both crystalloids and colloids may have a role in fluid resuscitation (Table 69-9; see Chapter 19).

TABLE 69-9
FLUID THERAPY FOR SHOCK

Fluid Type	Mechanism of Action	Type of Shock	Nursing Implications
Crystalloids			
Isotonic			
0.9% NaCl (N/S) most commonly used Lactated Ringer's solution	Fluid remains primarily in the intravascular space, increasing intravascular volume.	Used cautiously for initial volume replacement in most types of shock	Patient is monitored closely for circulatory overload. Lactated Ringer's solution is contraindicated for patients with liver failure.
Hypertonic			
1.8%, 3%, or 5% NaCl	Fluid remains in the intravascular space, producing rapid volume expansion.	May be used for initial volume expansion in hypovolemic shock	Patient is monitored closely for signs of hypernatremia (e.g., disorientation, convulsions). Central line is required to limit damage to veins.
Blood/Blood Products			
Whole blood or packed RBCs Fresh-frozen plasma	These replace blood loss and increase oxygen-carrying capability. They also replace coagulation factors.	All types of shock if hemoglobin is <120 g/L or if the patient does not respond to crystalloids	Same precautions as for any blood administration (see Chapter 33).
Colloids			
Hetastarch	This is made from starch and acts as volume expander; it is at least as effective as albumin; it can exert osmotic effect for up to 36 hr.	All types of shock except cardiogenic and neurogenic shock NOT recommended with severe sepsis and septic shock*	Use cautiously in patients with heart failure, renal failure, or bleeding disorders (because of antiplatelet effect).
Human serum albumin (5%, 25%), plasma protein fraction (5% albumin in 500 mL of N/S)	This can increase plasma colloid osmotic pressure and produces rapid volume expansion.	All types of shock except cardiogenic and neurogenic shock	Patient is monitored for circulatory overload. Mild adverse effects of chills, fever, and urticaria may develop. Use 5% for hypovolemia. Use 25% for patients with fluid and sodium restrictions.
Dextran; dextran 40; dextran 70	This is a hyperosmotic glucose polymer; similar degrees of volume expansion are achieved with dextran, dextran 40, and dextran 70; duration of action is longer with dextran 70.	Limited use because of adverse effects, including reducing platelet adhesion, diluting clotting factors	Increases risk of bleeding. Patient is monitored for allergic reactions and AKI.

*Dellinger, R. P., Levy, M. M., Rhodes, A., et al. (2013). Surviving Sepsis Campaign: International guidelines for management of severe sepsis and septic shock, 2012. *Intensive Care Medicine,* 39(2), 165–228. doi:10.1007/s00134-012-2769-8.

AKI, acute kidney injury; *N/S*, normal saline solution; *RBCs*, red blood cells.

Crystalloids (e.g., N/S 0.9%, lactated Ringer's solution) are the initial fluid of choice for severe hypovolemia to achieve at least 30 ml/kg and may increase the amount and rate of administration in more patients who are compromised (Dellinger et al., 2013). Lactated Ringer's solution should be used judiciously in all shock situations because the failing liver cannot convert lactate to bicarbonate, increasing serum lactate levels further.

Colloids (e.g., albumin) are effective volume expanders as they require less volume to improve hemodynamic effect (Rochwerg, Alhazzani, Sindi, et al., 2014). Albumin, a natural compound, is recommended when the patient requires substantial amounts of crystalloids (Dellinger et al., 2013). Albumin 5% is used in patients who are hypovolemic and 25% is used in patients with fluid and sodium restrictions. Synthetic colloids (e.g., hydroxyethyl starch [HES], gelatin, or dextran) are not recommended due to possible development of AKI and coagulation disorders (Dellinger et al., 2013; Rochwerg et al., 2014).

Serial BP measurements with an automatic BP cuff or an intra-arterial catheter can be used to monitor the patient's response. An indwelling bladder catheter to monitor urine output also assists in monitoring the patient's fluid status. Hemodynamic improvement may be *dynamic* (e.g., change in pulse pressure or stroke volume), or *static* (e.g., arterial pressure, heart rate) (Dellinger et al., 2013).

The doctor should choose the type of fluid that will best restore intravascular volume with the least untoward metabolic or systemic effects (Pavlik, Simpson, Horn, et al., 2015). When large amounts of fluids are required, the patient must be protected against complications—hypothermia and coagulopathy. Hypothermia can be prevented by warming both crystalloid and colloid solutions used during massive fluid resuscitation. If the patient is receiving large volumes of packed RBCs, it is important to remember that they do not contain clotting factors. Therefore, clotting factors must be replaced on the basis of the clinical situation and results of blood studies. If the patient has chronic hypotension after adequate fluid resuscitation, the physician may consider vasoactive drug therapy. Decisions about which drug to use should be based on the physiological goal. Although BP helps determine whether the patient's CO is adequate, an assessment of end-organ perfusion (e.g., urine output, neurological function, peripheral pulses) provides more relevant information.

Safety Alert

- Warm crystalloid and colloid solutions during massive fluid resuscitation.
- When administering large volumes of packed RBCs, remember that they do not contain clotting factors. Replace these factors based on the clinical situation and results of laboratory studies.

Drug Therapy.

The primary goal of drug therapy for shock is the correction of decreased tissue perfusion. Ideally, medications are administered intravenously via an infusion pump through a central venous catheter instead of a peripheral site as these drugs are quite viscous and may cause IV complications (e.g., extravasation) (Table 69-10).

TABLE 69-10

DRUG THERAPY
Shock*

Mechanism of Action	Hemodynamic Effects	Type of Shock	Nursing Implications
Dobutamine			
↑ Myocardial contractility ↓ Ventricular filling pressures	↑ CO, stroke volume, and CVP ↑ ↓ HR ↓ SVR and PAOP	Used for cardiogenic shock with severe systolic dysfunction Used for septic shock with normal CO that is not meeting metabolic demands	Hypovolemia is corrected. Should not be administered in same catheter with $NaHCO_3$. Administration via central catheter is recommended (infiltration leads to tissue sloughing). HR and BP are monitored (hypotension may worsen, necessitating addition of a vasopressor). Patient is monitored for tachydysrhythmias.
Dopamine			
Precursor to epinephrine and norepinephrine Hemodynamic effects from release of norepinephrine Positive inotropic effects: • ↑ Myocardial contractility • ↑ Automaticity • ↑ Atrioventricular conduction Low doses: ↑ blood flow to renal, mesenteric, and cerebral circulation High doses: can cause progressive vasoconstriction	↑ BP ↑ CO ↑ HR	Cardiogenic shock: • ↑ HR • ↑ Mean arterial pressure • ↑ MVO_2	Hypovolemia is corrected. Administer via central catheter (infiltration leads to tissue sloughing); should not be administered in same catheter with $NaHCO_3$. Patient is monitored for tachydysrhythmias. Patient is monitored for peripheral vasoconstriction at moderate to high doses (e.g., paresthesias, coldness in extremities).
Epinephrine (Adrenalin)			
Low doses: β-adrenergic agonist (cardiac stimulation, bronchial dilation, peripheral vasodilation)	↑ HR, contractility, and CO ↓ SVR	Cardiogenic shock combined with afterload reduction Anaphylactic shock	Hypovolemia is corrected if necessary. Patient is monitored for HR >110 beats/min. Patient is monitored for dyspnea and pulmonary edema.
High doses: α-adrenergic agonist (peripheral vasoconstriction)	↑ Stroke volume ↑ SVR ↑ Systolic BP, ↓ diastolic BP, widened pulse pressure ↑ CVP, PAOP	Cardiac arrest, pulseless ventricular tachycardia, ventricular fibrillation, asystole	Patient is monitored for renal failure secondary to ischemia. Patient is monitored for chest pain, dysrhythmias secondary to ↑ MVO_2.
Hydrocortisone (Solu-Cortef)			

Mechanism of Action	Hemodynamic Effects	Type of Shock	Nursing Implications
Decreases inflammation; reverses increased capillary permeability	↑ BP, HR	Septic shock necessitating vasopressor therapy, despite fluid resuscitation, to maintain adequate BP Anaphylactic shock if hypotension persists past initial therapy	Patient is monitored for hypokalemia and hyperglycemia.
Norepinephrine (Levophed)			
β_1-Adrenergic agonist (cardiac stimulation) α-Adrenergic agonist (peripheral vasoconstriction) Renal and splanchnic vasoconstriction	↑ BP, MAP ↑ CVP, PAOP ↑ SVR ↑ or ↓ CO	Cardiogenic shock after MI Septic shock: works by increasing vascular tone	Used for hypotension unresponsive to adequate fluid resuscitation. Administered via a central catheter (infiltration leads to tissue sloughing). Patient is monitored for dysrhythmias secondary to ↑ MVO_2 requirements.
Phenylephrine (Neo-Synephrine)			
α-Adrenergic agonist Vasoconstriction: renal, mesenteric, splanchnic, cutaneous, and pulmonary vessels	↑ HR ↑ BP ↑ SVR ↑ ↓ CO	Neurogenic shock	Patient is monitored for reflex bradycardia, headache, restlessness. Patient is monitored for renal failure secondary to ↓ renal blood flow. Administered via central catheter (infiltration leads to tissue sloughing).
Nitroglycerin			
Venodilation Dilates coronary arteries ↓ Preload ↓ MVO_2	↓ SVR ↓ BP	Cardiogenic shock	Patient is continuously monitored for BP and for reflex tachycardia. Use glass bottles for storage of drug.
Sodium Nitroprusside (Nipride)			
Arterial and venous vasodilation ↓ Preload, afterload	↓ BP ↑ ↓ CO ↓ CVP, PAOP	Cardiogenic shock with ↑ SVR	BP is continuously monitored. Solution should be protected from light; infusion bottle should be wrapped with opaque covering. Administered with D_5W only. Patient is monitored for cyanide toxicity (e.g., tinnitus, hyper-reflexia, confusion, seizures).
Vasopressin			
ADH, nonadrenergic vasoconstrictor	↑ MAP ↓ Need for other vasopressors ↑ Urine output	Shock states (most commonly septic shock) refractory to other vasopressors	Low dose usually administered. Hemodynamic pressures and urine output are monitored.

*Individual facility's guidelines, pharmacist, pharmacology references, and drug manufacturer's administration materials should be consulted for additional information and dosage recommendations.

ADH, antidiuretic hormone; *BP,* blood pressure; *CO,* cardiac output; *CVP,* central venous pressure; *D_5W,* 5% dextrose in water; *HR,* heart rate; *INR,* international normalized ratio; *MAP,* mean arterial pressure; *MI,* myocardial infarction; *MVO_2,* myocardial oxygen consumption; *PAOP,* pulmonary artery occlusive pressure; *PTT,* partial thromboplastin time; *SVR,* systemic vascular resistance.

Sympathomimetic Drugs.

Many of the drugs used in the treatment of shock have an effect on the SNS. Drugs that mimic the action of the SNS are termed *sympathomimetic.* The effects of these drugs are mediated through their binding to α-adrenergic or β-adrenergic receptors. The various drugs have different relative α-adrenergic and β-adrenergic effects (see Chapter 35, Table 35-1). Many of the sympathomimetic drugs cause peripheral vasoconstriction and are referred to as *vasopressor drugs* (e.g., epinephrine [Adrenalin], dopamine, norepinephrine [Levophed]). These drugs have the potential to cause severe peripheral vasoconstriction and an increase in SVR. This response further jeopardizes tissue perfusion, either directly or indirectly. The increased SVR increases the workload of the heart and can be detrimental to a patient in cardiogenic shock by causing further myocardial damage. Use of vasopressor drugs is generally reserved for patients who have been unresponsive to other therapies. Adequate fluid resuscitation must be achieved before the use of any vasopressor drug because peripheral vasoconstrictor effects in patients with low blood volume cause further reduction in tissue perfusion.

The goal of vasopressor therapy is to achieve and maintain a MAP of at least 65 mm Hg (Dellinger et al., 2013). The nurse must continuously monitor end-organ perfusion (e.g., urine output, SvO_2, serum lactate levels) to ensure that tissue perfusion is adequate.

Vasodilator Drugs.

Some patients in shock show evidence of excessive vasoconstriction and poor tissue perfusion in spite of fluid replacement and normal or even high systemic BP. This is especially true of patients in cardiogenic shock. Although generalized sympathetic vasoconstriction is a useful compensatory mechanism for maintaining systemic pressure, excessive constriction can reduce tissue blood flow and increase the workload of the heart. The rationale for using vasodilator therapy for a patient in shock is to break the deleterious cycle in which widespread vasoconstriction causes a decrease in CO and BP, resulting in further SNS-induced vasoconstriction.

The goal of vasodilator therapy, as in vasopressor therapy, is to maintain a MAP greater than 65 mm Hg. Other hemodynamic pressures are also monitored so that fluids can be increased or the dose of the vasodilator decreased if CO or BP falls dramatically. The vasodilator agent most often used in cardiogenic shock is nitroglycerin. Vasodilation may be enhanced with nitroprusside (Nipride) in non-cardiogenic shock.

Nutritional Therapy.

Protein–calorie malnutrition is one of the primary manifestations of hypermetabolism in shock. Nutrition is vital in decreasing morbidity. Enteral nutrition to enhance perfusion of the GI tract and help maintain the integrity of the gut mucosa should be initiated within the first 24 hours (Aitken et al., 2011; Dellinger et al., 2013; Miller et al., 2011). Slow continuous enteral feedings are started for the first week and advanced only as tolerated (Dellinger et al., 2013).

Parenteral nutrition is often required when enteral nutrition is contraindicated or not meeting nutritional needs; however, it must be used with caution because the dextrose can cause hyperglycemia and the lipids can have an immuno-suppressive effect (Miller et al., 2011) (see Chapter 42).

Patients should be weighed on the same scale at the same time of day. If significant weight loss is noted, dehydration should be ruled out before additional calories are provided. Large weight gains are common because of third spacing of fluids. Therefore, daily weight measurements may function better as an indicator of fluid status than caloric needs and balance do. Serum protein, nitrogen balance, BUN, serum glucose level, and serum electrolyte values are all used to assess nutritional status.

Collaborative Care: Specific Measures

Cardiogenic Shock.

For the patient in cardiogenic shock, the overall goal is to restore blood flow to the myocardium by restoring the balance between oxygen supply and demand. Specific measures to restore blood flow include thrombolytic therapy, angioplasty with stent implantation, emergency revascularization, and valve replacement (see Chapter 36). Cardiac catheterization should be performed as soon as possible after the initial insult. Coronary angioplasty with or without stent implantation may be performed during the cardiac catheterization. Until these interventions can

be performed, stroke volume and CO must be optimized in an effort to facilitate optimal perfusion (Table 69-11; see also Table 69-10).

TABLE 69-11

COLLABORATIVE CARE
Specific Strategies for the Treatment of Shock

Cardiogenic Shock	Hypovolemic Shock	Septic Shock	Neurogenic Shock	Anaphylactic Shock
Oxygenation				
Supplemental O_2 (e.g., via nasal cannula, non-rebreather mask) provided Intubation and mechanical ventilation, initiated, if necessary SvO_2 or $ScvO_2$ monitored	Supplemental O_2 provided SvO_2 or $ScvO_2$ monitored	Supplemental O_2 provided Intubation and mechanical ventilation initiated, if necessary SvO_2 or $ScvO_2$ monitored	Patency of airway maintained Supplemental O_2 provided Intubation and mechanical ventilation initiated, if necessary	Patency of airway maintained Oxygenation optimized with supplemental O_2 Intubation and mechanical ventilation initiated, if necessary
Circulation				
Blood flow restored with thrombolytics, angioplasty with stent implantation, emergency coronary revascularization Workload of the heart reduced with circulatory assist devices (IABP, VAD)	Fluid volume restored (e.g., blood or blood products, crystalloids) Rapid fluid replacement provided via two large-bore (14- to 16-gauge) peripheral IV lines End points of fluid resuscitation accomplished: • CVP of 15 mm Hg • PAOP of 10–12 mm Hg	Aggressive fluid resuscitation provided End points of fluid resuscitation accomplished: • CVP of 15 mm Hg • PAOP of 10–12 mm Hg	Fluids administered with caution	Aggressive fluid resuscitation provided with colloids
Drug Therapies				
Nitrates (e.g., nitroglycerin) Inotropes (e.g., dobutamine) Diuretics (e.g., furosemide) β-Adrenergic blockers (contraindicated with ↓ ejection fraction)	No specific drug therapies	Antibiotics as ordered Vasopressors (e.g., dopamine) Inotropes (e.g., dobutamine) Anticoagulants (e.g., low-molecular-weight heparin)	Vasopressors (e.g., phenylephrine) Atropine (for bradycardia)	Antihistamines (e.g., diphenhydramine) Epinephrine (subQ, IV, with nebulizer) Bronchodilators: with nebulizer (e.g., albuterol) Corticosteroids (if hypotension persists)
Supportive Therapies				

Cardiogenic Shock	Hypovolemic Shock	Septic Shock	Neurogenic Shock	Anaphylactic Shock
Dysrhythmias corrected	Cause corrected (e.g., stop bleeding, GI losses) Warmed fluids used	Cultures obtained (e.g., blood, wound) before beginning antibiotics Temperature monitored Blood glucose level controlled Stress ulcers prevented	Spinal cord trauma minimized with stabilization Temperature monitored	Offending cause identified and removed Prevented by avoidance of known allergens Patient premedicated according to history of prior sensitivity (e.g., contrast media)

CVP, central venous pressure; *GI,* gastro-intestinal; *IABP,* intra-aortic balloon pump; *IV,* intravenously; *PAOP,* pulmonary artery occlusive pressure; *subQ,* subcutaneously; $ScvO_2$, central venous oxygen saturation; SvO_2, venous oxygen saturation; *VAD,* ventricular assist device.

Hemodynamic management aims to decrease the workload of the heart through reperfusion, drug therapy, or mechanical interventions. Early recognition and prompt revascularization by means of percutaneous coronary intervention or coronary artery bypass graft (CABG) substantially improves survival rates. Fibrinolytic therapy is another option for reperfusion. Inotropes and vasopressors in low doses are effective pharmacological agents. Dopamine is the first drug of choice because it is both an inotrope and a vasopressor. Dobutamine is an effective inotrope for mild hypotension and can improve CO when combined with a vasopressor, such as norepinephrine or vasopressin. Patients with pulmonary edema should receive diuretics. Acetylsalicylic acid (ASA; Aspirin) is given to patients with acute MI. Amiodarone is used to treat arrhythmias. β-Blockers and nitrates should be given with caution and avoided in the acute stage (Patel & Hollenberg, 2011).

Patients may also benefit from a circulatory assist device such as an intra-aortic balloon pump (IABP) or a ventricular assist device (VAD) (see Chapter 68). The IABP is inserted into the femoral artery and placed in the aorta just distal to the aortic arch. The goal of this intervention is to increase coronary blood flow and thus decrease left ventricular workload. The VAD is used when cardiogenic shock is refractory to the IABP or fibrinolytic therapy. It is a temporary measure for patients who are in cardiogenic shock or awaiting cardiac transplantation. Cardiac transplantation is an option for a small and select group of patients with cardiogenic shock.

Hypovolemic Shock.

The underlying principles of managing hypovolemic shock focus on stopping the loss of fluid and restoring the circulating volume. Fluid resuscitation in hypovolemic shock initially is calculated according to a 3 : 1 rule (3 mL of isotonic crystalloid for every 1 mL of estimated blood loss). Table 69-9 delineates the different types of fluid used for volume resuscitation, the mechanisms of action, and specific nursing implications for each fluid type.

Septic Shock.

Patients in septic shock require large amounts of fluid replacement to achieve hemodynamic improvement (Dellinger et al., 2013). Predetermined end points of fluid resuscitation are suggested in Table 69-11. To optimize and evaluate large-volume fluid resuscitation, hemodynamic monitoring with a PA catheter or central venous catheter (target central venous pressure [CVP] of 8 to 12 mm Hg) and arterial pressure monitoring (target MAP of >65 mm Hg) may be necessary. If fluid resuscitation is unsuccessful, vasopressor drug therapy may be added. Vasodilation and low CO, or vasodilation alone, can cause low BP in spite of adequate volume resuscitation. Norepinephrine is the first-choice vasopressor to initially target a MAP of 65 mm Hg (Dellinger et al., 2013). Vasopressin, an antidiuretic hormone, may be given for patients whose condition is refractory to norepinephrine (Dellinger et al., 2013). Exogenous vasopressin is used to replace the stores of physiological vasopressin that are often depleted in septic shock.

Drug Alert

Vasopressin

- Infuse at low doses (e.g., 0.03 U/min)
- Do not titrate infusion
- Use cautiously in patients with coronary artery disease

Vasopressor drugs may increase BP but may also decrease stroke volume. Often, an inotropic agent (e.g., dobutamine) is added to offset the

decrease in stroke volume (see Table 69-10). Corticosteroids are not recommended; however, IV corticosteroids (e.g., hydrocortisone 200 mg/day) may be used only when hemodynamic status is not improving despite fluid resuscitation attempts and vasopressor therapy (Dellinger et al., 2013). In an attempt to meet the increasing tissue demands coupled with a low SVR, the patient initially demonstrates normal or high CO. If the patient is unable to achieve and maintain adequate CO and has unmet tissue oxygen demands, CO may have to be increased through drug therapy (e.g., dopamine) (Dellinger et al., 2013). The adequacy of CO can be assessed with SvO_2 monitoring. The SvO_2 (normal, 65%–75%) is a reflection of the balance between oxygen delivery and consumption (see Chapter 68). If the balance is maintained, the tissue demands are met.

Antimicrobial therapy is an important and early component of therapy. Outcomes are improved if administered within the first 45 minutes or at least the first 3 hours (Dellinger et al., 2013). Before definitive treatment for the infection begins, the cause of the infection must be identified. Cultures (e.g., blood, wound exudate, urine, stool, sputum) are obtained before antimicrobial medications are started. Broad-spectrum antimicrobials (e.g., antibiotics, antifungals, antivirals) are given initially, followed by more specific medication once the organism has been identified (Dellinger et al., 2013).

Glucose levels should be monitored every 1 to 2 hours and maintained at less than 10 mmol/L (Dellinger et al., 2013). Stress ulcer prophylaxis with histamine H_2-receptor blockers (e.g., famotidine [Pepcid]) or proton pump inhibitors (e.g., pantoprazole) are recommended for patients with risk of bleeding (Dellinger et al., 2013). Deep venous thrombosis prophylaxis using low-dose unfractionated heparin or low-molecular-weight heparin (e.g., enoxaparin [Lovenox]) is also recommended, in combination with intermittent pneumatic compressions devices (Dellinger et al., 2013).

Neurogenic Shock.

The specific treatment of neurogenic shock is dependent on the cause. If the cause is spinal cord injury, general measures to promote spinal stability (e.g., spinal precautions, cervical stabilization with a collar) are initially used. Once the spine is stabilized, definitive treatment of the hypotension and bradycardia is essential to prevent further spinal cord damage. Hypotension, which occurs as a result of a loss of sympathetic tone, is associated with peripheral vasodilation and decreased venous

return. Treatment involves the use of vasopressors (e.g., phenylephrine [Neo-Synephrine]) to maintain BP and organ perfusion (see Table 69-10). Bradycardia may be treated with atropine. Fluids are administered cautiously because the cause of the hypotension is not related to fluid loss (Casha & Christie, 2011).

The patient with a spinal cord injury also needs to be monitored for hypothermia because of hypothalamic dysfunction (see Table 69-11). Although corticosteroids do not have an effect in neurogenic shock, methylprednisolone (Solu-Medrol) is used for patients with a spinal cord injury to prevent secondary spinal cord damage caused by the release of chemical mediators (see Chapter 63).

Anaphylactic Shock.

Anaphylaxis can quickly progress to anaphylactic shock within minutes if not treated immediately. Triggers of anaphylaxis are foods (peanuts, shellfish, soy), stinging insect venoms (honeybee and yellow jacket), and drugs (nonsteroidal anti-inflammatory drugs [NSAIDs], antibiotics, and neuro-muscular blocking agents) (see Table 69-1).

World Allergy Organization anaphylaxis guidelines (2015) recommend epinephrine as the first line of treatment. Ideally, an intramuscular (IM) epinephrine auto-injector dose is self-administered at the onset of an event, prior to hospitalization. IV epinephrine is used with anaphylactic shock and must not be delayed. Overdosing of epinephrine can lead to detrimental cardiovascular effects, such as hypertension, stroke, and even death; however the benefits far outweigh the risks.

The second line of treatment includes H_1-antihistamines (e.g., diphenhydramine hydrochloride [Benadryl]), and H_2-antihistamines (e.g., Zantac) which block the histamine receptors. IV glucocorticoids are used to prevent further episodes or anaphylaxis. These drugs should be used in combination with epinephrine (Simons, Ebisawa, Sanchez-Borges, et al., 2015).

Maintaining patency of the airway is important because the patient can quickly develop airway compromise from laryngeal edema or bronchoconstriction. Nebulized bronchodilators are highly effective. Aerosolized epinephrine can also be used to treat laryngeal edema. Endotracheal intubation or cricothyroidotomy may be necessary to secure and maintain airway patency. Aggressive fluid resuscitation, predominantly with colloids, is necessary (see Tables 69-10 and 69-11).

Methylene blue can rapidly reverse anaphylaxis refractory to epinephrine, oxygen, and IV fluid resuscitation. It works by reversing vasodilation, thus improving hypotension and improving cerebral blood flow (Zheng, Barthel, Collange, et al., 2013).

Nursing Management Shock

Nursing Assessment

The initial assessment should be focused on the ABCs: **a**irway, **b**reathing, and **c**irculation. Further assessment should focus on tissue perfusion and includes evaluation of vital signs, level of consciousness, peripheral pulses, capillary refill, skin (e.g., temperature, colour, moisture), and urine output. As shock progresses, the patient's skin becomes cooler and mottled, urine output decreases, peripheral pulses diminish, and neurological status continues to deteriorate.

To understand the complexity of the patient's clinical status, the nurse must integrate all the assessment data. As care is initiated (see Tables 69-7 and 69-11), it is essential for the nurse to obtain a brief history from the patient or substitute decision maker. This information should include a description of the events leading to the shock condition, time at onset and duration of symptoms, and a health history (e.g., medications, allergies, date of last tetanus vaccination, recent travel). In addition, details should be obtained regarding any care that the patient received before hospitalization.

Nursing Diagnoses

Nursing diagnoses for the patient in shock may include, but are not limited to, the following:

- *Ineffective peripheral tissue perfusion, risk for decreased cardiac tissue perfusion, ineffective cerebral tissue perfusion, and risk for impaired liver function*
- *Anxiety* related to *threat of death, threat to current status* (severity of condition)

Additional information on nursing diagnoses for the patient with shock is presented in Nursing Care Plan (NCP) 69-1, available on the Evolve website. Many other diagnoses are relevant, and examples appear in other chapters.

Planning

The overall goals for patients in shock include (a) restoration of adequate tissue perfusion, (b) normal vital signs, specifically, MAP greater than 65 mm Hg, (c) recovery of organ function, and (d) prevention of progression toward further complications related to prolonged states of hypoperfusion.

Nursing Implementation

Health Promotion.

In order to prevent shock, the nurse must identify patients at risk. In general, patients who are older, those with debilitating illnesses, and those who are immuno-compromised are at increased risk. Any person who sustains surgical or accidental trauma is at high risk for shock as a result of hemorrhage, spinal cord injury, and other conditions (see Table 69-1). Any patient who is at risk for decreased oxygen delivery or tissue hypoxia is also at risk for the development of shock. Planning is essential to help prevent shock after a susceptible individual has been identified. For example, a patient diagnosed with an acute anterior MI is at risk for cardiogenic shock. The primary goal in this scenario is to limit the size of the infarction. The infarct size can be limited by restoring coronary blood flow through thrombolytic therapy, percutaneous coronary intervention, or surgical revascularization. Rest, analgesics, sedatives, and judicious use of paralytic agents (if the patient is intubated) can reduce the myocardial demand for oxygen. The nurse can modify the patient's environment to provide care intermittently so to not increase the patient's oxygen demand. For example, if the patient becomes fatigued or anxious during bathing, that activity can be planned at a time so as not to interfere with tests or other activities that may also increase oxygen demand.

A person with a severe allergy to such substances as drugs, shellfish, and insect bites is at increased risk of developing anaphylactic shock. The risk for anaphylactic shock can be decreased if the patient is carefully questioned about allergies before a drug is administered or before the patient undergoes diagnostic procedures involving the use of contrast media. If a patient's condition warrants receiving a medication to which he or she is at high risk for an allergic reaction (e.g., contrast media), the patient should receive a premedication such as diphenhydramine or methylprednisolone. Patients with severe allergies should wear a medical

alert tag that identifies their allergies. Patients and those close to them should always have an epinephrine EpiPen auto-injector ready.

Careful monitoring of fluid balance can help prevent hypovolemic shock. Ongoing monitoring of intake and output and daily weight measurements are important. In addition, monitoring the patient's clinical status is essential because trends in clinical findings are more meaningful than any single piece of clinical information.

All patients should be carefully monitored for the development of infection. Progression from an infection to sepsis and septic shock is dependent on the patient's host defence mechanisms. Patients who are immuno-compromised or immuno-suppressed are at especially high risk of developing an opportunistic infection. These patients may be ventilated or have numerous invasive lines. Strategies to decrease the risk for health care–associated infections (HAIs) include decreasing the number of indwelling catheters (e.g., central lines, urinary catheters), using aseptic technique during invasive procedures, and paying strict attention to handwashing. In addition, all equipment must be changed according to institutional policy or thoroughly cleaned or discarded (if disposable) before use with another patient. The use of standardized bundles, such as the central line bundle or the ventilator bundle should be considered (see the Resources at the end of Chapter 71).

Acute Intervention.

The nurse's role with patients in shock involves (a) monitoring the patient's ongoing physical and emotional status to detect subtle changes in the patient's condition, (b) planning and quickly implementing nursing interventions and therapy, (c) evaluating the patient's response to therapy, (d) providing emotional support to the patient and family, and (e) collaborating with other members of the health team to coordinate care (see NCP 69-1 on the Evolve website).

Neurological Status.

Neurological status, including orientation and level of consciousness, should be assessed every hour or more often. The patient's neurological status is the best indicator of cerebral blood flow. The nurse should be aware of neurological clinical manifestations such as changes in behaviour, restlessness, hyperalertness, blurred vision, confusion, and paresthesias. Note any subtle changes in the patient's mental status (e.g., mild agitation).

The patient should be oriented to time, place, person, and events. If the patient is in a critical care unit, orientation to the environment is particularly important. Measures such as minimizing noise and light levels should be taken to control sensory input. A day–night cycle of activity and rest should be maintained as much as possible. Sensory overload and disruption of the patient's diurnal cycle may contribute to delirium (see Chapter 68).

Cardiovascular Status.

Most therapy for shock is based on information about the patient's cardiovascular status. If the patient is unstable, careful assessment of the heart rate, the BP, the CVP, and the PA pressures, including continuous CO (if available), should be completed at least every 15 minutes. PAOP should be measured every 1 to 2 hours. (Hemodynamic monitoring is discussed in Chapter 68.) Monitoring trends in hemodynamic parameters yields more important information than individual numbers. Integration of hemodynamic data with physical assessment data is essential in planning strategies to manage the patient with shock.

Patients in shock classically exhibit hypotension, which should be treated with fluid resuscitation, medications, or a combination of these, after the type of shock has been identified. Trendelenburg position should be avoided as the patient could experience compromised pulmonary function and increased intracranial pressure.

The patient's ECG should be monitored continuously to detect dysrhythmias. Heart sounds should be assessed for the presence of an S_3 or S_4 sound or new murmurs. The presence of an S_3 sound in an adult may indicate heart failure. The frequency of monitoring is decreased as the patient's condition improves.

In addition to monitoring the patient's cardiovascular status, the nurse must administer the prescribed therapy to correct the dysfunctions of the cardiovascular system. The patient's response to fluid and medication administration is assessed and titrated as often as every 5 to 15 minutes. Once tissue perfusion is restored and the patient is stabilized, the frequency of monitoring is decreased, and the patient is slowly weaned off medications that support BP and tissue perfusion.

Respiratory Status.

The respiratory status of the patient in shock must be frequently assessed to ensure adequate oxygenation, detect complications early, and provide data regarding the patient's acid–base status. The rate, the depth, and the rhythm of respirations are initially monitored as frequently as every 15 to 30 minutes. Increased rate and depth provide information regarding the patient's attempts to correct metabolic acidosis. Breath sounds should be assessed every hour for any changes that may indicate fluid overload or accumulation of secretions.

Pulse oximetry is used to continuously monitor oxygen saturation. Pulse oximetry using a patient's finger or toe may not be accurate in an advanced shock state because of poor peripheral circulation. In this situation, the probe should be attached to the nose, the ear, or the forehead (according to the manufacturer's guidelines) to increase accuracy. Levels of ABGs provide definitive information on ventilation and oxygenation status and acid–base balance. Initial interpretation of ABGs is often the nurse's responsibility. A PaO_2 below 60 mm Hg (in the absence of chronic lung disease) indicates the presence of hypoxemia and the need for the administration of higher oxygen concentrations or for a different mode of oxygen administration. Low partial pressure of arterial carbon dioxide ($PaCO_2$) in the presence of a low pH and low bicarbonate level may indicate that the patient is attempting to compensate for metabolic acidosis. A rising $PaCO_2$ in the presence of a persistently low pH and PaO_2 may indicate the need for intubation and mechanical ventilation.

Most patients in shock are intubated and on mechanical ventilation. Maintaining airway patency and monitoring for ventilator-related complications are critical. (Artificial airways and mechanical ventilation are discussed in Chapter 68.)

Renal Status.

Hourly measurements of urinary output are essential in the assessment of the adequacy of renal perfusion. An indwelling bladder catheter is inserted to facilitate measurements. Urine output of less than 0.5 mL/kg/hr may indicate inadequate perfusion of the kidneys. BUN and serum creatinine values are additional indicators used to assess renal function. Serum creatinine is a better indicator of renal function because BUN levels can be influenced by the catabolic state of the patient.

Body Temperature and Skin Changes.

When temperature is normal, it should be monitored every 4 hours. If it is elevated or subnormal, tympanic or pulmonary arterial temperatures

should be monitored hourly. If the temperature rises above 38.6°C and the patient becomes uncomfortable or experiences cardiovascular compromise, the fever may be managed with NSAIDs (e.g., ibuprofen [Motrin]), with acetaminophen (Tylenol), or by removing some of the patient's covers.

The patient's skin should be monitored for temperature, pallor, flushing, cyanosis, diaphoresis, and piloerection. In addition, capillary refill should be assessed as an indicator of peripheral perfusion.

Gastro-Intestinal Status.

Bowel sounds should be auscultated at least every 4 hours, and abdominal distension should be assessed. If a nasogastric tube is inserted, drainage should be measured and checked for occult blood. Stools should also be checked for occult blood.

Personal Hygiene.

Hygiene is especially important for patients in shock because impaired tissue perfusion predisposes the skin to breakdown and infection. However, bathing and other nursing measures must be carried out judiciously due to problems with oxygen delivery to tissues. The nurse must use clinical judgement to determine priorities of care in order to limit the demands for increased oxygen.

Oral care is essential because mucous membranes may become dry and fragile in the state of volume depletion. In addition, patients who are intubated usually have difficulty swallowing, which results in pooled secretions in the mouth. A water-soluble lubricant applied to the lips prevents drying and cracking. Moist swabbing of the tongue and oral mucosa with saline solution or diluted mouthwash is also beneficial.

Passive range of motion (ROM) should be performed three to four times per day to maintain joint mobility. The patient should be turned at least every 1 to 2 hours and positioned in good body alignment to help prevent pressure injuries. A pressure-relieving mattress or a specialty bed may also be needed. If possible, oxygen consumption (e.g., SvO_2 or $ScvO_2$) should be monitored during all nursing interventions to monitor the patient's tolerance of activity.

Emotional Support and Comfort.

The nurse must recognize that the patient and family are faced with a critical, life-threatening situation and may experience problems such as anxiety, fear, and pain (see Chapter 68). The nurse should address these

responses because such symptoms may aggravate respiratory distress and increase the release of catecholamines. Medications to decrease anxiety and pain are common modes of therapy. Continuous infusions of a benzodiazepine (e.g., lorazepam [Ativan]), an opioid or anaesthetic (e.g., morphine, propofol [Diprivan]), and occasionally a neuro-muscular blocking agent (e.g., cisatracurium) are extremely helpful in decreasing anxiety, pain, and oxygen demand. Goals of care and prognosis should be discussed as early as feasible, considering end-of-life care planning and palliative care principles where appropriate (Dellinger et al., 2013).

Ambulatory and Home Care.

Rehabilitation involves ensuring that the precipitating cause is corrected, preventing or treating complications, and providing education focused on disease management or prevention of recurrence. A collaborative approach involving allied health services on discharge is necessary for success (e.g., transitional and rehabilitation units, home health care, occupational therapists, physiotherapists, and dietitians, to name a few).

Rehabilitation of the patient who has experienced critical illness must be monitored for indications of complications throughout the recovery period. Complications may include decreased ROM, decreased physical endurance, renal failure after ATN (see Chapter 49), and the development of fibrotic lung disease as a result of ARDS (see Chapter 70). Thus, patients recovering from shock may require diverse services on discharge. These can include admission to transitional care units (e.g., for weaning from mechanical ventilation), rehabilitation centres (inpatient or outpatient), or home health care agencies. The nurse should begin to anticipate and facilitate a safe transition from the hospital to home when the patient is admitted.

Evaluation

Expected outcomes for the patient with shock are addressed in NCP 69-1, available on the Evolve website.

Systemic Inflammatory Response Syndrome and Multiple-Organ Dysfunction Syndrome

Etiology and Pathophysiology

Systemic inflammatory response syndrome (SIRS) is a systemic inflammatory response to a variety of insults, including infection, ischemia, infarction, and injury (see Table 69-5). SIRS is characterized by at least two of the following: fever, edema, hypotension, tachycardia, impaired oxygenation, and elevated white blood cell (WBC) count (Moser, 2014).

A systemic inflammatory response can be triggered by many mechanisms. Examples are as follows:

- *Abscess formation:* intra-abdominal, on extremities
- *Endotoxin release:* Gram-negative bacteria
- *Global perfusion deficits:* after cardiac resuscitation, in shock states
- *Ischemic or necrotic tissue:* pancreatitis, vascular disease, MI
- *Mechanical tissue trauma:* burns, crush injuries, surgical procedures
- *Microbial invasion:* bacteria, viruses, fungi, parasites
- *Regional perfusion deficits:* distal perfusion deficits

It is important to determine if SIRS is caused by an infection, as early treatment is crucial to deter sepsis from advancing to severe sepsis or septic shock (Moser, 2014).

To differentiate between SIRS and sepsis, a useful biomarker is to check serum procalcitonin (PCT) levels, as well as other diagnostic criteria (see Table 69-5) (Meynaar, Droog, Batstra, et al., 2011).

Supportive measures, such as mechanical ventilation, aggressive fluid resuscitation, nutritional support, cardiac pharmacology, and broad-

spectrum antibiotics can assist to survive the acute hypoperfusion state of SIRS; however, many patient progress to multiple-organ dysfunction syndrome (MODS) (Fry, 2012).

Multiple-organ dysfunction syndrome (MODS) is the failure of two or more organ systems in a patient who is acutely ill to such a degree that homeostasis cannot be maintained without intervention. MODS is a progression from SIRS. The mortality rate is 70% when three or more organs fail (Dellinger et al., 2013; see Figure 69-1).

Organ and Metabolic Dysfunction.

When the inflammatory response is not controlled, the consequences that occur include activation of inflammatory cells and release of mediators, direct damage to the endothelium, and hypermetabolism. Vasodilation becomes excessive and leads to decreased SVR and hypotension. In addition, vascular permeability increases, which allows mediators and protein to leak out of the endothelium and into the interstitial space. The WBCs begin to phagocytize the foreign debris, and the coagulation cascade is activated (see Chapter 32). Organ perfusion may be compromised because of hypotension, decreased perfusion, microemboli, and redistributed or shunted blood flow.

The respiratory system is most commonly affected in MODS (Aitken et al., 2011; Dellinger et al., 2013). Inflammatory mediators have a direct effect on the pulmonary vasculature. The endothelial damage from the release of inflammatory mediators results in an increase in capillary permeability and facilitates movement of proteinaceous fluid from the pulmonary vasculature into the pulmonary interstitial spaces. The fluid then moves to the alveoli, causing alveolar edema. Type I pneumocytes (alveolar cells) are destroyed. Type II pneumocytes become dysfunctional, and surfactant production decreases. The alveoli collapse, which leads to an increase in shunt (blood flow to the lungs that does not participate in gas exchange) and a worsening of the ventilation–perfusion mismatch. The end result is ARDS. Patients with ARDS require aggressive pulmonary management with mechanical ventilation. (See Chapter 70 for more on ARDS and mechanical ventilation.)

Cardiovascular changes in MODS include myocardial depression and massive vasodilation in response to increasing tissue demands. Vasodilation results in decreased SVR and BP. The baroreceptor reflex causes release of *inotropic* factors (which increase force of contraction) and *chronotropic* factors (which increase heart rate) that enhance CO. To

compensate for hypotension, CO rises by means of an increase in heart rate and stroke volume. Increases in capillary permeability cause a shift of albumin and fluid out of the vascular space, further diminishing venous return and thus preload. The patient becomes warm and tachycardic, with a high CO and a low SVR. Other signs of MODS include decreased capillary refill, skin mottling, increases in CVP and PAOP, and dysrhythmias. SvO_2 may be abnormally high because areas not consuming much oxygen (e.g., skin, nonworking muscle) are being perfused but other areas may have blood shunted away from them. Eventually, either perfusion of vital organs becomes insufficient, or the cells are unable to use oxygen and their function is further compromised.

Neurological dysfunction with SIRS and MODS commonly manifests as mental status changes. Acute alteration in mental status can be an early sign of MODS. The patient may become confused and agitated, combative, disoriented, lethargic, or comatose. These changes may be caused by hypoxemia, the direct effect of the inflammatory mediators, or impaired perfusion. AKI is frequent in SIRS and MODS. AKI can be caused not only by hypoperfusion but also by the effects of the mediators. When kidney perfusion is decreased, the SNS and the renin–angiotensin system are activated. The stimulation of the renin–angiotensin system results in systemic vasoconstriction and aldosterone-mediated sodium and water reabsorption. Another risk factor for the development of AKI is the use of nephrotoxic drugs. Antibiotics commonly used to treat Gram-negative bacteria, such as aminoglycosides, can be nephrotoxic. Careful monitoring of drug levels is essential to avoid the nephrotoxic effects.

The GI tract also plays a key role in the development of MODS. GI motility is often decreased in critical illness, and this condition results in abdominal distension and paralytic ileus. In the early stages of SIRS and MODS, blood also is shunted away from the GI mucosa; thus the mucosa is highly vulnerable to ischemic injury. Decreased perfusion leads to a breakdown of this normally protective mucosal barrier, thus increasing the risk for ulceration and GI bleeding. The breakdown of the mucosal barrier of the gut increases the potential for bacterial translocation from the GI tract into the systemic circulation, which provides a pathway to the lungs, liver, and kidneys (Miller et al., 2011).

Metabolic changes are pronounced in SIRS and MODS. Both syndromes trigger a hypermetabolic response. Glycogen stores are rapidly converted to glucose (glycogenolysis). Once glycogen is depleted, amino acids are converted to glucose (gluconeogenesis), which reduces protein stores. Fatty acids are mobilized for fuel. Catecholamines and glucocorticoids are

released, which results in hyperglycemia and insulin resistance. The net result is a catabolic state, and lean body mass (muscle) is lost.

The hypermetabolism associated with SIRS and MODS may last for several days and results in liver dysfunction. Liver dysfunction in MODS may exist long before it is clinically evident. The liver is unable to synthesize albumin, one of the key proteins that has an essential role in maintaining plasma oncotic pressure. Consequently, plasma oncotic pressure is altered, and fluid and protein leak from the vascular spaces to the interstitial space. Administration of albumin does not normalize oncotic pressure in this situation.

As the state of hypermetabolism persists, the patient becomes unable to convert lactate to glucose, and lactate accumulates (lactic acidosis). Despite increases in glycogenolysis and gluconeogenesis, the liver eventually becomes unable to maintain a glucose level, and the patient becomes hypoglycemic.

DIC, or simultaneous microvascular clotting and bleeding, may occur because of the depletion of clotting factors and platelets in addition to excessive fibrinolysis. (DIC is discussed in Chapter 33.)

Electrolyte imbalances are common and result from hormonal and metabolic changes and fluid shifts. These changes exacerbate mental status changes, neuro-muscular dysfunction, and dysrhythmias. The release of ADH and aldosterone results in sodium and water retention. Aldosterone increases urinary potassium loss, and catecholamines cause potassium to move into the cell, which results in hypokalemia. Hypokalemia is associated with dysrhythmias and muscle weakness. Metabolic acidosis results from impairment in tissue perfusion, hypoxia, and a shift to anaerobic metabolism with a resultant increase in hydrogen ion production. Progressive renal dysfunction also contributes to metabolic acidosis. Hypocalcemia, hypomagnesemia, and hypophosphatemia are common.

Clinical Manifestations

The clinical manifestations of MODS are presented in Table 69-12.

TABLE 69-12

MULTIPLE-ORGAN DYSFUNCTION SYNDROME: CLINICAL MANIFESTATIONS AND MANAGEMENT

Clinical Manifestations of Organ Failure	Management
Cardiovascular System	
Biventricular failure ↓ Ejection fraction, contractility ↑ HR, ↑ SVR, ↓ CO ↓ MAP ↓ Stroke volume Myocardial depression Systolic, diastolic dysfunction	Balancing O_2 supply and demand • Supplemental O_2 • Continuous SvO_2 monitoring Circulatory assist devices • Intra-aortic balloon pump • Ventricular assist devices Continuous ECG monitoring Hemodynamic monitoring • Arterial pressure catheter • Central venous or PA catheter • PAOP readings • Maintaining MAP >65 mm Hg Maintaining CO • Volume management • Vasopressors, inotropes, vasodilators VTE prophylaxis
Central Nervous System	
Acute change in neurological status Confusion, disorientation Failure to wean, prolonged rehabilitation Fever Hepatic encephalopathy Seizures	Evaluation for hepatic and metabolic encephalopathy Optimization of cerebral blood flow ↓ Cerebral oxygen requirements Prevention of secondary tissue ischemia • Calcium channel blockers (reduce cerebral vasospasm) Prevention of further compromise
Endocrinological System	
Hyperglycemia → hypoglycemia	Continuous infusion of insulin and glucose to maintain blood glucose at <8.33 mmol/L
Gastro-Intestinal System	
Mucosal ischemia • ↓ Intramucosal pH • Potential translocation of gut bacteria Hypoperfusion → ↓ peristalsis, paralytic ileus Mucosal ulceration on endoscopy GI bleeding	Dietary consultation Enteral feedings • Provide essential nutrients and optimal calories • Stimulate mucosal activity Stress ulcer prophylaxis • Antacids (e.g., Maalox) • Histamine H_2-receptor blockers (e.g., famotidine [Pepcid]) • Proton pump inhibitors (e.g., omeprazole) • Sucralfate
Hematological System	
↑ Bleeding times, ↑ PT, ↑ PTT, ↑ INR ↑ D-dimer test results ↑ Fibrin split products ↓ Platelet count (thrombo-cytopenia)	Minimizing traumatic interventions (e.g., intramuscular injections, multiple venipunctures) Observation for bleeding from obvious and occult sites Replacement of factors being lost (e.g., platelets)
Hepatic System	

Clinical Manifestations of Organ Failure	Management
Bilirubin >34 mcmol/L ↑ Liver enzymes (ALT, AST, GGT) ↑ Serum NH_3 ↓ Serum albumin, prealbumin, transferrin Jaundice Hepatic encephalopathy	Maintenance of adequate tissue perfusion Nutritional support (e.g., enteral feedings) Judicious use of hepatically metabolized drugs
Renal System	
Prerenal: renal hypoperfusion • BUN/creatinine ratio >20 : 1 • ↓ Urine Na^+ level to <40 mmol/L • ↑ Urine specific gravity to >1.020 • ↑ Urine osmolality Intrarenal: ATN BUN/creatinine ratio <10 : 1–15 : 1 • ↑ Urine Na^+ level to >40 mmol/L • ↓ Urine osmolality • Urine specific gravity (≈1.010)	Diuretics • Loop diuretics (e.g., furosemide [Lasix]) • May need to increase dose owing to ↓ glomerular filtration rate Dopamine (Intropin) • Enhances renal blood flow • Improves renal perfusion • Increases urine output (if volume resuscitated) • May work synergistically with diuretics Continuous renal replacement therapy (see Chapter 49)
Respiratory System	
Development of ARDS (see Chapter 70): • Severe dyspnea • PaO_2/FiO_2 ratio <200 • Bilateral fluffy infiltrates on chest radiograph • PAOP <18 mm Hg • Ventilation–perfusion mismatch • Pulmonary hypertension • Increased minute ventilation • Increased respiratory rate • Decreased compliance • Refractory hypoxemia	Prevention Optimizing oxygen delivery, minimizing oxygen consumption Mechanical ventilation (see Chapter 68) • Positive end-expiratory pressure • Lung protective modes (e.g., pressure control or inverse ratio ventilation, low tidal volumes) • Permissive hypercapnia Positioning (e.g., continuous lateral rotation therapy, prone positioning)

ALT, alanine aminotransferase; *ARDS,* acute respiratory distress syndrome; *AST,* aspartate aminotransferase; *ATN,* acute tubular necrosis; *BUN,* blood urea nitrogen; *CO,* cardiac output; *FiO_2,* fraction of inspired oxygen; *ECG,* electrocardiograph; *GGT,* γ-glutamyl transferase; *GI,* gastro-intestinal; *HR,* heart rate; *INR,* international normalized ratio; *MAP,* mean arterial pressure; *PA,* pulmonary artery; *PaO_2,* partial pressure of arterial oxygen; *PAOP,* pulmonary artery occlusive pressure; *PT,* prothrombin time; *PTT,* partial thromboplastin time; *SvO_2,* venous oxygen saturation; *SVR,* systemic vascular resistance; *VTE,* venous thrombo-embolism.

Nursing and Collaborative Management SIRS and MODS

Without early, goal-directed therapy, the prognosis for patients with SIRS and MODS is poor. Mortality rates have been as high as 70% to 80% when three or more organs are involved (Dellinger et al., 2013). A critical component of the nursing role is vigilant assessment and ongoing monitoring to detect early signs of deterioration or organ dysfunction. Collaborative care for patients with MODS focuses on (a) prevention and treatment of infection, (b) maintenance of tissue oxygenation, (c) nutritional and metabolic support, and (d) appropriate support of individual failing organs. Table 69-12 summarizes the management for patients with MODS.

Prevention and Treatment of Infection

Aggressive infection control strategies are essential to decrease the risk for HAIs. Strict asepsis can decrease infections related to intra-arterial lines, endotracheal tubes, urinary catheters, IV lines, and other invasive devices or procedures. Daily assessment of the ongoing need for invasive lines is an important strategy to prevent or limit HAIs.

Despite these strategies, host dysfunction may lead to the development of an infection. Once an infection is suspected, interventions to control the source must be instituted. Appropriate cultures should be taken, and broad-spectrum antibiotic therapy should be initiated. Early, aggressive surgery is recommended to remove necrotic tissue (e.g., early debridement of burn tissue) that may provide a culture medium for microorganisms. Once a specific organism is identified, therapy should be modified if necessary. Aggressive pulmonary management, including early ambulation, can reduce the risk for infection devices or procedures.

Maintenance of Tissue Oxygenation

Hypoxemia frequently occurs in patients with SIRS and MODS. These patients have greater oxygen needs and decreased oxygen supply to the tissues. Interventions that decrease oxygen demand and increase oxygen delivery are essential. Sedation, mechanical ventilation, analgesia, paralysis, and rest may decrease oxygen demand and should be considered. Oxygen delivery may be optimized by maintaining normal

levels of hemoglobin (e.g., transfusion of packed RBCs) and PaO_2 (80 to 100 mm Hg), using individualized tidal volumes with positive end-expiratory pressure (PEEP), increasing preload or myocardial contractility to enhance CO, or reducing afterload to increase CO.

Nutritional and Metabolic Needs

Hypermetabolism in SIRS or MODS can result in profound weight loss, cachexia, and further organ failure. Protein–calorie malnutrition is one of the primary manifestations of hypermetabolism and MODS. Total energy expenditure is often increased to 1.5 to 2.0 times the normal metabolic rate. Because of their relatively short half-life, plasma transferrin and prealbumin levels are monitored to assess hepatic protein synthesis.

The goal of nutritional support is to preserve organ function. Providing early and optimal nutrition decreases morbidity and mortality rates in patients with SIRS and MODS (Dellinger et al., 2013). Ideally, the patient consumes intake orally. If the patient is unable to do so, the enteral route is initiated slowly and increased as tolerated (Dellinger et al., 2013). If enteral nutrition is not meeting caloric needs, parenteral nutrition should be initiated or added. (Enteral and parenteral nutrition are discussed in Chapter 42.) Attention to tight glycemic control (blood glucose level of <10 mmol/L) with the use of insulin protocols is important in these patients (Dellinger et al., 2013).

Support of Failing Organs

Support of any failing organs is a primary goal of therapy. For example, the patient with ARDS requires aggressive oxygen therapy and mechanical ventilation (see Chapter 70). DIC should be treated appropriately (e.g., blood products; see Chapter 33). Renal failure may necessitate dialysis. Continuous renal replacement therapy (CRRT) is better tolerated than hemodialysis, especially in a patient with hemodynamic instability (see Chapter 49).

Given the poor prognosis for MODS, withdrawal of life support may need to be considered when all resuscitative attempts fail. It is important to ensure that advance directives are clearly indicated and that the nurse follows the patient's wishes regarding end-of-life care.

Case Study

Shock

Source: Scott Dumas/Shutterstock.com.

Patient Profile

Ken Masaki, a 25-year-old male patient, was not wearing his seat belt when the car he was driving was involved in a motor vehicle accident. The windshield was broken, and Mr. Masaki was found 5 metres from his car. He was face down, conscious, and moaning. His wife and daughter were found in the car with their seat belts on. They sustained no serious injuries but were upset. All passengers were taken to the emergency department (ED). The following information pertains to Mr. Masaki.

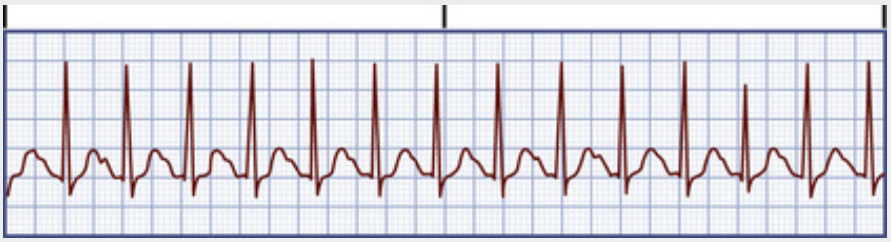
Subjective Data

- States, “I can't breathe”
- Cries out when abdomen is palpated

Objective Data

Physical Examination

- Abdomen: slightly distended and left upper quadrant painful on palpation
- Cardiovascular: BP 80/56 mm Hg; apical pulse 138 but no palpable radial or pedal pulses; carotid pulse present but weak
- ECG as follows:



- Lungs: respiratory rate 38 breaths/min; laboured breathing with shallow respirations; asymmetric chest wall movement; absence of breath sounds on left side
- Musculo-skeletal: open compound fracture of the lower left leg
- Trachea deviated slightly to the right

Diagnostic Studies

Chest radiograph: Hemothorax and six rib fractures on left side
Hematocrit: 0.28 volume fraction

Collaborative Care (in the ED)

- Left chest tube placed, draining bright red blood
- IV access obtained via one peripheral line and right subclavian central line
- Fluid resuscitation started with crystalloids
- High-flow O_2 via nonrebreather mask

Surgical Procedure

- Repair of compound fracture
- Repair of torn intercostal artery
- Splenectomy

Discussion Questions

1. What types of shock is Mr. Masaki experiencing? What clinical manifestations did he display that support this answer?

2. What were the causes of Mr. Masaki's shock states? What are other causes of these types of shock?
3. ***Priority decision:*** What are the priority nursing responsibilities for Mr. Masaki?
4. ***Priority decision:*** What ongoing nursing assessment parameters are essential for this patient?
5. What are his potential complications?
6. ***Priority decision:*** Based on the assessment data presented, what are the priority nursing diagnoses?
7. ***Evidence-informed practice:*** The nurse is orienting a new graduate RN. He asks why crystalloids are used instead of colloids for fluid resuscitation. What should the nurse's response be?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. A client has a spinal cord injury at T4. Vital signs include falling blood pressure with bradycardia. The nurse recognizes that the client is experiencing which of the following?
   a. A relative hypervolemia
   b. An absolute hypovolemia
   c. Neurogenic shock from low blood flow
   d. Neurogenic shock from massive vasodilation
2. A 78-year-old man has confusion and temperature of 40°C. He has diabetes with purulent drainage from his right heel. After an infusion of 3 L of normal saline solution, his assessment findings are BP 84/40 mm Hg; heart rate 110; respiratory rate 42 and shallow; CO 8 L/min; and PAOP 4 mm Hg. This client's symptoms are most likely indicative of which of the following?
   a. Sepsis
   b. Septic shock
   c. Multiple-organ dysfunction syndrome
   d. Systemic inflammatory response syndrome
3. Appropriate treatment modalities for the management of cardiogenic shock include which of the following? *(Select all that apply)*
   a. Dobutamine to increase myocardial contractility
   b. Vasopressors to increase systemic vascular resistance
   c. Circulatory assist devices such as an intra-aortic balloon pump
   d. Corticosteroids to stabilize the cell wall in the infarcted myocardium
   e. Trendelenburg positioning to facilitate venous return and increase preload
4. The most accurate assessment parameters for the nurse to use to determine adequate tissue perfusion in the client with MODS are which of the following?
   a. Blood pressure, pulse, and respirations
   b. Breath sounds, blood pressure, and body temperature
   c. Pulse pressure, level of consciousness, and pupillary response

d. Level of consciousness, urine output, and skin colour and temperature

1. d, 2. b, 3. a, c, 4. d.

CHAPTER 70

Nursing Management

Respiratory Failure and Acute Respiratory Distress Syndrome

Written by, Richard Arbour

Adapted by, Debbie Rickeard

LEARNING OBJECTIVES

1. Compare the pathophysiological mechanisms that result in hypoxemic and hypercapnic respiratory failure.
2. Differentiate between early and late clinical manifestations of acute respiratory failure.
3. Describe the nursing and collaborative management of a patient with hypoxemic or hypercapnic respiratory failure.
4. Explain how the pathophysiological mechanisms that result in acute respiratory distress syndrome are related to the clinical manifestations of this syndrome.
5. Describe the nursing and collaborative management of a patient with acute respiratory distress syndrome.
6. Identify complications that may result from acute respiratory failure or acute respiratory distress syndrome and measures to prevent or reverse these complications.

KEY TERMS

acute respiratory distress syndrome (ARDS), p. 1794

alveolar hypoventilation, p. 1785

diffusion limitation, p. 1785

hypercapnia, p. 1783

hypercapnic respiratory failure, p. 1783

hypoxemia, p. 1783

hypoxemic respiratory failure, p. 1783

hypoxia, p. 1788

refractory hypoxemia, p. 1795

The normal function of the respiratory system is to facilitate gas exchange. Without an adequate exchange of oxygen (O_2) and carbon dioxide (CO_2), the metabolic demands of the tissues would not be met, and body systems would begin to rapidly fail. The management of patients in acute respiratory distress or failure revolves around the improvement of oxygenation and ventilation, treatment of the underlying disease state, reduction of anxiety, and prevention and management of complications. Acute respiratory failure and acute respiratory distress syndrome (ARDS) represent important and costly public health problems. The global effect of ARDS is difficult to estimate. The in-hospital rate of mortality from ARDS has remained high since it was first described; current mortality rates range from 40% to 50% (Villar, Blanco, & Kacmarek, 2016). Patients with ARDS require critical nursing assessments and collaborative management to improve their outcomes, which is the focus of this chapter.

Acute Respiratory Failure

The major function of the respiratory system is gas exchange, which involves the transfer of O_2 and CO_2 between the atmosphere and the blood (Figure 70-1; Urden, Stacy, & Lough, 2014). *Respiratory failure* is the state in which one or both gas-exchanging functions are inadequate: Either the amount of O_2 transferred to the blood is insufficient or the amount of CO_2 removed from the lungs is inadequate. Clinical states that interfere with O_2 transfer result in **hypoxemia**—a state of low oxygen tension in the blood (partial pressure of oxygen in arterial blood [PaO_2] <60 mm Hg), characterized by a variety of nonspecific clinical signs and symptoms—and a decrease in arterial oxygen saturation (SaO_2) as determined by measurements of arterial blood gases (ABGs). Insufficient CO_2 removal results in **hypercapnia,** the presence of excessive amounts of CO_2 in the blood; also called *hypercarbia,* it is manifested by an increase in partial pressure (or tension) of carbon dioxide in arterial blood ($PaCO_2$; Brashers & Huether, 2014; Fournier, 2014). ABGs can be measured to intermittently assess changes in pH, PaO_2, $PaCO_2$, bicarbonate, and SaO_2; and oxygen saturation can be assessed intermittently or continuously with pulse oximetry (SpO_2). Pulse oximetry offers advantages of noninvasiveness and real-time values; however, the accuracy of readings depends on correct application of the sensor to a well-perfused digit, usually a middle or ring finger. When the SpO_2 is 90%, the PaO_2 is approximately 60 mm Hg, if factors such as temperature, $PaCO_2$ and pH are normal (Brashers & Huether, 2014; Fournier, 2014). Data should be interpreted alongside clinical assessment findings and the patient's baseline values. For example, an individual with chronic lung disease may have a baseline $PaCO_2$ higher than what is considered the "normal" range. (To assist the reader, Table 70-1 summarizes abbreviations used in this chapter.)

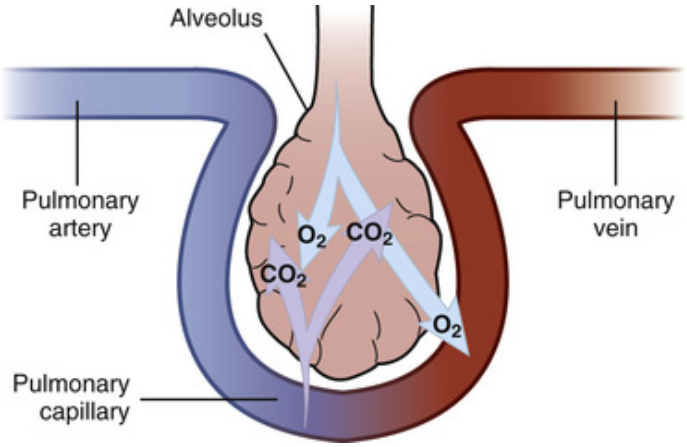

FIGURE 70-1 Normal gas-exchange unit in the lung.

TABLE 70-1
ABBREVIATIONS OF COMMON PULMONARY TERMS

Arterial Blood Monitoring	
ABGs	Arterial blood gases
pH	Negative log of the free hydrogen ion [H^+]
PaO_2	Partial pressure of oxygen in arterial blood
$PaCO_2$	Partial pressure of carbon dioxide in arterial blood
SaO_2	Oxygen saturation in arterial blood as measured by ABGs
SpO_2	Oxygen saturation in arterial blood as measured by pulse oximetry
Oxygen and Lung Function Monitoring	
FiO_2	Fraction of inspired oxygen concentration
FRC	Functional residual capacity (volume of air in lung at end of expiration)
PEEP	Positive end-expiratory pressure (pressure in lungs at end of expiration)
PEFR	Peak expiratory flow rate (maximum airflow during a forced expiration)
VQ	Ventilation–perfusion ratio (relationship of ventilation to perfusion in the lungs)
V_E	Minute ventilation (tidal volume × respiratory rate)
V_T	Tidal volume (volume of air inspired with each breath)

Respiratory failure is not a disease; it is a condition that occurs as a result of one or more diseases involving the lungs or other body systems (see Tables 70-2 and 70-3). It is classified as hypoxemic or hypercapnic (Figure 70-2). *Hypoxemic respiratory failure* is also referred to as *oxygenation failure* because the primary problem is inadequate O_2 transfer between the alveoli and the pulmonary capillary bed (Fournier, 2014). Although no universal definition exists, **hypoxemic respiratory failure** is commonly defined as a PaO_2 of 60 mm Hg or less when the patient is receiving inspired oxygen at a fractional concentration (FiO_2) of 60% or greater. This definition incorporates two important concepts: (1) the PaO_2 level indicates inadequate O_2 saturation of hemoglobin; and (2) this PaO_2 level exists

despite administration of supplemental O_2 at a percentage (60%) that is three times that in room air (21%). Disorders that interfere with O_2 transfer into the blood include pneumonia, pulmonary edema, pulmonary emboli, alveolar injury related to inhalation of toxic gases (e.g., smoke inhalation), and ventilator-induced lung injury. In addition, states of low cardiac output (e.g., heart failure, shock) can also cause hypoxemic respiratory failure (Urden, Stacy, & Lough, 2014).

TABLE 70-2
TYPES OF RESPIRATORY FAILURE AND COMMON CAUSES*

Hypoxemic Respiratory Failure	
Respiratory system	Acute respiratory distress syndrome Pneumonia Toxic inhalation (smoke inhalation) Hepatopulmonary syndrome (low-resistance flow state, ventilation–perfusion [VQ] mismatch) Massive pulmonary embolism (e.g., thrombus emboli, fat emboli)
Cardiac system	Anatomical shunt (e.g., ventricular septal defect) Cardiogenic pulmonary edema Shock (decreasing blood flow through pulmonary vasculature)
Hypercapnic Respiratory Failure	
Respiratory system	Asthma Chronic obstructive pulmonary disease Cystic fibrosis
Central nervous system	Brainstem infarction Sedative and opioid overdose Spinal cord injury Severe head injury
Chest wall	Thoracic trauma (e.g., flail chest) Kyphoscoliosis Pain Morbid obesity
Neuro-muscular system	Myasthenia gravis Critical illness polyneuropathy Acute myopathy Toxic ingestion (e.g., tree tobacco) Amyotrophic lateral sclerosis Phrenic nerve injury Guillain-Barré syndrome Poliomyelitis Muscular dystrophy Multiple sclerosis

*This list is not all-inclusive.

TABLE 70-3
PREDISPOSING FACTORS FOR ACUTE RESPIRATORY FAILURE

Predisposing Factors	Mechanisms of Respiratory Failure
Airways and Alveoli	
Acute respiratory distress syndrome • *Direct lung injury:* Aspiration; severe, disseminated pulmonary infection; near-drowning; toxic gas inhalation; airway contusion • *Indirect lung injury:* Sepsis or septic shock, severe nonthoracic trauma, cardiopulmonary bypass	Fluid enters the interstitial space and the alveoli, markedly impairing gas exchange. The result is an initial ↓ in PaO_2 and a later ↑ in $PaCO_2$. A low-flow state to pulmonary capillaries can result in ischemic injury to lung tissues with loss of integrity of the alveolar–capillary membrane.
Asthma	Bronchospasm escalates in severity rather than responding to therapy. Bronchospasm, edema of the bronchial mucosa, and plugging of small airways with secretions greatly reduce airflow.
	Work of breathing increases, causing respiratory muscle fatigue. ↓ in PaO_2 and ↑ in $PaCO_2$ (see Chapter 31).
Chronic obstructive pulmonary disease (COPD)	Alveoli are destroyed by protease–antiprotease imbalance or respiratory infection, or an exacerbation of COPD escalates in severity rather than responding to therapy. Secretions obstruct airflow. Work of breathing increases and causes respiratory muscle fatigue. ↓ in PaO_2 and ↑ in $PaCO_2$.
Cystic fibrosis	Abnormal Na^+ and Cl^- transport results in secretions that are viscous, poorly cleared, and therefore foci for infection. Over time, the airways become clogged with copious, purulent sputum. Secretions obstruct airflow. Repeated infections destroy alveoli. Work of breathing increases, causing respiratory muscle fatigue. ↓ in PaO_2 and ↑ in $PaCO_2$.
Central Nervous System	
Overdose of opioid or other CNS depressant	Respirations are slowed by drug effect. Insufficient CO_2 is excreted, resulting in ↑ $PaCO_2$.
Brainstem infarction, head injury	Medulla cannot alter respiratory rate in response to changes in $PaCO_2$.
Chest Wall	
Severe soft tissue injury, flail chest, rib fracture, pain	Structural dysfunction and pain prevent normal rib cage expansion, resulting in inadequate gas exchange.
Kyphoscoliosis	Change in spinal configuration compresses the lungs and prevents normal expansion of the chest wall, resulting in inadequate gas exchange.
Morbid obesity	Weight of the chest and abdominal contents prevents normal rib cage movement, resulting in inadequate gas exchange.
Neuro-Muscular Conditions	
Cervical cord injury, phrenic nerve injury	Neural control is lost, preventing use of the diaphragm, the major muscle of respiration. Consequently, the patient inspires a smaller tidal volume, which predisposes to an ↑ in $PaCO_2$.
Amyotrophic lateral sclerosis (ALS), Guillain-Barré syndrome, muscular dystrophy, multiple sclerosis, poliomyelitis, myasthenia gravis, myopathy, critical illness polyneuropathy, prolonged use of neuro-muscular blocking agents	Respiratory muscle weakness or paralysis occurs, preventing normal CO_2 excretion. Dysfunction may be progressive (muscular dystrophy, multiple sclerosis), progressive with no potential of recovery (ALS), rapid with good expectation of recovery (Guillain-Barré), or stable for extended periods (poliomyelitis, myasthenia gravis).

CNS, central nervous system; *$PaCO_2$*, partial pressure of carbon dioxide in arterial blood; *PaO_2*, partial pressure of oxygen in arterial blood.

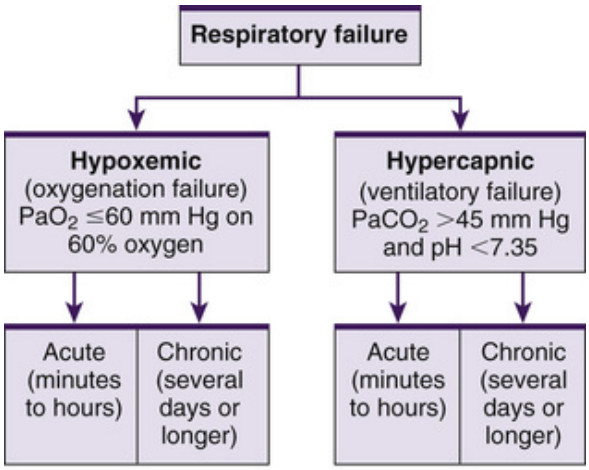

FIGURE 70-2 Classification of respiratory failure. *$PaCO_2$*, partial pressure of carbon dioxide in arterial blood; *PaO_2*, partial pressure of oxygen in arterial blood.

Hypercapnic respiratory failure is referred to as *ventilatory failure* because the primary problem is insufficient CO_2 removal. **Hypercapnic respiratory failure** is commonly defined as a $PaCO_2$ above normal (>45 mm Hg) in combination with acidemia (arterial pH <7.35). This definition incorporates three important concepts: (1) the $PaCO_2$ is higher than normal; (2) there is evidence of the body's inability to compensate for this increase (acidemia); and (3) the pH is at a level at which a further decrease may lead to severe acid–base imbalance. (See Chapter 19 for a discussion of acid–base balance.) Conditions that compromise lung ventilation and subsequent CO_2 removal include drug overdoses with central nervous system (CNS) depressants, neuro-muscular diseases (e.g., myasthenia gravis), and trauma or diseases involving the spinal cord and its role in lung ventilation. Many patients experience both hypoxemic and hypercapnic respiratory failure.

Etiology and Pathophysiology

Hypoxemic Respiratory Failure.

Common diseases and conditions that cause hypoxemic respiratory failure are listed in Table 70-2. Four physiological mechanisms may cause hypoxemia and subsequent hypoxemic respiratory failure: (1) mismatch between ventilation (V) and perfusion (Q), commonly referred to as *VQ mismatch*; (2) shunting; (3) diffusion limitation; and (4) hypoventilation.

The most common causes are VQ mismatch and shunting (Urden, Stacy, & Lough, 2014).

Ventilation–Perfusion Mismatch.

In normal lungs, the volume of blood perfusing the lungs each minute (4 to 5 L) approximates the amount of fresh gas that reaches the alveoli each minute (4 to 5 L). In a perfectly matched system, each portion of the lung would receive approximately 1 mL of air for each 1 mL of blood flow. This match of ventilation and perfusion would result in a VQ ratio of 1 : 1 (e.g., 1 mL of air per 1 mL of blood), which is expressed as VQ = 1; thus ventilation volume would be identical to perfusion volume. Although this example implies that the ideal situation is that ventilation and perfusion are matched in all areas of the lung, this situation does not normally exist. In reality, there is some regional mismatch even under normal conditions. At the lung apex, VQ ratios are greater than 1 (more ventilation than perfusion). At the lung base, VQ ratios are less than 1 (less ventilation than perfusion). Because changes at the lung apex balance changes at the base, the net effect is a close overall match (Figure 70-3).

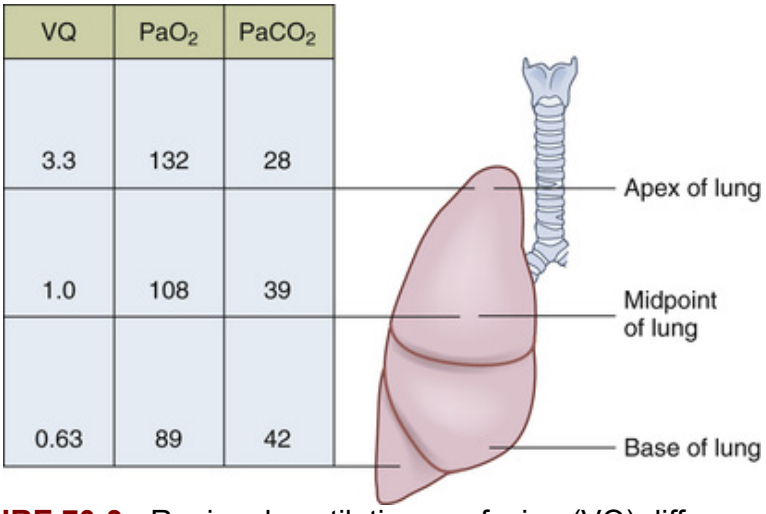

FIGURE 70-3 Regional ventilation–perfusion (VQ) differences in the normal lung. At the lung apex, the VQ ratio is 3.3; at the midpoint, it is 1.0; and at the base, it is 0.63. This difference causes the arterial partial pressure of oxygen (PaO_2) to be higher at the apex of the lung and lower at the base. Values for arterial partial pressure of carbon dioxide ($PaCO_2$) are the opposite (i.e., lower at the apex and higher at the base). Blood that exits the lung has a mixture of these values.

Many diseases and conditions alter overall VQ matching and thus cause VQ mismatch (Figure 70-4). The most common are those in which increased secretions are present in the airways (as in chronic obstructive pulmonary disease [COPD]) or the alveoli (as in pneumonia) and when bronchospasm is present (as in asthma). VQ mismatch may also result from alveolar collapse (atelectasis) or from pain. Uncontrolled pain interferes with chest and abdominal wall movement, compromising lung ventilation. In addition, pain increases muscle and motor tension, which leads to generalized muscle rigidity; causes systemic vasoconstriction and activation of the stress response; and increases O_2 consumption and CO_2 production (Brashers & Huether, 2014; Fournier, 2014). All of these conditions may increase both metabolic demands (for O_2) and ventilatory demands, and, at the same time, airflow (ventilation) to alveoli is limited. Because no effect on blood flow (perfusion) to the gas-exchange units is exerted to balance the equation, the consequence is VQ mismatch. A pulmonary embolus affects the perfusion portion of the VQ relationship. The embolus limits blood flow but has no effect on airflow to the alveoli, which again causes VQ mismatch (see Figure 70-4).

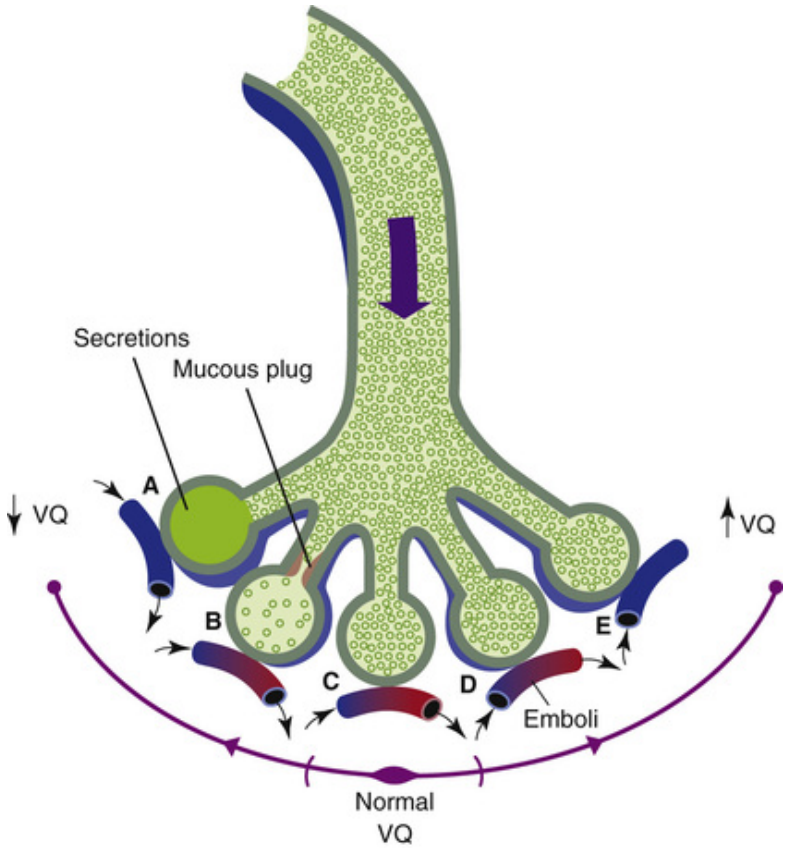

FIGURE 70-4 Range of ventilation–perfusion (VQ) relationships. **A,** Absolute shunt: no ventilation as a result of fluid filling the alveoli. **B,** VQ mismatch in which ventilation partially compromised by secretions in the airway. **C,** Normal lung unit. **D,** VQ mismatch in which perfusion is partially compromised by emboli obstructing blood flow. **E,** Dead space: no perfusion as a result of obstruction of the pulmonary capillary.

Oxygen therapy is an appropriate first step to reverse hypoxemia caused by VQ mismatch because not all gas-exchange units are affected. Oxygen therapy increases the PaO_2 in blood leaving normal gas-exchange units, thus causing the PaO_2 to be higher than normal. The well-oxygenated blood mixes with poorly oxygenated blood, which raises the overall PaO_2 of blood leaving the lungs. Optimal treatment for hypoxemia caused by VQ mismatch is directed at the cause.

Shunt.

Shunting is the situation in which blood exits the heart without having participated in gas exchange. A shunt can be viewed as an extreme VQ mismatch (see Figure 70-4). There are two types of shunts: In an *anatomical*

shunt, blood passes through an anatomical channel in the heart (e.g., ventricular septal defect), bypassing the lungs. In an *intrapulmonary shunt*, blood flows through the pulmonary capillaries without participating in gas exchange. Intrapulmonary shunt occurs in conditions in which alveoli fill with fluid (e.g., ARDS, pneumonia, pulmonary edema). In hypoxemia due to shunt, O_2 therapy alone may not effectively increase the PaO_2 because (a) blood passes from the right side of the heart to the left side without passing through the lungs (anatomical shunt) or (b) the alveoli are filled with fluid, which prevents gas exchange (intrapulmonary shunt). Patients with such shunts are usually more hypoxemic than patients with VQ mismatch, and they may require both mechanical ventilation and a high FiO_2 to improve gas exchange.

Diffusion Limitation.

Diffusion limitation is the decrease in gas exchange across the alveolar–capillary membrane by processes that thicken or destroy the membrane (Figure 70-5). Conditions that affect the pulmonary vascular bed, such as severe emphysema or recurrent pulmonary emboli, can worsen diffusion limitation. Some diseases (e.g., pulmonary fibrosis, interstitial lung disease, ARDS) cause the alveolar–capillary membrane to become thicker (fibrotic), which slows gas transport. Diffusion limitation is more likely to cause hypoxemia during exercise than at rest. During exercise, blood moves more rapidly through the lungs. Because the transit rate is increased, red blood cells are in the lungs for a shorter time, limiting opportunity for diffusion of O_2 across the alveolar–capillary membrane. The classical sign of diffusion limitation is hypoxemia that is present during exercise but not at rest.

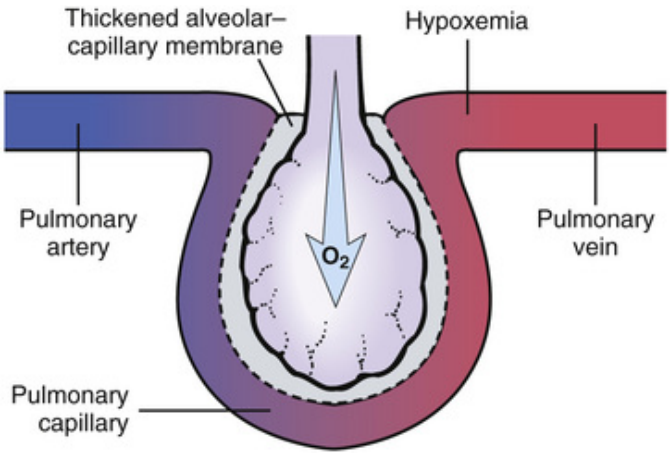

FIGURE 70-5 Diffusion limitation. Exchange of CO_2 and O_2 cannot occur because of the thickened alveolar–capillary membrane.

Alveolar Hypoventilation.

Alveolar hypoventilation is a decrease in ventilation that results in an increase in $PaCO_2$ and a consequent decrease in PaO_2. Alveolar hypoventilation may result from restrictive lung disease, CNS disease, chest wall dysfunction, or neuro-muscular disease. Although primarily a mechanism of hypercapnic respiratory failure, alveolar hypoventilation is mentioned here because it also causes hypoxemia.

Interrelationship of Mechanisms.

Frequently, hypoxemic respiratory failure is caused by a combination of two or more of the following: VQ mismatch, shunting, diffusion limitation, and hypoventilation. Patients with acute respiratory failure secondary to pneumonia may have a combination of VQ mismatch and shunting because inflammation, edema, and the hypersecretion of exudate within the bronchioles and the terminal respiratory units obstruct the airways (VQ mismatch) and fill the alveoli with exudate (shunt). In addition, shunting may be increased because of improper positioning (affected lung down). Patients with cardiogenic pulmonary edema or ARDS may have a combination of shunting and VQ mismatch because some alveoli are completely filled with fluid from edema (shunting) and others are partially filled with fluid (VQ mismatch).

Hypoxemia resulting from shunting does not respond to increases in supplemental oxygen because the capillary bed surrounding the affected alveoli is never exposed to oxygen-rich gas. As a result, hypoxemia that

results from shunting is difficult to treat (Brashers & Huether, 2014; Fournier, 2014).

Hypercapnic Respiratory Failure.

Hypercapnic respiratory failure results from an imbalance between ventilatory supply and ventilatory demand. *Ventilatory supply* is the maximum ventilation (gas flow in and out of the lungs) that the patient can sustain without developing respiratory muscle fatigue. *Ventilatory demand* is the amount of ventilation needed to keep the $PaCO_2$ normal. Normally, ventilatory supply far exceeds ventilatory demand. As a consequence, individuals with normal lung function can engage in strenuous exercise, which increases CO_2 production without an elevation in $PaCO_2$. Patients with pre-existing lung disease (e.g., severe emphysema) do not have this advantage and cannot effectively increase lung ventilation in response to exercise or metabolic demands. Typically, considerable dysfunction is present before ventilatory demand exceeds supply.

When ventilatory demand does exceed supply, a normal $PaCO_2$ cannot be sustained, and hypercapnia occurs, which reflects substantial lung dysfunction. Hypercapnic respiratory failure is sometimes called *ventilatory failure* because it represents primarily an inability of the respiratory system to clear sufficient CO_2 and maintain a normal $PaCO_2$.

The associated respiratory acidosis that accompanies hypercapnia can result in dysrhythmias, somnolence, and even coma. There are changes in intracranial pressure associated with high levels of CO_2. Hypoventilation may be overlooked because the ventilator rate and pattern may appear normal initially (Brashers & Huether, 2014; Fournier, 2014).

Diseases involving respiratory failure can be grouped into four categories: (1) abnormalities of the airways and alveoli, (2) abnormalities of the CNS, (3) abnormalities of the chest wall, and (4) neuro-muscular conditions (Table 70-3).

Airways and Alveoli.

Patients with asthma, emphysema, chronic bronchitis, and cystic fibrosis are at high risk for hypercapnic respiratory failure because the underlying pathophysiology of these conditions results in airflow obstruction and air trapping.

Central Nervous System.

A variety of problems may suppress the drive to breathe. Commonly, overdose of an opioid or other CNS depressant drug decreases CO_2 reactivity in the brainstem, which allows arterial CO_2 levels to rise. A brainstem infarction or severe head injury may also interfere with normal function of the respiratory centre in the medulla. Affected patients are at risk for respiratory ailure because the medulla does not alter the respiratory rate in response to changes in $PaCO_2$. Independent of direct brainstem dysfunction, brain injury resulting in significant CNS depression or loss of consciousness may impair the patient's ability to protect the airway. CNS dysfunction may also include high-level spinal cord injuries that limit innervation of the respiratory muscles.

Chest Wall.

Various conditions prevent normal chest wall movement, thereby limiting lung expansion. In patients with flail chest, the rib cage cannot expand normally because of painful fractures, mechanical restriction, and muscle spasm. In patients with kyphoscoliosis, changes in spinal configuration compress the lungs, preventing normal chest wall expansion. In patients with massive obesity, the weight of the chest and abdominal contents may limit lung expansion. Patients with these conditions are at risk for respiratory failure because these dysfunctions limit lung expansion or diaphragmatic movement and, consequently, gas exchange.

Neuro-muscular Conditions.

Various types of neuro-muscular diseases may result in respiratory muscle weakness or paralysis (see Table 70-2). For example, patients with Guillain-Barré syndrome, muscular dystrophy, myasthenia gravis (acute exacerbation), or multiple sclerosis are at risk for respiratory failure because the respiratory muscles are weakened or paralyzed. Therefore, they are unable to maintain normal $PaCO_2$ levels.

Note that respiratory failure occurs in three of these categories (CNS, chest wall, neuro-muscular conditions) even if the lungs are normal. Affected patients may have no damage to lung tissue but are unable to inspire sufficient tidal volume to expel CO_2 from the lungs.

Tissue Oxygen Needs.

Even though respiratory failure is determined by the PaO_2 and $PaCO_2$, the major threat is the inability of the lungs to meet the oxygen demands of

the tissues, whether as a result of inadequate O_2 delivery or because the tissues are unable to use the O_2 delivered to them. Respiratory failure may also occur as a result of the stress response and dramatic increases in tissue oxygen consumption (Brashers & Huether, 2014; Fournier, 2014). Tissue O_2 delivery is determined by the amount of O_2 carried in the hemoglobin, as well as by cardiac output. Therefore, respiratory failure increases risk if the patient has coexisting cardiac problems or anemia. Failure of O_2 utilization most commonly occurs as a result of septic shock. In this situation, adequate O_2 may be delivered to the tissues, but an abnormally high amount of O_2 returns in the venous blood, which indicates that it is not being extracted and used at the tissue level. (Shock is discussed in Chapter 69.) Acid–base alterations (e.g., alkalosis, acidosis) may also interfere with oxygen delivery to peripheral tissues (see Chapter 28).

Clinical Manifestations

Respiratory failure may develop suddenly or gradually over several days or longer. A sudden decrease in PaO_2 or a rapid rise in $PaCO_2$ implies a serious condition, which can rapidly become a life-threatening emergency. An example is the development of severe bronchospasm and a marked decrease in airflow in a patient with asthma, which can result in respiratory arrest. A more gradual change in PaO_2 and $PaCO_2$ is better tolerated because compensation can occur. An example is the development of a progressive increase in $PaCO_2$ over several days after the onset of a respiratory infection in a patient with COPD. Because the change occurs gradually over several days, there is time for renal compensation (e.g., retention of bicarbonate), which minimizes the change in arterial pH. The patient has compensated respiratory acidosis (Urden, Stacy, & Lough, 2014). (See Chapter 19 for a discussion of renal compensation for acid–base disorders.)

Manifestations of respiratory failure are related to the extent of change in PaO_2 or $PaCO_2$, the rapidity of change (acute versus chronic), and the ability to compensate or overcome this change. When the patient's compensatory mechanisms fail, respiratory failure occurs. Because clinical manifestations are variable, it is important to monitor trends in ABGs and pulse oximetry to evaluate the extent of change. These measurements cannot substitute for clinical assessment and should be interpreted within the context of clinical assessment findings. Frequently, the initial indication of respiratory failure is a change in the patient's mental status.

The cerebral cortex is very sensitive to variations in oxygenation and acid–base balance, and mental status changes occur early and frequently before ABG results show change. Restlessness, confusion, agitation, and combative behaviour suggest inadequate delivery of O_2 to the brain and should be investigated.

The nurse may detect manifestations of respiratory failure that are specific (arise from the respiratory system) or nonspecific (arise from other body systems; Table 70-4). An understanding of these manifestations is critical for detecting the onset of respiratory failure and effective treatment.

TABLE 70-4
CLINICAL MANIFESTATIONS OF HYPOXEMIA AND HYPERCAPNIA*

Specific	Nonspecific
Hypoxemia	
Respiratory • ↓ SpO_2 (<80%) • Dyspnea • Intercostal muscle retraction • Prolonged expiration (ratio of length of inspiration to that of expiration: 1 : 3, 1 : 4) • Tachypnea • Use of accessory muscles in respiration • Cyanosis (late) • Paradoxical chest or abdominal wall movement with respiratory cycle (late)	Cerebral • Agitation • Coma (late) • Confusion • Delirium • Disorientation • ↓ Level of consciousness • Restlessness, combativeness Cardiac • Dysrhythmias (late) • Hypertension • Hypotension (late) • Skin cool, clammy, and diaphoretic • Tachycardia Other • Fatigue • Inability to speak without pausing to breathe
Hypercapnia	
Respiratory • Dyspnea • ↓ Minute ventilation • ↓ Respiratory rate or ↑ rate with shallow respirations • ↓ Tidal volume	Cerebral • Coma (late) • Disorientation • Morning headache • Progressive somnolence Cardiac • Bounding pulse • Dysrhythmias • Hypertension • Tachycardia Neuro-muscular • ↓ Deep tendon reflexes • Muscle weakness • Tremor, seizures (late) Other • Pursed-lip breathing

*This list is not all-inclusive.

SpO_2, oxygen saturation in arterial blood as measured by pulse oximetry.

Tachycardia and mild hypertension can also be early signs of respiratory failure. They may indicate an attempt by the heart to compensate for decreased O_2 delivery. A severe morning headache may suggest that hypercapnia occurred during the night, increasing cerebral blood flow by vasodilation. At night, the respiratory rate is slower, and the lungs of patients at risk for respiratory failure may remove less $PaCO_2$. Rapid, shallow breaths suggest that the tidal volume may be inadequate to remove CO_2 from the lungs. Cyanosis is an unreliable indicator of

hypoxemia and is a late sign of respiratory failure because it does not occur until hypoxemia is severe (PaO_2 ≤45 mm Hg).

Consequences of Hypoxemia and Hypoxia.

Hypoxemia occurs when the amount of O_2 in arterial blood is less than the normal value (see Chapter 28). **Hypoxia** is the condition in which the PaO_2 has fallen sufficiently to cause signs and symptoms of inadequate oxygenation (see Table 70-4). Hypoxemia can lead to hypoxia if not corrected. If hypoxia or hypoxemia is severe, cell metabolism shifts from aerobic to anaerobic. Anaerobic metabolism entails the use of more fuel, produces less energy, and is less efficient than aerobic metabolism. The waste product of anaerobic metabolism, lactic acid, is more difficult to remove from the body than CO_2 because lactic acid must be buffered with sodium bicarbonate. When the body does not have adequate sodium bicarbonate to buffer the lactic acid produced by anaerobic metabolism, metabolic acidosis and cell death may result.

Hypoxia and metabolic acidosis have adverse effects on the vital organs and systems, especially the heart and the CNS. To compensate for decreased O_2 in the blood, the heart rate and cardiac output increase. A cardiovascular hyperdynamic state may also occur as a result of catecholamine release in association with the physiological stress response. This response can occur fairly rapidly. As the PaO_2 decreases and acidosis increases, the heart muscle may become dysfunctional, and cardiac output may decrease. In addition, angina and dysrhythmias may occur. All of these consequences result in a further decrease in oxygenation. Permanent brain damage may occur because of O_2 deprivation. Renal function may also be impaired, and sodium retention, edema formation, acute tubular necrosis, and uremia may occur. Gastro-intestinal system alterations include tissue ischemia, increased permeability of the intestinal wall, and possible translocation of bacteria from the gastro-intestinal tract into the circulation.

Specific Clinical Manifestations.

A patient in respiratory failure may have several clinical findings indicating distress, such as rapid, shallow breathing or a respiratory rate slower than normal. Both changes predispose to insufficient CO_2 removal. The patient may increase the respiratory rate in an effort to blow off

accumulated CO_2. This breathing pattern requires a substantial amount of work and predisposes to respiratory muscle fatigue. A change from a rapid rate to a slower rate in a patient in acute respiratory distress suggests extreme fatigue and possible impending respiratory arrest.

The position that the patient assumes is an indication of the effort associated with breathing. The patient may be able to lie down (mild distress), be able to lie down but prefer to sit (moderate distress), or be unable to breathe unless sitting upright (severe distress). A common position is to sit with the arms propped on the overbed table. This position, called the *tripod position,* helps decrease the work of breathing because propping the arms increases the anterior–posterior diameter of the chest and changes pressure in the thorax. The patient may use pursed-lip breathing (see Chapter 31) because it increases SaO_2 by slowing respirations, allowing more time for expiration, and preventing the small bronchioles from collapsing, thus facilitating air exchange. Another assessment parameter is the number of pillows the patient requires in order to breathe comfortably when resting. The degree of dyspnea that the patient experiences when lying flat is termed *orthopnea,* documented as one-, two-, three-, or four-pillow orthopnea.

A person experiencing dyspnea is working hard to breathe and may be able to speak only a few words between breaths. The degree to which the patient is able to speak without pausing to breathe is an indication of the severity of dyspnea. The patient may speak in sentences (mild or no distress), phrases (moderate distress), or words (severe distress). The patient may have "two-word" or "three-word" dyspnea, signifying that only two or three words can be said before pausing to breathe. When walking, the patient may also experience earlier onset of fatigue. An additional assessment parameter is how far the patient is able to walk without stopping to rest.

There may be a change in the *inspiratory-to-expiratory (I : E) ratio*. Normally, the I : E ratio is 1 : 2, meaning expiration is twice as long as inspiration. In respiratory distress, the ratio may increase to 1 : 3 or 1 : 4, which signifies airflow obstruction, and more time is necessary to empty the lungs.

The nurse may observe *retraction* (inward movement) of the intercostal spaces or the supraclavicular area and use of the accessory muscles during inspiration or expiration, which signifies moderate distress. Paradoxical breathing indicates severe distress. Normally, the thorax and the abdomen move outward on inspiration and inward on exhalation. During *paradoxical breathing,* the abdomen and the chest move in the opposite manner:

outward during exhalation and inward during inspiration. Paradoxical breathing results from maximal use of the accessory muscles of respiration. The patient may also be diaphoretic from the work associated with breathing.

Auscultation should be performed in order to assess the patient's baseline breath sounds, as well as any changes from baseline. The nurse should note the presence and the location of any adventitious breath sounds. Crackles and wheezes may indicate pulmonary edema or emphysema. Absence of or diminished breath sounds may indicate atelectasis or pleural effusion. Bronchial breath sounds over the lung periphery often result from lung consolidation, as occurs with pneumonia. A pleural friction rub may also be heard in the presence of pneumonia that has involved the pleura.

A thorough nursing assessment may result in early detection of manifestations associated with respiratory insufficiency, which allows therapy to be instituted before the patient experiences respiratory failure. Patients with end-stage (severe) chronic lung disease may have low PaO_2 values or elevated $PaCO_2$ values and crackles as their "normal" baseline. It is especially important to monitor specific and nonspecific signs of respiratory failure in patients with COPD or other pre-existing chronic diseases because a small change can cause significant decompensation (see Table 70-4). Any deterioration in mental status, such as agitation, combative behaviour, confusion, or decreased level of consciousness, should be reported immediately because this may indicate deterioration in clinical status and the need for mechanical ventilation.

Diagnostic Studies

After physical assessment, the diagnostic studies most commonly used to determine respiratory failure are ABG analysis and chest radiographic studies. ABG measurements are used to determine the levels of $PaCO_2$, PaO_2, bicarbonate, and pH. An indwelling catheter may be inserted into a peripheral artery for monitoring systemic blood pressure and obtaining ABGs measurements. Pulse oximetry is used for monitoring oxygenation but reveals little about ventilation. In respiratory failure, ABG measurements are necessary to determine both oxygenation (PaO_2) and ventilation ($PaCO_2$) status, as well as obtain information related to acid–base balance (Burns, 2014). Chest radiographic examination helps identify possible causes of respiratory failure (e.g., atelectasis, pneumonia). In

patients with respiratory failure that does not necessitate acute intervention, pulmonary function tests may be performed.

Other diagnostic studies that may be done include a complete blood cell count (CBC), serum electrolyte measurements, urinalysis, and electrocardiography. Sputum and blood cultures are obtained if infection is likely. If pulmonary embolus is suspected, a VQ lung scan or pulmonary angiography may be done. For a patient requiring endotracheal intubation, end-tidal CO_2 is measured to assess tube placement immediately after intubation and during ventilator management to assess trends in lung ventilation.

In severe respiratory failure, a pulmonary artery catheter may be inserted to measure pressures on the right side of the heart and cardiac output, as well as mixed venous oxygen saturation. This information is helpful in determining the adequacy of tissue perfusion and the patient's response to treatment. Pulmonary artery, pulmonary artery wedge (occlusion), and left atrial pressures are monitored to determine whether the accumulation of fluid in the lungs is the result of cardiac or pulmonary problems. These parameters are also monitored to determine the response of the lungs and heart to hypoxemia and the patient's response to therapy. Pulmonary arterial pressure monitoring can also provide feedback about the physiological effects of mechanical ventilation on hemodynamic status. (See Chapter 68 for a discussion of hemodynamic monitoring.)

Nursing and Collaborative Management Acute Respiratory Failure

Because many different problems cause respiratory failure, care of affected patients varies. This section is a discussion of general assessment and collaborative treatments that apply to patients with acute respiratory failure. In acute care settings, there is often an overlap of function between nursing and other members of the health care team. Aside from the multidisciplinary health care team, family members play a valuable role in the patient's care and recovery. Further discussion of issues related to the family and caregivers can be found in Chapter 68.

Nursing Assessment

Subjective and objective data that should be obtained from patients with acute respiratory failure are listed in Table 70-5.

TABLE 70-5

NURSING ASSESSMENT
Acute Respiratory Failure

Subjective Data
Important Health Information
Past health history: Chronic lung disease; potential occupational exposures to lung toxins; smoking (pack-years); childhood illnesses, previous hospitalizations related to lung disease; thoracic or spinal cord trauma; extreme obesity; altered consciousness; age (physiological and chronological); use or abuse of alcohol, other drugs; drug allergies, recent travel, SARS
Medications: Use of oxygen, inhalers (bronchodilators), home nebulization, over-the-counter medications; immuno-suppressant (corticosteroid) therapy, CNS depressants; vitamin and herbal supplements
Surgery or other treatments: Previous intubation and mechanical ventilation; recent thoracic or abdominal surgery
Symptoms
• Anorexia, bloatedness, heartburn; weight gain or loss; decreased appetite • Anxiety, depression • Changes in sleep pattern • Dyspnea at rest or with activity; wheezing or cough (productive or nonproductive); sputum (volume, colour, viscosity) • Fatigue, dizziness; diaphoresis • Headache, chest pain or tightness • Palpitations, swollen feet
Objective Data
General
Restlessness, agitation
Integumentary
Pale, cool, clammy skin or warm flushed skin; peripheral and central cyanosis; peripheral dependent edema
Respiratory
Shallow, increased respiratory rate progressing to decreased rate; use of accessory muscles with evidence of retractions, altered I : E ratio; increased diaphragmatic excursion or asymmetrical chest expansion; asynchronous respirations; tactile fremitus, crepitus, or deviated trachea on palpation; resonant, hyper-resonant, or dull percussion note; absence of, diminished, or adventitious breath sounds; bronchial or bronchovesicular sounds heard in other than normal location, inspiratory stridor, pleural friction rub
Cardiovascular
Tachycardia progressing to bradycardia, dysrhythmias, extra heart sounds (S_3, S_4); bounding pulse; hypertension progressing to hypotension; pulsus paradoxus; jugular vein distension; pedal edema
Gastro-Intestinal
Abdominal distension with tympany; ascites, epigastric tenderness, hepatojugular reflex
Neurological
Somnolence, confusion, slurred speech, restlessness, delirium, agitation, tremors, seizures, coma; asterixis, decreased deep tendon reflexes; papilledema
Possible Laboratory Findings
↑ or ↓ pH, ↑ or ↓ $PaCO_2$, ↓ PaO_2, ↑ or ↓ bicarbonate, ↓ SaO_2, ↓ PEFR, ↓tidal volume, ↓ forced vital capacity, ↓ minute ventilation, ↓ negative inspiratory force; altered serum electrolyte values, hemoglobin, white blood cells, and hematocrit; abnormal findings on chest radiograph; abnormal pulmonary artery and pulmonary artery wedge pressures

CNS, central nervous system; *I : E,* inspiratory to expiratory; *$PaCO_2$,* partial pressure of carbon dioxide in arterial blood; *PaO_2,* partial pressure of oxygen in arterial blood; *PEFR,* peak expiratory flow rate; *SaO_2,* oxygen saturation in arterial blood as measured by arterial blood gases; *SARS*, severe acute respiratory syndrome.

Nursing Diagnoses

Nursing diagnoses for the patient with acute respiratory failure include, but are not limited to, the following:

- *Impaired gas exchange* (related to alveolar hypoventilation, intrapulmonary shunting, VQ mismatch, and diffusion impairment)
- *Ineffective airway clearance* related to *excessive mucus, retained secretions*
- *Ineffective breathing pattern* related to *neuro-muscular impairment of respirations, pain, anxiety, decreased level of consciousness, respiratory muscle fatigue, and bronchospasm*

Additional information on nursing diagnoses for the patient with acute respiratory failure is presented in Nursing Care Plan (NCP) 70-1, available on the Evolve website.

Planning

The overall goals for patients in acute respiratory failure are to restore baseline (a) ABG values, (b) breath sounds, (c) breathing patterns, and (d) ability to clear secretions.

Prevention

Prevention and early recognition of respiratory distress are important aspects of care for any patient at risk for respiratory failure. Prevention involves a thorough physical assessment and history (to identify patients at risk for respiratory failure) followed by appropriate nursing interventions. For example, a patient at risk for respiratory failure should receive teaching regarding coughing, deep breathing, incentive spirometry, and ambulation as appropriate. Prevention of atelectasis, pneumonia, and complications of immobility, as well as optimizing hydration and nutrition, can potentially decrease the risk of respiratory failure in acute or critically ill patients.

Respiratory Therapy

The major goals of care for acute respiratory failure include maintaining adequate oxygenation and ventilation. This is accomplished by collaboration among the nursing, medical, and respiratory care teams. The interventions used include O_2 therapy, mobilization of secretions, and positive-pressure ventilation (Table 70-6).

TABLE 70-6
COLLABORATIVE CARE
Acute Respiratory Failure

Diagnostic • History and physical examination • ABG measurements • Blood and sputum cultures (if indicated) • Chest radiography • Complete blood cell count • Electrocardiography • O_2 saturation • Pulmonary artery pressure, pulmonary artery occlusive (wedge) pressure, and left atrial pressure • Serum electrolyte mesurements and urinalysis **Collaborative Therapy** ***Respiratory Therapy*** • Airway suctioning • Chest physiotherapy • Effective coughing • Hydration and humidification • Incentive spirometry • Intubation with mechanical ventilation • Mobilization of secretions	• Noninvasive positive-pressure ventilation • O_2 therapy • Positive-pressure ventilation ***Drug Therapy*** • Reduction of airway inflammation (corticosteroids) • Reduction of anxiety and restlessness (e.g., lorazepam [Ativan]) • Reduction of pulmonary congestion (e.g., furosemide [Lasix]) • Relief of bronchospasm (e.g., salbutamol) • Treatment of pulmonary infections (e.g., antibiotics) ***Medical Supportive Therapy*** • Maintenance of adequate cardiac output • Maintenance of adequate hemoglobin concentration • Management of the underlying cause of respiratory failure ***Nutritional Therapy*** • Enteral nutrition support • Parenteral nutrition support

ABG, arterial blood gas.

Oxygen Therapy.

The primary goal of O_2 therapy is to correct hypoxemia. If hypoxemia is secondary to VQ mismatch, supplemental O_2 administered at 1 to 3 L/min by nasal cannula or at 24% to 32% by simple face mask or Venturi mask should improve the PaO_2 and SaO_2. Hypoxemia secondary to intrapulmonary shunt is usually not responsive to high O_2 concentrations, and affected patients usually require positive-pressure ventilation (PPV). PPV helps provide O_2 therapy and humidification, decrease the work of breathing, and reduce respiratory muscle fatigue. In addition, the positive pressure may assist in opening collapsed airways and decreasing shunting. PPV may be provided via an endotracheal tube (most

frequently) or noninvasively by means of a tight-fitting mask (Messika, Ahmed, Gaudry, et al., 2015). (See Chapter 68 for a detailed discussion of mechanical ventilation.)

The type of O_2 delivery system chosen for a patient in acute respiratory failure should (a) be tolerated by the patient, inasmuch as feelings of claustrophobia related to the face mask may prompt the patient to remove it, and (b) maintain PaO_2 at 55 to 60 mm Hg or more and SaO_2 at 90% or more at the lowest O_2 concentration possible. High O_2 concentration is associated with adverse effects. Intubated patients who receive more than 50% FiO_2 for more than 24 hours are at greatest risk to develop O_2 toxicity (Urden, Stacy, & Lough, 2014). Toxic O_2 free radicals are a metabolite of O_2 metabolism; in the setting of extended exposure to high concentrations, the supply of enzymes responsible for neutralizing those radicals is exhausted, which results in in acute lung injury. Absorption atelectasis can also occur when excess O_2 displaces the nitrogen normally present in alveoli, causing alveolar collapse (Brashers & Huether, 2014; Fournier, 2014). The effects of prolonged exposure to high levels of O_2 include increased pulmonary microvascular permeability, decreased surfactant production and surfactant inactivation, and fibrotic changes in the alveoli. (Oxygen delivery devices are discussed in Chapter 31.)

Additional risks of O_2 therapy are specific to patients with chronic hypercapnia, such as those with COPD. Chronic hypercapnia may blunt the response of chemoreceptors in the medulla. In this situation, respirations are stimulated by hypoxia. If the PaO_2 is suddenly increased, the patient is no longer hypoxemic, the stimulus to breathe is decreased, and respiratory arrest may occur. Patients with chronic hypercapnia should receive O_2 through a low-flow device such as a nasal cannula at 1 to 2 L/min or a Venturi mask at a volume of 24% to 28%. Close monitoring for changes in mental status and of respiratory rate and ABG results is essential until PaO_2 levels have reached their baseline value.

Mobilization of Secretions.

Retained pulmonary secretions may cause or exacerbate acute respiratory failure by blocking both movement of O_2 into the alveoli and the pulmonary capillary blood and removal of CO_2 during the respiratory cycle. Secretions can be mobilized through effective coughing, adequate

hydration and humidification, chest physiotherapy, and tracheal suctioning.

Effective Coughing and Positioning.

If secretions are obstructing the airway, the patient should be encouraged to cough. Patients with a neuro-muscular weakness from a disease or exhaustion may not be able to generate sufficient airway pressures to produce an effective cough. *Augmented coughing (quad coughing)* may be of benefit to such patients. Augmented coughing is performed by placing the palm of the hand or hands on the abdomen below the xiphoid process (Figure 70-6). As the patient ends a deep inspiration and begins the expiration, the hands should be moved forcefully upward, increasing abdominal pressure and facilitating the cough. This measure helps increase expiratory flow and thereby facilitates secretion clearance. Health care providers need to receive appropriate training before using augmented coughing techniques.

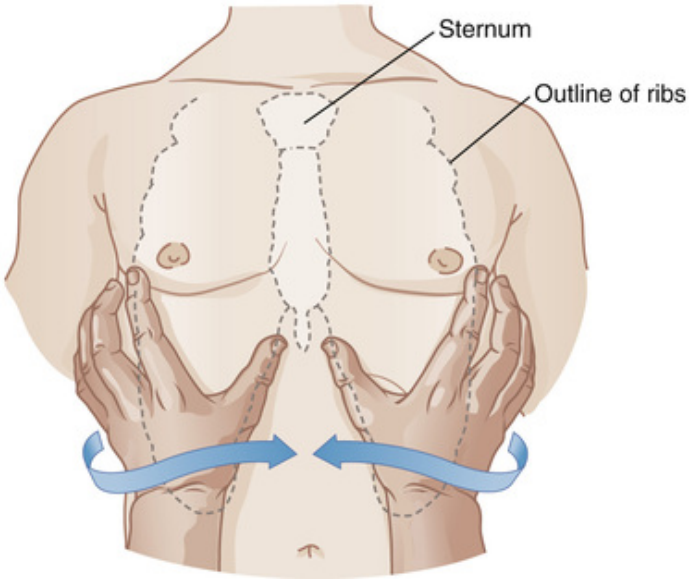

FIGURE 70-6 Augmented coughing is performed by placing one or both hands over the anterolateral base of the lungs. After the patient takes a deep inspiration and at the beginning of expiration, the hand or hands are moved forcefully upward. This increases abdominal pressure and aids in producing a forceful cough.

Some patients may benefit from therapeutic cough techniques. *Huff coughing* is a series of coughs performed while saying the word "huff."

This technique prevents the glottis from closing during the cough. Patients with COPD generate higher flow rates with a huff cough than they can with a normal cough. The huff cough is effective in clearing only the central airways, but it may assist in moving secretions upward. The *staged cough* also assists secretion mobilization. To perform the staged cough, the patient sits in a chair, breathes three or four times in and out through the mouth, and coughs while bending forward and pressing a pillow inward against the diaphragm.

Positioning the patient either by elevating the head of the bed at least 45 degrees or with a reclining chair or chair bed may help maximize thoracic expansion, thereby decreasing dyspnea and improving secretion mobilization. A sitting position improves pulmonary function and assists in venous pooling in dependent body areas such as the lower extremities. When lungs are upright, ventilation and perfusion are best in the lung bases. Lateral or side-lying positioning, termed *good lung down,* may be used in patients with disease involving only one lung and allows for improved VQ matching in the affected lung. Pulmonary blood flow and ventilation are optimal in dependent lung areas. This positioning also allows for secretions to drain out of the affected lung to the point at which they may be removed by suctioning. For example, in patients with significant right-sided pneumonia, optimal positioning would be to place them on their left side to maximize ventilation and perfusion in the "good" lung and facilitate secretion removal from the affected lung (postural drainage). All patients should be lying on the side if there is any possibility that the tongue will obstruct the airway or that aspiration may occur. Equipment to create an oral or nasal airway should be kept at the bedside for use if necessary.

Hydration and Humidification.

Thick and viscous secretions should be thinned to facilitate removal. Adequate fluid intake (2 to 3 L/day) is necessary to keep secretions thin and easy to expel. If a patient is unable to take sufficient fluids orally, intravenous (IV) hydration is used. Thorough assessment of the patient's cardiac and renal status determines whether he or she can tolerate the intravascular volume and avoid heart failure and pulmonary edema. Assessment for signs of fluid overload (e.g., crackles, dyspnea, and increased central venous pressure) at regular intervals is essential. These considerations would also apply to patients with renal dysfunction.

An appropriate humidification device is an adjunct in secretion management. Aerosols of sterile normal saline, administered by a nebulizer, may be used to liquefy secretions. Oxygen may also be administered by aerosol mask to thin secretions and facilitate their removal. Aerosol therapy may induce bronchospasm and severe coughing, causing a decrease in PaO_2. In such cases, frequent assessment of the patient's tolerance of therapy is paramount (Ari, Fink, & Dhand, 2012). Mucolytic agents such as nebulized acetylcysteine (Mucomyst) mixed with a bronchodilator may be used to thin secretions; however, as an adverse effect, such mixtures may also cause airway erythema and bronchospasm. Therefore, they are used only in special situations (e.g., during bronchoscopy to remove thick, copious secretions).

Chest Physiotherapy.

Chest physiotherapy is indicated in patients who produce more than 30 mL of sputum per day or have evidence of severe atelectasis or pulmonary infiltrates. If tolerated, postural drainage, percussion, and vibration to the affected lung segments may assist in moving secretions to the larger airways, where they may be removed by coughing or suctioning. Because positioning may affect oxygenation, patients may not tolerate head-down or lateral positioning as a result of extreme dyspnea or hypoxemia caused by VQ mismatch. (Chest physiotherapy is discussed in Chapter 31.)

Airway Suctioning.

If the patient is unable to expectorate secretions, then nasopharyngeal, oropharyngeal, or nasotracheal suctioning (blind suctioning without a tracheal tube in place) is indicated. Suctioning through an artificial airway, such as endotracheal or tracheostomy tubes, may also be performed (see Chapters 29 and 68). A mini-tracheostomy (commonly called a "mini-trach") may be used to perform suction in patients who have difficulty mobilizing secretions and when blind suctioning is difficult or ineffective. The *mini-tracheostomy* is a 4-mm indwelling plastic cuffless cannula inserted through the cricothyroid membrane. It is used to instill sterile normal saline solution to elicit a cough and to perform suctioning with a size 10 or smaller French catheter. Contraindications for a mini-tracheostomy include absence of the gag reflex, a history of aspiration, and the need for long-term mechanical ventilation.

Positive-Pressure Ventilation.

If intensive measures fail to improve ventilation and oxygenation and the patient continues to exhibit acute respiratory failure, ventilatory assistance may be initiated. PPV may be provided invasively through endotracheal or nasotracheal intubation or noninvasively through a nasal or face mask. Patients who require PPV are typically cared for in an intensive care unit. (See Chapter 68 for a discussion of artificial airways and mechanical ventilation.)

Noninvasive positive-pressure ventilation (NIPPV) may be used to treat patients with acute or chronic respiratory failure. During NIPPV, a mask is placed over the patient's nose or nose and mouth while the patient breathes spontaneously (Figure 70-7). With NIPPV, it is possible to decrease the work of breathing without the use of invasive endotracheal intubation. Bilevel positive airway pressure ventilation is a form of NIPPV in which different positive-pressure levels are set for inspiration and expiration (see Figure 70-7). In continuous positive airway pressure, another form of NIPPV, the positive pressure delivered to the airway is constant during inspiration and expiration (Urden, Stacy, & Lough, 2014).

FIGURE 70-7 Noninvasive bilevel positive airway pressure ventilation. A mask is placed over the nose or the nose and mouth. Positive pressure from a mechanical ventilator assists the patient's breathing efforts, decreasing the work of breathing. Source: Courtesy Richard Arbour, RN, MSN, CCRN, CNRN, CCNS, FAAN, and Anna Kirk, RN, MSN.

NIPPV is most useful in managing chronic respiratory failure in patients with chest wall and neuro-muscular disease (see Table 70-3). NIPPV has been used in patients with hypoxemic respiratory failure (e.g., those with ARDS, cardiogenic pulmonary edema) but with less success (Luo, Wang, Zhu, et al, 2014; Wang, Singh, Tian, et al., 2013). NIPPV may also be used for patients who refuse endotracheal intubation but still desire some palliative ventilatory support (e.g., patients with end-stage COPD). NIPPV is not appropriate for the patient who has no spontaneous respirations, excessive secretions, decreased level of consciousness, high O_2 requirements, facial trauma, or hemodynamic instability (Urden, Stacy, & Lough, 2014).

Drug Therapy

Goals of drug therapy for patients in acute respiratory failure include relief of bronchospasm, reduction of airway inflammation and pulmonary congestion, treatment of pulmonary infection, and reduction of severe anxiety and restlessness.

Relief of Bronchospasm.

Alveolar ventilation will be increased with relief of bronchospasm. To reverse bronchospasm, short-acting *bronchodilators,* such as fenoterol hydrobromide and salbutamol, are frequently administered through either a hand-held nebulizer or a metered-dose inhaler with a spacer (Ari, Fink, & Dhand, 2012). For acute bronchospasm, these drugs may be given at 15- to 30-minute intervals until a response can be determined. If severe bronchospasm continues, IV aminophylline may be administered. The bronchodilator effects of all of these medications can sometimes cause a worsening of arterial hypoxemia by redistributing the inspired gas to areas of decreased perfusion. Administering the bronchodilator with an O_2-enriched gas mixture usually alleviates this effect (Ari, Fink, & Dhand, 2012). (See Chapter 31 for nursing management related to bronchodilators.) In addition to bronchodilators, IV magnesium sulphate may be beneficial in cases of severe asthma and asthma refractory to conventional treatment (Goodacre, Cohen, Bradburn, et al., 2013; Urden, Stacy, & Lough, 2014).

Reduction of Airway Inflammation.

Corticosteroids (e.g., methylprednisolone [Solu-Medrol]) may be used in conjunction with bronchodilating drugs when bronchospasm and inflammation are present. They may be administered intravenously, orally, or as aerosols. In acute exacerbations, high-dose IV steroids such as methylprednisolone are used. The dosage is then tapered as tolerated by the patient. Because long-term regimens of oral steroids are associated with systemic adverse effects, they should be avoided if possible. Instead, inhaled steroids such as fluticasone (Flovent) or budesonide (Pulmicort) are used to reduce the risk of those systemic adverse effects (Hough, 2014).

Reduction of Pulmonary Congestion.

Pulmonary interstitial fluid can accumulate as a consequence of direct or indirect injury to the alveolar capillary membrane (as in ARDS) or from right- or left-sided heart failure and can therefore be either cardiac or noncardiac in origin. The result is decreased alveolar ventilation and hypoxemia. IV diuretics (e.g., furosemide [Lasix]) and nitroglycerine are used to decrease the pulmonary congestion caused by heart failure. If atrial fibrillation is also present, calcium channel blockers (e.g., diltiazem) and β-adrenergic blockers (e.g., metoprolol) may be used to decrease heart rate and improve cardiac output. (See Chapter 37 for discussion of heart failure.)

Treatment of Pulmonary Infections.

Pulmonary infections (pneumonia, acute bronchitis) result in excessive mucus production, fever, and increased oxygen consumption, and alveoli become inflamed or fluid filled or collapse. Alveoli that are fluid filled or collapsed cannot participate in gas exchange. Pulmonary infections can either cause or exacerbate acute respiratory failure. IV antibiotics, such as vancomycin (Vancocin) or ceftriaxone, are frequently administered to inhibit bacterial growth. Chest radiographic examinations are performed to determine the location and the extent of a suspected infectious process. Sputum cultures are used to determine the type of organisms causing the infection and their sensitivity to antimicrobial medications.

Reduction of Severe Anxiety, Pain, and Agitation.

Anxiety, restlessness, and agitation result from cerebral hypoxia. In addition, fear caused by the inability to breathe and a sense of loss of control may exacerbate anxiety. Anxiety, pain, and agitation increase O_2

consumption, which may worsen the degree of hypoxemia. Increase in anxiety and agitation can affect ventilator management. Administration of sedatives, opioids, or muscle relaxants may be necessary to provide adequate oxygenation and ventilation. Several nursing strategies can assist the patient in reducing the level of anxiety and pain (see NCP 70-1, available on the Evolve website).

Sedation and analgesia with drug therapy such as benzodiazepines (e.g., lorazepam [Ativan], midazolam) and opioids (e.g., morphine, fentanyl) may decrease anxiety, agitation, and pain. Continued agitation increases the patient's work of breathing, O_2 consumption, CO_2 production, and risk of injury (e.g., accidental extubation). In the intensive care setting, sedatives and analgesics are commonly administered, and patients must be monitored closely for cardiovascular and respiratory depression. Of importance is that agitation is best characterized as a symptom and may be caused by pain, hypoxemia, electrolyte imbalance, evolution of structural or metabolic brain injury, and adverse drug reactions; therefore, potentially reversible causes should always be assessed and treated. Sedative and analgesic drugs may have prolonged duration of action in critically ill patients. This may contribute to increased length of stay and prolonged time on a ventilator (Mendez, Lazar, Digiovine, et al., 2013). Patients receiving these drugs are best managed with a research-based, protocol-driven plan of care (Mendez, Lazar, Digiovine, et al., 2013).

Sedation protocols can be used to guide the level of sedation. Most patients in whom oxygenation is difficult require heavy sedation (4 to 5 on the Richmond Agitation Sedation Scale). Patients who breathe asynchronously with mechanical ventilation may also benefit from titration of ventilator settings, as well as addressing underlying causes of agitation.

Once complete sedation is achieved, if the patient is still hypoxic, the use of neuro-muscular blockade may be indicated with agents such as vecuronium or cisatracurium (Nimbex). Neuro-muscular blockade produces skeletal muscle relaxation and synchrony with mechanical ventilation. These drugs may also decrease the patient's risk of lung injury related to excessive intrathoracic pressures and promote optimal ventilatory support. Patients receiving neuro-muscular blockade should receive sedation and analgesia to the point of unconsciousness for comfort, pain relief, and elimination of the awareness of being paralyzed, which is a terrifying experience (Hraiech, Yoshida, & Papazian, 2015). The level of pharmacological paralysis is monitored with a peripheral nerve stimulator and clinical correlation to achieve absence of respiratory effort. Daily

interruption of sedative drug infusions decreases the duration of mechanical ventilation and length of stay in the intensive care unit (Mendez, Lazar, Digiovine, et al., 2013).

Medical Supportive Therapy

Interventions to maximize O_2 delivery and treat the underlying cause of respiratory failure are essential for improving the patient's oxygenation and ventilation status. The primary goal is to treat the underlying cause of the respiratory failure. Other goals include maintaining an adequate cardiac output and hemoglobin concentration.

Treating the Underlying Cause.

Interventions are directed toward reversing the disease process that resulted in the development of acute respiratory failure. Patients with hypoventilation can be diagnosed and treated rapidly. Patients with VQ mismatch, shunting, or diffusion limitation are managed differently depending on the underlying cause. In all patient situations, monitoring treatment effects, including trends in ABGs and changes in respiratory status, is a continuous process.

Maintaining Adequate Cardiac Output.

Cardiac output reflects the blood flow reaching the tissues. Blood pressure and mean arterial pressure are important indicators of the adequacy of cardiac output and should be interpreted within the context of the overall assessment to determine adequacy of cardiac output and tissue perfusion. Usually, a systolic blood pressure of 90 mm Hg or higher and a mean arterial pressure of 60 mm Hg or higher is adequate to maintain perfusion to the vital organs; therefore, changes in mental status can usually be attributed to the level of O_2 and CO_2, rather than to decreased cerebral perfusion, when these pressures are maintained. Patients with chronic, uncontrolled hypertension may require higher systemic arterial pressures and mean arterial pressures to prevent episodes of brain ischemia.

Decreased cardiac output is treated by administration of IV fluids, medications, or both. (See Chapter 69 for a discussion of drugs used to treat decreased cardiac output and shock.) Cardiac output may also be decreased by changes in intrathoracic or intrapulmonary pressures from PPV. Patients experiencing exacerbation of COPD or asthma and those receiving controlled ventilation are at risk of alveolar hyperinflation,

increased right ventricular afterload, and excessive intrathoracic pressures. These alterations in thoracic pressure dynamics may cause an increase in right ventricular afterload, which limits blood flow from the right side of the heart through the pulmonary vasculature to the left side of the heart; dramatic hemodynamic compromise may result. In addition, blood return from the systemic circulation to the right side of the heart may be impaired, decreasing preload (Urden, Stacy, & Lough, 2014). Each of these physiological consequences can potentially compromise hemodynamics. Consequently, clinical indicators of adequate cardiac output and tissue perfusion should be monitored alongside initiation or titration of mechanical ventilation by mask or endotracheal intubation.

Maintaining Adequate Hemoglobin Concentration.

Hemoglobin is the primary carrier when blood delivers O_2 to the tissues. In patients who are anemic, tissue O_2 delivery is compromised. A hemoglobin concentration of 6 mmol/L or greater typically ensures adequate O_2 saturation of the hemoglobin. Patients should be monitored for sites of blood loss and receive transfusions of packed red blood cells if an adequate hemoglobin concentration cannot be maintained.

Nutritional Therapy

Maintenance of protein and energy stores is especially important in patients with acute respiratory failure because nutritional depletion causes loss of muscle mass, including the respiratory muscles, and may prolong recovery. During the acute manifestations of respiratory failure, the risk of aspiration typically prevents oral intake; therefore, enteral or parenteral nutrition may be administered until symptoms subside and the patient tolerates oral intake. A multitude of nutritional supplements are available (Matos, Manzanares, & Nava, 2015). The prescription of a high-carbohydrate diet should be based on individual patient needs (Taylor, McClave, Martindale, et al., 2016), It may be avoided in patients who retain CO_2 because carbohydrates metabolize into CO_2, further increasing CO_2 load. However, the hypermetabolic state present in critical illness can dramatically increase caloric requirements.

Evaluation

The expected outcomes for the patient with acute respiratory failure are presented in NCP 70-1, on the Evolve website.

Age-Related Considerations

Respiratory Failure

The older adult population is the fastest growing age group in North America, and this trend is reflected within acute and intensive care settings. Of importance is that older adults are more vulnerable to delirium, hospital-acquired infections, and medication effects. Multiple factors contribute to an increased risk of respiratory failure in older adults, including the reduction in ventilatory capacity that accompanies aging, especially if risk factors are present. Physiological aging of the lung may produce alveolar dilation, diminish elastic recoil within the airways, decrease chest wall compliance, and decrease respiratory muscle strength. In older adults, the PaO_2 falls further and the $PaCO_2$ rises to a higher level before the respiratory system is stimulated to alter the rate and the depth of breathing. This delayed response can contribute to the development of respiratory failure. In addition, smoking is a risk factor that accelerates age-related respiratory changes. Poor nutritional status predisposes to decreased muscle mass, and less physiological reserve in cardiovascular, respiratory, and autonomic nervous systems increases the risk of additional diseases such as pneumonia and cardiac disease that may compromise respiratory function and precipitate respiratory failure (Schmidt, Balzer, Pille, et al., 2013; Urden, Stacy, & Lough, 2014).

Assessment parameters should be adjusted for age. For example, heart rate and blood pressure generally increase with age and with changes in the cardiovascular system. Therefore, determination of baseline vital signs and using them as a basis for comparison of physical assessment findings is most appropriate in evaluating changes in cardiopulmonary function in older adults.

Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS) is a sudden and progressive form of acute respiratory failure in which the alveolar–capillary membrane becomes damaged and more permeable by intravascular fluid (Figure 70-8). The alveoli fill with fluid, which results in severe dyspnea, hypoxemia refractory to supplemental O_2, reduced lung compliance, and diffuse pulmonary infiltrates (Fournier, 2014; Urden, Stacy, & Lough, 2014). Despite the fact that ARDS has been the focus of extensive clinical research, survival rates have not significantly improved (Grek, Booth, Festic, et al., 2017; Schell-Chaple, Puntillo, Matthay, et al., 2015). Despite supportive therapy, the rate of mortality from ARDS is approximately 50% (Villar, Blanco, & Kacmarek, 2016). Patients who have both Gram-negative septic shock and ARDS have a significantly higher rate of mortality (Fratantoro, 2015).

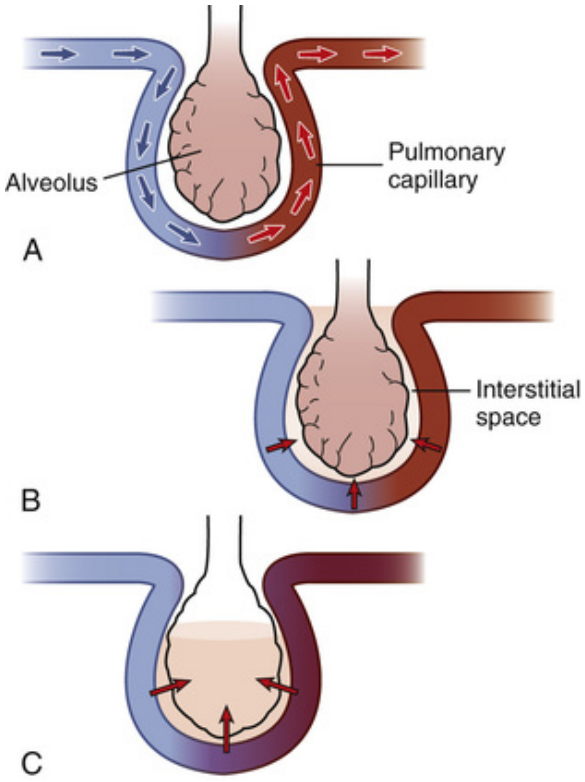

FIGURE 70-8 Stages of edema formation in acute respiratory distress syndrome. **A,** Normal alveolus and pulmonary capillary. **B,** Interstitial edema occurs with increased flow of fluid into the interstitial space. **C,** Alveolar edema occurs when the fluid crosses the blood–gas barrier.

Etiology and Pathophysiology

Table 70-7 lists conditions that predispose patients to the development of ARDS. The most common cause of ARDS is sepsis. Patients with multiple risk factors are three to four times more likely to develop ARDS than are those without risk factors. Community-acquired pneumonia is another common cause of ARDS that develops outside of the hospital community. Common pathogens include *Streptococcus pneumoniae, Legionella pneumophila,* and a variety of respiratory viruses. Nosocomial (health care–related) pneumonias, including ventilator-associated pneumonia, can also progress to ARDS (see Chapter 68).

TABLE 70-7

CONDITIONS PREDISPOSING TO ACUTE RESPIRATORY DISTRESS SYNDROME

Direct Lung Injury	Indirect Lung Injury
Common Causes	
• Aspiration • Viral or bacterial pneumonia	• Sepsis (especially Gram-negative infection) • Severe massive trauma
Less Common Causes	
• Chest trauma • Embolism: fat, air, amniotic fluid • Inhalation of toxins • Near-drowning • O_2 toxicity • Radiation pneumonitis	• Acute pancreatitis • Anaphylaxis • Blood transfusions • Cardiopulmonary bypass • Disseminated intravascular coagulation • Opioid overdose (e.g., heroin) • Nonpulmonary systemic diseases • Severe head injury • Shock

Patients may develop ARDS in the setting of influenza infection. ARDS is a fatal complication of influenza infection (Töpfer, Menk, Weber-Carstens, et al., 2014).

Direct lung injury may cause ARDS (Figure 70-9), or ARDS may develop as a consequence of the systemic inflammatory response syndrome (see Chapter 69, Figure 69-1). This syndrome may have an infectious or a noninfectious etiology and is characterized by widespread inflammation or clinical responses to inflammation after a variety of physiological insults, including severe trauma, gut ischemia, lung injury, and sepsis (Urden, Stacy, & Lough, 2014). ARDS may also develop as a consequence of multiple-organ dysfunction syndrome, which results from organ system dysfunction that progressively increases in severity and ultimately results in multisystem organ failure. (Systemic inflammatory response syndrome and multiple-organ dysfunction syndrome are discussed in Chapter 69.)

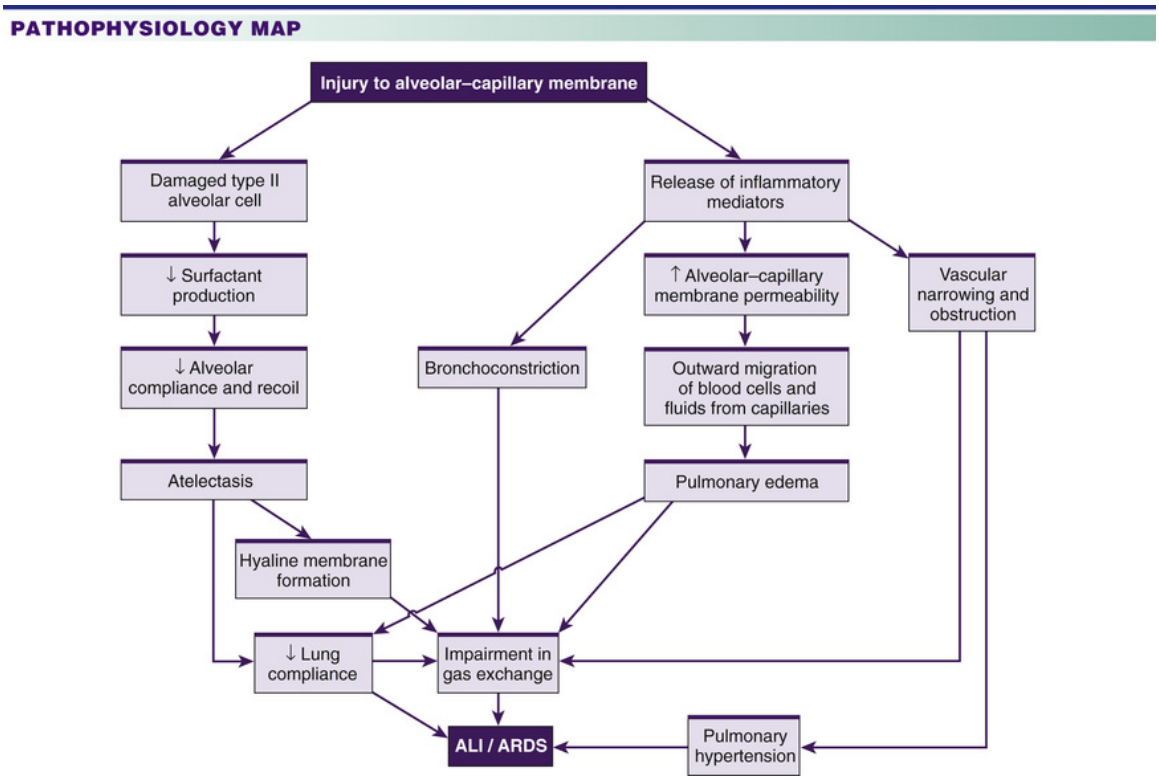

FIGURE 70-9 Pathophysiology of acute respiratory distress syndrome (ARDS). *ALI*, acute lung injury.

In the initial injury to the lungs, the alveolar–capillary membrane is damaged. This activates complement and stimulates platelet aggregation and intravascular thrombus formation. Platelets release substances that attract and activate neutrophils (Brashers & Huether, 2014; Fournier, 2014). The neutrophils cause a release of biochemical, humoral, and cellular mediators (Table 70-8) that produce changes in the lung, including increased pulmonary capillary membrane permeability, destruction of elastin and collagen, formation of pulmonary microemboli, and pulmonary artery vasoconstriction (see Figure 70-9). (Mediators are discussed in Chapters 14 and 16.) The pathophysiological changes in ARDS are divided into three phases: (1) injury or exudative phase, (2) reparative or proliferative phase, and (3) fibrotic phase.

TABLE 70-8
MEDIATORS OF ACUTE LUNG INJURY

- Arachidonic acid metabolites, including prostaglandins and leukotrienes
- Coagulation products, including kallikreins, kinins, fibrin degradation products, and plasminogen-activating factor
- Collagenase
- Complement component C5a
- Elastase
- Histamine
- Monocyte and macrophage products, including tumour necrosis factor, interleukin-1, and colony-stimulating factor
- Neutrophil products, including proteases and O_2 radicals
- Serotonin endotoxin

Injury or Exudative Phase.

The *injury or exudative phase* occurs approximately 1 to 7 days (usually 24 to 48 hours) after the initial direct lung injury or host insult. Neutrophils adhere to the pulmonary microcirculation, causing damage to the vascular endothelium and increased capillary permeability. In the earliest phase of injury, the peribronchial and perivascular interstitial spaces become engorged with fluid, which produces interstitial edema. Next, fluid from the interstitial space crosses the alveolar epithelium and enters the alveolar space. Intrapulmonary shunting develops because the alveoli fill with fluid, and blood passing through them cannot be oxygenated (see Figures 70-4 and 70-8).

Type I and type II alveolar cells (which produce surfactant) are damaged by the changes caused by ARDS. This damage, in addition to further fluid and protein accumulation, results in surfactant dysfunction. The function of *surfactant* is to maintain alveolar stability by decreasing alveolar surface tension and preventing alveolar collapse. Decreased synthesis of surfactant and inactivation of existing surfactant cause the alveoli to become unstable and collapse (atelectasis). Widespread atelectasis further decreases lung compliance, compromises gas exchange, and contributes to hypoxemia (Urden, Stacy, & Lough, 2014).

Also during this stage, hyaline membranes begin to line the alveoli. These membranes are composed of necrotic cells, protein, and fibrin, and they lie adjacent to the alveoli wall. They are thought to result from the exudation of high-molecular-weight substances (particularly fibrinogen) in the edematous fluid. Hyaline membranes contribute to the development of fibrosis and atelectasis, which lead to a decrease in gas-exchange capability and lung compliance.

The primary pathophysiological changes that characterize the injury or exudative phase of ARDS are interstitial and alveolar edema (noncardiogenic pulmonary edema) and atelectasis (Brashers & Huether, 2014; Modrykamien & Gupta, 2015). Severe VQ mismatch and shunting of pulmonary capillary blood result in hypoxemia unresponsive to increasing concentrations of O_2 (termed **refractory hypoxemia**). Diffusion limitation, caused by hyaline membrane formation, further contributes to the severity of the hypoxemia. As the lungs become less compliant ("stiffer") because of decreased surfactant, pulmonary edema, and atelectasis, the patient must generate higher airway pressures to inflate them. Reduced lung compliance greatly increases the patient's work of breathing. During ventilator management at this stage, a progressive increase in plateau and inspiratory pressures may be noted as lung compliance worsens.

Hypoxemia and the stimulation of juxtacapillary receptors in the stiff lung parenchyma (the juxtacapillary [J] reflex) initially cause an increase in respiratory rate and a decrease in tidal volume. This breathing pattern increases CO_2 removal, which leads to respiratory alkalosis. Cardiac output increases in response to hypoxemia, a compensatory effort to increase pulmonary blood flow. However, as atelectasis, pulmonary edema, and pulmonary shunting increase, compensation fails, and hypoventilation, a decrease in cardiac output, and a decrease in tissue O_2 perfusion eventually occur.

Reparative or Proliferative Phase.

The *reparative or proliferative phase* of ARDS begins 1 to 2 weeks after the initial lung injury. During this phase the inflammatory response includes an influx of neutrophils, monocytes, and lymphocytes, together with fibroblast proliferation. The injured lung has an immense regenerative capacity after acute lung injury. The proliferative phase is complete when the diseased lung becomes characterized by dense, fibrous tissue. Increased pulmonary vascular resistance and pulmonary hypertension may occur in this stage because fibroblasts and inflammatory cells destroy the pulmonary vasculature. Lung compliance continues to decrease as a result of interstitial fibrosis. Hypoxemia worsens because of the thickened alveolar membrane, causing diffusion limitation and shunting. If the reparative phase persists, widespread fibrosis results. If the reparative phase is arrested, the lesions resolve (Brashers & Huether, 2014; Meduri & Eltorky, 2015; Urden, Stacy, & Lough, 2014).

Fibrotic Phase.

The *fibrotic phase* of ARDS, also called the *chronic* or *late phase,* occurs approximately 2 to 3 weeks after the initial lung injury. During this time, the lung is completely remodelled by sparsely collagenous and fibrous tissues. Diffuse scarring and fibrosis further decrease lung compliance. In addition, the surface area for gas exchange is significantly reduced because the interstitium is fibrotic, and therefore, hypoxemia continues. Pulmonary hypertension results from pulmonary vascular destruction and fibrosis.

Clinical Progression

Progression of ARDS varies among patients. Some people survive the acute phase of lung injury; pulmonary edema resolves, and complete recovery occurs in a few days. The chance for survival is poor in patients who enter the fibrotic (chronic or late) phase, which necessitates long-term mechanical ventilation. It is not known why injured lungs repair and recover in some patients whereas ARDS progresses in others. Several factors seem to be important in determining the course of ARDS, including the nature of the initial injury, the extent and the severity of coexisting diseases, and pulmonary complications (Koh, 2014; Kress, 2015).

Clinical Manifestations

The initial presentation of ARDS is often insidious. At the time of the initial injury, and up to 48 hours afterward, the patient may exhibit only dyspnea, tachypnea, cough, and restlessness. Chest auscultation may be normal or reveal fine, scattered crackles. ABG measurements usually indicate mild hypoxemia and respiratory alkalosis caused by hyperventilation. Respiratory alkalosis results from tachypnea, hypoxemia, and the stimulation of juxtacapillary receptors. The chest radiograph may be normal or exhibit evidence of minimal scattered interstitial infiltrates. Bilateral infiltrates become visible the radiographs as ARDS progresses. As ARDS progresses, symptoms worsen because of increased fluid accumulation and decreased lung compliance. Respiratory distress becomes evident as the work of breathing increases. Tachypnea and intercostal and suprasternal retractions may be present. Pulmonary function tests in ARDS reveal decreased compliance and decreased lung volumes, particularly a decreased functional residual capacity. Tachycardia, diaphoresis, changes in sensorium with decreased mentation, cyanosis, and pallor may be present. Chest auscultation usually reveals

scattered to diffuse crackles and wheezes. Chest radiographs demonstrate diffuse and extensive bilateral interstitial and alveolar infiltrates. A pulmonary artery catheter may need to be inserted. Pulmonary artery wedge pressure does not increase in ARDS because the cause is noncardiogenic (not related to cardiac function).

Hallmarks of ARDS include hypoxemia and a PaO_2/FiO_2 ratio below 200 despite increased FiO_2 by mask, cannula, or endotracheal tube. ABG measurements may initially demonstrate a normal or decreased $PaCO_2$ despite severe dyspnea and hypoxemia. Hypercapnia signifies that hypoventilation is occurring and the patient is no longer able to maintain the level of ventilation needed to provide optimum gas exchange.

As ARDS progresses, it is associated with profound respiratory distress that necessitates endotracheal intubation and PPV. The chest radiograph (Figure 70-10) shows what is often termed *whiteout* or *white lung* because consolidation and coalescing infiltrates are widespread throughout the lungs, leaving few recognizable air spaces. Pleural effusions may also be present. Severe hypoxemia, hypercapnia, and metabolic acidosis, with symptoms of target organ or tissue hypoxia, may ensue if therapy is not instituted promptly.

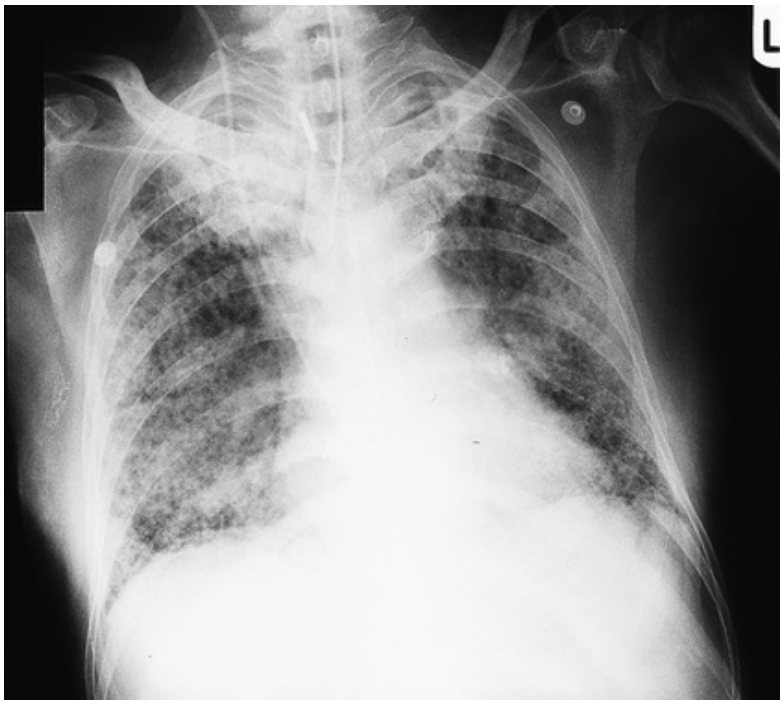

FIGURE 70-10 Chest radiograph of a patient with acute respiratory distress syndrome. The image shows new, bilateral diffuse, homogeneous pulmonary infiltrates without cardiac failure, fluid overload, chest infection, or chronic lung disease. Source: Cohen, J., & Powderly, W. G. (2004). *Infectious diseases* (2nd ed.). St. Louis: Mosby.

No precise criteria define ARDS. ARDS is considered to be present if (a) the patient has refractory hypoxemia, (b) a chest radiograph shows new bilateral interstitial or alveolar infiltrates, (c) the pulmonary artery wedge pressure is 18 mm Hg or less with no evidence of heart failure, and (d) a predisposing condition for ARDS develops within 48 hours of clinical manifestations (Table 70-9).

TABLE 70-9

DIAGNOSTIC FINDINGS IN ACUTE RESPIRATORY DISTRESS SYNDROME

Chest radiograph	New bilateral interstitial and alveolar infiltrates
Predisposing condition	Identification of a predisposing condition for ARDS within 48 hr of clinical manifestations
Pulmonary artery wedge pressure	≤18 mm Hg and no evidence of heart failure
Refractory hypoxemia	PaO_2 <50 mm Hg, with an FiO_2 >40% and with PEEP >5 cm H_2O
	PaO_2/FiO_2 ratio <200

ARDS, acute respiratory distress syndrome; *FiO_2,* fraction of inspired oxygen; *PaO_2,* partial pressure of oxygen in arterial blood; *PEEP,* positive end-expiratory pressure.

Complications

Complications may develop as a result of ARDS or its treatment. (Table 70-10 lists the common complications of ARDS.) The major cause of death in ARDS is multiple-organ dysfunction syndrome, often accompanied by sepsis. The vital organs most commonly involved are the kidneys, liver, and heart. The organ systems most often involved are the CNS and the hematological and gastro-intestinal systems.

TABLE 70-10

COMPLICATIONS ASSOCIATED WITH ACUTE RESPIRATORY DISTRESS SYNDROME

Cardiac complications	Decreased cardiac output Dysrhythmias
Endotracheal intubation complications	Laryngeal ulceration Tracheal malacia Tracheal stenosis Tracheal ulceration
Gastro-intestinal complications	Hypermetabolic state, dramatically increased nutritional requirements Paralytic ileus Pneumoperitoneum Stress ulceration and hemorrhage
Hematological complications	Anemia Disseminated intravascular coagulation Thrombo-cytopenia
Infection	Catheter-related infection Hospital-acquired pneumonia Sepsis (bacteremia)
Renal complications	Acute kidney injury
Respiratory complications	O_2 toxicity Pulmonary barotraumas (e.g., pneumothorax, pneumomediastinum, subcutaneous emphysema) Pulmonary emboli Pulmonary fibrosis Ventilator-associated pneumonia

Hospital-Acquired Pneumonia.

A frequent complication of ARDS is hospital-acquired pneumonia, occurring in as many as 68% of patients with ARDS. Risk factors include impaired host defences, contaminated medical equipment, invasive monitoring devices, aspiration of gastro-intestinal contents, and prolonged mechanical ventilation as well as colonization of the respiratory tract. Strategies to prevent hospital-acquired pneumonia include infection control measures (e.g., strict handwashing and sterile technique during endotracheal suctioning) and elevating the head of the bed 45 degrees or more to prevent aspiration (Moazed & Calfee, 2014; Urden, Stacy, & Lough, 2014). (See Chapter 30 for discussion of pneumonia.)

Barotrauma.

Barotrauma may result from rupture of overdistended alveoli during mechanical ventilation. The high airway pressures necessary to ventilate patients with ARDS predispose to this complication. Barotrauma results in the presence of alveolar air in locations where it is not usually found. This

can lead to pulmonary interstitial emphysema, pneumothorax, subcutaneous emphysema, pneumoperitoneum, pneumomediastinum, and tension pneumothorax. (See Chapter 30 for discussion of pneumothorax.)

To avoid barotrauma, patients with ARDS are ventilated with smaller tidal volumes. Different approaches to lung-protective ventilation are in current clinical use. Ventilation protocol include the use of small tidal volumes (e.g., 6 mL/kg) and varying amounts of positive end-expiratory pressure (PEEP) while the $PaCO_2$ gradually rises above normal *(permissive hypercapnia),* with the pH supported at 7.2 to 7.25 or above (Marhong & Fan, 2014). Permissive hypercapnia is commonly accepted as a consequence of lung-protective ventilation in ARDS (Marhong & Fan, 2014). High-frequency oscillation uses a constant mean airway pressure to maintain the alveoli in a recruited state while low tidal volumes are oscillated at a fast rate. Ventilation is achieved by the generation of extremely rapid pressure oscillations, usually in the range of 300 to 900 cycles/minute (Koh, 2014).

Volutrauma.

Volutrauma, or *volupressure trauma,* can occur in patients with ARDS when large tidal volumes (10 to 15 mL/kg) are used to ventilate noncompliant lungs. Volutrauma results in alveolar fractures and movement of fluids and proteins into the alveolar spaces. To limit this complication, it is recommended that smaller (lower) tidal volumes or pressure ventilation be used in patients with ARDS (Bein, Weber-Carstens, Goldmann, et al., 2013; see Chapter 68). Ventilation with low tidal volume reduces the damaging, excessive stretch of lung tissue that results in volutrauma.

Stress Ulcers.

Critically ill patients with acute respiratory failure are at high risk for stress ulcers. Bleeding from stress ulcers occurs in 30% of patients with ARDS who require PPV, a higher incidence than those with other causes of acute respiratory failure. Management strategies include correction of predisposing conditions such as hypotension, shock, and acidosis. Prophylactic management includes antiulcer agents (e.g., famotidine [Pepcid], omeprazole [Losec], sucralphate [Sulcrate]) and early initiation of enteral nutrition (see Chapters 42 and 68).

Renal Failure.

Renal failure results from decreased renal tissue oxygenation owing to hypotension, hypoxemia, or hypercapnia and from administration of nephrotoxic drugs (e.g., aminoglycosides).

Nursing and Collaborative Management Acute Respiratory Distress Syndrome

The collaborative care for acute respiratory failure (see Table 70-6) and the nursing care plan for acute respiratory failure (see NCP 70-1, available on the Evolve website) are applicable to ARDS. The following section is a discussion of additional collaborative care measures for patients with ARDS (Table 70-11). Patients with ARDS are commonly cared for in intensive care units.

TABLE 70-11

COLLABORATIVE CARE
Acute Respiratory Distress Syndrome

Diagnostic See Table 70-9. **Collaborative Therapy** ***Respiratory Therapy*** • High-frequency oscillation • Lateral rotation therapy • Mechanical ventilation with PEEP • O_2 administration • Prone positioning	***Supportive Therapy*** • Diuretics • Dobutamine • Dopamine • Hemodynamic monitoring • Identification and treatment of underlying cause • Inotropic or vasopressor medications • IV fluid administration (fluid resuscitation early and less fluid later)

IV, intravenous; *PEEP,* positive end-expiratory pressure.

Nursing Assessment

Because ARDS causes acute respiratory failure, the subjective and objective data that should be obtained from a patient with ARDS are the same as that for acute respiratory failure (see Table 70-5). Abnormal findings on physical examination are indications that ARDS has progressed beyond the initial stages.

Nursing Diagnoses

Nursing diagnoses for patients with ARDS may include, but are not limited to, those described for acute respiratory failure (see also NCP 70-1, available on the Evolve website).

Planning

With appropriate therapy, the overall goals for the patient with ARDS are a PaO_2 of at least 60 mm Hg and adequate lung ventilation to maintain normal pH. After recovery from ARDS, (a) the patient's PaO_2 should be within normal limits for age or baseline values on room air (FiO_2 of 21%), (b) the SaO_2 should be greater than 90%, (c) the patient's airway should be patent, and (d) on auscultation, the lungs should sound clear.

Respiratory Therapy

Oxygen Administration.

The primary goal of O_2 therapy is to correct hypoxemia. Use of a simple face mask or nasal cannula is usually inadequate to treat refractory hypoxemia associated with ARDS. Masks with high-flow systems that deliver higher O_2 concentrations are initially used to maximize O_2 delivery, and O_2 saturation is monitored continuously to assess their effectiveness. The standard for O_2 administration is to administer the lowest concentration that results in a PaO_2 of 60 mm Hg or higher so as to minimize the risk of O_2 toxicity.

Early noninvasive ventilation application may be extremely helpful in immuno-compromised patients with pulmonary infiltrates, in whom intubation dramatically increases the risk of infection, pneumonia, and death. Overall, because of the high rate of failure with noninvasive ventilation, noninvasive ventilation should be used with caution in patients with acute lung injury/ARDS. Prompt intubation is required if signs of noninvasive ventilation failure emerge (Wang, Singh, Tian, et al., 2013). Patients with ARDS commonly need intubation with mechanical ventilation because the PaO_2 cannot otherwise be maintained at acceptable levels.

Mechanical Ventilation.

Endotracheal intubation and mechanical ventilation provide additional respiratory support. However, FiO_2 of 50% or greater may still be necessary to maintain the PaO_2 at 60 mm Hg or higher. During mechanical ventilation, it is common to apply PEEP at 5 cm H_2O to compensate for loss of glottic function caused by the presence of the endotracheal tube. In patients with ARDS, higher levels of PEEP (e.g., 10–20 cm H_2O) may be used to increase functional residual capacity and recruit (open up)

collapsed alveoli. PEEP is typically applied in increments of 3 to 5 cm H_2O until oxygenation is adequate with FiO_2 of 60% or lower. PEEP may improve VQ in respiratory units that collapse at low airway pressures, thus allowing the FiO_2 to be lowered.

PEEP, however, is not a benign therapy. The additional intrathoracic and intrapulmonic pressures can compromise venous return to the right side of the heart, thereby decreasing preload, cardiac output, and blood pressure. PEEP can also cause hyperinflation of the alveoli, compression of the pulmonary capillary bed, a reduction in blood return to the left side of the heart, and a dramatic reduction in blood pressure. In addition, PEEP and excessive inspiratory pressures can contribute to barotrauma and volutrauma (Retamal, Bugedo, Larsson, et al., 2015).

If hypoxemia persists despite high PEEP, alternative modes and therapies may be used. These include pressure-support ventilation, pressure-release ventilation, pressure-control ventilation, inverse-ratio ventilation, high-frequency oscillation, and permissive hypercapnia. (Additional information on mechanical ventilation and PEEP is provided in Chapter 68.)

In extracorporeal membrane oxygenation and extracorporeal carbon dioxide removal, blood passes across an external gas-exchanging membrane, is oxygenated, and returns to the body. Although extracorporeal membrane oxygenation has not clearly been demonstrated to be better than the standard of care for ARDS, referral to a specialized centre with extracorporeal membrane oxygenation experience should be considered early after the initiation of high-level ventilator support (Papazian & Herridge, 2013).

Positioning Strategies.

Some patients with ARDS demonstrate an improvement in PaO_2 when turned from supine to prone position with no change in FiO_2. The response may be sufficient to allow a reduction in FiO_2 or PEEP.

In early ARDS, fluid moves freely throughout the lung. Because of gravity, this fluid pools in dependent lung regions in such a way that some alveoli are fluid filled (dependent areas), whereas others are air filled (nondependent areas). In addition, when the patient is supine, the mediastinal contents place more pressure on the lungs than in the prone position, which changes pleural pressure and predisposes to atelectasis. If the patient is turned to the prone position, air-filled, nonatelectic alveoli in

the ventral (anterior) lung become dependent. Perfusion may be better matched to ventilation, causing less VQ mismatch. Prone positioning is typically reserved for patients with refractory hypoxemia, but not all respond with an increase in PaO_2. When prone positioning is used, there must be a plan for immediate repositioning for cardiopulmonary resuscitation in the event of a cardiac arrest (Kallet, 2015; Koh, 2014). The RotoProne Therapy System (Figure 70-11) is a bed that is designed for a patient placed in the prone position and provides kinetic therapy in which the patient is turned side to side to any angle between 40 and 62 degrees (Jackson, Verano, Fry, et al., 2012).

FIGURE 70-11 RotoProne bed. The RotoProne Delta Therapy System allows clinicians to place patients in the prone position, safely and effectively. This product is not specifically indicated for the treatment of acute respiratory distress syndrome or ventilator-associated pneumonia (VAP). Source: Photo courtesy Arjo Inc.

Other positioning strategies used in ARDS are lateral rotation therapy and kinetic therapy (Kallet, 2015; Koh, 2014). The purpose of this therapy is to provide continuous, slow, side-to-side turning of the patient by rotation of the bed frame. Lateral movement of the bed is maintained for 18 hours daily to simulate postural drainage and help mobilize secretions. In addition, the bed may also contain a vibrator pack that can provide

chest physiotherapy to further assist with secretion removal (Figure 70-12). The patient's pulmonary status (e.g., respiratory rate and rhythm, breath sounds, ABGs, SpO_2) should be assessed before initiation of the therapy and continued throughout.

FIGURE 70-12 TotalCare SpO_2RT Bed System offers continuous lateral rotation therapy and percussion and vibration therapies. Patients can be repositioned easily and quickly.

Medical Supportive Therapy

Maintenance of Cardiac Output and Tissue Perfusion.

Patients receiving PPV and PEEP frequently experience decreased cardiac output in relation to impaired contractility, decreased preload, decreased venous return, or some combination, as a result of PEEP-induced increases in intrathoracic pressure. Continuous hemodynamic monitoring is essential for detecting changes and titrating therapy. An arterial catheter is inserted for continuous blood pressure monitoring and ABG sampling. A pulmonary artery catheter enables monitoring of pulmonary artery pressures, pulmonary artery wedge pressures (which reflect the fluid status of the left side of the heart), mixed venous oxygen saturation, and cardiac output. If the cardiac output falls, it may be necessary to

administer fluids or to lower the PEEP. Use of inotropic drugs such as dobutamine or dopamine may also be necessary. (See Chapter 68 for discussion of hemodynamic monitoring.)

The hemoglobin is usually kept above 6 mmol/L with an O_2 saturation of 90 or higher (when PaO_2 ≥60 mm Hg). Packed red blood cells may be administered to increase hemoglobin and thus the O_2-carrying capacity of the blood.

Maintenance of Nutrition and Fluid Balance.

Maintenance of nutrition and fluid balance is challenging in patients with ARDS. Nutrition consultations determine optimal caloric needs. Attaining access and initiating enteral nutrition should be considered as soon as fluid resuscitation is completed and the patient is hemodynamically stable. A "window of opportunity" exists in the first 24 to 72 hours after the patient's admission or the onset of a hypermetabolic insult. However, current research has shown that the use of enteral omega-3 fatty acids did not significantly reduce all-cause 28-day mortality rates (Zhu, Zhang, Li, et al., 2014).

Increased pulmonary capillary permeability results in pulmonary edema. However, the patient may be volume depleted, hypotensive, and prone to decreased cardiac output from mechanical ventilation and PEEP. Pulmonary artery wedge pressures, daily weights, and intake and output are monitored to assess fluid status. Fluid replacement with crystalloids or colloids is controversial. Critics of colloids believe that proteins in colloid solutions leak into the pulmonary interstitium, exacerbating the movement of proteinaceous fluid into the alveoli (Kallet, 2015). Advocates of colloids as replacement believe that colloids help keep fluid from leaking into the alveoli (Neamu & Martin, 2013). The pulmonary artery wedge pressure is kept as low as possible without impairing cardiac output in order to limit pulmonary edema. Fluids are usually restricted mildly, with diuretics administered as needed (Urden, Stacy, & Lough, 2014).

Evaluation

The expected outcomes for patients with ARDS are similar to those for patients with acute respiratory failure and are presented in NCP 70-1, available on the Evolve website.

Severe Acute Respiratory Syndrome

Severe acute respiratory syndrome (SARS) is a serious, acute respiratory infection caused by a coronavirus. The virus spreads by close contact between people. The SARS coronavirus is probably spread via droplets in the air. It is possible that SARS coronavirus may also be spread more broadly through the air or from touching contaminated objects.

Most patients with SARS coronavirus have a history of exposure to another patient with SARS or to a setting in which SARS coronavirus transmission is occurring, and they develop pneumonia (Khandelwal, Hough, Bansal, et al., 2014). In general, SARS begins with a fever greater than 38°C. Other manifestations may include sore throat, headache, chills, generalized discomfort, and muscle aches. After 2 to 7 days, affected patients may develop a dry cough and dyspnea.

Because the disease is severe, treatment is started immediately on the basis of symptoms, before the illness is confirmed. First, patients with suspected SARS should be placed in isolation to protect others. There is no definitive treatment for SARS, but antiviral medications (such as ribavirin) and corticosteroids may be used. Although antibiotics do not help with SARS (because it is believed to be caused by a virus), they may be used in cases in which the patient also has a bacterial infection.

Approximately 80% to 90% of infected people start to recover after 6 to 7 days. However, 10% to 20% go on to develop severe breathing problems and may need mechanical ventilation. The risk of death is higher among such patients and appears to be linked to pre-existing health conditions. People older than 40 years are more likely than those younger to develop severe breathing problems (Khandelwal, Hough, Bansal, et al., 2014).

Case Study

Acute Respiratory Distress Syndrome

Source: Phovoir/Shutterstock.com.

Patient Profile

Farid Habib is a 55-year-old man who was admitted to a surgical intensive care unit (ICU) 72 hours ago after bowel resection. The surgery was extensive to repair a perforated colon, irrigate the abdominal cavity, and provide hemostasis. During surgery, his systolic blood pressure (BP) dropped to 70 mm Hg. Seven units of packed red blood cells and 4 L of normal saline were administered to restore blood loss and circulating volume. He is currently receiving 60% FiO_2 through an aerosol face mask and has continuous cardiac monitoring and O_2 saturation in place. He is receiving 0.9% normal saline at 125 mL/hr through a central line. A urinary catheter is in place.

Subjective Data

- He complains of shortness of breath, inability to lie flat, and diffuse abdominal pain.
- His wife and two adult children are at the bedside voicing concerns and asking questions about his condition.

Objective Data

Physical Assessment

- *General:* Alert, well nourished, appears restless and anxious; head of bed elevated 30 degrees; skin cool, moderate diaphoresis
- *Respiratory:* No accessory muscle use, retractions, or paradoxical breathing; respiration rate, 28 breaths/min; SpO_2, 85%; fine crackles at lung bases
- *Cardiovascular:* BP, 90/60 mm Hg; sinus tachycardia at 130 beats/min; equal apical–radial pulse; temperature, 38°C orally

- *Gastro-intestinal:* No bowel sounds heard; surgical dressing dry and intact
- *Urological:* Catheter draining concentrated urine at <30 mL/hr

Diagnostic Findings

- ABG results: pH, 7.35; PaO_2, 55 mm Hg; $PaCO_2$, 27 mm Hg; bicarbonate level, 16 mmol/L; SaO_2, 86%
- Chest radiograph: new scattered interstitial infiltrates compatible with ARDS

Discussion Questions

1. How does the pathophysiology of ARDS predispose to the development of refractory hypoxemia?
2. What clinical manifestations does Mr. Habib exhibit that support a diagnosis of ARDS?
3. What are the possible causes of ARDS in Mr. Habib?
4. What are the possible complications that Mr. Habib is at risk for developing secondary to ARDS?
5. ***Evidence-informed practice:*** A new nurse who is being oriented asks why Mr. Habib's family was offered the opportunity to stay at the bedside while the chest tube was placed. How should the nurse respond?
6. ***Priority decision***: What priority interventions should be implemented to improve Mr. Habib's respiratory status and hypoxemia?
7. ***Priority decision:*** On the basis of the assessment data presented, what are the priority nursing diagnoses?
8. What information should the nurse provide to the caregivers, in view of Mr. Habib's decline in cardiopulmonary function?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Which signs and symptoms differentiate hypoxemic respiratory failure from hypercapnic respiratory failure? *(Select all that apply)*
   a. Cyanosis
   b. Tachypnea
   c. Morning headache
   d. Paradoxical breathing
   e. Use of pursed-lip breathing
2. What is an early sign of acute respiratory failure?
   a. Coma
   b. Cyanosis
   c. Restlessness
   d. Paradoxical breathing
3. Which type of oxygen delivery system should be chosen for clients in acute respiratory failure?
   a. Always use a low-flow device, such as a nasal cannula
   b. One that should correct the partial pressure of oxygen in arterial blood (PaO_2) to a normal level as quickly as possible
   c. Positive-pressure ventilation to prevent CO_2 narcosis
   d. One that should maintain the PaO_2 at 60 mm Hg or higher at the lowest fraction of inspired oxygen (FiO_2) possible
4. What are the early clinical manifestations of ARDS?
   a. Dyspnea and tachypnea
   b. Cyanosis and apprehension
   c. Hypotension and tachycardia
   d. Respiratory distress and frothy sputum
5. How is fluid balance maintained in clients with ARDS?
   a. Hydration with colloids
   b. Administration of surfactant
   c. Mild fluid restriction and diuretics as necessary

d. Keeping the hemoglobin at levels of 9.5 mmol/L (15 g/dL)

6. Which of the following is designed to prevent barotrauma in clients with ARDS?

   a. Increasing positive end-expiratory pressure (PEEP)

   b. Increasing the tidal volume

   c. Permissive hypercapnia

   d. Pressure support ventilation

1. a, b, d; 2. c; 3. d; 4. a; 5. c; 6. c.

CHAPTER 71

Nursing Management

Emergency Care Situations

Written by, Linda Bucher

Adapted by, Jane Tyerman

LEARNING OBJECTIVES

1. Apply the sequential steps in the primary and secondary surveys to assess a patient in an emergency situation.
2. Describe the pathophysiology, the assessment, and the collaborative care of select environmental emergencies, including hyperthermia, hypothermia, submersion injury, bites, and stings.
3. Discuss the assessment and the collaborative care of select toxicological emergencies.
4. Discuss the nurse's role in the process of organ and tissue donations.
5. Recognize the nurse's role in assessing and caring for survivors of domestic violence in the emergency department and in the mandatory reporting of abuse and weapon-related injuries.
6. Summarize the clinical manifestations of sexual assault and the appropriate nursing and collaborative management of the patient who has been sexually assaulted.

submersion injury, p. 1814

triage system, p. 1804

Most patients with life-threatening problems arrive at the hospital through the emergency department (ED). According to the National Trauma Registry of the Canadian Institute for Health Information (CIHI, 2013), there were 15 190 major-injury cases in 2010 and 2011. The leading causes of injury were unintentional falls and motor vehicle collisions, each responsible for 39% of the identified cases. Blunt trauma was the most common injury (95%), followed by penetrating injuries (4%) and burn injuries (1%). Intentional injuries, both self-inflicted and through assaults, accounted for 10% of injuries (CIHI, 2013).

Many patients report to the ED for less urgent conditions, often because they do not have access to a health care provider. Emergency nurses care for patients of all ages and with a variety of problems, especially in the areas of health promotion and prevention and chronic disease management. Some EDs specialize in certain patient populations, such as pediatric patients, or certain conditions, such as trauma.

Nursing roles within the ED include patient care, research, and management. The National Emergency Nurses Association (NENA) is the Canadian specialty nursing organization aimed at advancing emergency nursing practice. NENA publishes standards of care for nurses working in the ED and endorses the Canadian Nurses Association (CNA) certification process to become a certified emergency nurse, ENC(C). This certification validates the knowledge and skills that a nurse needs to provide competent care in emergency settings (CNA, 2018; NENA, 2016).

Specific emergency management of patients with various medical, surgical, and traumatic emergencies is described throughout this book (Table 71-1).

TABLE 71-1

This chapter focuses on initial assessment and management of patients with trauma and emergency conditions not addressed elsewhere in this book. These include heat- and cold-related emergencies, submersion injuries, bites, stings, poisonings, abuse, and violence.

Care of the Emergency Patient

A **triage system** identifies and categorizes patients' conditions so that those in most critical condition are treated first. The process is based on the premise that patients who have a threat to life, limb, or vision should be treated before other patients. Unique to the ED, the triage nurse performs a brief patient assessment to categorize and prioritize the needs of each patient seeking care. This categorization is facilitated through the Canadian Triage and Acuity Scale (CTAS). CTAS is used in the ED and by community paramedics to define the urgency of a patient's presenting problem (Bullard, Chan, Brayman, et al., 2014; Bullard, Unger, Spence, et al., 2008).

The CTAS is a five-level scale consisting of the following categories: resuscitation, emergency, urgent, less urgent, and nonurgent (Table 71-2). Patients who are assigned a high triage level (level I: resuscitation) are allocated the most health care resources and are assessed immediately. Those assigned to a low triage level (e.g., level V: nonurgent) wait longer for nurse and physician assessment unless they experience a deterioration in clinical status while they wait (Bullard, Chan, Brayman, et al., 2014). The CTAS has four major components: (1) five *triage levels* (ranging from nonurgent to resuscitation); (2) a *time to nurse and physician assessment*, which is based on the assigned triage level; (3) *usual presentation of the patient* (e.g., head injury, alert, with no vomiting; sore throat with no respiratory symptoms), which is based on the patient's complaints and presentation; and (4) a sentinel diagnosis (e.g., head injury; upper respiratory infection).

TABLE 71-2

THE CANADIAN EMERGENCY DEPARTMENT TRIAGE AND ACUITY SCALE

Consideration	Resuscitation (Level I)	Emergency (Level II)	Urgent (Level III)	Less Urgent (Level IV)	Nonurgent (Level V)
Condition	Threat to life or limb; immediate assessment required Example: cardiac or respiratory arrest, major trauma, shock state	Potential threat to life, limb, or function Example: altered mental state, head injury, cardiac chest pain, stroke	Potential to progress to serious problem Example: asthma, GI bleed, acute pain	May progress to urgent status Example: headache, corneal foreign body, chronic back pain	Acute or chronic but nonurgent Example: sore throat, mild abdominal pain that is chronic or recurring
Time to nurse and physician assessment	Immediate	15 min	30 min	60 min	120 min
Recommended re-evaluation	Continuous	Every 15 min	Every 30 min	Every 60 min	Every 120 min

GI, gastro-intestinal.

The emergency nurse must complete an initial assessment to determine the presence of actual or potential threats to life and then rapidly initiate interventions appropriate for the patient's condition. Simultaneously, the nurse collects a history. A systematic approach to the initial assessment of the patient decreases the time required to identify potential threats and keeps to a minimum the risk of missing a life-threatening condition. Two systematic approaches initially developed for use with patients with trauma, a primary and a secondary survey, can be applied to emergency assessment.

Primary Survey

The **primary survey** (Table 71-3) focuses on *a*irway, *b*reathing, *c*irculation, and *d*isability (ABCDs) and serves to identify life-threatening conditions so that appropriate interventions can be

initiated. Life-threatening conditions related to airway, breathing, circulation, and disability (Table 71-4) may be identified during the primary survey, and the nurse starts interventions immediately before proceeding to the next step of the survey.

TABLE 71-3
PRIMARY SURVEY OF A PATIENT IN AN EMERGENCY

Assessment	Interventions
Airway With Simultaneous Cervical Spine Stabilization and Immobilization	
• Assessment of airway for patency • Assessment for respiratory distress • Check for loose teeth and foreign objects • Assessment for bleeding, vomitus, or edema	• Open airway. • Perform jaw-thrust manoeuvre. • Remove or suction any foreign objects. • Insert oropharyngeal or nasopharyngeal airway, endotracheal tube, cricothyroidectomy. • Immobilize cervical spine with collar, backboard, or soft rolls; tape forehead to board.
Breathing	
• Assessment of ventilation • Chest scan for signs of breathing • Observation for paradoxical movement of the chest wall during inspiration and expiration • Observation for use of accessory muscles or abdominal muscles • Observation and count of respiratory rate • Colour of nail beds, mucous membranes, and skin • Auscultation of lungs • Assessment for jugular venous distension and position of trachea	• Administer supplemental O_2 via appropriate delivery system (e.g., nonrebreather mask) • Ventilate with bag–valve–mask device with 100% O_2 if respirations are inadequate or absent. • Prepare to intubate if respiratory distress is severe (e.g., agonal breaths, respiratory arrest). • Have suction available. • If breath sounds are absent, prepare for needle thoracostomy and chest tube insertion.
Circulation	
• Check of carotid or femoral pulse • Palpation of pulse for quality and rate • Assessment of skin colour, temperature, and moisture • Check of capillary refill • Assessment for external bleeding • Measurement of blood pressure	• If pulse is absent, initiate cardiopulmonary resuscitation and advanced life-support measures. • If shock symptoms are present, insert two large-bore (14- to 16-gauge) intravenous catheters and initiate infusions of normal saline or lactated Ringer's solution. • Control bleeding with direct pressure. • Administer blood products, if ordered. • Consider autotransfusion if chest trauma is isolated. • Obtain blood samples for type and crossmatch.
Disability: Brief Neurological Assessment	
• Assessment of level of consciousness by determining response to verbal stimuli, painful stimuli, and motor response (e.g., Glasgow Coma Scale) • Assessment of pupils for size, shape, equality, and response to light	• Periodically reassess level of consciousness. • Consider the possibility of hyperventilation if signs of brain herniation are present (e.g., motor posturing).

TABLE 71-4

CAUSES OF LIFE-THREATENING CONDITIONS IDENTIFIED DURING THE PRIMARY SURVEY*

Airway • Inhalation injury • Obstruction, partial or complete, by foreign bodies, debris (e.g., vomitus), or tongue • Penetrating wounds, blunt trauma, or both to the upper airway structures **Breathing** • Anaphylaxis • Flail chest with pulmonary contusion • Hemothorax • Pneumothorax (e.g., open, tension)	**Circulation** • Direct cardiac injury (e.g., myocardial infarction, trauma) • Pericardial tamponade • Shock (e.g., massive burns, hypovolemia) • Uncontrolled external hemorrhage • Hypothermia **Disability** • Head injury • Stroke

*This list is not all-inclusive.

A = Airway With Cervical Spine Stabilization or Immobilization

Nearly all immediate deaths from trauma occur because of airway obstruction. Saliva, bloody secretions, vomitus, laryngeal trauma, facial trauma, fractures, and the tongue can obstruct the airway. Patients at risk for airway compromise include those who have seizures, near-drowning, anaphylaxis, foreign body obstruction, or cardiopulmonary arrest. If an airway is not maintained, airflow is obstructed, and hypoxia, acidosis, and death result.

Primary signs and symptoms in a patient with a compromised airway include dyspnea, inability to vocalize, presence of a foreign body in the airway, and trauma to the face or neck. Airway maintenance should progress rapidly from the least to the most invasive method. One treatment method is to open the airway by means of the **jaw-thrust manoeuvre,** in which the rescuer uses forearms to stabilize the patient's head (while avoiding neck hyperextension) and then applies pressure with the index fingers to push the patient's jaw forward (Figure 71-1). Other treatment methods include suctioning and removal of foreign objects; insertion of a nasopharyngeal or oropharyngeal airway (which causes a conscious patient to gag); and endotracheal intubation. If the patient

cannot be intubated because of airway obstruction, an emergency cricothyroidotomy or tracheotomy should be performed (Chapter 29). Patients should be ventilated with 100% oxygen (O_2) through a bag–valve–mask (BVM) device before intubation or cricothyroidotomy (Bair, Walls, & Grayzel, 2017).

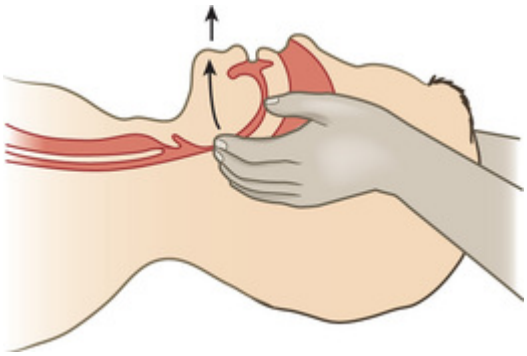

FIGURE 71-1 The jaw-thrust manoeuvre is the only widely recommended procedure for use on an unconscious patient with possible neck or spinal injuries. The patient should be lying supine, and the rescuer should kneel at the top of the patient's head. The rescuer carefully reaches forward and gently places one hand on each side of the patient's chin at the lateral angles of the lower jaw. The patient's head should be stabilized by the rescuer's forearms; then the rescuer applies pressure with the index fingers to push the patient's jaw forward.

Rapid-sequence intubation is the preferred procedure for securing an unprotected airway in the ED. The patient is given a rapid-acting sedative (e.g., midazolam) and a paralyzing neuromuscular blocking agent (e.g., succinylcholine) to facilitate intubation and minimize the risk for aspiration and airway trauma (Stollings, Diedrich, Oyen, et al., 2013; Patanwala, Stahle, Sakles, et al., 2011).

The nurse should suspect cervical spine trauma in any patient with significant injuries to the upper torso or trauma to the face, head, or neck. The cervical spine should be stabilized with the head maintained in a neutral position. At the scene of the injury, the cervical spine is immobilized with a rigid cervical collar or an

immobilization device such as head blocks or towel rolls that are secured to a backboard on either side of the head. The patient's forehead then is taped to the backboard.

B = Breathing

Adequate airflow through the upper airway does not ensure adequate ventilation. Breathing alterations are caused by many conditions, including fractured ribs, pneumothorax, penetrating injuries, allergic reactions, pulmonary emboli, and asthma attacks. Patients may exhibit a variety of signs and symptoms, including dyspnea (e.g., pulmonary emboli), stridor, accessory muscle use, paradoxical or asymmetrical chest wall movement (e.g., flail chest), decreased or absent breath sounds on the affected side (e.g., pneumothorax), visible wound to chest wall (e.g., penetrating injury), cyanosis (e.g., asthma), tachycardia, and hypotension.

Every critically injured or ill patient has increased metabolic and oxygen demands and should receive supplemental O_2. The nurse should administer high-flow O_2 (100%) via a nonrebreather mask and monitor the patient's response. Life-threatening conditions, (e.g., tension pneumothorax, flail chest) can severely compromise ventilation. Interventions in these situations include BVM ventilation with 100% O_2, intubation, needle decompression, and treatment of the underlying cause. In patients with established chronic obstructive pulmonary disease, carbon dioxide retention and level of consciousness must be monitored.

C = Circulation

An effective circulatory system includes the heart, intact blood vessels, and adequate blood volume. Uncontrolled internal or external bleeding increases the risk for hemorrhagic shock (Chapter 69). Because peripheral pulses may be absent as a result of direct injury or vasoconstriction, the central (e.g., carotid) pulse should be checked. Palpating the pulse allows for assessment of the quality, rate, and regularity. The nurse should also assess skin for colour, temperature, and moisture. A capillary refill delay longer than 3

seconds and altered mental status are the most significant signs of shock. Care must be taken when capillary refill is evaluated in cold environments because the cold can cause vasoconstriction, which delays refill.

Two large-bore (14- to 16-gauge) intravenous (IV) catheters should be inserted into veins in the upper extremities unless this location is contraindicated, for example, due to a massive fracture or an injury that affects limb circulation, and aggressive fluid resuscitation initiated with lactated Ringer's solution or normal saline. The nurse should apply direct pressure with a sterile dressing to obvious bleeding sites. Blood samples should be obtained for typing to determine ABO and Rh group and then type-specific packed red blood cells administered. In an emergency (life-threatening) situation, blood that is not crossmatched may be given if immediate transfusion is warranted.

D = Disability

A brief neurological examination completes the primary survey. The degree of disability is measured by level of consciousness, which is assessed by determining the patient's alertness and response to verbal and painful stimuli with the following scale:

A Alert
V Responsive to voice
P Responsive to pain
U Unresponsive

The Glasgow Coma Scale (GCS) and the Canadian Neurological Scale are used to further assess the arousal aspect of the patient's consciousness (The GCS is further discussed in Chapter 59, and the Canadian Neurological Scale is discussed in Chapter 60). Pupils should be also assessed for size, shape, equality, and response or reactivity to light.

Secondary Survey

After each step of the primary survey is addressed and any necessary life-saving interventions are initiated, the secondary survey begins. The **secondary survey** is a brief, systematic process that is aimed at identifying *all* injuries and continues the ABCD mnemonic through EFGHI: *e*xposure and *e*nvironmental control; *f*ull set of vital signs/*f*ive interventions/*f*acilitating family presence; *g*iving comfort measures; *h*istory and *h*ead-to-toe assessment; and *i*nspection of the posterior surfaces (Table 71-5).

TABLE 71-5
SECONDARY SURVEY OF A PATIENT IN AN EMERGENCY

Parameter	Assessment
Exposure and environmental control	Removal of clothing for adequate examination; keeping patient warm with blankets, IV fluids, and overhead lights
Full set of vital signs	Obtainment of vital signs: temperature, heart rate, respiratory rate, and blood pressure bilaterally
Five interventions	(a) Monitoring and recording of heart rhythm; (b) monitoring of O_2 saturation; (c) insertion of a urinary catheter (if not contraindicated); (d) insertion of a gastric tube; and (e) obtainment of specimens for laboratory studies
Facilitating family presence	Determining family's desire to be present during resuscitation
Giving comfort measures	Addressing patient's level of pain and anxiety
History and head-to-toe assessment	
• History	Documentation of details of the incident or illness, mechanism and pattern of injury, length of time since incident occurred, injuries suspected, treatment provided and patient's response, and patient's level of consciousness Assessment for allergies Documentation of medication history Documentation of past health history (e.g., pre-existing medical conditions, most recent menstrual period) Determination of the patient's most recent meal Documentation of events and environment preceding illness or injury
• Head, neck, face	Notation of general appearance, skin, and colour Examination of face and scalp for lacerations, bone or soft-tissue deformity, tenderness, bleeding, and foreign bodies Examination of eyes, ears, nose, and mouth for bleeding, foreign bodies, drainage, pain, deformity, ecchymosis, and lacerations Examination of head for depressions of cranial or facial bones, contusions, hematomas, areas of softness, and bony crepitus Examination of neck for stiffness, pain in cervical vertebrae, tracheal deviation, distended neck veins, bleeding, edema, difficulty swallowing, bruising, subcutaneous emphysema, and bony crepitus
• Chest	Observation of rate, depth, and effort of breathing, including chest wall movement Palpation for bony crepitus and subcutaneous emphysema Observation for use of accessory muscles Auscultation of breath sounds Obtainment of ECG Documentation of external signs of injury: petechiae, bleeding, cyanosis, bruises, abrasions, lacerations, or scars
• Abdomen and flanks	Assessment of symmetry of external abdominal wall and bony structures Observation for external signs of injury: bruising, abrasions, lacerations, or punctures Assessment for masses, notation of guarding, and checking of femoral pulses Documentation of type and location of pain, rigidity, or distension of abdomen Assessment of bowel sounds

Parameter	Assessment
• Pelvis and perineum	Assessment of genitalia for blood at meatus and for priapism, ecchymosis, rectal bleeding, and anal sphincter tone
• Extremities	Documentation of signs of external injury: deformity, ecchymosis, abrasions, lacerations, or swelling Assessment for pain Evaluation of movement and strength in arms and legs Assessment of sensation in each limb Evaluation of colour of skin Documentation of presence and quality of peripheral pulses
Inspection of posterior surfaces	Inspection and palpation of back for deformity, bleeding, lacerations, or bruising (performed by log-rolling patient)

ECG, electrocardiogram; *IV*, intravenous; O_2, oxygen.

E = Exposure and Environmental Control

Any patient who has suffered trauma should have clothes removed so that a thorough physical assessment can be performed. Once the patient is exposed, it is important to limit heat loss and prevent hypothermia by using warming blankets, overhead warmers, and warmed IV fluids. The nurse should observe for medical alert bracelets or necklaces, tattoos, or wallet cards for ongoing health illnesses. Any faith-based objections to blood transfusions should be ascertained.

F = Full Set of Vital Signs/Five Interventions/Facilitating Family Presence

A complete set of vital signs, including blood pressure (BP), heart rate, respiratory rate, and temperature, should be measured after the patient's clothes are removed. BP should be obtained in both arms if the patient has sustained or is suspected of having chest trauma.

At this point, it must be determined whether to proceed with the secondary survey or to perform additional interventions. The availability of other team members often influences this decision. For patients who have sustained significant trauma and have required life-saving interventions during the primary and secondary surveys, the following five interventions should be performed next:

1. The patient should be monitored by electrocardiography for heart rate and rhythm.
2. Pulse oximetry and O_2 saturation monitoring are initiated.
3. An in-dwelling catheter should be inserted to monitor urine output and to check for hematuria, unless a urethral tear is suspected. Patients with pelvic injuries or blood at the meatus, and men with a high-riding prostate gland (detected on digital rectal examination), are at risk for a urethral tear or transection. Urethrography should be performed before a catheter is inserted.
4. An orogastric or nasogastric tube should be inserted to provide gastric decompression and emptying to reduce the risk for aspiration and to test contents for blood. A nasogastric tube should not be placed in the nares in a patient suspected of having facial fractures or a basilar skull fracture because the tube could enter the brain through the cribriform plate; it should be placed orally.
5. Laboratory studies should be performed for typing and crossmatching, hematocrit, hemoglobin, blood urea nitrogen, creatinine, blood alcohol level, toxicology screening, arterial blood gases (ABGs), electrolytes, coagulation profile, liver enzymes, cardiac enzymes, and pregnancy.

Facilitating *family presence* completes this step of the secondary survey. Although research findings support the positive benefits of family presence during invasive procedures and cardiopulmonary resuscitation (CPR), it is not a widely accepted practice (Jabre, Tazarourte, Azoulay, et al., 2013; NENA, 2014a). The most significant barrier to family presence during CPR was the concern that conflicts may occur within the emergency team. If family presence during CPR is allowed, written policies, guidelines, and education on the practice need to be developed (Edwards, Despotopulos, & Carroll, 2013; Porter, Cooper, & Sellick, 2014). It is essential that a member of the team explain to the family the care delivered and be available to answer their questions.

G = Giving Comfort Measures

Provision of comfort measures is of paramount importance during care for patients in the ED. It has been reported that pain (both acute and chronic) is the primary complaint of all patients who come to the ED (Iyer, 2011). Many EDs have developed pain management guidelines to treat pain early, beginning at triage. Pain management strategies should include a combination of pharmacological (e.g., opioids) and nonpharmacological (e.g., imagery) measures (Kahan, Mailis-Gagnon, Wilson, et al., 2011). Emergency nurses play a pivotal role in pain management because of their frequent contact with patients. General comfort measures such as offering verbal reassurance, listening, reducing stimuli (e.g., dimming lights), and developing a trusting relationship with the patient and family should be provided in the ED. Additional measures include splinting, elevating, and icing injured extremities as appropriate.

H = History and Head-to-Toe Assessment

The history of the incident, injury, or illness provides clues to the cause of the crisis and suggests specific assessment and intervention needs. The patient may be unable to provide a history; however, family, friends, witnesses, and personnel involved before arrival at the hospital can frequently provide important information. Prehospital information should focus on the mechanism and the pattern of injury, injuries suspected, vital signs, treatment initiated, and the patient's responses.

Details of the incident are extremely important because the mechanism of injury and injury patterns can help predict specific injuries. For example, a front-seat passenger with a seat belt may have a head injury from hitting the steering wheel; knee, femur, or hip fractures or dislocation from striking the dashboard; and an abdominal injury from the seat belt. If other victims were dead at the scene, the patient has a high chance of significant injury.

Patients who jump from buildings or bridges may have bilateral calcaneal (heel) fractures, wrist fractures, or lumbar spine compression fractures, and they may be at risk for aortic tears. In

older patients who have climbed ladders and fallen, a stroke or myocardial infarction may have led to the fall.

Prehospital personnel often provide a detailed description of the patient's general condition, level of consciousness, and apparent injuries. An experienced ED team can complete a history within 5 minutes of the patient's arrival. If the patient's condition is classified by triage as resuscitative, a thorough history is obtained from family or friends after the patient is taken to the treatment area. The history should include the following questions:

1. What is the chief complaint? What caused the patient to seek attention?
2. What are the patient's subjective complaints?
3. What is the patient's description of pain (e.g., location, duration, quality, character)?
4. What are witnesses' (if any) descriptions of the patient's behaviour since the onset?
5. What is the patient's health care history? The mnemonic AMPLE helps:
   - **A** Allergies
   - **M** Medication history
   - **P** Past health history (e.g., pre-existing medical conditions, previous hospitalizations and surgeries, smoking history, recent use of drugs or alcohol, tetanus immunization, most recent menstrual period)
   - **L** Last meal
   - **E** Events or environment preceding illness or injury

Head, Neck, and Face.

The patient should be assessed for general appearance, skin colour, and temperature, and the eyes should be checked for extraocular movements. A disconjugate gaze is an indication of neurological damage. Periorbital ecchymosis (“raccoon eyes”) is usually caused by a basilar skull fracture. The tympanic membranes and the external canals are checked for blood and cerebro-spinal fluid.

Cerebro-spinal fluid is allowed to flow freely because the leak usually resolves in 2 to 10 days (Chapter 59).

The nurse should assess the airway for foreign bodies, bleeding, edema, and loose or missing teeth; check for the ability to open the mouth and swallow; examine the neck for bruising, edema, bleeding, pain, or distended neck veins; and palpate the trachea to determine whether it is in the midline. A deviated trachea may signal a life-threatening tension pneumothorax. Subcutaneous emphysema may indicate laryngotracheal disruption. A stiff or painful cervical spine area may signify a fracture of a cervical vertebra. The cervical spine should be protected with a rigid collar and supine positioning, and patients with cervical spine injuries must be log-rolled when movement is necessary.

Chest.

The chest should be inspected for paradoxical chest movements and large, sucking chest wounds and assessed for pain on palpation, respiratory distress, decreased breath sounds, distant or muffled heart sounds (e.g., pericardial tamponade), and distended neck veins. Palpation of the sternum, the clavicles, and the ribs can reveal any deformity or point tenderness. In addition to tension and open pneumothorax, the patient should be evaluated for rib fractures, pulmonary contusion, blunt cardiac injury, and simple pneumothorax. A 12-lead ECG should be obtained to detect dysrhythmias and evidence of ischemia or infarction, particularly for an older patient or a patient with suspected heart disease.

Abdomen and Flanks.

Assessment of the abdomen and the flanks is more difficult. Frequent evaluation for subtle changes in the abdominal examination is essential. Motor vehicle collisions and assaults can cause blunt trauma. Penetrating trauma tends to injure specific organs. Decreased bowel sounds may indicate a temporary paralytic ileus. Bowel sounds in the chest may indicate a diaphragmatic rupture. The abdomen is percussed for distension (e.g., tympany [excessive air] and dullness [excessive fluid]) and palpated for peritoneal irritation.

If intra-abdominal hemorrhage is suspected, diagnostic peritoneal lavage may be performed to determine the presence of blood in the peritoneal space (hemoperitoneum) (Harris, 2013). Before the procedure, a gastric tube and a bladder catheter must be inserted to decompress these organs and reduce the possibility of perforation. An alternative to diagnostic peritoneal lavage that is gaining support is bedside ultrasonography: *focused abdominal sonography for trauma (FAST).* This procedure is noninvasive and can be performed quickly.

Pelvis and Perineum.

The pelvis is gently palpated. If pain is elicited, the patient may have a pelvic fracture. The genitalia are inspected for bleeding and obvious injuries. A rectal examination is performed to check for blood, a high-riding prostate gland, and loss of sphincter tone. The examiner should assess for bladder distension, hematuria, dysuria, or the inability to void.

Extremities.

The upper and the lower extremities are assessed for point tenderness, crepitus, and deformities. Injured extremities are splinted above and below the injury to decrease the occurrence of further soft-tissue injury and pain. Grossly deformed, pulseless extremities should be realigned and splinted. Pulses are checked before and after movement or splinting. A pulseless extremity represents a time-critical vascular or orthopedic emergency.

Injured extremities should be elevated, and ice applied. Fractures necessitate splinting, and patients may need pain control with analgesics. Prophylactic antibiotics are administered for open fractures.

I = Inspect the Posterior Surfaces

All patients who have suffered trauma should be turned using spinal precautions to inspect the posterior surfaces. The back is inspected for ecchymosis, abrasions, puncture wounds, cuts, and obvious

deformities. The entire spine is palpated for misalignment, deformity, and pain.

Intervention and Evaluation

Once the secondary survey is complete, all findings are recorded. Patients should be evaluated to determine their need for tetanus prophylaxis. It is not uncommon for older adults to have an outdated tetanus status. Information is needed about previous vaccinations and the condition of any wounds to make an appropriate decision (Table 71-6).

TABLE 71-6
PROPHYLAXIS AGAINST TETANUS IN WOUND MANAGEMENT

Vaccination History	Type of Wound	
	Clean, Minor Wounds	All Other Wounds
Age 11–64 Yr*		
Unknown or <3 doses of tetanus toxoid–containing vaccine	Tdap and recommend catch-up vaccination	Tdap and recommend catch-up vaccination TIG
≥3 doses of tetanus toxoid–containing vaccine *and* <5 yr since last dose	No indication	No indication
≥3 doses of tetanus toxoid–containing vaccine *and* 5–10 yr since last dose	No indication	Tdap preferred (if not yet received) or Td
≥3 doses of tetanus toxoid–containing vaccine *and* >10 yr since last dose	Tdap preferred (if not yet received) or Td	Tdap preferred (if not yet received) or Td
Age ≥65 Yr		
Unknown or <3 doses of tetanus toxoid–containing vaccine	Td or Tdap and recommend catch-up vaccination. Tdap preferred if patient has close contact with children <12 mo of age	Td or Tdap and recommend catch-up vaccination. Tdap preferred if patient has close contact with children <12 mo of age TIG
≥3 doses of tetanus toxoid–containing vaccine *and* <5 yr since last dose	No indication	No indication
≥3 doses of tetanus toxoid–containing vaccine *and* 5–10 yr since last dose	No indication	Td or Tdap. Tdap preferred if patient has close contact with children <12 mo of age
≥3 doses of tetanus toxoid–containing vaccine *and* >10 yr since last dose	Tdap preferred (if not yet received) or Td	Td or Tdap. Tdap preferred if patient has close contact with children <12 mo of age

*Pregnant women: As part of standard wound management care to prevent tetanus, a tetanus toxoid–containing vaccine might be recommended for wound management in a pregnant woman if ≥5 yr has elapsed since last receiving Td. If a tetanus booster is indicated for a pregnant woman who previously has not received Tdap, Tdap should be administered (at any gestational age).

TD, tetanus–diphtheria toxoid absorbed (adult use); *Tdap,* tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine; *TIG,* tetanus immune globulin (human).

https://www.cdc.gov/disasters/disease/tetanus.html.

Regardless of the patient's chief complaint, ongoing monitoring and evaluation are critical in an emergency situation. The nurse is responsible for providing appropriate interventions and assessing the patient's response. The evaluation of airway patency and the effectiveness of breathing always assume highest priority. The nurse monitors O_2 saturation and ABGs to help determine the patient's progress. Level of consciousness, vital signs, quality of peripheral pulses, urine output, and skin temperature, colour, and moisture provide key information about circulation and perfusion.

Depending on the patient's injuries or illness, the patient may be (a) transported for diagnostic tests such as a computed tomographic (CT) scan, radiography, or magnetic resonance imaging (MRI); (b) admitted to a general or critical care unit; or (c) transferred to another facility. The emergency nurse is responsible for monitoring the patient during transport and notifying the team if the patient's condition changes from baseline. Nurses accompanying critically ill patients must be competent in advanced life-support measures.

Mandatory Reporting of Gunshot and Stab Wounds

Most provinces have legislation that requires mandatory reporting of gunshot and stab wounds by health care agencies. Emergency staff must be familiar with their specific provincial law.

Reporting of Abuse of Children

Mandatory reporting of suspected or confirmed child abuse and maltreatment is a strategy to address violence against children. Therefore, health professionals must be aware of the legislation that governs their jurisdiction. In Canada, the Canadian Child Welfare Research Portal website (see the Resources at the end of the chapter) provides provincial and territorial policies and legislation. Professional organizations collaborate to align reporting policies for health care providers. For example, the Ontario Association of Children's Aid Societies and the College of Nurses of Ontario

mandate that nurses be vigilant and accountable in reporting abuse concerns:

1. If the nurse suspects that a child is being abused or neglected, it is the nurse's legal duty to report the situation to the local Children's Aid Society.
2. Maltreatment may be in the form of physical or sexual abuse. It can also be in the form of neglect: failure to meet a child's basic needs for food, clothing, shelter, sleep, medical attention, education, and protection from harm.
3. Unexplained injuries, fear of a specific adult, difficulty trusting others or making friends, sudden changes in eating or sleeping patterns, poor hygiene, secrecy, and inappropriate sexual behaviour may be signs of abuse.

Death in the Emergency Department

Unfortunately, a number of patients in the ED do not survive, despite the skill, expertise, and technology available in the ED. It is important for the emergency nurse to be able to deal with his or her own feelings about sudden death so that the nurse can help families and significant others begin the grieving process. The nurse may require debriefing when dealing with traumatic deaths.

The emergency nurse should recognize the importance of rituals in preparing the bereaved to grieve, such as multicultural differences, the collection of belongings, coroner considerations, arranging for autopsy, viewing of the body, and the making of mortuary arrangements. The emergency nurse plays a significant role in providing comfort to and advocacy for the surviving loved ones after a death. Collaborations with clergy and social workers are valued enhancements to the team's crisis management and grief work.

Organ and Tissue Donation

Transplantation is a critical component of the health care system. Many patients who die in the ED are potential candidates for tissue and organ donation. Over 1 600 Canadians are added to organ wait

lists yearly (Canadian Transplant Society, 2014). The solid organs that can be procured include the heart, lungs, liver, pancreas, and kidney. Certain tissues and organs, including corneas, heart valves, skin, bone, and kidneys, can be harvested from patients after death. Everyone is a potential donor, regardless of age, if the organs and the tissue are healthy at the time of death. Organ and tissue recovery is carried out with confidentiality, respect, and dignity and does not interfere with funeral practices.

Approaching families about donation after an unexpected death is distressing to both the staff and the family. For many families, however, the act of donation may be the first positive step in the grieving process. Studies show that donating the organs and tissue of a loved one who has died can provide immediate comfort and lasting consolation to family members in their grieving (Trillium Gift of Life Network, 2017). Before families are made aware of the option for donation, they must be told that the patient has died, and they must accept the fact that death has occurred. Once the family has accepted the patient's death, then the nurse can provide the family with the choice to donate, offer information, and support the family's decision.

Careful assessment of patients with standardized criteria is necessary to make an accurate determination of death. Neurological determination of death is defined as "a permanent loss of all brain function" (BC Transplant, 2017). Once this determination is complete, the donor is screened to ensure that only viable organs are recovered for transplantation. *Organ donor coordinators* are available in most institutions to assist in the process of screening potential donors, counselling donor families, obtaining informed consent, and retrieving organs from patients who have died in the ED.

The organ donor who is on a mechanical ventilator is often hemodynamically unstable, with many fluid and electrolyte imbalances. The nurse carries out interventions in an attempt to stabilize the patient's condition until the organs can be retrieved. Nursing care may consist of administration of fluids (crystalloids and colloids) and medications (vasopressors and hormones); promotion of normothermia; maintenance of ventilation and oxygenation through ventilator manipulation; and review of

laboratory values such as electrolytes, blood urea nitrogen, creatinine, hematological studies, ABGs, liver function studies, and cardiac enzymes. (Transplantation is discussed in Chapter 16.)

Emergency Department Wait Times.

In the period 2014 to 2015, Canadians made more than 10 million visits to EDs (CIHI, 2015). Of these visits, 21.7% were for trauma (CIHI, 2015). The amount of time that people spent in the ED varied according to the severity of their illness, the patient's age, how many other patients were being cared for, and the time of day the visit took place. Admitted patients spent almost five times longer in the ED (30.5 hours/visit) than patients not admitted (6.5 hours/visit). While the decision to admit was usually reached within 11.9 hours, the remaining time involved waiting for an inpatient bed to become available (CIHI, 2015). Individuals aged 65 years and older spent more time in the ED and were more likely to be admitted (CIHI, 2015).

Age-Related Considerations

Emergency Care

The proportion of the population older than 65 is growing; most older adults lead active lives. Regardless of a patient's age, aggressive interventions are warranted for all injuries or illnesses, unless the patient is known to have a pre-existing terminal illness, an extremely low probability of survival, or an advance directive indicating a different course of action.

The older population is at high risk for injury because of many anatomical and physiological changes that occur with aging (e.g., reduced visual acuity, limited neck rotation, slower gait, reduced reaction time).

Of the injury-related admissions of people aged 65 or older, many are for fractures resulting from falls. Age-related decline in balance and gait stability, as well as in cardiovascular function, increases the risk of falling (Kiel, 2016). When assessing a patient who has experienced a fall, the nurse must determine whether the physical findings may have caused the fall or may have been caused by the fall. For example, a patient may exhibit acute confusion (delirium). The confusion may be the result of an acute myocardial infarction that caused the patient to lose consciousness and fall, or the patient may have suffered a head injury as a result of a fall from tripping.

Knowledge of the concepts of aging improves the care delivered to older adults in the ED (Chapter 7). Older adults and their conditions must be fully investigated because of atypical presentations and comorbid conditions. The expertise of advanced-practice nurses, such as nurse practitioners or clinical nurse specialists, should be put to use in caring for this complex population to improve access to care. In Ontario, geriatric emergency medicine (GEM) nurse clinicians target the older population in the ED and have been found to improve care and clinical outcomes (Wilding, Gilsenan, Dalziel, et al., 2015).

The Triage Risk Screening Tool is a brief screening tool that can identify older patients as being at high risk and can predict adverse

health outcomes (Foo, Sui, Ang, et al., 2014). The results enable GEM nurses to deliver targeted interventions. It is a risk stratification tool used to predict functional decline. The six-item questionnaire is completed by registered nurses to identify older patients at risk for repeat ED visits, hospitalization, and nursing home placement after an index ED visit. Risk factors include being 75 years of age or older when discharged home; having cognitive impairment; living alone; having difficulty transferring or a history of falling; taking five or more medications (polypharmacy); and having used the ED recently (previous 30 days) or having been hospitalized recently (previous 90 days). Other risk factors are identified by registered nurses' recommendation for issues such as malnutrition, depression, and failure to cope. Patients are considered at high risk if cognitive impairment or two or more other risk factors are present, and the GEM nurse is consulted.

Environmental Emergencies

Increased interest in outdoor activities such as running, hiking, cycling, skiing, sailing, and swimming has resulted in more environmental emergencies seen in the ED. Illness or injury may be caused by the activity, exposure to weather, or attack from various animals or humans. Specific environmental emergencies discussed in this section include heat-related emergencies, cold-related emergencies, submersion injuries, bites, and stings.

Heat-Related Emergencies

Brief exposure to intense heat or prolonged exposure to less intense heat leads to heat stress. Thermoregulatory mechanisms such as sweating, vasodilation, and increased respirations cannot compensate for such exposure to increased ambient temperatures (Atha, 2013; Krau, 2013). Ambient temperature is a product of environmental temperature and humidity. Strenuous activities in hot or humid environments, clothing that interferes with perspiration, high fevers, and pre-existing illnesses predispose individuals to heat stress (Table 71-7). Effects can be mild (heat rash and heat edema) or severe (heat exhaustion and heatstroke). The management of heat-related emergencies is summarized in Table 71-8.

TABLE 71-7
RISK FACTORS FOR HEAT-RELATED EMERGENCIES

Age	**Prescription Drugs**
• Extremely young age	• Anticholinergics
• Older age	• Antihistamines
Environmental Conditions	• Antiparkinsonian drugs
• High environmental temperature	• Antispasmodics
• High relative humidity	• β-Adrenergic blockers
• Low wind	• Butyrophenones
Pre-Existing Illness	• Diuretics
• Cardiovascular disease	• Phenothiazines
• Cystic fibrosis	• Tricyclic antidepressants
• Diabetes	**Street Drugs**
• Obesity	• Amphetamines
• Previous stroke or other central nervous system lesion	• Jimson weed
	• Lysergic acid diethylamide (LSD)
• Skin disorders (e.g., large burn scars)	• 3,4-Methylenedioxy-methamphetamine (MDMA, Ecstasy)
	• Phencyclidine (PCP)
	Alcohol

TABLE 71-8

EMERGENCY MANAGEMENT
Hyperthermia

Etiology	Assessment Findings	Interventions
Environmental • Lack of acclimatization • Physical exertion, especially during hot weather • Prolonged exposure to extreme temperatures **Trauma** • Head injury • Spinal cord injury Metabolic • Dehydration • Diabetes • Thyrotoxicosis **Drugs** • Antihistamines • Cocaine • Diuretics • Ethanol • Phenothiazines • Tricyclic antidepressants	**Heat Cramps** • Excessive thirst • Severe muscle contractions in muscles subjected to exertion **Heat Exhaustion** • Altered mental status (e.g., irritability) • Fatigue, weakness • Hypotension • Pale, ashen complexion • Profuse sweating • Tachycardia • Temperature >37.8°C but <40°C • Weak, thready pulse **Heatstroke** • Altered mental status (e.g., ranging from confusion to coma) • Hot, dry skin • Hypotension • Tachycardia • Temperature >40°C • Weakness	**Initial** • Manage and maintain ABCs. • Provide high-flow O_2 via nonrebreather mask or BVM device. • Establish IV access, and begin fluid replacement for significant heat injury. • Place patient in a cool environment. • For patient with heatstroke, initiate rapid cooling measures: remove patient's clothing, place wet sheets over patient, and place patient in front of fan; immerse in ice-water bath; administer cool IV fluids or perform lavage with cool fluids. • Obtain ECG. • Obtain blood specimens for electrolytes and CBC. • Insert urinary catheter. **Ongoing Monitoring** • Monitor ABCs, vital signs, level of consciousness. • Monitor cardiac rhythm, O_2 saturation, electrolyte levels, and urinary output. • Monitor clotting studies for development of disseminated intravascular coagulation. • Monitor urine for development of myoglobinuria.

ABCs, airway, breathing, and circulation; *BVM,* bag–valve–mask; *CBC,* complete blood cell count; *ECG,* electrocardiogram; *IV,* intravenous; *O_2,* oxygen.

Heat rash (miliaria or prickly heat) is a fine, red, papular rash that occurs on the torso and the neck and in skin folds. The rash occurs when sweat ducts are obstructed and become inflamed so that sweat excretion does not occur. The rash usually occurs in warm weather, but it has also been reported in cold weather as a result of clothing.

Heat syncope is associated with prolonged standing and heat exposure. Manifestations include dizziness, orthostatic hypotension, and syncope. Inadequate vasomotor tone associated with aging increases older adults' risk for heat syncope.

Heat edema is characterized by swelling of the hands, the feet, and the ankles, usually in nonacclimatized individuals as a result of prolonged standing or sitting. Swelling usually resolves in days with rest, elevation, and support hose. Diuretics are not recommended because this condition is self-limiting and necessitates no additional treatment.

Heat Cramps

Heat cramps are severe cramps in large muscle groups fatigued by heavy work. Cramps are brief and intense and tend to occur during rest after exercise or heavy labour. Nausea, tachycardia, pallor, weakness, and profuse diaphoresis are often present. The condition occurs most often in healthy, acclimated athletes with inadequate fluid intake. Cramps resolve rapidly with rest and oral or parenteral replacement of sodium and water. Elevation, gentle massage, and analgesia keep pain to a minimum. The patient should avoid strenuous activity for at least 12 hours after the development of heat cramps. Education should emphasize salt replacement during strenuous exercise in hot, humid environments. Commercially prepared electrolyte solutions and sports drinks are recommended.

Heat Exhaustion

Prolonged exposure to heat over hours or days leads to **heat exhaustion,** a clinical syndrome characterized by fatigue, light-headedness, nausea, vomiting, diarrhea, and a sensation of impending doom (see Table 71-8). Tachypnea, hypotension, tachycardia, elevated body temperature, dilated pupils, mild

confusion, ashen colour, and profuse diaphoresis are also present. Hypotension and mild to severe temperature elevation (37.5°–40°C) are caused by dehydration (Becker & Stewart, 2011). Heat exhaustion usually occurs in individuals engaged in strenuous activity in hot, humid weather, but it also occurs in sedentary individuals.

Treatment begins with placing the patient in a cool area and removing constrictive clothing. The patient is monitored for airway, breathing, and circulation (ABCs), including cardiac dysrhythmias. Oral and parenteral fluid replacement should correspond to clinical and laboratory parameters. Salt tablets are not recommended because of potential gastric irritation and hypernatremia. A 0.9% normal saline solution is initiated intravenously when oral solutions are not tolerated. An initial fluid bolus may be used to correct hypotension. Admission is considered for affected older adults, chronically ill patients, and those whose condition does not improve within 4 hours.

Heatstroke

Heatstroke, the most serious form of heat stress, results from failure of the central thermoregulatory mechanisms and is considered a medical emergency. Table 71-7 lists risk factors for heat-related emergencies. Increased sweating, vasodilation, and increased respiratory rate, which occur in an attempt to lower temperature, deplete fluids and electrolytes. Eventually, sweat glands stop functioning, and so core temperature increases rapidly. The patient exhibits a core temperature higher than 40°C, altered mentation, absence of perspiration, and circulatory collapse. The skin is hot, dry, and ashen. Because the brain is extremely sensitive to thermal injuries, a range of neurological symptoms occur, such as hallucinations, combativeness, and loss of muscle coordination. Cerebral edema and hemorrhage may occur as a result of direct thermal injury to the brain and decreased cerebral blood flow.

The development of heatstroke is a potentially fatal disorder that directly relates to the amount of time that the patient's core body temperature remains elevated from either activity or the external environment (Crawford Mechem, 2017; Epstein & Roberts, 2011;

Hammond & Zimmermann, 2013). Prognosis is affected by age, baseline health status, and length of exposure. Older adults and individuals with diabetes mellitus, chronic renal disease, cardiovascular disease, pulmonary disease, or other physiological compromise are vulnerable.

Collaborative Care.

Treatment of heatstroke focuses on stabilizing the patient's ABCs and rapidly reducing the core temperature. Administration of 100% O_2 compensates for the patient's hypermetabolic state. Ventilation with a BVM device or intubation and mechanical ventilation may be required. Fluid and electrolyte imbalances are corrected, and continuous cardiac monitoring for dysrhythmias is initiated.

Various cooling methods are available, such as removing clothing, covering with wet sheets, and placing the patient in front of a large fan (evaporative cooling); immersing the patient in cold water (conductive cooling); and administering cool fluids or performing lavage with cool fluids (Hammond & Zimmermann, 2013; Crawford Mechem, 2017). Whatever method is selected, the nurse is responsible for closely monitoring the patient's temperature and controlling shivering. Shivering increases core temperature and is associated with heat generated by muscle activity, which complicates cooling efforts. Aggressive temperature reduction should continue until core temperature reaches 38.9°C. Antipyretics are not recommended because they have no effect on the nonfunctioning thermoregulatory mechanisms.

The patient is also monitored for signs of *rhabdomyolysis,* a fatal disease characterized by the breakdown of skeletal muscle. Muscle breakdown leads to myoglobinuria, which increases the risk for acute kidney injury or failure. Therefore, urine should be carefully monitored for colour, amount, pH, and myoglobin. Finally, clotting studies are performed to monitor the patient for signs of disseminated intravascular coagulation (clotting studies are discussed in Chapter 32, and DIC is discussed in Chapter 33).

Patient and caregiver teaching focuses on how to avoid future problems. Providing essential information regarding proper hydration during hot weather and physical exercise is imperative.

Patients should also be instructed on the early signs of and interventions for heat-related stress.

Cold-Related Emergencies

Cold-related injuries may be localized (frostbite) or systemic (hypothermia). Contributing factors include age, duration of exposure, environmental temperature, homelessness, pre-existing conditions (e.g., diabetes), medications that suppress shivering (opioids, heroin, psychotropic agents, and antiemetics), and alcohol intoxication, which causes peripheral vasodilation, increases sensations of warmth, and depresses shivering. People who smoke have an increased risk for cold-related injury as a result of the vasoconstrictive effects of nicotine.

Frostbite

Frostbite can be described as "true tissue freezing," which results in the formation of ice crystals in the tissues and cells. Peripheral vasoconstriction is the initial response to cold stress and results in a decrease in blood flow and vascular stasis. As cellular temperature decreases and ice crystals form in intracellular spaces, intracellular sodium and chloride levels increase, the cell membrane is destroyed, and organelles are damaged. These alterations result in edema. The depth of frostbite is the result of ambient temperature, length of exposure, type and condition of clothing (wet or dry), and contact with metal surfaces. Other factors that affect severity include skin colour (dark-skinned people are more prone to frostbite), lack of acclimatization, previous episodes, exhaustion, and poor peripheral vascular status.

Superficial frostbite involves skin and subcutaneous tissue, usually the ears, the nose, the fingers, and the toes. The skin appearance ranges from pale and blue to mottled, and the skin feels crunchy and frozen. The patient may complain of tingling, numbness, or a burning sensation. Injured tissue is easily damaged, and so the area should be handled carefully and never squeezed, massaged, or scrubbed. Clothing and jewellery should be removed because they may constrict the extremity and decrease circulation. The affected

area should be immersed in a water bath of 37° to 39°C (Hammond & Zimmermann, 2013; Crawford Mechem & Zafren, 2017). Warm soaks may be used for the face. The patient often experiences a warm, stinging sensation as tissue thaws. Blisters form within a few hours (Figure 71-2). Nonhemorrhagic blisters should be drained, debrided, and covered with a sterile dressing. Heavy blankets and clothing should be avoided because friction and weight can lead to sloughing of damaged tissue. Rewarming is extremely painful. Residual pain may last for weeks or even years. Analgesics should be administered, and tetanus prophylaxis should be provided as appropriate (see Table 71-6). The patient should be evaluated for systemic hypothermia.

FIGURE 71-2 Edema and blister formation 24 hours after frostbite injury occurring in an area covered by a tightly fitted boot. Source: Courtesy Cameron Bangs, MD. From Auerbach, P. S., Donner, H. J., & Weiss, E. A. (2007). *Wilderness medicine* (5th ed., p. 201, Figure 8-2, *A*). St. Louis: Mosby.

Deep frostbite involves muscle, bone, and tendon. The skin is white, hard, and insensitive to touch and involves complete tissue necrosis. The area has the appearance of deep thermal injury with mottling gradually progressing to gangrene (see Figure 14-1 in Chapter 14). Significant edema may begin within 3 hours, with blistering in 6 hours to days. Intravenous analgesia is always required in severe frostbite because of the pain associated with tissue thawing. Tetanus prophylaxis should be given (see Table 71-6), and the patient should be evaluated for systemic hypothermia. Amputation may be required if the injured area is untreated or if treatment is unsuccessful. Thrombolytic agents have been shown to reduce the need for amputation when used within the first 24 hours of injury. The use of thrombolytic agents may be considered if there are no

contraindications (Crawford Mechem & Zafren, 2017; Gross & Moore, 2012). The patient may be admitted to the hospital, with bed rest and elevation of the injured part. Prophylactic antibiotics are used if the wound is at risk for infection.

Hypothermia

Hypothermia, defined as a core temperature lower than 35°C, occurs when heat loss exceeds production. Up to 60% of all body heat is lost as radiant energy; the loss is greatest from the head, the thorax, and the lungs (with each breath). Wet clothing increases evaporative heat loss five times greater than normal; immersion in cold water (e.g., near-drowning) increases evaporative heat loss 25 times greater than normal. Environmental exposure to freezing temperatures, cold winds, and wet, damp terrain in the presence of physical exhaustion, inadequate clothing, or inexperience predisposes individuals to hypothermia (Crawford Mechem & Zafren, 2017). Near-drowning and water immersion are also associated with hypothermia.

Older adults are more prone to hypothermia because of decreased body fat, diminished energy reserves, decreased basal metabolic rate, decreased shivering response, decreased sensory perception, chronic medical conditions, and medications that alter body defences. In addition, certain drugs, alcohol, and diabetes are considered risk factors for hypothermia.

Hypothermia mimics cerebral or metabolic disturbances, causing ataxia, confusion, and withdrawal, and so the condition may be misdiagnosed. Peripheral vasoconstriction is the body's first attempt to conserve heat. As cold temperatures persist, shivering and movement are the body's only mechanisms for producing heat. Death usually occurs when core temperature falls below 25.6°C.

Core temperature below 30.6°C is severe and potentially life-threatening. Assessment findings in hypothermia are variable and dependent on core temperature (Table 71-9). Patients with *mild hypothermia* (34°–36°C) exhibit shivering, increased heart rate, slurred speech, and incoordination. *Moderate hypothermia* (30°–34°C) causes decreased shivering, bradycardia, slowed respiratory rate, and lethargy. *Severe hypothermia* (≤30°C) causes coma, hypotension,

arrhythmias, and muscle rigidity (Zafren & Crawford Mechem, 2017).

TABLE 71-9

EMERGENCY MANAGEMENT
Hypothermia*

Etiology	Assessment Findings	Interventions

Environmental
• Inadequate clothing for environmental temperature
• Prolonged exposure to cold
• Prolonged submersion
	• Altered mental status (ranging from confusion to coma)
	• Areflexia (absence of reflexes)
	• Blue, white, or frozen extremities
	• Core body temperature:
	  • Mild hypothermia: 34°–36°C
	  • Moderate hypothermia: 30°–34°C
	  • Severe hypothermia: ≤30°C
	• Dysrhythmias: bradycardia, atrial fibrillation, ventricular fibrillation, asystole
	• Fixed, dilated pupils
	• Hypotension
	• Hypoventilation
	• Pale, cyanotic skin
	• Shivering (diminished or absent at core body temperature ≤30°C)
		Initial
		• Remove patient from cold environment.
		• Manage and maintain ABCs.
		• Provide high-flow O_2 via nonrebreather mask or BVM device.
		• Anticipate intubation if gag reflex is diminished or absent.*
		• Rewarm patient:
		  • *Passive external warming:* Remove wet clothing, apply dry clothing and warm blankets, and administer warm fluids.
		  • *Active external warming:* Use body-to-body contact; apply heating devices (e.g., air-filled warming blankets) or radiant lights.
		  • *Active core warming:* Administer warmed IV fluids; heated, humidified O_2; and peritoneal, gastric, or colonic lavage with warmed fluids.
		• Anticipate the need for hemodialysis or cardiopulmonary bypass.
		• Obtain 12-lead ECG.
		• Warm central trunk first in patients with moderate, severe, or profound hypothermia to prevent aftershock.
		• Establish IV access with two large-bore catheters for fluid resuscitation.
		• Assess for other injuries.
		• Keep patient's head covered with warm, dry towels, or stocking cap, to limit loss of heat.
		• Treat patient gently to avoid increased cardiac irritability.
		Ongoing Monitoring
		• Monitor ABCs, level of consciousness, temperature, and vital signs.
		• Monitor O_2 saturation and cardiac rhythm.
		• Monitor electrolyte and glucose levels.

*NOTE: Medications and defibrillation may not be effective with core temperatures <30°C.

ABCs, airway, breathing, and circulation; *BVM,* bag–valve–mask; *ECG,* electrocardiogram; *IV,* intravenous; *O_2,* oxygen.

As core temperature drops, basal metabolic rate decreases to 50% or 25% of normal. The cold myocardium is extremely irritable, making it vulnerable to dysrhythmias (e.g., atrial and ventricular fibrillation). Decreased renal blood flow decreases glomerular filtration rate, which impairs water reabsorption and leads to dehydration. Hematocrit increases as intravascular volume decreases. Cold blood becomes viscous and acts as a thrombus, increasing the patient's risk for stroke, myocardial infarction, pulmonary emboli, acute tubular necrosis, and renal failure. Decreased blood flow leads to lactic acid accumulation from anaerobic metabolism and subsequent metabolic acidosis.

In *severe hypothermia* (≤30°C), the person appears dead. Metabolic rate, heart rate, and respirations are so slow that they may be difficult to detect. Reflexes are absent, and the pupils are fixed and dilated. Profound bradycardia, asystole, or ventricular fibrillation may be present. Every effort is made to warm the patient to at least 32°C before the person is pronounced dead. The cause of death is usually refractory ventricular fibrillation.

Collaborative Care.

Treatment of hypothermia focuses on managing and maintaining ABCs, rewarming the patient, correcting dehydration and acidosis, and treating cardiac dysrhythmias. Passive or active external rewarming is used for mild hypothermia. *Passive external rewarming* involves moving the patient to a warm, dry place; removing damp clothing; and placing warm blankets on the patient. Gentle handling is essential to prevent stimulation of the cold myocardium. *Active external rewarming* involves body-to-body contact (when the patient cannot access health care), fluid- or air-filled warming blankets, or radiant heat lamps. The patient should be closely monitored for marked vasodilation and hypotension during rewarming.

Active core rewarming is used for moderate to profound hypothermia and involves heat applied directly to the core. Techniques include the use of heated, humidified O_2; warmed intravenous fluids; and peritoneal, gastric, or colonic lavage with warmed fluids. Hemodialysis or cardiopulmonary bypass may also

be considered for profound hypothermia (Rahman, Rubinstein, Singh, et al., 2012).

Core temperature should be carefully monitored during rewarming procedures. Warming places the patient at risk for *afterdrop,* a further drop in core temperature, which occurs when cold peripheral blood returns to the central circulation. Rewarming shock can produce hypotension and dysrhythmias. Thus, in patients with moderate to profound hypothermia, the core should be warmed before the extremities.

Patient teaching should focus on how to avoid future cold-related problems. Essential education includes dressing in layers for cold weather, covering the head, carrying high-carbohydrate foods for extra calories, and developing a plan for survival should an injury occur.

Submersion Injuries

Submersion injury results when a person becomes hypoxic as a result of submersion in a substance, usually water. The primary risk factors for submersion injury include inability to swim, risk taking, inadequate adult supervision, use of alcohol or drugs, trauma, seizures, and hypothermia (Chandy & Weinhouse, 2017).

Drowning is death from suffocation after submersion in water or other fluid medium. *Near-drowning* is defined as survival from potential drowning. *Immersion syndrome* occurs with immersion in cold water, which leads to stimulation of the vagus nerve and potentially fatal dysrhythmias (e.g., bradycardia).

Death from a submersion injury is caused by hypoxia secondary to aspiration and swallowing of fluid. Swallowed water may cause vomiting and additional aspiration. The majority of all drowning victims aspirate water into the pulmonary tree and develop pulmonary edema. Victims who do not aspirate fluid develop intense laryngospasm and airway obstruction; the cause of death is "dry drowning." The osmotic gradient that results from aspirated fluid causes fluid imbalances. Hypotonic fresh water is rapidly absorbed into the circulatory system through the alveoli. Fresh water may be contaminated with chlorine, mud, and algae, which cause

the breakdown of lung surfactant, fluid seepage, and pulmonary edema. Hypertonic salt water draws protein-rich fluid from the vascular space into the alveoli, impairing alveolar ventilation and resulting in hypoxia. Figure 71-3 shows the pulmonary effects of salt water and fresh water aspiration.

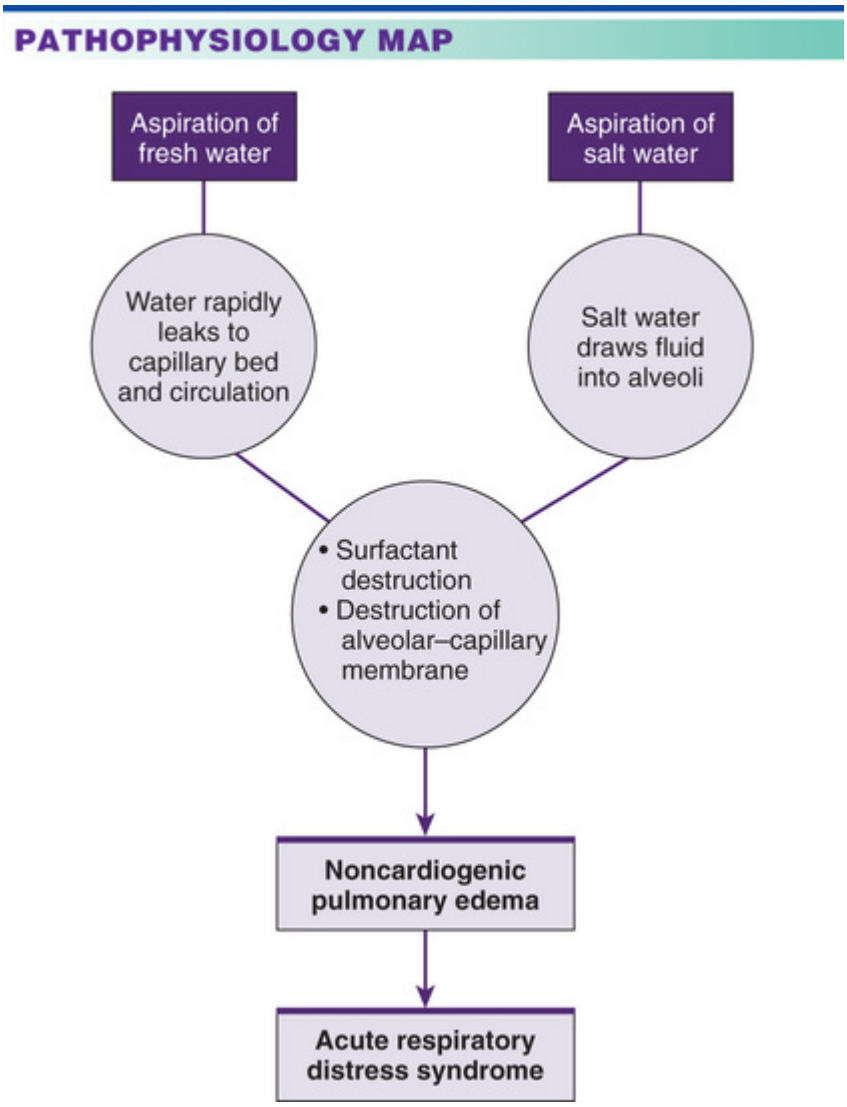

FIGURE 71-3 Pathophysiology of submersion injury.

The body attempts to compensate for hypoxia by shunting blood to the lungs. As a result, pulmonary pressures increase and respiratory status deteriorates. Blood is shunted through the alveoli; however, it is not adequately oxygenated, and so the hypoxemia

worsens. Anaerobic metabolism occurs, which leads to lactic acidosis.

The assessment findings of a patient with a submersion injury are listed in Table 71-10. Aggressive resuscitation efforts and the mammalian diving reflex improve survival of near-drowning victims even after submersion in cold water for long periods (Chandy & Weinhouse, 2017). Cold water lowers the body's metabolic rate and O_2 demand. The mammalian diving reflex causes apnea, bradycardia, and peripheral vasoconstriction and further decreases the metabolic rate. Blood flow is redistributed to the most vital organs (i.e., heart, lungs, and brain).

TABLE 71-10

EMERGENCY MANAGEMENT
Submersion Injuries

Etiology	Assessment Findings	Interventions
• Inability to swim or exhaustion while swimming • Entrapment in or entanglement with objects in water • Loss of ability to move secondary to trauma, stroke, hypothermia, acute MI • Poor judgement as a result of alcohol or drugs • Seizure while in water	**Pulmonary** • Cough with pink, frothy sputum • Crackles, wheezes • Cyanosis • Dyspnea • Ineffective breathing • Respiratory distress/arrest **Cardiac** • Bradycardia • Cardiac arrest • Dysrhythmia • Hypotension • Tachycardia **Other** • Coexisting illness (e.g., MI) or injury (e.g., cervical spine injury) • Coma • Core temperature slightly elevated or below normal depending on water temperature and length of submersion • Exhaustion • Panic	**Initial** • Manage and maintain ABCs. • Assume cervical spine injury in all drowning victims, and stabilize or immobilize cervical spine. • Provide 100% O_2 via nonrebreather mask or BVM device. • Anticipate need for intubation if gag reflex is absent. • Establish IV access with two large-bore catheters for fluid resuscitation and infuse warmed fluids if appropriate. • Assess for other injuries. • Remove wet clothing and cover with warm blankets. • Measure temperature, and begin rewarming if needed. • Obtain cervical spine and chest radiographs. • Insert gastric tube. **Ongoing Monitoring** • Monitor ABCs, vital signs, and level of consciousness. • Monitor O_2 saturation and cardiac rhythm. • Monitor temperature, and maintain normothermia. • Monitor for signs of acute respiratory failure. • Monitor for signs of secondary drowning.

ABCs, airway, breathing, and circulation; *BVM,* bag–valve–mask; *IV,* intravenous; *MI,* myocardial infarction; *O_2,* oxygen.

Collaborative Care

Treatment of submersion injuries includes aggressive resuscitation efforts that focus on correcting hypoxia and acid–base and fluid imbalances; support of basic physiological functions; and rewarming when hypothermia is present. Initial evaluation and interventions

involve assessment of airway, cervical spine, breathing, and circulation (see Table 71-10).

Mechanical ventilation with positive end-expiratory pressure or continuous positive airway pressure may be used to improve gas exchange across the alveolar–capillary membrane when significant pulmonary edema is present. Ventilation and oxygenation are the primary techniques used to treat acidosis. Mannitol or furosemide (Lasix) may be used with caution to decrease the amount of free water and treat cerebral edema.

Deterioration of neurological status is suggestive of cerebral edema, increased hypoxia, or profound acidosis. Near-drowning victims may also have head injuries that cause prolonged alterations in level of consciousness. All victims of near-drowning should be observed in a hospital for a minimum of 4 to 6 hours. Delayed pulmonary edema *(secondary drowning),* aspiration pneumonia, and cerebral edema have been reported in patients who were essentially free of symptoms immediately after the near-drowning episode (Chandy & Weinhouse, 2017).

Teaching should focus on water safety and minimizing the risks for drowning. Swimming pool gates should be locked; life jackets should be used on all watercraft and tubes; and water survival skills (i.e., swimming lessons and the buddy system) should be learned. The dangers of combining alcohol and drugs with swimming and other water sports should be emphasized.

Bites and Stings

Animals, spiders, and insects cause injury and even death by biting or stinging. Morbidity is a result of either direct tissue damage or lethal toxins. Direct tissue damage is a result of animal size, characteristics of the animal's teeth, and strength of the jaw. Tissue may be lacerated, crushed, or chewed, and toxins that are released through teeth, fangs, stingers, spines, or tentacles provoke local or systemic effects. Death associated with animal bites is caused by blood loss, allergic reactions, or lethal toxins. Injuries caused by insects, spiders, ticks, snakes, dogs, cats, rodents, and humans are described below.

Hymenopteran Stings

The Hymenoptera order includes bees, yellow jackets, hornets, and wasps. Stings can cause reactions ranging from mild discomfort to life-threatening anaphylaxis (Chapters 16 and 69). Venom may be cytotoxic, hemolytic, allergenic, or vasoactive. Symptoms may begin immediately or may be delayed up to 48 hours. Reactions are more severe with multiple stings. Most hymenopterans sting repeatedly. However, the honeybee stings only once, usually leaving the stinger in the skin so that the release of venom continues. A scraping motion with a fingernail, knife, or needle is recommended for removing the stinger. Tweezers squeeze the stinger and may cause more venom release. However, the fastest method of removing the stinger is ultimately the best, so if tweezers are available, they can be used.

Manifestations vary and range from stinging, burning sensation, swelling, and itching to edema, headache, fever, syncope, malaise, nausea, vomiting, wheezing, bronchospasm, laryngeal edema, and hypotension. Treatment depends on the severity of the reaction. Mild reactions are treated with elevation, cool compresses, antipruritic lotions, and oral antihistamines. Rings, watches, and restrictive clothing must be removed. More severe reactions necessitate intramuscular or intravenous antihistamines (diphenhydramine [Benadryl]), subcutaneous epinephrine, and corticosteroids. Allergic reactions and anaphylaxis are discussed in Chapter 16.

Spider Bites (Arachnid)

Although there are 20 000 species of venomous spiders in the world, only 50 species cause illness. The venomous black widow spider is found in southern parts of Canada and also has been found in imported grapes. The venom can provoke responses ranging from a localized reaction to systemic anaphylaxis. Tarantulas look more dangerous than they actually are; their bite causes only localized stinging and pain. Other types of spiders release venom when they bite and may cause allergic reactions in some individuals, but they are not considered poisonous.

Black Widow Spiders.

Black widow spiders are the most feared of all spiders. The female's venom is especially poisonous. Both the female and the male are black. The fully grown female is about 1.2 cm long and is jet black, with an hourglass-shaped red mark on the underside of the abdomen (Figure 71-4). Males are only about half as long and usually have four pairs of red dots along the sides of the abdomen. Males are rarely seen and are generally harmless. The female rarely leaves the web, biting defensively if disturbed. Black widow spiders are found among fallen branches and firewood and under objects such as furniture, outhouse seats, and garbage.

FIGURE 71-4 Female black widow spider. Source: Auerbach, P. S., Donner, H. J., & Weiss, E. A. (2003). *Field guide to wilderness medicine* (2nd ed.). St. Louis: Mosby.

The black widow spider's venom is neurotoxic. When bitten, the patient feels a pinprick-like sensation, and a tiny, red bite mark appears. Approximately 15 to 60 minutes later, the patient experiences severe pain that increases over the next 12 to 48 hours. Systemic symptoms develop 30 minutes after *envenomation* (introduction of poisonous venom into the body by a bite or sting).

These symptoms can include nausea, vomiting, abdominal cramping, hypertension, dyspnea, paresthesias, and tachycardia. Symptoms usually peak 2 to 3 hours after onset; however, muscle spasms and hypertension can recur for 12 to 24 hours. Chest and abdominal pain, seizures, and shock can also occur. Bites on the lower body cause abdominal rigidity, whereas bites on the upper body lead to chest, back, and shoulder rigidity. A black widow spider bite is not prominent and can be easily missed. In patients not aware of the bite, the envenomation can be misdiagnosed because symptoms mimic those of a perforated ulcer, appendicitis, pancreatitis, or other abdominal emergency.

Treatment includes IV access and O_2 administration as needed. The wound should be cleaned and tetanus prophylaxis given as appropriate. Muscle spasms are treated with benzodiazepines such as lorazepam. Pain medication may be required either orally or parentally. Antivenin may be used to reduce the duration of symptoms (Vetter, Swanson, & White, 2017).

Tick Bites

Ticks are found in various parts of Canada. Emergencies associated with tick bites include Rocky Mountain spotted fever, Lyme disease, and tick paralysis. Disease is caused by an infected tick or by the release of neurotoxin. Ticks release a neurotoxic venom for the duration that the tick head is attached to the body (Hammond & Zimmermann, 2013). Early removal of the attached tick is essential for effective treatment, ideally within less than 24 hours as it greatly reduces the risk for tickborne illness transmission. Forceps may be used to safely remove the tick by grasping at the point of entry and pulling upward in a steady motion (Figure 71-5). Additional information and instructional videos can be found on the Canadian Lyme Disease Foundation website (see the Resources at the end of this chapter).

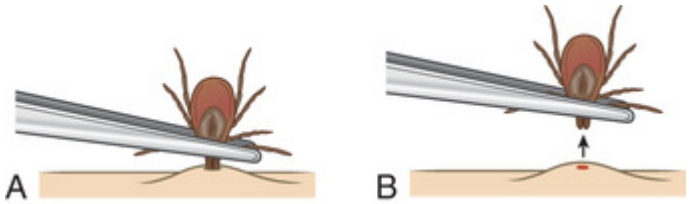

FIGURE 71-5 Tick removal. **A,** Use tweezers to grasp the tick close to the skin. **B,** With a steady motion, pull the tick's body up and away from the skin. Do not be alarmed if the tick's mouthparts remain in the skin. Once the mouthparts are removed from the rest of the tick, it can no longer transmit disease.

Lyme disease, an arthropod-borne disease, is becoming more prevalent in Canada. Most of the reported Canadian cases have occurred in Ontario and Quebec (Government of Canada, 2017; Public Health Agency of Canada & Health Canada, 2017). It develops from a bite from the *Ixodes* tick and results from exposure to the spirochete *Borrelia burgdorferi,* which is found on the tick. Symptoms range from mild to severe and can occur in overlapping stages: early localized Lyme disease, early disseminated Lyme disease, and late Lyme disease. The initial stage of this disease is characterized by nonspecific influenza-like symptoms (e.g., headache, stiff neck, fatigue) and a characteristic bull's-eye rash—an expanding circular area of redness that is 5 cm in diameter or more. Monoarticular arthritis, meningitis, and neuropathies occur days or weeks after the initial symptoms. Chronic arthritis and myocarditis characterize the later stage of the disease, which can develop several months to 2 years after the initial skin lesion. When symptoms include a bull's-eye rash, oral antibiotic treatment is recommended. (Lyme disease is discussed in Chapter 67.)

Rocky Mountain spotted fever caused by *Rickettsia rickettsii* has an incubation period of 2 to 14 days. A pink, macular rash appears on palms, wrists, soles, feet, and ankles within 10 days of exposure. Other symptoms include fever, chills, malaise, myalgias, and headache. Treatment is antibiotic therapy.

Within 5 to 7 days after exposure to a wood or dog tick, tick paralysis occurs. Classic symptoms are flaccid ascending paralysis, which develops over 1 to 2 days. Without tick removal, the patient

dies as respiratory muscles become paralyzed. Tick removal leads to return of muscle movement, usually within 48 to 72 hours.

Animal and Human Bites

Children are at greatest risk for animal bites. The most significant associated problems are infection and mechanical destruction of skin, muscle, tendons, blood vessels, and bone. The bite may cause a simple laceration or be associated with a crush injury, puncture wound, or tearing or avulsion of tissue. The severity of injury depends on animal size, victim size, and anatomical location of the bite. Animal bites from cats and dogs are common; dog bites account for the majority of the bite injuries that are treated in the ED. Wild or domestic rodents are ranked behind dogs and cats as the third most frequent offenders in reported animal bites (Ricci & Rizzolo, 2011). All animal bites should be reported to the local public health unit.

Dog bites usually occur on the extremities; however, facial bites are common in small children. Most victims own the dogs that bite them. Dog bites may involve significant tissue damage, and fatalities have been reported, usually in children. Skull fractures with intracranial injury and death may occur in children younger than 2 years. Disfiguring wounds of the face should be evaluated by a plastic surgeon.

Cat bites cause deep puncture wounds that can involve tendons and joint capsules and result in a greater incidence of infection (Enzler, Berbari, & Osmon, 2011). The most common causative organisms of infections from cat and dog bites are from species of the genus *Pasteurella* (e.g., *P. canis*). This organism is found in the mouths of most healthy cats and dogs (Ricci & Rizzolo, 2011). Septic arthritis, osteomyelitis, and tenosynovitis have been reported as a result of cat bites.

Human bites also cause puncture wounds or lacerations and carry a high risk for infection from oral bacterial flora, most commonly *Staphylococcus aureus*, streptococci, and hepatitis virus. The hands, fingers, ears, nose, vagina, and penis are the most common sites of human bites and are frequently a result of violence or sexual activity. Boxer's fracture of the fifth metacarpal is often associated with an

open wound when knuckles strike teeth. The human jaw has great crushing ability, causing laceration, puncture, crush injury, soft-tissue tearing, and even amputation. More than 40 potential pathogens found in the human mouth account for an infection rate of approximately 50% in cases in which victims do not seek medical intervention within 24 hours of injury.

Collaborative Care.

Initial treatment for animal and human bites includes cleaning with copious irrigation, debridement, tetanus prophylaxis, and analgesics as needed. Prophylactic antibiotics are used for animal and human bites at risk for infection such as wounds over joints, wounds more than 6 to 12 hours old, puncture wounds, and bites of the hand or foot. Individuals at greatest risk for infection are infants, older adults, immuno-suppressed patients, people with alcohol use disorder, people with diabetes, and people taking corticosteroids (Ricci & Rizzolo, 2011).

Puncture wounds are left open, whereas lacerations are loosely sutured. Wounds over joints are splinted. Initial closure is reserved only for facial wounds. The patient may require intravenous antibiotic therapy when an infection is present because of an increased incidence of cellulitis, osteomyelitis, and septic arthritis.

Consideration of rabies prophylaxis is an essential component in management of animal bites. A neurotoxic virus found in the saliva of some mammals causes rabies. If untreated, the condition is fatal in humans. Rabies exposure should be considered if an animal attack was not provoked, involved a wild animal, or involved a domestic animal not immunized against rabies. Rabies prophylaxis is always given when the animal cannot be found or when a carnivorous wild animal causes the bite. The prophylaxis regimen begins with an injection of rabies immune globulin to provide passive immunity. This is followed by a series of five injections of human diploid cell vaccine on days 0, 3, 7, 14, and 28 to provide active immunity. Dosage is based on the patient's weight.

Poisonings

A poison is any chemical that harms the body. Poisoning is the third leading cause of unintentional death in Canada (Chen, Mo, Yi, et al., 2013). Poisonings can be accidental, occupational, recreational, or intentional. Natural or manufactured toxins can be ingested, inhaled, injected, splashed in the eye, or absorbed through the skin. Common poisons are reviewed in Table 71-11. Other poisonings related to the use of illegal drugs such as amphetamines, opioids, and hallucinogens are discussed in Chapter 11. Poisoning may also be caused by toxic plants or contaminated foods. (Food poisoning is discussed in Chapter 44.)

TABLE 71-11
COMMON POISONS

Substance	Manifestations	Treatment
Acetaminophen (Tylenol)	*Phase 1* (within 24 hr of ingestion): malaise, diaphoresis, nausea, and vomiting *Phase 2* (24–28 hr): right upper quadrant pain, decreased urine output, diminished nausea; increase in LFTs *Phase 3* (72–96 hr): nausea and vomiting; malaise; jaundice; hypoglycemia; enlarged liver; possible coagulopathies, including DIC *Phase 4* (7–8 days after ingestion): recovery, resolution of symptoms; results of LFTs return to normal	Activated charcoal *N*-acetylcysteine (oral form may cause vomiting; IV form can be used)
Acetylsalicylic acid (ASA; Aspirin) and ASA-containing medications	Tachypnea, tachycardia, hyperthermia, seizures, pulmonary edema, occult bleeding or hemorrhage, metabolic acidosis	Gastric lavage, activated charcoal, urine alkalinization, hemodialysis for severe acute ingestion, intubation and mechanical ventilation, supportive care
Acids and alkalis • *Acids:* toilet bowl cleaners, antirust compounds • *Alkalis:* drain cleaners, dishwashing detergents, ammonia	Excess salivation, dysphagia, epigastric pain, pneumonitis; burns of mouth, esophagus, and stomach	Immediate dilution (water, milk); corticosteroids (for alkali burns) Induced vomiting is contraindicated
Alcohol, barbiturates, benzodiazepines, cocaine, hallucinogens, stimulants	See Chapter 11	See Chapter 11
Bleaches	Irritation of lips, mouth, and eyes; superficial injury to esophagus; chemical pneumonia and pulmonary edema	Washing of exposed skin and eyes, dilution with water and milk, gastric lavage, prevention of vomiting and aspiration
Carbon monoxide	Dyspnea, headache, tachypnea, confusion, impaired judgement, cyanosis, respiratory depression	Removal from source; administration of 100% O_2 via nonrebreather mask, BVM device, or intubation and mechanical ventilation; hyperbaric oxygen therapy a consideration
Cyanide	Almond odour to breath, headache, dizziness, nausea, confusion, hypertension, bradycardia followed by hypotension and tachycardia, tachypnea followed by bradypnea and respiratory arrest	Amyl nitrate (nasally), IV sodium nitrate, supportive care

Substance	Manifestations	Treatment
Ethylene glycol	Sweet aromatic odour to breath, nausea and vomiting, slurred speech, ataxia, lethargy, respiratory depression	Gastric lavage, activated charcoal, supportive care
Iron	Vomiting (often bloody), diarrhea (often bloody), fever, hyperglycemia, lethargy, hypotension, seizures, coma	Gastric lavage, chelation therapy (deferoxamine [Desferal])
Nonsteroidal anti-inflammatory drugs	Gastro-enteritis, abdominal pain, drowsiness, nystagmus, hepatic and renal damage	Gastric lavage, activated charcoal, cathartics, supportive care
Tricyclic antidepressants (e.g., amitriptyline [Elavil])	In low doses: anticholinergic effects, agitation, hypertension, tachycardia In high doses: central nervous system depression, dysrhythmias, hypotension, respiratory depression	Multidose activated charcoal, gastric lavage, serum alkalinization with sodium bicarbonate, intubation and mechanical ventilation, supportive care Never induce vomiting

BVM, bag–valve–mask; *DIC*, disseminated intravascular coagulation; *IV*, intravenous; *LFTs*, liver function tests; O_2, oxygen.

The severity of the poisoning depends on type, concentration, and route of exposure. Toxins can affect every tissue of the body, and so symptoms can be manifested by any body system. Specific management of toxins involves decreasing absorption, enhancing elimination, and implementing toxin-specific interventions. Local poison control centres are available 24 hours a day and should be consulted for the most current treatment-specific protocols.

Options for decreasing absorption of poisons include emesis, gastric lavage, activated charcoal, dermal cleansing, and eye irrigation. Gastric lavage involves oral insertion of a large-diameter (36- to 40-French) gastric tube for instillation of copious amounts of saline. The head of the bed should be elevated or the patient placed in the side-lying position to prevent aspiration. Patients with an altered level of consciousness or diminished gag reflex are intubated before lavage. Lavage is contraindicated in patients who ingested caustic agents, sharp objects, or nontoxic substances. Otherwise, gastric lavage must be performed within 1 hour of ingestion of most poisons to be effective (Denke, 2010; Burchum & Rosenthal, 2016). Problems associated with lavage include epistaxis, esophageal perforation, and aspiration.

The most effective intervention for management of poisonings is administration of activated charcoal orally or via a gastric tube. Toxins adhere to charcoal and are excreted through the gastro-

intestinal (GI) tract rather than absorbed into the portal circulation. Adults receive 50 to 100 g of charcoal. Activated charcoal can absorb a number of poisons from the GI tract, but it does not absorb ethanol, alkali, iron, boric acid, lithium, methanol, or cyanide. For some toxins (e.g., phenobarbital), multiple doses of charcoal may be required (Burchum & Rosenthal, 2016; Hammond & Zimmermann, 2013). Contraindications to charcoal administration are diminished bowel sounds, ileus, ingestion of a substance poorly absorbed by charcoal, or previous administration of *N*-acetylcysteine because charcoal inactivates oral *N*-acetylcysteine, the antidote used for acetaminophen toxicity.

Skin and ocular decontamination involves copious amounts of water or saline. With the exception of mustard gas, most toxins can be safely removed with water or saline (Hammond & Zimmermann, 2013). Water mixes with mustard gas and releases chlorine gas. As a general rule, dry substances should be brushed from the skin and clothing before water is used. Powdered lime should not be removed with water; it should just be brushed off. Health care providers should wear personal protective equipment (gloves, gowns, goggles, and respirators) for decontamination to prevent secondary exposure. Decontamination procedures are usually performed by professionals specially trained in hazardous material decontamination before the patient arrives at the hospital. Decontamination takes priority over all interventions except basic life-support techniques. Resources such as the Workplace Hazardous Materials Information System are part of mandatory orientation.

Elimination of poisons is increased through administration of cathartics, whole-bowel irrigation, hemodialysis, hemoperfusion, urine alkalinization, chelating agents, and antidotes. Cathartics such as sorbitol, magnesium citrate, and magnesium sulphate are administered with activated charcoal to stimulate intestinal motility and increase elimination. The use of cathartics is controversial, and multiple doses should be avoided because they can induce potentially fatal electrolyte abnormalities. Whole-bowel irrigation is controversial and involves administration of a nonabsorbable bowel evacuant solution (e.g., GoLYTELY). The solution is administered every 4 to 6 hours until stools are clear. This process can be effective

for swallowed objects such as cocaine-filled balloons or condoms. There is a high risk for electrolyte imbalance from fluid and electrolyte losses with this intervention (Burchum & Rosenthal, 2016).

Hemodialysis and hemoperfusion are reserved for patients who develop severe acidosis from ingestion of toxic substances (e.g., acetylsalicylic acid [ASA; Aspirin]). Other interventions include alkalinization and chelation therapy. Sodium bicarbonate administration raises the pH (to >7.5), which is particularly effective for phenobarbital and salicylate poisoning. Vitamin C may be added to IV fluids to enhance excretion of amphetamines and quinidine. Chelation therapy may be considered for heavy-metal poisoning (e.g., edetate calcium disodium [calcium EDTA] for lead poisoning). A limited number of true antidotes are available, and many are themselves toxic (Burchum & Rosenthal, 2016).

Education for toxic emergencies focuses on how the poisoning occurred. Patients who experience poisoning because of a suicide attempt or related to substance abuse should be evaluated by a mental health care provider and referred for alcohol or drug detoxification if required. Patients who have been exposed to poison in their jobs should be made aware of Canadian Centre for Occupational Health and Safety measures for a safe work environment.

Violence

Violence is the acting out of the emotions of fear or anger to cause harm to someone or something. It may be the result of organic disease (e.g., temporal lobe epilepsy), psychosis (e.g., schizophrenia), or antisocial behaviour (e.g., assault, murder). The patient cared for in the ED may be the victim or the perpetrator of violence. Violence can take place in a variety of settings, including the home, community, and workplace.

EDs have been identified as high-risk areas for *workplace violence* (NENA, 2014b). Violence within the ED that puts staff, patients, and visitors at risk for harm includes physical attacks, verbal abuse, and intimidating behaviour. Violent incidents are often under-reported

by nurses; however, without reports being made, the implementation of safe policies and practices can hindered.

Domestic Violence

Domestic violence, or intimate partner violence, is a pattern of coercive behaviour in a relationship that involves fear; humiliation; intimidation; neglect; intentional physical, emotional, financial, or sexual injury or assault; or a combination of these (sexual assault is discussed separately). It occurs in all professions, cultures, and socioeconomic groups. People of all ages and of either gender may be victims, although most victims are women, children, and older adults. Domestic violence is often hidden and undiagnosed (Halter, 2014).

It is recommended that all patients arriving at the ED be screened to determine whether they are victims of domestic violence. Barriers to conducting effective screening include limited privacy for screening, lack of time, and lack of knowledge about how to inquire about domestic violence. The development and implementation of policies, procedures, and education programs can improve the practices of ED staff in screening for domestic violence. Screening should begin by creating a safe and supportive environment in which to talk with the patient. Privacy must be provided, and the patient should not be questioned in the presence of the possible abuser. Several instruments have been developed for screening, but research has shown that a few short questions are the most realistic for health care providers (Nelson, Bougatsos, & Blazina, 2012). The Partner Violence Screen includes the following three questions:

1. Have you been hit, kicked, punched, or otherwise hurt by someone within the past year? If so, by whom?
2. Do you feel safe in your current relationship?
3. Is there a partner from a previous relationship who is making you feel unsafe?

In addition to questioning the patient, the nurse must assess for risk factors such as injuries consistent with abuse; fearfulness of

caregivers, including health care providers; withdrawn behaviour; regular ED use; and mental health and sleep disorders (Hammond & Zimmermann, 2013). If the assessment reveals physical and behavioural findings suggestive of abuse, a more detailed assessment should be completed. A caring, nonjudgemental, and respectful approach should be used to facilitate patient disclosure. Detailed documentation and preservation of forensic evidence may be necessary, and appropriate interventions should be initiated, such as making referrals, providing emotional support, and informing victims about their options (e.g., safe plan, safe house, legal rights). Some EDs have an affiliated sexual assault care centre or domestic violence centre to facilitate ED and community referrals and linkages and to support discharges into the community.

Elder Abuse.

Elder abuse (physical, psychological, and financial) is any action by someone in a relationship of trust that causes harm or distrust in an older adult (Government of Canada, 2016). Because the older adult rarely self-reports abuse, it is often identified, reported, and reported by health care providers (Bond & Butler, 2013). (See Chapter 7 for a discussion of elder abuse.)

Sexual Assault

In Canada, **sexual assault** is the legal term used to refer to any form of sexual contact imposed on another person without that person's voluntary consent. Kissing; fondling; and vaginal, oral, or anal intercourse are all examples of sexual assault if done without voluntary consent.

The large majority of sexual assault crimes (91%) are not reported to authorities, so the prevalence of sexual assault is hard to quantify (Statistics Canada, 2013). According to the most recent data from Statistics Canada (2017), women self-reported 555 000 sexual assaults in 2014 while men reported 80 000.

Sexual assault may be committed by a stranger or by an intimate partner. Intimate partner violence (IPV) is defined as “violence perpetrated against spouses and dating partners, either in current or

former relationships" (Sinha, 2013, p. 38). Survivors can suffer physical trauma and mental health consequences. Pregnancy, sexually transmitted infections (STIs), and gynecological problems can also result from IPV. More than half of all female sexual assault survivors were assaulted by an intimate partner. Female survivors of IPV frequently report chronic pain, sleep disturbances, poor physical health, and activity limitations. According to Sinha (2013), in 2011, there were approximately 97 500 survivors of IPV, representing a rate of 341 survivors per 100 000 population (p. 38).

Clinical Manifestations

Physical.

Many women and men who seek help immediately will not have any evidence of physical trauma. Evidence of trauma may be limited because survivors do not resist for fear of physical danger and injury. When present, physical injuries may include bruising and lacerations to perineum, hymen, vulva, vagina, cervix, and anus. Fractures, subdural hematomas, cerebral concussions, and intra-abdominal injuries have resulted in the need for hospitalization. Sexual assault also places survivors at risk for STIs and pregnancy in the case of women survivors.

Psychological.

Immediately after the assault, survivors may show shock, numbness, denial, or withdrawal. Some may seem unnaturally calm; others may cry or express anger. Feelings of humiliation, degradation, embarrassment, anger, self-blame, and fear of another assault are commonly expressed. These symptoms usually decrease after 2 weeks, and survivors may appear to have adjusted. Yet, any time from 2 to 3 weeks to months to years after the assault, symptoms may return and become more severe. *Rape trauma syndrome* is a classification of post-traumatic stress disorder. Flashbacks, intrusive recall, sleep disturbances, gastro-intestinal symptoms, and numbing of feelings are common initial symptoms. Survivors of assault will feel embarrassment, self-blame, and powerlessness. Later symptoms

include mood swings, irritability, and anger. Feelings of despair, shame, and hopelessness are often the cause of the anger. These feelings may be internalized and expressed as depression. Suicidal ideations may also occur.

Collaborative Care

In the acute care of an assault survivor, ensuring the patient's emotional and physical safety has the highest priority. Table 71-12 outlines the emergency management of the patient who has been sexually assaulted. Most EDs have identified personnel who have received special training in order to work with people who have been assaulted.

TABLE 71-12
EMERGENCY MANAGEMENT
Sexual Assault

Etiology	Assessment Findings	Interventions
• Assault involving genitalia (male or female) without consent • Sexual molestation • Sodomy	• Agitation • Anger • Crying • Decreased level of consciousness • Emotional or physical manifestations of shock • Extragenital injuries • Hyperventilation • Hysteria • Oral, vaginal, and rectal injuries • Pain in genital area or extragenital area • Silence	**Initial** • Treat shock and other urgent medical problems (e.g., head injury, hemorrhage, wounds, fractures). • Assess emotional state. • Contact support person (e.g., social worker, rape advocate, sexual assault nurse examiner). • Do *not* clean the patient until all evidence is collected. Make sure the patient does not wash, douche, urinate, brush teeth, or gargle. • Place sheet on floor. Then have patient stand on sheet to remove clothing. Place sheet with clothing in paper bag. • SANE will collect forensic evidence per local protocol (i.e., body hair, nail scrapings, tissue, dried semen, vaginal washing, blood samples). • Maintain chain of evidence for all legal specimens. Clearly label evidence and keep in locked cabinet until given to law enforcement agency. • Obtain baseline HIV, syphilis, and other STI screening. • Obtain toxicology sample to evaluate drug-facilitated sexual assault. • Determine method of contraception, date of last menstrual period, and date of last tetanus immunization. • Consider tetanus prophylaxis if lacerations contain soil or dirt. • Vaccinate for hepatitis B if not already done. **Ongoing Monitoring** • Monitor vital signs and emotional status. • Provide clothing as needed. • Counsel patient regarding confidential HIV and STI testing.

HIV, human immunodeficiency virus; *SANE,* sexual assault nurse examiner; *STI,* sexually transmitted infection.

Each province and territory has created the position of sexual assault nurse examiner (SANE). The SANE is a registered nurse who is certified to provide care to survivors of sexual assault while ensuring evidence is safeguarded. Special procedures are followed in taking the history and conducting the examination in order to preserve all evidence in case of future prosecution.

When the survivor of an assault is admitted to the ED or clinic, a specific chain of events occurs (Table 71-13). A signed informed

consent is obtained before any data are collected. All materials gathered are well documented, labelled, and given to the appropriate person, such as a pathologist or a police officer. The materials are handled by as few people as possible, and signatures of all responsible for keeping and handling the data are obtained. Many items can be used as evidence if the survivor chooses to file a complaint. Consequently, the integrity of the material must be maintained. The nurse's involvement in the medicolegal process depends on the policies of the individual institution and provincial or territorial law.

TABLE 71-13
EVALUATION OF ALLEGED SEXUAL ASSAULT

1. Medicolegal
• Valid written consent for examination, photographs, laboratory tests, release of information, and laboratory samples • Appropriate "chain of evidence" documentation
2. History
• Activities since assault (e.g., changed clothes, bathed, douched) • Current symptoms • Emotional status • History of assault (who, what, when, where) • Inquiries about safety • Medical history • Menstrual and contraceptive history • Penetration, ejaculation, extragenital acts
3. General Physical Examination
• Cuts, bruises, scratches (photographs taken) • Extragenital trauma—mouth, breasts, neck • Vital signs and general appearance
4. Pelvic Examination (Females)
• Adnexa, especially hematomas • Matted hairs or free hairs • Uterine size • Vaginal examination with unlubricated speculum for discharge, blood, lacerations • Vulvar trauma, erythema; hymen, anal, and rectal status
5. Laboratory Samples
• Blood samples—VDRL serology, pregnancy test; serological testing for HIV and hepatitis B infection • Clipping of matted pubic hairs • Cultures—cervix and other areas (if indicated) for gonorrhea and chlamydial infection • Fingernail scrapings • Serum sample frozen for later testing • Oral or rectal swabs and smears, if indicated • Pubic hair scrapings • Vaginal smears—microscope evaluation for trichomonads and semen • Vaginal vault content sampling
6. Treatment
• Care of injuries and emotional trauma • Prophylaxis for STIs, tetanus, and hepatitis B (see Chapters 55, 63, and 46, respectively) • If appropriate, consider levonorgestrel (Plan B) emergency contraceptive pill up to 72 hr after assault; follow-up for pregnancy test in 2–3 wk • Follow-up for pregnancy test in 2–3 wk (if appropriate) • Testing for HIV, syphilis, and hepatitis B may be done at 6–8 wk • Protection of legal rights • Recommendation of continued follow-up and services of rape crisis centre

HIV, human immunodeficiency virus; *STIs*, sexually transmitted infections; *VDRL*, venereal disease research laboratory.

A gynecological and sexual history and an account of the assault (who, what, when, and where), as well as a general physical and pelvic examination, add further information about the incident. In

the case of female survivors, laboratory tests are done primarily to look for sperm in the vagina and to identify any existing STIs or pregnancy.

Follow-up physical and psychological care is essential. Survivors of assault should return weekly for the first month following the assault. This time period is when psychological reactions may be the most severe. Health care providers should have the telephone numbers and names of contact people for local resources for sexual assault survivors, including rape crisis centres, legal and law enforcement authorities, and human services.

Nursing Management Sexual Assault

Nurses can assist people to become aware of prevention tactics (Table 71-14). They should also be encouraged to learn some basic self-defence techniques. Local high schools and the YWCA usually have self-defence classes for formal instruction. Practising the various techniques with a friend builds a person's confidence in his or her ability to fight back. Learning self-defence can make a person less vulnerable and more self-reliant.

TABLE 71-14

PATIENT & CAREGIVER TEACHING GUIDE
Sexual Assault Prevention

The following suggestions should be included when discussing ways to prevent sexual assault.
• Avoid walking alone in deserted areas. Walk to the parking lot with a friend; be sure you see each other leave.
• Be aware of date-rape drugs (e.g., gamma-hydroxybutyrate [GHB], flunitrazepam [Rohypnol], ketamine). Do not leave your beverage unattended or accept a drink from an open container.
• Be proactive and take a self-defence class.
• Carry a loud whistle and use it when you think you are in danger.
• Consume alcohol in moderation if you drink. Many sexual assaults involve the use of alcohol by the offender, the survivor, or both.
• Do not advertise that you live alone. List only your initials with your last name in the telephone directory or on the mailbox. Never reveal to a caller that you are home alone.
• Have your keys ready as you approach your car or home.
• Keep all doors locked and windows up when driving.
• Keep your residence doors locked, and do not open them to a stranger; ask for identification if a service person comes to the door.
• Never get on an elevator with a person behaving suspiciously or furtive. Pretend you have forgotten something and get off.
• Place and maintain lights at all entrances to your home.
• Proceed with caution in online correspondence.
• Say what you mean in social situations. Be sure your voice and body language reflect your response.
• Yell “fire” if you are attacked, and run toward a lighted area.

When a sexual assault survivor is brought to the clinic or ED, a quiet, private area should be used for the initial assessment and the examinations that follow. The patient should not be left alone. Whenever possible, the same nurse should remain with the person throughout the hospital stay and provide needed emotional support. The patient's actions and words while describing the incident may

be inconsistent, confused, and inappropriate. The nurse should maintain a nonjudgemental attitude.

The patient usually has many feelings and thoughts about the assault and generally wants to talk about them. Talking may help the patient feel better and gain an understanding of her or his reactions to the incident. When the nurse listens carefully, the patient feels less alone and is better able to gain control over the situation.

The nurse should assess the patient's stress before preparing him or her for the various procedures that will follow. The patient's coping mechanisms are supported when he or she knows what to expect and what is expected as well as why the particular procedure must be done. Because the pelvic examination may trigger a flashback of the attack for female survivors, the nurse should answer all related questions before the examination and be a supportive presence during the examination.

After the examinations, the patient's physical comfort needs should be considered. The patient will need a change of clothing because original garments may have been torn or soiled or may need to be kept as evidence. Most people who have been sexually assaulted feel dirty and would appreciate a place to wash as well as to use a mouthwash, especially if oral sex was involved. Food and drink may also provide comfort to the survivor.

For female survivors of sexual assault, the possibility of pregnancy should be discussed and the patient can be offered emergency contraception (sold as levonorgestrel [Plan B or Option 2] in Canada) to prevent an unintended pregnancy. It is similar to birth control pills but taken in different doses and can be used up to 3 to 5 days after unprotected sex, reducing the risk of getting pregnant by approximately 75% to 89% (Dunn & Guilbert, 2012). The effectiveness of emergency contraception (EC) is highest when taken within 24 hours after unprotected sexual intercourse and declines over time. EC pills might be less effective in women weighing 75 to 80 kg, and are not effective in women over 80 kg (Government of Canada, 2014).

Many sexual assault survivors are unaware of the availability of compensation or financial assistance programs and appreciate information about the application process. All provinces and

territories except Newfoundland and Labrador, Yukon, and Nunavut have financial compensation programs for victims and survivors of violent crime such as sexual assault to cover some, but not all, expenses incurred as the direct result of a violent crime (Canadian Resource Centre for Victims of Crime, 2016). The programs were created to recognize the harm done to innocent people and to ease the financial burden that often accompanies victimization. All other coverage must be exhausted before claims for compensation are considered (Canadian Resource Centre for Victims of Crime, 2016).

When the patient is discharged, the nurse should make certain the patient has transportation home. If friends or family members are not available, the hospital or clinic should make arrangements with an appropriate community resource. The patient should not be sent home alone. The survivor's partner and family have a tremendous potential for both negative and positive influence. If the partner is the perpetrator of the assault, consultation with the risk management department and law enforcement is necessary to protect the patient.

Many communities today have crisis centres. These public service organizations have trained professional and nonprofessional volunteers who provide an emotional support system for survivors on request. Their programs provide advocacy to ensure dignified treatment throughout the medical and police procedures, short-term counselling for survivors and their families, and court assistance and public education on rape-related issues.

Case Study

Trauma

Source: Monkey Business Images/Shutterstock.com.

Patient Profile

Lian Wu, a 20-year-old woman, is brought to the ED in an ambulance. She was the driver in a motor vehicle collision and was not wearing a seat belt. Two children in the car were pronounced dead at the scene. The paramedics stated that there was significant damage to the car on the driver's side.

Subjective Data

- Ms. Wu asks, “What happened? Where are the children?”
- Complains of shortness of breath and abdominal pain

Objective Data

Physical Examination

- Asymmetrical chest movement
- Badly deformed right lower leg with a pedal pulse detectable only by Doppler ultrasonography
- Decreased breath sounds on left side of chest
- Glasgow Coma Score of 14; unequal pupils
- O_2 saturation, 82%
- One 4-cm head laceration
- Vital signs: blood pressure, 90/40 mm Hg; heart rate, 130 beats/min; respiratory rate, 36 breaths/min

Discussion Questions

1. What life-threatening injury does Ms. Wu probably have?
2. ***Priority decision:*** What is the priority of care for Ms. Wu?
3. ***Priority decision:*** What interventions are needed immediately?
4. What other interventions should the nurse consider?
5. Several family members have arrived in the ED, including the mother of one of the children who died. The second child who died was Ms. Wu's child. How should the nurse approach the family of the first child?
6. ***Priority decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. An older man arrives at the ED disoriented and breathing rapidly. He has hot, dry skin. What is the priority for treatment at this point?
   a. To assess his airway, breathing, and circulation
   b. To obtain a detailed medical history from his family
   c. To determine that he has his health card before treating him
   d. To start oxygen administration and have the ED physician see him
2. A client has a core temperature of 32°C. Which of the following is the most appropriate rewarming technique?
   a. Passive rewarming with body-to-body contact
   b. Active core rewarming using warmed IV fluids
   c. Passive rewarming using air-filled warming blankets
   d. Active external rewarming by submersion in a warm bath
3. Effective interventions to decrease absorption or increase elimination of an ingested poison include which of the following? *(Select all that apply)*
   a. Hemodialysis
   b. Milk dilution
   c. Eye irrigation
   d. Gastric lavage
   e. Activated charcoal
4. Of clients who die in the ED, whom should the nurse regard as potential organ donors?
   a. Those who were young and strong
   b. Victims of accidents who were otherwise disease free
   c. Clients who can be kept on life support until the transplantation team is ready

d. Anyone whose organs and tissues were healthy at the time of death

5. An older-adult client arrives in the ED with his son. The older man is in no apparent physical distress, although his clothes are soiled with urine and feces and he is tearful. Which of the following should the nurse consider?
   a. Cancer
   b. Stroke
   c. Neglect
   d. Depression
6. Which of the following would be the first nursing intervention for the client who has been sexually assaulted?
   a. Treat urgent medical problems.
   b. Contact a support person for the client.
   c. Provide supplies for the client to cleanse himself or herself.
   d. Document bruises and lacerations of the perineum and the cervix.

1. a; 2. b; 3. a, d, e; 4. d; 5. c. 6. a.

CHAPTER 72

Emergency Management and Disaster Planning

Written by, Karen Baguley

LEARNING OBJECTIVES

1. Differentiate between an emergency and a disaster situation.
2. Identify the roles and responsibilities of individuals, communities, and select provincial or territorial and federal agencies in emergency planning and disaster management.
3. Define and describe the characteristics of disaster nursing.
4. Outline the components of a comprehensive emergency management program.
5. Describe the four phases of disaster management and the nursing role in each phase.
6. Describe the application of the Incident Management System and the roles of command centre team members.
7. Describe the differences between daily emergency department triage and triage in disaster situations.
8. Outline the components of START triage and its application in disaster situations.
9. Classify the major types of disasters based on their characteristics and describe their consequences.
10. Identify those agents most likely to be used in a terrorist attack and their health impact.
11. Describe key differences between chemical, biological, radiological, nuclear, and explosive (CBRNE) events and the relevance of casualty decontamination in health care settings.
12. Describe the difference between epidemics and pandemics and discuss the importance of pandemic planning.

terrorism, p. 1835
triage, p. 1833

Daily media coverage has allowed the world to witness first-hand the depth and overwhelming impact of natural and human-made or human-induced disasters. The increasing frequency of disasters globally emphasizes the pivotal need for advanced planning and collaboration to effectively mitigate and manage the outcomes. Disasters have extensive history within the human experience, resulting in premature death, diminished quality of life, and altered health status (Veenema & Woolsey, 2013). Hurricane Katrina (2005), the earthquakes in Haiti (2010) and in Great East Japan (2011), and more recently the Fort McMurray forest fires (2016), coupled with the images of the Paris (2015), Orlando (2016), and Nice (2016) terrorist attacks, and the Las Vegas (2017) mass shooting reflect the far-reaching impact of disasters and the critical need for broad-scale planning, prevention, response, and recovery mechanisms.

Nurses, as the largest sector of the health care workforce in Canada, can expect to be on the front lines of an emergency at some point in their careers. In recent years, nurses have played a pivotal role in responding to emergency situations nationally and internationally, contributing to large-scale health surveillance, education, and the assessment of health needs and service and resource allocation (Canadian Nurses Association [CNA], 2012). According to the World Health Organization and the International Council of Nurses (WHO & ICN, 2009), the unique knowledge, skills, and abilities possessed by nurses allow them to support humanitarian efforts and positively contribute to disaster response. It is an expectation that all nurses demonstrate an awareness of the impact of emergency planning on disaster response and that they work collaboratively to implement strategies to prevent illness and injuries that are a result of community disasters and global health issues (CNA, 2012; College of Nurses of Ontario, 2014; WHO & ICN, 2009).

Emergency Management and Disaster Planning

Emergency management and disaster planning involve advanced preparation for a variety of potential situations, including mass casualty incidents, natural or biological events, technological failures, human conflicts, and acts of terrorism. Advanced planning, when done in a comprehensive and diligent manner, decreases the impact that an emergency or disaster situation has on individuals, organizations, and communities. When discussing emergency management and disaster planning, it is important to differentiate between the terms. According to WHO and ICN (2009), no single, agreed-upon definition of the term *disaster* exists. Disasters are often defined by governments, humanitarian groups, and other agencies, reflecting the mission and needs of that agency. While events may be labelled as "disasters," by the communities affected and by the media, many events are more accurately classified as emergencies.

An **emergency** may be described as a present or imminent event that requires a rapid and skilled response to protect the health, safety, and wellness of individuals and to limit damage to property or the environment (Public Safety Canada [PSC], 2015a). Emergency situations are typically able to be quickly managed without requiring the support and resources of other communities but require urgent intervention to prevent worsening of the situation. A **disaster** is the outcome of a natural hazard or event (e.g., hurricane, flood, earthquake) or a result of human action or error, whether malicious (e.g., terrorist attacks, use of biological warfare) or unintentional (e.g., an accidental chemical spill), that seriously disrupts the functioning of a community or society (PSC, 2015a). Disasters typically occur suddenly and can result in mass casualties (i.e., large numbers of people injured); loss of human life and materials; and significant destruction of property, the environment, and critical infrastructure (e.g., government, water, power, food supply) (Veenema & Woolsey, 2013). A disaster, owing to its scale and impact, exceeds the capacity of a community to cope and respond with existing resources, requiring "outside" assistance from trained responders, government, nongovernmental organizations, humanitarian relief agencies, or some combination of all of these (WHO & ICN, 2009; PSC, 2015b).

Two approaches are used in disaster planning initiatives: an *agent-specific approach,* in which planning efforts are directed at those threats most likely to take place within a single geographical location (e.g., earthquakes in California); and more commonly, an *all-hazards approach,* a comprehensive strategy, where vulnerabilities to both natural and human-induced hazards are considered to be potential possibilities even if they have never happened or are unlikely to ever occur (PSC, 2015b; Veenema & Woolsey, 2013). An all-hazards approach to emergency management is used across all jurisdictions in Canada and helps to ensure that managing one type of risk does not increase vulnerability to other risks. **Hazards** are defined as anything that has the potential to cause harm or loss. Hazards can be substances, human activities, or physical events that may cause injury or loss of life, threaten the delivery of critical services, cause social and economic disruption, or cause property or environmental damage (PSC, 2015a). Disasters occur when a hazard interacts with a vulnerable area to produce serious adverse consequences that may exceed a community's or society's ability to cope for an unknown period of time.

Individual, Local–Municipal, Provincial–Territorial, and Federal and First Nations Responsibilities

To be successful, emergency and disaster planning initiatives must be done at a variety of levels, specifically the individual and family; local, community, or municipal; provincial or territorial; and federal levels. *Emergency management and disaster planning* involves having plans of action, supplies, and resources in place to respond in a timely and efficient manner to inevitable events.

Preparedness starts at an individual level and requires that individuals and families assume responsibility for taking appropriate steps to ensure that they have the basics of what might be required for short-term survival. This level of preparation requires stockpiling items that would be needed to be self-sufficient for a period of at least 72 hours and a detailed plan, considering risks to the region, knowledge of safe exits and evacuation routes, advanced identification of emergency contacts and meeting places for reunification, and an awareness of where to find household fire extinguishers, water and gas valves, floor drains, and electrical control panels (Canadian Red Cross, 2016a; Government of Canada, 2015a). Emergency workers focus on community members with the most urgent needs, and search and rescue efforts for casualties take precedence in the first 72 hours of an emergency event. Critical

infrastructure (e.g., water and power) could potentially be interrupted for an extended period of time, reflecting the need for advanced planning and availability of basic survival resources. Table 72-1 details items that should be included in an individual or family emergency preparedness kit.

TABLE 72-1
INDIVIDUAL OR FAMILY EMERGENCY PREPAREDNESS KIT

Meeting Places
Safe meeting place near home: _____ Safe meeting place outside immediate neighbourhood: _____ Evacuation routes from neighbourhood: _____
Basic Emergency Kit Items to Include
Food and drinking water: Have at least a 3-day (72-hr) supply of food and water on hand ***Food:*** Ready-to-eat foods that will not spoil, such as canned food, energy bars, and dried foods (replace food and water once per year) ***Drinking water:*** At least two litres of water per person per day (include small water bottles that can be carried easily)
Equipment for Emergency Survival
□ A copy of emergency plan and contact information and numbers □ Cash (include smaller bills, such as $10 bills and change for pay phones) □ Extra keys for car and house □ First-aid kit □ Wind-up or battery-powered flashlight (with extra batteries) □ Wind-up or battery-powered radio (with extra batteries)
Additional Supplies That Should Be Considered
□ Additional bottles of water (2 L per person) for cooking and cleaning □ Backpack or duffel bag (in case of evacuation) □ Blankets or sleeping bags for each household member □ Candles in a deep can; matches or lighter □ Change of clothing and footwear (one change of clothes per person) □ Duct tape and basic tools (hammer, pliers, wrench, screwdriver, pocket knife) □ Garbage bags □ Important papers (identification, personal documents) □ Manual can opener, bottle opener □ Playing cards and games □ Small, fuel-operated stove and fuel □ Toiletries, hand sanitizer □ Utensils, disposable cups and plates □ Warning light or road flares □ Whistle (to attract attention)
Any Special Needs Family Members Might Have
□ Equipment for people with disabilities □ Infant formula, diapers □ Personal prescription medications, including allergy medications □ A record of details about medical conditions, allergies, medication, family medical history, recent vaccinations, health screenings, and surgeries □ Pet food

Most emergencies in our country are local in nature and are managed by municipalities and, when required, with provincial or territorial support.

Accountability for emergency planning and response in Canada is held by individual municipalities, the underlying principle being that communities possess the greatest knowledge of their individual needs and, thus, are in a strategic position to most effectively plan for and manage local events (PSC, 2015b; PSC, 2015c). Local first responders (fire, police, and paramedics) are typically the first to respond to an emergency as a component of the municipal emergency plan. While most situations can be effectively handled by a community, different levels of organizations are introduced progressively if the situation escalates and as additional help and resources are needed. When a community is unable to provide required response efforts because of the scope of the situation or because of inadequate personnel or equipment, a "community emergency" is declared and the province or territory is contacted for support (PSC, 2015a).

The *Emergency Management Act* (EMA) was developed with the goal of strengthening emergency management efforts in this country. The Act sets out clear roles and responsibilities for all stakeholders within Canada's emergency management system and is directed at ensuring that our country and its jurisdictions are engaged in disaster mitigation and response activities (PSC, 2015b). All provinces and territories have an *Emergency Management Organization* (EMO) that is responsible for the development, coordination, training, and response operations in their jurisdiction. EMOs typically manage large-scale emergencies, providing assistance to municipal or community response teams (PSC, 2015a; 2015b). Recognizing the potential for emergencies to escalate rapidly in scope and severity, cross jurisdictional lines, and have an international impact, the provincial–territorial EMO will notify the federal government for assistance when required. Federal assistance is most commonly dispatched in disaster situations—for example, in those involving mass casualties or in areas under federal authority, such as nuclear safety, national defence, and border security (PSC 2015a; 2015b; 2015c).

Public Safety Canada (PSC) is the department of the federal government accountable for Canadian safety and protection. Created after the events of September 11, 2001, PSC plays a role in the development of national policy, response systems, and standards and is responsible for providing guidance to federal government institutions on the development of emergency management plans. This approach strengthens the Canadian government's capacity to prevent, protect against, respond to, and recover from major disasters and other emergencies (PSC, 2015b; 2015c; 2015d).

PSC also plays a critical role by establishing partnerships across sectors with key organizations, like the provincial–territorial EMOs, Canadian Security Intelligence Services, the Royal Canadian Mounted Police, and the United States Department of Homeland Security, as a means of managing national risks, reducing vulnerabilities to hazards, and strengthening the resilience of critical infrastructure (PSC, 2015b; 2015c; 2015d). *Critical infrastructure* consists of physical and information technology facilities, networks, services, and assets that are considered to be essential to the health, safety, security, and economic well-being of Canadians and to the continued functioning of the country as a whole. Examples of critical infrastructure include power, water, government, and sewage services. Several federal departments work alongside PSC to provide emergency response resources. For example, Health Canada plays a role in implementing strategies aimed at reducing risks to individual health and the overall environment. The Department of National Defence administers the Canadian Forces Disaster Assistance Response Team (DART), a multidisciplinary military organization designed to deploy on short notice anywhere in the world in response to situations ranging from natural disasters to complex humanitarian emergencies (Government of Canada, 2015b).

Around the world, many government and nongovernmental organizations deliver expert humanitarian aid programs and services. *Nongovernmental organizations* (NGOs) are an important component of the emergency response system. These nonprofit agencies offer assistance with disaster prevention and preparedness, response, and recovery. The Canadian Red Cross, St. John Ambulance, and the Salvation Army are examples of NGOs that provide resources that support emergency response (equipment, supplies, and human resources) and that address basic human needs (food, clothing, shelter, emotional support, and family reunification) in times of disaster (Canadian Red Cross, 2016b; St. John Ambulance, 2016).

Disaster Response in First Nations Communities

First Nations are responsible for developing and implementing emergency plans that address the needs of their communities. When an emergency occurs in a First Nations community, it is the responsibility of the chief and council to use all available resources to respond to the situation. As is true of other communities, if the situation extends beyond the capacity and resources available to respond, additional support is requested. Disaster

response in First Nations communities involves a collaborative agreement between Indigenous and Northern Affairs Canada (INAC) and provincial–territorial governments, ensuring community access to comparable emergency assistance services available to other residents in their respective provinces or territories. Through these agreements, INAC provides funding to cover eligible costs related to emergency assistance, while the provincial or territorial government provides the service (INAC, 2017). INAC also collaborates with provinces and territories to manage situations on reserves that have the potential to affect communities, lands, assets, and the environment (INAC, 2017).

Emergency/Disaster Management

Emergency/disaster management is a process that includes a series of steps, from the anticipation of a hazardous event, to minimizing the risks from such an event, to responding to and recovering from an emergency or disaster. The life cycle of a disaster is commonly referred to as the *disaster management continuum* and is accepted globally as the method for addressing all aspects of a disaster (WHO & ICN, 2009) (Figure 72-1). This cycle is characterized by three major phases that provide the disaster timeline: (1) pre-incident (before the event); (2) incident (during the event); and (3) post-incident (after the event) (WHO & ICN, 2009; Veenema & Woolsey, 2013). Within each phase of the disaster management continuum are activities that include the following: (1) pre-incident: activities designed to plan, prevent or mitigate, and prepare for the potential impact of an emergency or disaster; (2) incident: all activities involved in the response to and management of an emergency or disaster situation; and (3) post-incident: recovery or rehabilitation from said situation with evaluation of efforts (WHO & ICN, 2009; Moore, Geller, & Clark, 2015). Actions taken at each phase aim to reduce harm to populations and critical infrastructure and to build community resilience. The nature and scope of planning will influence the extent of illness, injury, and death that occur following a disaster. The use of an all-hazards approach to planning, multilevel partnerships to respond to emergency and disaster situations, and integration of activities outlined in each phase together comprise a *comprehensive emergency and disaster management program*.

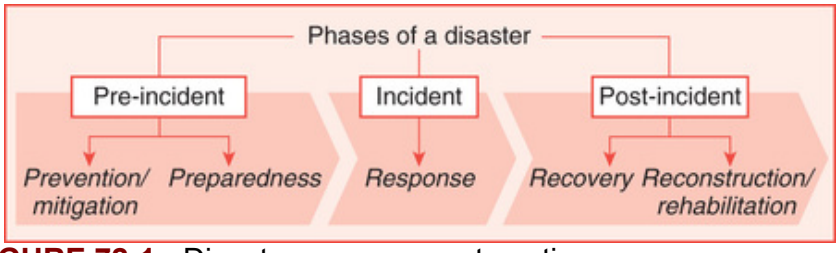

FIGURE 72-1 Disaster management continuum. Source: World Health Organization and International Council of Nurses (2009). ICN Framework of Disaster Nursing Competencies (p. 40, Figure 1). Retrieved from *http://www.icn.ch/images/stories/documents/networks/DisasterPreparednessNetwork/Disaster_Nursing_Competencies_lite.pdf*.

Mitigation

Mitigation, also called *prevention,* is a critical first step to emergency management that occurs in the pre-incident phase of the disaster management continuum. Mitigation involves reducing the impact of disasters on communities, helps to reduce financial costs of disaster response and recovery (PSC, 2015b), and starts with an assessment of potential risks. A *risk* is defined as the combination of the likelihood that a hazard or event will occur and the consequences that may result if it does (PSC, 2015a). Emergency management is a *risk-based* process, meaning that decisions and activities are based on an assessment, understanding, and evaluation of hazards, risks, and vulnerabilities. *Vulnerabilities* are conditions that increase the susceptibility of communities to the negative impact of a hazard and are a measure of how prepared a community is to cope with the impact of a hazard (PSC, 2015a). Examples of vulnerabilities include poor construction and design of buildings, lack of public information, and inadequate preparation. Mitigation, therefore, involves the identification of potential hazards faced by an organization or a community and the minimization of possible consequences from those hazards.

The goal of mitigation is to identify and implement in advance long-term strategies to reduce, deflect, or altogether avoid the consequences a hazard might have on human health, organizational or community function, and critical infrastructure (PSC, 2015a; 2015c). Examples of mitigation strategies within a community include flood mapping; the use of water-resistant building materials to decrease the effects of floods and hurricanes; and the development of public warning systems to assist with evacuation in times of emergency (PSC, 2015a). In the hospital setting, mitigation might include ensuring the availability of essential equipment (e.g., portable medical gases) that does not require the use of electricity, or availability of backup emergency generators for critical equipment, thereby decreasing the impact on patients should critical infrastructure fail (Markenson, 2013; Veenema & Landesman, 2013). Nurses play a pivotal role in mitigation activities across acute care and community settings. Nurses' knowledge of community needs, available resources, populations at risk, and workforce issues is essential in preparing an organization or a community for emergency situations (WHO & ICN, 2009).

Preparedness

Preparedness is a proactive activity that occurs in the pre-incident phase and that involves preplanning for emergency situations that could occur within an organization, a community, or a jurisdiction. Preparedness is closely tied to emergency response and involves delineation of "what should happen, when" and "who does what, where," at the time of an emergency. Preparedness includes the knowledge and capacity developed by individuals, organizations, communities, governments, and response organizations to anticipate, respond to, and recover from the impact of a hazard (PSC, 2015a). Nurses play an important role in preparedness by educating individuals and communities on disaster preparedness; working to reduce hazards in the home, in work settings, and within communities; by participating in drills and training exercises; and through the development of emergency operations plans and protocols (WHO & ICN, 2009). Within the hospital setting, the nursing role is one of leadership and advocacy, through participation on unit- and corporate-based committees and task forces and in the development of disaster protocols and exercises.

Health Care Emergency Operations Plans.

An *emergency operations plan* (EOP) is a comprehensive document that describes strategies and frameworks for how emergencies or disasters will be planned for and managed and that delineates training requirements with the goal of increasing resilience. Accreditation Canada requires health care organizations to have policies and processes in place to respond to internal emergencies as well as those arising external to the organization that, owing to their size and impact, have the potential of affecting day-to-day operations and patient care.

Internal and External Disasters.

Internal disasters refer to any situation that threatens or disrupts the daily, routine services of a health care facility. These situations present a potential danger to patients and staff and may or may not occur at the same time as an external event (Veenema & Woolsey, 2013). Some of the causes of internal disasters include bomb threats, chemical or radiological accidents, fire, spills, power and water loss, unavailability of staff, outbreaks of communicable disease, and violence. Internal disasters have the potential to result in a series of outcomes, including patient and staff evacuation, decreased levels of service, diversion of transportation (e.g.,

ambulance and air transport), and reallocation of patient care (Gebbie & Qureshi, 2013; Veenema & Woolsey, 2013).

External disasters are a result of events that originate outside of a health care organization. This type of disaster has the potential to threaten a facility when the consequences of the event create a demand for service that exceeds what is routinely available (Gebbie & Qureshi, 2013). External disasters may be the result of *mass casualty incidents*, which involve an influx of patients from a single incident and that exceed the capacity of a system to manage within its current resources. A health care organization can also experience an external disaster during an influx of patients who have been exposed to a hazardous material, or *chemical-biological-radiological-nuclear-explosive* (CBRNE) *event*.

Combined external–internal disasters occur as a result of external situations or events that trigger a response within the internal environment of a health care facility (Gebbie & Qureshi, 2013). In Canada, severe weather conditions (e.g., snowstorms) can result in a combined external–internal disaster. For example, the inability of staff to travel to work, coupled with an increased volume of trauma patients due to a winter storm, can precipitate a staffing crisis in the internal hospital setting. Consequently, remaining staff resources may be unable to address demands due to increased volumes and acuity in patients needing care.

Contents of Health Care Emergency Operations Plans.

Most disaster response activities occur in the hospital setting. An effective EOP uses an all-hazards approach to ensure preparedness for any event and is able to be implemented almost automatically in an emergency or disaster situation (Markenson, 2013). A hospital EOP must be flexible and scaleable to the situation and consider actions required for emergencies that are a result of internal, external, or a combination of external–internal circumstances. Some plans further delineate disaster responses according to the level or to the organization's ability to respond. Furin (2016) describes a three-phase classification system that reflects the magnitude of a disaster relative to an organization's ability to respond:

Level 1 Disaster: The organization or community is able to effectively respond to the event utilizing its own resources.

Level II Disaster: The emergency or disaster situation requires support and assistance from sources external to the organization that can be attained through nearby agencies or communities.

Level III Disaster: The emergency or disaster situation exceeds the ability and resources available in the community, requiring support from provincial–territorial or federal-level organizations.

The EOP starts with a risk assessment that evaluates the likelihood of disasters for the organization or community. Potential hazards to consider include weather patterns; geographical location, age, and condition of the facility; industries in close proximity (nuclear plants or factories); and large-scale public events (Gebbie & Qureshi, 2013). The assessment also includes an evaluation of staffing resources needed under various situations and supplies considered to be essential. Stockpiles of medications (analgesics, sedatives, vaccines, and antidotes); required personal protective equipment (PPE) (masks, splash suits, chemical-resistant gloves); and medical supplies (stretchers, ventilators, bandages, dressings) to support patient care should be identified, with processes for acquisition developed. Information technology requirements may include computers (for documentation and patient registration); televisions and radios (for external coverage of emergency events); telephones, two-way radios, and fax machines. Space and needed resources for emergency response (emergency operations centre, media centre, staffing and patient–family information centres, and patient surge locations) should also be included in the plan. Basic human-needs requirements (nonperishable food, water, accommodations, and rest areas) for staff and family members who stay and work for prolonged periods should be identified as essential resources.

Numerous challenges have been identified in the management of disaster situations. These include communication difficulties; lack of leadership, planning, and clear lines of accountability; inadequate surge capacity, casualty triage, transportation, and evacuation processes; poor safety, security, and control of entry points; patient identification and data tracking processes; management of resources; and resistance to planning initiatives (Andress, 2010a). Addressing these challenges in advance in the EOP will facilitate effective management. Components of a health care EOP are as follows:

1. *Activation of Emergency Status.* The EOP should outline how emergency or disaster notification is received. Notification of an internal event normally comes from an inpatient unit or department, based on staff observation and escalation; whereas, in an external disaster situation, notification may come from

emergency medical services or the media. The EOP must describe how notification and escalation of emergency status occurs, when, and to whom.

2. *Communication Plan.* This portion of the EOP provides details highlighting internal and external communication processes that should take place between first responders and the hospital; among staff members (front-line and management staff); and between the hospital and family members of casualties. It is essential that response activities also include a designated individual who is prepared and able to effectively communicate with the public and the media (Nacos, 2013), through a *media communication plan.* Documentation tools and tracking forms are of assistance in enhancing communication between departments and with family members. Communication of decisions made, requests for support, and initiation and setup of emergency response centres follow a hierarchical process and this communication is a component of the Incident Management System (California Emergency Medical Services Authority [CEMSA], 2014; Gebbie & Qureshi, 2013).
3. *Plan for the Coordination of Patient Care.* This section of the EOP outlines processes for managing patient care with a specific focus on the area(s) most affected by the event; this might be the emergency department as the portal of entry for those injured or, in the case of an internal disaster, those areas directly affected by the situation. *Surge capacity* reflects an organization's ability to manage an unanticipated increase in patient numbers, with higher demands on the skills of the staff involved (Veenema, 2013a). Surge planning involves a calculation of the number of available beds and potential care locations (including potential transfers and discharges) and access to and availability of multidisciplinary staff and supplies (backboards, ventilators, medications) (Lentz, Reid, & Primomo, 2013). A process for the suspension of normal daily services (e.g., elective surgeries, outpatient clinics) should be included in the plan, with triggers, should it be required.
4. *Staffing Plan.* This plan provides a detailed process for calling in additional staff when required (a process referred to as *fan-out*) to support surges in patient volumes and acuity and delineates processes for staff reassignment to areas with the highest volume, acuity level, and patient concentration. Staffing needs are determined based on the total number of care areas, the size of the disaster and anticipated number of patients, the type of event, and

the medical problems that are anticipated to be seen relative to the incident (Veenema, 2013a). An inventory of staff skill sets across the facility assists with this process. Reassignment of staff is typically coordinated via the facility's emergency operations centre, through use of a *labour pool and staffing centre*.

5. *Equipment and Supply Plan.* This plan includes tracking of equipment and supplies that will be needed in an emergency response. These inventories should include medical (e.g., PPE, medications) and nonmedical (e.g., food, linen, water, fuel) supplies. Storage for the stockpiling of equipment and supplies should be considered and a process outlined for accessing additional resources from suppliers. Access to equipment and supplies is of particular importance in situations involving exposure to hazardous materials, as safe patient care cannot be provided without immediate access to PPE. The availability of equipment required in an emergency situation must be assessed on a regular basis, and a process for monitoring expiration dates and ensuring circulation of supplies before their expiration should be a component of planning activities (Markenson, 2013).
6. *Security Plan.* This plan outlines procedures for ensuring a secure work and patient care environment and is key to supporting safe response. This response includes procedures for instating *lockdown status* within the organization. Lockdown, a process that involves restricting access to entry points to a health care facility, should ideally be an instantaneous process (CEMSA, 2014). This process is of particular importance to control flow through the organization, accounting for patients and staff should evacuation be required; to prevent acts of violence or terrorism; and to avert entry of potentially contaminated patients to the hospital (Markenson, 2013). For example, in cases in which there is chemical, biological, radiological, or nuclear exposure, lockdown will assist in redirecting contaminated patients to a single designated point of entry, where decontamination can occur before entry to common areas.
7. *Documentation and Data Management Strategy.* This component of the EOP outlines how patients will be rapidly identified (also called *banded*) and tracked when moving within and across departments or institutions. Standard medical record items requiring documentation in a disaster include demographic data, brief medical history, medications and allergies, type of illness or injury,

treatment provided, and patient disposition (Veenema, 2013a). Detailed records of the sickest patients, who are unable to self-identify, includes documenting characteristics (age, gender, clothing, tattoos, and piercings) to assist with identification and reunification. Due to the potential for loss of critical infrastructure (e.g., power, communication) during an emergency, backup paper-based systems should be created. Hand-held devices and smartphones may enhance and expedite documentation in the medical record (Veenema, 2013a).

8. *Deactivation and Recovery Process.* Deactivation and recovery processes should be outlined in the EOP, describing how emergency status will be terminated. Clear delineation as to who is able to deactivate disaster response activities, how this is to be done and when, as well as next steps to restore core services and operations is included.
9. *Post-Incident Debriefing Plan.* This plan provides guidelines as to when debriefing of individuals involved in emergency response will occur and in what format. Health care providers involved in disaster response are at high risk for stress, due not only to extended periods of demanding workload, but by the need to respond to families and the media while bearing witness to pain and suffering. Because stress on workers may continue for some time after the event, early debriefing will support coping and a return to normalcy. Debriefing also assists in improving components of the emergency plan and future response activities (Grigg & Hughes, 2010; Coyne-Plum & Meeker, 2013).
10. *Educational Plan.* An educational plan for emergency drills and training exercises should be outlined in the EOP and include dates, times, frequency, and format for testing the plan (Andress, 2010).

Testing of Emergency Plans.

Organizations and staff respond to and recover from disaster situations based on their level of preparation, the culture of the organization, past experiences in dealing with emergencies, and the nature or scale of the situation (Veenema, 2013a; Markenson, 2013). Testing exercises are a key component of emergency management and are done to promote preparation, evaluate an organization's level of readiness, identify process gaps and alternate strategies, and assist in training staff in understanding and enacting response roles. While the most effective form of testing an

EOP is its use in an actual disaster situation, other strategies, including traditional educational formats (e.g., lectures, case studies) and hands-on learning (e.g., tabletop exercises, computer simulations, role-play, drills), complement and enhance individual and organizational response (Andress, 2010a). Responders require an understanding of the core competencies of emergency preparedness, incident command, risk communication, and roles relative to other responders (WHO & ICN, 2009).

Response

Response occurs in the incident phase of the disaster management continuum, either on impact of an event (e.g., explosion, fire) or upon an imminent event (e.g., hurricane, tornado). The EOP is critical in this stage because it provides details and information as to how response initiatives should occur. Response involves execution of the plan, where trained and exercised staff are in place, possessing the knowledge of where they need to be and the skill to do what they need to do when confronted with an emergency situation. The goal of response is to save lives, reduce health impacts, ensure public safety, and meet the needs of individuals affected by the event (Gebbie & Qureshi, 2013). It is in the response phase that the Incident Management System is enacted and triage of patients occurs.

The nursing role is most visible in the response phase of a disaster. Nurses provide care in a variety of areas, including patient triage, emergency and trauma care, critical care, infection control and occupational health and safety, supportive and palliative care, and public health. Nurses are also pivotal in acute care, inpatient settings in disaster response because they receive the casualties who may require care on a longer-term basis as they recover from their injuries. Nurses may be required to work in a variety of alternate settings during the response phase, such as emergency aid shelters, homes, mass immunization sites, shelters, mortuaries, or makeshift clinics (WHO & ICN, 2009).

The Incident Management System.

The Incident Management System (IMS) used in Canada is based on the incident command system that was developed as a result of mass wildfires that took place in California in the 1970s. These incidents were poorly managed as a result of competition for supplies and equipment between response agencies, precipitating the need for a systematic and coordinated process (Menzel & White, 2015). IMS is used by police, fire, emergency

medical services, health care organizations, power utilities, and government agencies, as well as in many areas of the private sector.

IMS, an integrated and flexible framework that identifies disaster response roles, ensures that effective communication, incident command, and control are maintained during disaster response (Figure 72-2). Communication and teamwork between groups of people and departments that do not usually work together are emphasized (CEMSA, 2014). IMS in the hospital setting, also referred to as the *hospital incident command system (HICS),* enables quick action, provides access to needed resources, and ensures continuation of essential services through all phases of a disaster (Gebbie & Qureshi, 2013; DeAtley, 2010).

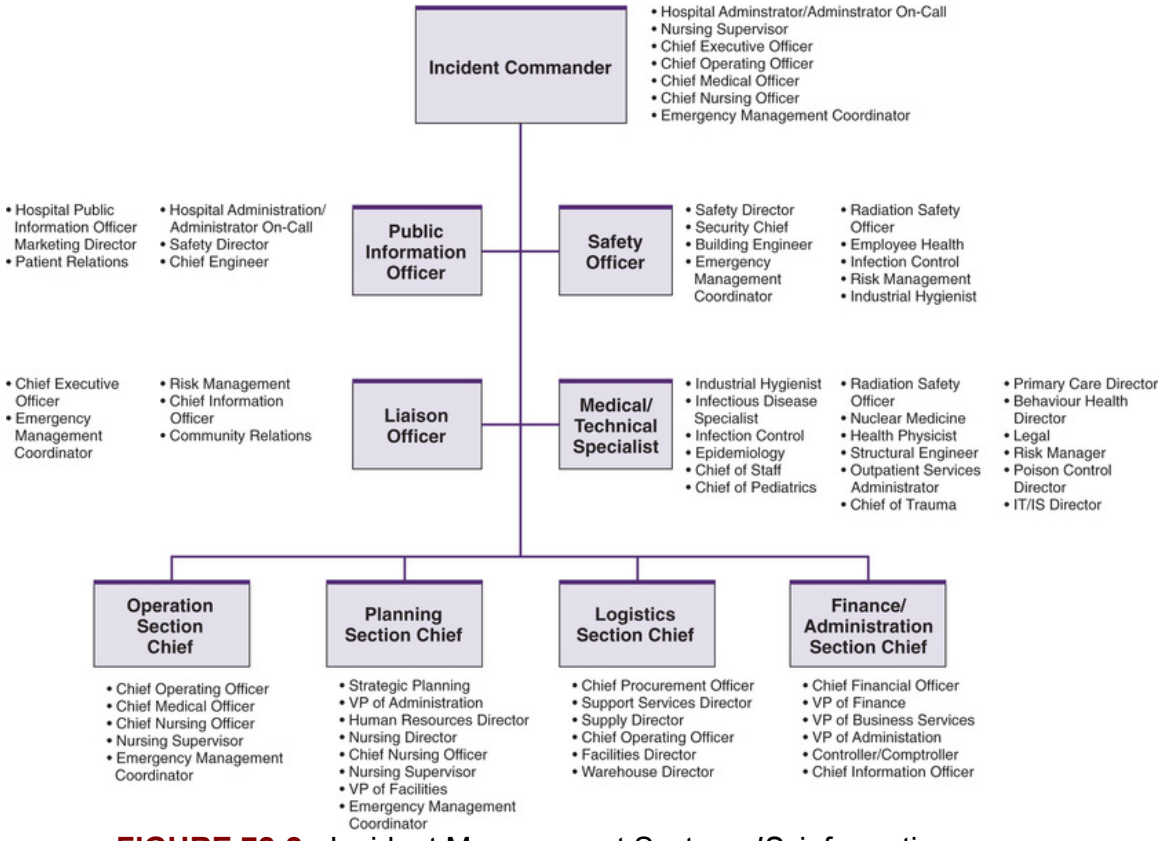

FIGURE 72-2 Incident Management System. *IS,* information services; *IT,* information technology; *VP,* vice-president. Source: California Emergency Medical Services Authority. (2014). *Hospital incident command system guidebook* (Appendix D, p. D-2). Retrieved from *http://hicscenter.org/Shared%20Documents/Appendices/Appendix%20D%20Potential%20Candidates_3.pdf.*

IMS is a modular organizational structure that can be used in small- and large-scale emergency situations. All directives, information, and requests flow up or down the hierarchical structure through a chain of command. Using this structure, organizations identify problems and develop and coordinate plans of action by delegated positions (CEMSA, 2014; DeAtley, 2010). Each position in the IMS structure has an accompanying job action, accountabilities, and a set of tasks and responsibilities that must be fulfilled. Typically, the role of *incident manager* is held by an individual with sound knowledge of the organization and of disaster management processes. The incident manager is in charge of the mission, directs response processes, and monitors and oversees deviations from the EOP. The incident manager appoints other command staff and establishes the emergency operations centre, which serves as the control point for disaster oversight (DeAtley, 2010; Gebbie & Qureshi, 2013).

IMS command roles are filled by individuals possessing knowledge of the tasks required to successfully address the emergency situation and include the following: (1) a *public information officer,* who is responsible for coordinating and overseeing public affairs. This includes providing information to the public and media, helping to create media releases, coordinating interviews and media tours, and developing question-and-answer sheets or other resources required; (2) a *safety officer,* whose role is to ensure the safety of staff, patients, visitors, and the facility during the emergency operation; (3) a *liaison officer,* who serves as a link to external agencies and emergency response services, and (4) a *medical–technical specialist,* who possesses the specific knowledge required (e.g., legal affairs, risk management, ethics, infectious diseases) to guide decision making and response actions (CEMSA, 2014; DeAtley, 2010).

Additional positions in the IMS structure include (1) a *logistics section chief,* who ensures that resources—including staff, fuel, and services to support staff (equipment, supplies, and food)—are available as needed; (2) a *finance section chief,* whose role is to monitor financial assets used; (3) a *planning section chief,* who is accountable for gathering information (data and research) and assisting with planning decisions; and (4) an *operations section chief,* who directs patient care activities and is responsible for work direction of staff at the scene of the incident (CEMSA, 2014; DeAtley, 2010; Gebbie & Qureshi, 2013). Unit-specific supervisors oversee activities at the ground or unit level and are required to report progress and difficulties in emergency response activities to people in the IMS structure if and when these arise.

Triage.

Triage involves the sorting or ranking of casualties to prioritize health care needs and to allocate resources. It is a process that ensures "the right patient is in the right place, at the right time, so he/she may receive the right level of care" (Rice & Abel, 1992, p. 67). The Canadian Triage and Acuity Scale (CTAS) is used in emergency departments (EDs) in nonemergency or nondisaster situations (see Chapter 71, Table 71-2). Using this five-level scale, care providers assign high priority to those who are most critically ill, according to the seriousness of their condition, reported signs, and symptoms (CAEP, 2016; Bullard, Chan, Brayman, et al., 2014). Daily ED triage is described with greater detail in Chapter 71.

Triage in Disaster Situations.

Effective and timely prehospital triage is pivotal to human survival, helping to ensure equitable distribution of patients to appropriate services and facilities through the health system. Although several mass casualty triage systems exist, one of the more common types, *simple triage and rapid treatment* (START), offers a systematic approach to triage that may be used to rank the seriousness of casualty injuries in a mass casualty incident (MCI) (Table 72-2). MCIs can be as simple as an overturned bus with five passengers or as severe as a collapsed building, a terrorist explosion, or a chemical or biological event (Critical Illness and Trauma Foundation [CITF], 2001). This process, used at the disaster scene by first responders, involves rapid assessment and sorting of casualties by a *triage officer.* The START system is based on five clinical observations: (1) the person's ability to ambulate; (2) the presence of spontaneous breathing; (3) the respiratory rate (greater or less than 30 breaths per min); (4) perfusion and circulation (i.e., palpable radial pulse or visible capillary refill rate); and (5) mental status (as assessed by an ability to obey commands) (U.S. Department of Health and Human Services [USDHHS], 2016a). These parameters are referred to as *RPM* (respirations, perfusion, and mental status) (CITF, 2001; Romig, 2013).

TABLE 72-2
SIMPLE TRIAGE AND RAPID TREATMENT (START)

START Category/Triage Tag Colour	Type of Injury	Patient Condition and Examples of Presenting Features	Clinical Indicators
Green "MINOR"	MINOR injuries Walking wounded; minor injuries	Sprains Lacerations	Able to ambulate
Yellow "DELAYED"	DELAYED Transport can be delayed; non–life-threatening	Open fractures Soft tissue wounds	Respiration rate: <30 breaths/min Perfusion: <2 sec Mental status: Follows commands
Red "IMMEDIATE"	Unstable; immediate transport needed; life-threatening, requiring immediate intervention	Shock Airway obstruction Unstable wounds	Respiration rate: >30 breaths/min Perfusion: capillary refill >2 sec Mental status: Does not follow commands
Black "EXPECTANT"	Deceased or expected to die owing to injuries	Massive head trauma Profound shock with multiple injuries	Respirations/spontaneous breathing: not breathing/apnea

Retrieved from *http://www.remm.nlm.gov/startadult.htm;* and Critical Illness and Trauma Foundation (CITF). (2001). START Simple triage and rapid treatment. Retrieved from *http://citmt.org/Start/default.htm.*

Triage is followed by tagging and transportation to a medical facility or the provision of lifesaving interventions (e.g., intubation, defibrillation) by members of the first-response team. *Patient tagging* involves a system of coloured tags (see Figure 72-3) that are used to designate both the seriousness of the injury and the likelihood of survival (Romig, 2013; USDHHS, 2016a; CITF, 2001). A green tag using the START approach indicates a *minor* injury (i.e., walking wounded: sprains, lacerations), and is used for patients who may be able to assist with their own care. A yellow tag indicates a non–life-threatening injury where transport can be delayed (e.g., open fractures, soft tissue wounds). A red tag is used to indicate a life-threatening injury requiring immediate intervention (e.g., shock, airway obstruction, unstable wounds). These patients require immediate intervention and transport for survival. A black tag is used to identify those casualties who are deceased or who are unlikely to survive as a result of their injuries (e.g., profound shock with multiple injuries) (Markenson, 2013; Romig, 2013; USDHHS, 2016a). Triage of children, or

people who look like children, is done using the *JumpSTART* framework, which addresses the physiological differences between children and adults (USDHHS, 2016b; Romig, 2008).

Disaster Triage in the Hospital Setting.

Triage of casualties in a disaster situation differs from routine emergency triage processes. Disaster response is dependent on the size of the organization, the number of staff and amount of resources available, and past experience in dealing with large-scale events. All health care organizations must be able to implement disaster triage with minimal notice (Romig, 2013).

When an emergency occurs in the community, hospitals are typically notified by emergency medical services in the field, and the facility prepares for a potential influx of patients. This preparation includes gathering necessary equipment, including first-aid supplies, PPE, and medications (e.g., analgesics, antidotes). As patients are triaged, they are given a pre-assigned medical record number, allowing care to be provided

immediately, without formal registration (Romig, 2013). Disaster charts should include a prestamped triage slip, a patient identification band with medical identification number, medical and nursing documentation forms, and laboratory and radiographic examination requisitions and labels. Chart numbers should be entered onto a log so patient allocation and destination can be tracked (Romig, 2013).

As patients enter the ED, they are greeted by a triage team. In mass-casualty incidents, several triage teams may be used, usually consisting of one to two experienced triage nurses, a physician (the triage officer), a porter (who assists with patient transportation), and a registration clerk (who assists with patient banding and data entry on the tracking form) (Romig, 2013). Disaster triage in the hospital setting must be rapid and should be conducted in less than 15 seconds per patient. Following this rapid assessment, patients assigned with higher levels of acuity are directed to a treatment location in the ED. In situations in which patient volume is high and ED space is limited, another predesignated area of the facility to accommodate surge may be used for the care of less-acute casualties.

Recovery and Rehabilitation

Recovery and rehabilitation takes place in the post-incident phase of the disaster management continuum (WHO & ICN, 2009) and is the process through which staff, an organization, or a community regains the ability to function after a disaster. Services have typically been disrupted during the disaster response, and the goal is to return to a state of "normal." This includes the restoration of vital services normally provided by an organization, within a community, or by local government, rebuilding infrastructure and meeting the needs of the population served (WHO & ICN, 2009; Markenson, 2013). Nurses are critical in the recovery and rehabilitation phase and in re-establishing health care infrastructure and must consider the psychosocial impact of a disaster on its survivors. Nursing functions related to the care and coordination of health care services, case management, identification, and implementation of casualty referrals (e.g., social services) are essential for return to normal activities. Nurses play a key role in the documentation, review, and evaluation of the disaster response as well as in championing changes to EOPs and to corporate, municipal, and provincial or territorial policy (WHO & ICN, 2009).

Critical Incident Stress Management.

The massive effort put forth by health care workers in response to a catastrophic event is critical to a community's recovery. Health care workers, who are already at risk of experiencing high levels of stress and burnout, are at increased risk following participation in a disaster event (Public Health Agency of Canada [PHAC], 2011). A critical incident is a situation faced by individuals involved in a disaster that causes them to experience strong emotional reactions that have the potential to interfere with their ability to return to a normal state of functioning at work and at home during or after the event (McMahon, 2010; PHAC, 2011). Multiple deaths; inadvertent exposure to hazardous materials; exposure to shocking sights, sounds, or smells; and incidents with high media coverage are examples of critical incidents. Challenging triage decisions, the volume of seriously injured people, limited resources, ethical issues that accompany disasters, concern for personal safety and liability, lack of sleep, heavy workload, time pressures and unmet basic needs, and political and organizational pressures also significantly contribute to the stress and an individual's resilience in the aftermath of a disaster event (Coyne-Plum & Meeker, 2013; McMahon, 2010; PHAC, 2011).

All disasters have the potential to cause psychological stress to the individuals involved. This stress can persist for an extended period and is influenced in part by the nature of the event and the individual's age, pre-existing coping mechanisms, role in the event, and prior medical and psychological history (Coyne-Plum & Meeker, 2013). Although the psychological trauma that results from involvement in a critical incident varies, common symptoms range from insomnia to excessive sleeping, from loss of appetite to overeating, and a loss of interest in activities normally considered pleasurable (PHAC, 2011). Post-traumatic stress disorder (PTSD) is a response to a specific, identifiable stressor that severely affects an individual's ability to function at a normal level. The diagnosis is given to individuals who have experienced or witnessed situations involving death or serious injury or a threat to self or others. PTSD can result in the development of symptoms in the first few weeks or months, or up to years following an event, that include avoidance, numbing, or the individual re-experiencing the event, causing significant impairment in function (McMahon, 2010; Coyne-Plum & Meeker, 2013). PTSD requires ongoing psychological counselling, psychiatric support, or both.

Critical incident stress management (CISM) or debriefing is a comprehensive approach to preventing and managing the emotional

trauma that can be a result of involvement in a disaster response. Strategies may include pre-incident education; individual crisis intervention and on-the-scene support; defusing and debriefing sessions; support services for families and children; and follow-up professional intervention (Meeker, Coyne-Plum, & Veenema, 2013; McMahon, 2010). Debriefing occurs as a part of the incident review within the first 24 to 72 hours, particularly among police officers, firefighters, and medical teams. *Defusing sessions* occur within a few hours of the incident and may be offered as a group discussion prior to staff going off duty. This process involves brief discussion of the incident and assistance with stress management (Meeker, Coyne-Plum, & Veenema, 2013).

The Role of Nursing Leadership in Disaster Preparedness and Response

Leadership at all levels is essential for a positive outcome after a disaster event. However, nurses who hold formal leadership roles have extended responsibilities to ensure the delivery of safe care at all stages of the disaster management continuum. Leadership in times of disaster involves recognition of the uncertainty created during the response and requires open, consistent communication, flexibility, and creative problem solving (Druce, 2009). Clear communication of expectations and goals, and a commitment to cause with an expectation of success, is an antecedent to a positive outcome. Nursing leadership plays a role in advocating for individual and community needs and services in the recovery and rehabilitation stage and ensuring that staff have the emotional support needed (WHO & ICN, 2009; Druce, 2009). At the executive level, nurse leaders play a key role in ensuring organizations are prepared for response; providing oversight for recovery processes; creating safe work environments; influencing policy and financial decisions; and ensuring that needed resources and supports are available and accessible before, during, and following a disaster event (Fahlgren & Drenkard, 2002).

Natural and Human-Made or Induced Disasters

A *disaster* can be defined in numerous ways, but the term is generally interpreted to mean a destructive event that disrupts the normal functioning of a community. There are two general classifications of disasters: *natural disaster* and *human-made or human-induced disasters.* Disease outbreaks and epidemics are usually considered to be "natural" events, but they can also be classified as "human-made" disasters when disease-causing organisms are used as an agent of terrorism with the goal of inducing large-scale epidemics. Because of these variations, disease outbreaks and epidemics are described in a separate section of this chapter. Table 72-3 presents a timeline of notable disasters in Canadian history.

TABLE 72-3
BEST-KNOWN CANADIAN DISASTERS

Year	Disaster and Place	Approximate # of Fatalities	Injured/Infected	Evacuated
1862	Smallpox epidemic (nationwide)	20 000		0
1885	Smallpox epidemic, Montreal, Quebec	6 000	9 600	0
1903	Rock slide in town of Frank (Frank Slide), Turtle Mountain, Alberta	70	23	0
1910	Avalanche, Rogers Pass, Bear Creek, British Columbia	62	0	0
1912	Tornado, Regina, Saskatchewan	28	100	2 500
1917	Harbour explosion, Halifax, Nova Scotia	2 000	9 000	6 000
1918	Spanish influenza pandemic (Spanish flu) across Canada	50 000	2 000 000	0
1922	Wildfire, Timiskaming District, Ontario	43	0	11 000
1942	Building fire, Knights of Columbus hostel, St. John's, Newfoundland	100	100	0
1954	Hurricane Hazel, Ontario	81	0	7 472
1958	Mining accident, Springhill, Nova Scotia	75	99	0
1971	Landslide, St-Jean-Vianney, Quebec	31	99	1 500
1974	Airplane crash, Rea Point, Northwest Territories	32	0	0
1978	Soviet satellite, COSMOS 954, came down in the Northwest Territories, scattering 65 kg of radioactive material over a wide area	0	0	0
1985	Airplane crash, Gander, Newfoundland	256	0	0
1986	Train derailment, Hinton, Alberta	23	71	0
1987	Tornado, Edmonton, Alberta	27	600	1 700
1992	Westray mining accident, Plymouth, Nova Scotia	26	0	0
1996	Floods, Saguenay, Quebec	10	0	15 825
1997	Bus crash, St. Joseph de la Rive, Quebec	43	0	0
1998	Plane crash, Peggy's Cove, Nova Scotia	230	0	0
1998	Ice storm, Eastern Ontario, Quebec, Maritimes	35	0	0
2000	Contaminated water, Walkerton, Ontario	7	2 300	0
2000	Tornado, Pine Lake, Alberta	12	140	1 000
2003	Severe acute respiratory syndrome (SARS), Toronto, Ontario	44	375	0
2005	Legionnaire's disease outbreak, Toronto, Ontario	23	112	0
2008	Listeriosis outbreak across Canada	22	57	0
2009–2010	New strain of pandemic influenza	425	8 582	0
2010	Hurricane Igor, Cape Race, Newfoundland	1	0	300
2011	Slave Lake Wildfire, Slave Lake, Alberta	1	0	12 055
2011	First Air Flight 6560 crash near Resolute Bay, Nunavut	12	0	3
2012	Wildfire, Timmins, Ontario	0	0	1 000
2012	Legionnaire's disease epidemic, Quebec, Quebec	13	180	0
2012	Train derailment, Burlington, Ontario	3	45	0
2013	Alberta floods, Calgary, Alberta	4	0	100 000
2013	Rail disaster, Lac-Mégantic, Quebec	47	0	2 000
2014	Nursing home fire, near L'Isle-Verte, Quebec	32	15	0
2014	Terrorist shooting, Ottawa, Ontario	2	0	0
2014	Wildfire due to heatwave, British Columbia	0	0	4 500
2016	School shooting, La Loche, Saskatchewan	4	0	0
2016	Forest fire, Fort McMurray, Alberta	0	0	90 000
2017	Quebec City, Mosque shooting	6	19	0

Natural Disasters

Due to its size and geographical location, our country poses a host of threats. Its landforms and variation in weather patterns makes severe weather and the threat of natural hazards a significant reality for Canadians. *Natural disasters* are caused by nature or the environment, are often unpredictable, and can happen at a rapid or slow rate. Natural disasters include extreme natural events such as forest fires, avalanches, landslides, storm surges, cold or heat waves, hurricanes, tsunamis, floods, drought, earthquakes, and volcanic eruptions (PSC, 2015a). Human-caused damage to the environment and the resultant climate change has also altered the intensity, pattern, and distribution of natural forces, contributing to an increase in the number of natural disasters (Veenema & Landesman, 2013).

Human-Made or Human-Induced Disasters

Human-made, also referred to as *human-induced disasters,* can be accidental or deliberate and can cause injuries, deaths, and long-term consequences for individuals and communities. *Accidental human-made disasters* include industrial accidents, chemical spills, inadvertent release of nuclear energy, explosions (e.g., from hazardous materials such as chemicals, nuclear materials, fuel), contamination, fires, structural collapse, large transportation accidents, and power outages. *Deliberate human-made disasters* include warfare, civil unrest, and acts of terrorism. Computer viruses or cyber-attacks are classified as human-made disasters because of their cost and potential impact on critical infrastructure.

Natural and human-made disasters can trigger one another, with both having the ability to elicit secondary disasters. These events, referred to as *synergistic disasters*, often occur simultaneously. As an example, an earthquake causes an explosion at a nuclear plant, requiring large-scale evacuation and causing illness and population displacement. The synergistic effects are exacerbated by death and devastation created by each event (Veenema & Woolsey, 2013).

Terrorism.

September 11, 2001, marks a tragic day of death and destruction, when two of four hijacked planes crashed into the Twin Towers in New York City, the others crashing into the Pentagon in Washington, DC, and a field near Shanksville, Pennsylvania. More recently, terrorist attacks across several public sites in Paris, France, (2015) and in a nightclub in Orlando, Florida, (2016) further illustrate the far-reaching impact of terrorism and the critical need for emergency planning.

Terrorism involves intentional and overt actions that are committed to cause fear, panic, destruction, injury, and death in service of political, religious, or ideological goals. The intent of a terrorist event is to intimidate the public or to compel a specific person, government, or international organization to take specific action. Terrorist events include threats, assassinations, kidnappings, hijackings, bomb scares and bombings, and computer cyber-attacks. The use of chemical or biological agents as the element of a terrorist attack is referred to as *chemical terrorism* or **bioterrorism**, respectively (Croddy & Ackerman, 2013). In both cases, the terms refer to a type of terrorist event involving the deliberate spreading of microbes or chemical toxins with the intent of causing disease or death in animals, plants, or humans (Croddy & Ackerman, 2013). Plans for dealing with each type of event, coupled with advanced training exercises and availability of necessary protective personal equipment, are essential to a safe, expedient response.

Chemical–Biological–Radiological–Nuclear–Explosive Events.

A *CBRN event* refers to any situation in which weapons of a *chemical, biological, radiological,* or *nuclear* nature are used with the goal of causing harm. A CBRN event can also be the result of a civilian or military accident. More recently, the term **CBRNE event** has been used, with "E" representing situations in which an *explosive or incendiary device* is used. *Weapons of mass destruction* refers to a broad range of weapons that have the potential to affect the health and the well-being of a large population.

Under ideal circumstances, decontamination following a CBRNE event will occur in the field, prior to the casualties' arrival to hospital. A response in the field may not occur when exposure is a result of a terrorist event as casualties are likely to flee the site, not knowing they have been contaminated, and pose a risk to others. People may arrive at health care facilities in large or small numbers and without advanced notice or may delay seeking treatment until they become symptomatic or once public information has been shared about potential exposure (Crowe, 2010; Holland & Cawthon, 2015). Consequently, CBRNE events have significant

implications for the health and safety of those who come into contact with casualties and, to ensure public safety, health care staff should assume, until it has been proven otherwise, that all individuals presenting to hospital have *not* undergone adequate decontamination (Koenig, Boatright, Hancock, et al., 2008; Veenema, 2013b). Hospitals must have plans in place to address CBRNE exposure, which requires advanced planning and input from nurses, physicians, medical toxicologists, hazardous materials (HAZMAT) teams, and health and safety team members (Moore, Geller, & Clark, 2015). The use of evidence-informed protocols and systems for triage and decontamination, combined with the application of appropriate PPE, is essential for safe response, not only for first responders in the field but also for health care workers in hospital settings (Veenema, 2013b; Holland & Cawthon, 2015). Despite significant focus over the last decade on emergency planning and preparation, there is still broad discomfort across the health care sector with addressing and responding to these types of events (Moore, Geller, & Clark, 2015).

Early identification, diagnosis, and treatment of people exposed to CBRNE substances is essential to preventing secondary injury and avoiding contamination of the public, staff, and the health care facility (Croddy & Ackerman, 2013; Rihl-Pryor, 2013), requiring people to be decontaminated *before* medical care or surgical intervention is provided. **Decontamination** is the process of removing or neutralizing a hazardous agent from the environment, property, equipment, or a life form, through the use of water, cleansers, or neutralizers (Veenema, 2013b; Moore, Geller, & Clark, 2015). Decontamination accomplishes the following: (1) decreases absorption and toxicity of the agent; (2) reduces contamination of other people and equipment by substances on casualties' bodies, clothing, or belongings; and (3) prevents potential closure of a health care organization where people who have been contaminated may seek care (Koenig et al., 2008). The degree of casualty contamination is affected by four factors: (1) the contact time with the agent; (2) the concentration of the agent; (3) temperature, which affects the agent's permeative characteristics; and (4) the physical state of the agents (i.e., liquids, solids, vapours) (Koenig et al., 2008).

For a safe response in the hospital setting, it is necessary to have decontamination teams and advanced preparation for activation of a decontamination area complete with showers, scrubbing instruments, and ventilation (Moore, Geller, & Clark, 2015; Holland & Cawthon, 2015). Decontamination is a multidisciplinary strategy that includes participation from a team of trained and prepared nursing and physician staff, security

and housekeeping, engineering and occupational health and safety members, and porters. Participation in casualty decontamination requires significant education and training before a potential event on the application and use of PPE, activation of decontamination equipment (showers, tents, etc.), setup of operation zones, and decontamination and scrubbing processes, through regular, full-scale hospital drills (Koenig et al., 2008; Moore, Geller, & Clark, 2015). Hospitals are to ensure they have adequate amounts of antidotes, adequate numbers of showers and decontamination tents, appropriate availability of PPE, and staff trained to participate in response (Veenema, 2013b). Triage will require, when possible, identification of the contaminant and an assessment of the degree of contamination and casualty distress. Information about the event and the casualties is to be provided on an ongoing basis to the Incident Command Centre, which will oversee operations and decision making for response efforts.

Casualties should be segregated from other patient populations until appropriate decontamination takes place, and security must be in place to prevent inadvertent contamination (Holland & Cawthon, 2015). Similar to decontamination in the field, decontamination in hospital settings requires activation of *Operation or Decontamination Zones.* Typically, these zones are created through the use of barricades to determine points of entry from one area to the next. Crowd control, safety, and security are of primary concern—first responders, health care workers, and other patients who have physical contact with contaminated casualties, their belongings, or both without appropriate protection may also require decontamination (Koenig et al., 2008; Holland & Cawthon, 2015). Lockdown of entry points to a health care facility, with the exception of a designated access point for those who require decontamination, is one strategy to prevent inadvertent exposure of patients and staff to the contaminant (Markenson, 2013).

Three operation zones—*hot, warm, and cold*—support triage and decontamination activities. The *hot zone* is the area farthest from hospital entry and requires all responders to don full PPE. Minimal triage is provided in this area and is limited to life-saving measures and administration of antidotes. The *warm zone* is typically adjacent to the ED and is the location where staff in full PPE provide decontamination of casualties (Veenema, 2013b). Nonambulatory patients will be scrubbed by staff through the use of hoses, trailers, or tents, using conveyor belts and trolley systems, whereas ambulatory patients will be directed to remove contaminated clothing and then assist with personal scrubbing and decontamination, using hoses and warm showers. Patients with the most

severe symptoms receive priority for decontamination. The *cold zone* is the treatment location adjacent to the warm zone and is the location where patients, once decontaminated, enter. All staff who have worked in hot or warm zones also require decontamination prior to entering the cold zone. A more thorough triage occurs in the cold zone, following which people are directed to treatment areas (Veenema, 2013b).

The health and safety of health care providers is essential in a CBRNE event. A combination of respirators and protective gear (goggles, boots, full-facepiece respirators, protective suits, chemically resistant gloves) must be used (Holland & Cawthon, 2015; Veenema, 2013b). Because of the equipment that is required to be worn, workers must undergo medical screening or surveillance (including a full set of vital signs) before donning and after removing protective gear. Staff also need to be monitored by a designated surveyor while involved in the decontamination process (Koenig et al., 2008). Staff who have higher-than-normal blood pressure; rashes, open sores, or wounds; a previous history of nausea, vomiting, or diarrhea; an upper respiratory infection or history of respiratory illness (e.g., asthma); allergies; sensitivities or phobias (e.g., claustrophobia); or who are potentially or known to be pregnant may not participate in the decontamination process. Time in decontamination gear is usually limited to 30 minutes or less because extreme heat, poor ventilation, and the heavy weight of the suit cause fatigue and other common adverse effects (Veenema, 2013b). These risks also make it necessary to monitor hydration status before and after protective gear is donned.

Biological Agents of Terrorism.

Biological terrorism involves the deliberate use of microbial pathogens or toxins, the effects of which may not be known until many hours or days after exposure. Terrorist attacks using biological agents represent challenges for health care providers because they can be difficult to detect and can have a prolonged impact on health care facilities. Contaminants can range from accidental releases of biohazardous waste to intentional exposure from bioweapons (Koenig et al., 2008; Rihl-Pryor, 2013). People exposed in a bioterrorist attack typically do not require decontamination (the exception being exposure to anthrax spores), and most agents are noncontagious (Croddy & Ackerman, 2013). Hospitals should have access to a variety of antidotes for biological agents and should have plans that include means for urgent acquisition of antidotes from other sources (Moore, Geller, & Clark, 2015). Table 72-4 summarizes general information regarding biological agents of terrorism. The pathogens most likely to be

used as biological weapons include anthrax, smallpox, botulism, plague, tularemia, and hemorrhagic fever. Anthrax, plague, and tularemia can be treated effectively with antibiotics if the organisms are not resistant and if there is an available and sufficient quantity of the appropriate drug. Smallpox can be prevented or ameliorated by vaccination, even if it is first given after initial exposure. Botulism can be treated with antitoxin. In most cases, supportive treatment is the primary mode of care for viruses that cause hemorrhagic fever (Centers for Disease Control and Prevention [CDC], 2013a).

TABLE 72-4
BIOLOGICAL AGENTS OF TERRORISM

Pathogen and Description	Clinical Manifestations	Transmissibility	Treatment
Anthrax (Bacillus anthracis)			
Inhalation			
• Bacterial spores multiply in the alveoli • High mortality rate • Toxins cause hemorrhage and destruction of lung tissue	• Incubation period: 1–7 days; can be delayed up to 60 days (2 months) • Abrupt onset • Dyspnea • Diaphoresis • Fever • Cough • Chest pain • Septicemia • Shock • Meningitis • Respiratory failure • Widened mediastinum (seen on chest radiograph)	• No person-to-person spread • Found in nature; most commonly infects wild and domestic hoofed animals • Spread through direct contact with bacterium and its spores • Spores are dormant, encapsulated bacteria that become active when they enter a living host	• Antibiotics prevent systemic manifestations • Effective only if treated early • Ciprofloxacin (Cipro) is the treatment of choice • Penicillin • Doxycycline • Post-exposure prophylaxis for 30 days (if vaccine available) or 60 days (if vaccine not available) • Vaccine has limited availability
Cutaneous			
• 95% of anthrax infections • Least lethal form • Spores enter skin through cuts or abrasions • Handling of contaminated animal skin products • Toxins destroy surrounding tissue	• Incubation period: 2–6 days • Small papule resembles an insect bite • Advances to a depressed, black ulcer • Swollen lymph nodes in adjacent areas • Edema	—	—
Gastro-Intestinal			
• Ingestion of contaminated, undercooked meat • Intestinal lesions in ileum or cecum • Acute inflammation of intestines	• Abdominal pain • Anorexia • Ascites • Diarrhea • Hematemesis • Incubation period: 3–7 days • Nausea • Sepsis • Vomiting	—	—
Smallpox (Variola Major and Minor Viruses)			

Pathogen and Description	Clinical Manifestations	Transmissibility	Treatment
• Canada ended routine vaccination in 1972 • Global eradication declared in 1980	• Incubation period: 7–17 days • Sudden onset of symptoms • Fever • Headache • Myalgia • Lesions that progress from macules to papules to pustular vesicles • Malaise • Back pain	• Direct person-to-person spread • Highly contagious • Transmitted by handling contaminated materials • Transmitted in air droplets	• Cidofovir (Vistide) under testing • Isolation for containment • No known cure • Vaccine available for those exposed • Vaccinia immune globulin (VIG) available
Botulism *(Clostridium botulinum)*			
• Spore-forming anaerobe • Found in soil • Seven different toxins • Lethal bacterial neurotoxin • Can die within 24 hr	• Incubation period: 12–36 hr • Abdominal cramps • Diarrhea • Nausea • Vomiting • Cranial nerve palsies (diplopia, dysarthria, dysphonia, dysphagia) • Skeletal muscle paralysis • Respiratory failure	• Spread through air or food • No person-to-person spread • Improperly canned foods • Contaminated wound	• Induce vomiting • Enemas • Antitoxin • Mechanical ventilation • Penicillin • No vaccine available • Toxin can be inactivated by heating food or drink to 100°C for at least 10 min
Plague *(Yersinia pestis)*			
• Bacteria found in rodents and fleas ***Forms*** • Bubonic (most common) • Pneumonic • Septicemic (most deadly)	• Incubation period: 2–4 days • Hemoptysis • Cough • High fever • Chills • Myalgia • Headache • Respiratory failure • Lymph node swelling	• Direct person-to-person spread • Transmitted through flea bites • Ingestion of contaminated meat	• Antibiotics only effective if administered immediately • Drug of choice: streptomycin or gentamicin • Vaccine under development • Hospitalization • Isolation for containment
Tularemia *(Francisella tularensis)*			
• Bacterial infectious disease of animals • Mortality rate about 35% without treatment	• Incubation period: 3–10 days • Sudden onset • Fever • Swollen lymph nodes • Fatigue • Sore throat • Weight loss • Pneumonia • Pleural effusion • Ulcerated sore from tick bite	• No person-to-person spread • Aerosol or intradermal route • Spread by rabbits and ticks • Contaminated food, air, water	• Gentamicin treatment of choice • Streptomycin, doxycycline, and ciprofloxacin are alternatives • Vaccine in developmental stage
Hemorrhagic Fever			

Pathogen and Description	Clinical Manifestations	Transmissibility	Treatment
• Caused by several viruses, including Marburg, Ebola, Lassa fever, yellow fever, and Rift Valley fever	• Fever • Conjunctivitis • Headache • Malaise • Prostration • Hemorrhage of tissues and organs • Nausea • Vomiting • Hypotension • Organ failure	• Carried by rodents and mosquitoes • Direct person-to-person spread by body fluids • Virus can be aerosolized	• No intramuscular injections • No anticoagulants • Isolation for containment • Ribavirin (Virazole) effective in some cases • Supportive treatment only, for most • Vaccine available for yellow fever only

Source: Adapted from Lewis, S. L., Heitkemper, M. M., Dirksen, S. R., et al. (2011). *Medical-surgical nursing: Assessment and management of clinical problems* (8th ed., Table 69-12). St. Louis: Mosby.

Chemical Agents of Terrorism.

Typically, a chemical event is overt, with a sudden onset in a localized area, and has potential for vast spread, making rapid containment and decontamination essential (Rihl-Pryor, 2013; Koenig et al., 2008). Chemically exposed individuals are more likely to seek care in large numbers and to have early, external evidence of contamination (Powers, 2010). These events are most likely to cause significant limitations of health care personnel, time, equipment, and space and have potential to cause major disruptions in clinical care due to their rarity and the psychological impact on both casualties and responders (Croddy & Ackerman, 2013; Moore, Geller, & Clark, 2015).

Certain chemicals may be used as agents of terrorism because their toxic properties produce significant physiological and psychological effects. Chemical agents are categorized according to their target organ or effect (Andress, 2010b). For example, sarin, a highly toxic nerve gas that enters the body through the eyes and the skin, acts by paralyzing the respiratory muscles, potentially causing death within minutes of exposure. Phosgene, a colourless gas normally used in chemical manufacturing, can cause severe respiratory distress, pulmonary edema, and death when it is inhaled at high concentrations for a long enough time (Andress, 2010b). Mustard gas, an agent used during World War I, is yellow to brown in colour and has a garlic-like odour and acts by irritating the eyes and causing skin burns and blisters. Protocols to treat people with chemical exposure are varied but are specific for the causative agent (Croddy & Ackerman, 2013). Table 72-5 details the effects chemical agents have on various human organs.

TABLE 72-5

CHEMICAL AGENTS OF TERRORISM BY TARGET ORGAN OR EFFECT

Nerve	Blood	Pulmonary	Blister or Vesicants
• Sarin (isopropyl methylphosphonofluoridate) • Tabun (ethyl *N,N*-dimethylphosphoramidocyanidate) • Soman (pinacolyl methylphosphonofluoridate) • GF (cyclohexylmethylphosphonofluoridate) • VX (O-ethyl S-[2-diisopropylaminoethyl]methylphosphonothiolate)	• Hydrogen cyanide • Cyanogen chloride	• Phosgene • Chlorine • Vinyl chloride	• Nitrogen and sulphur mustards • Lewisite (an aliphatic arsenic compound, 2-chlorovinyldichloroarsine) • Phosgene oxime

Radiological and Nuclear Agents of Terrorism.

Radiological and nuclear substances can also be categorized as agents of terrorism. Radiological dispersal devices (RDDs), or "dirty bombs," consists of chemical explosives mixed with radioactivity (Karam, 2013). When an RDD is detonated, the blast is likely to lead to widespread radioactive contamination through dispersed dust, smoke, and other material into the surrounding environment (CDC, 2013b). Uranium and iodine-131, the radioactive materials used in RDDs, typically generate only enough radiation to cause immediate serious illness to those in close proximity to the explosion. Health care personnel will confront large volumes of patients, some with high levels of radioactivity contamination and many others with high levels of anxiety without presenting illness from exposure (Karam, 2013). The main danger of an RDD results from the explosion itself, with those patients suffering traumatic injury combined with significant exposure to radiation having substantially worse prognosis (Karam, 2013). Because radiation cannot be seen, has no scent, and is unable to be felt or tasted, measures to limit contamination, like covering the patient's nose and mouth and prompt decontamination (e.g., through the use of a decontamination shower), are best initiated in a timely manner (CDC, 2013b). Ionizing radiation, which comes from a nuclear bomb or damage to a nuclear reactor, represents a serious threat to the health and safety of casualties and the environment. Although exposure to ionizing radiation may or may not include skin contamination, decontamination procedures should be initiated immediately in circumstances in which radioactive contaminants are present (Andress, 2010b).

Explosive Agents of Terrorism.

MCIs involving explosives have occurred globally, with the most known examples being in London, Madrid, Oklahoma City, Brussels, Burkina Faso, and Mogadishu. Compared to other events, injuries that are a result of terrorist attacks with explosives typically involve younger civilian casualties, with critical severity, requiring longer hospitalization and surgical interventions, and result in higher mortality rates (Sacco, 2013). Whether the result of an accident or terrorist event, the use of explosion devices (TNT, dynamite) in acts of terrorism results in blunt, crush, penetrating, and burn injuries as well as injuries from the blast itself (Sacco, 2013). *Blast injuries* occur from the supersonic overpressurization shock wave that results from the explosion, having the potential to cause mass injury to multiple body systems (Plurad, 2011). This shock wave primarily causes damage to the lungs, gastro-intestinal tract, and middle ear; the injuries are the result of casualties being blown by the blast wind against objects and structures. *Crush injuries* (i.e., blunt trauma) often ensue from explosions that occur in confined spaces and result from structural collapse (e.g., falling debris). Some explosive devices contain materials that are projected during the explosion (e.g., shrapnel), leading to *penetrating injuries* (Plurad, 2011).

Epidemics and Pandemics

Nurses are required to have an understanding of the etiology and impact of communicable disease, whether a consequence of a natural disaster (e.g., contaminated water during flooding) or a result of a deliberate act (e.g., bioterrorism) (CNA, 2012). Morbidity, mortality, and disruption from an infectious disease epidemic overwhelm a community and its infrastructure. Lessons learned as a result of SARS (2003) and the H1N1 (2009) infectious disease outbreaks highlight the enormous toll on individuals, communities, and health care workers and the need for advanced planning.

Communicable diseases may occur in an individual or a group of individuals. The term *outbreak* refers to an illness occurring amongst a cluster of individuals. When the number of cases of a communicable disease exceeds the normal expected occurrence during a given period, it is referred to as an **epidemic.** If transmission of the disease is widespread and affects large numbers of people across several countries or continents or globally, it is considered to be a **pandemic** (Slepski, 2010). The investigation and management of an outbreak requires recognition; investigation of the source, mode of transmission, and risk factors for infection; and implementation of appropriate control measures (Veenema & Woolsey, 2013).

Severe Acute Respiratory Syndrome

Severe acute respiratory syndrome, also known as *SARS,* refers to an outbreak that occurred primarily in Canada and Asia in 2003. SARS is a contagious, severe, febrile respiratory illness caused by a coronavirus and characterized by a fever of 38°C or higher; myalgia; headache; malaise; chills; a dry, nonproductive cough; and shortness of breath (Farquharson & Baguley, 2003). The illness is spread through close contact with someone who is infected with the virus, such as those living in the same household, providing unprotected care to someone with SARS, or having direct contact with respiratory secretions of someone affected by SARS.

The SARS outbreak was a critical juncture in Canadian emergency management because it demonstrated the tremendous impact a communicable disease outbreak could have on individuals, communities, and the economy (PSC, 2015e). SARS cost billions of dollars across Asia and Canada as a result of its impact on health care, critical infrastructure,

trade, and tourism and served as a wake-up call for health care institutions, governments, and health care providers, highlighting Canada's inadequacies in responding to public health threats. Since 2003, our country has recognized the central role of health care services in disaster mitigation and response, resulting in enhanced planning initiatives. Stockpiles of medications and PPE, and mobile hospital response teams have been put in place in anticipation of future communicable disease outbreaks (Amaratunga, Carter, O'Sullivan, et al., 2008).

Outbreak Management

Studies of the SARS outbreak across numerous countries have provided insight into the need for diligent infection control practices and disease monitoring. The effects of globalization and the ease of air travel have led not only to the "shrinking" of the world but also to the global mobility of people, food, viruses, and bacteria. In the Middle Ages, cities and towns could close their gates and erect high walls to keep out disease; now, our global problems demand a global response. The strategies used to prevent and contain communicable diseases are fundamental, and nurses play an essential role in understanding common outbreak management strategies. This knowledge helps nurses working in acute and chronic care and within community settings to implement containment interventions and to understand how best to protect themselves and their patients.

Outbreak Management Strategies.

Outbreak management refers to the strategies used to prevent the spread of communicable disease among clusters of people. Management of outbreaks within health care facilities begins with recognition of potentially exposed patients by trained staff or through public health notification. Case-finding, early-detection, and treatment strategies not only improve the health of the infected individuals but also prevent transmission to others.

Surveillance is the ongoing and systematic process of gathering, analyzing, and disseminating data on communicable diseases or events to detect changes in trends or distribution of diseases. In the case of disease outbreaks, surveillance processes gather the data that epidemiologists analyze to determine the *who, what, when, where, and why* behind the outbreak (Stanhope, Lancaster, Jessup-Falcioni, et al., 2017). There have been major efforts across our country to develop and strengthen early-

warning mechanisms at local and global levels. The Public Health Agency of Canada (PHAC) operates a number of national surveillance systems on health problems that range from chronic diseases and congenital anomalies to the *Respiratory Virus Detection Surveillance System* and *FluWatch.* These systems are in place to observe and scrutinize changes in the number of febrile and respiratory illnesses across the country. Many communicable diseases are considered to be reportable or notifiable diseases and must be reported to local public health units (PHAC, 2017). Nurses are often involved, both formally and informally, in different levels of the surveillance system, being the first to detect an outbreak through abnormal clusters of illness among populations, for example, in a school setting.

Isolation is an outbreak management strategy that separates infected people from those assumed to be unaffected during a period of the disease's communicability (Figure 72-4). In Toronto, the SARS epidemic demonstrated how rapidly airborne diseases can spread through crowded spaces, EDs, or shared rooms (Varia, Wilson, Sarwal, et al., 2003). Infected individuals may be confined to a hospital room or unit or to their home. There are varying types of isolation, depending on the disease, its route of transmission, and the period of communicability.

FIGURE 72-4 A critical strategy in managing the severe acute respiratory syndrome (SARS) outbreak was screening patients for possible signs of the disease. Source: CP PHOTO/J.P. Moczulski.

Quarantine involves the isolation of people who have been exposed, or potentially exposed, to an infection or contagious disease but who are not yet sick or showing signs of illness. These individuals are assumed to be incubating the disease and may be infectious to other people before they display symptoms. The quarantine period is the longest usual incubation period for the disease (Richter, 2010). During the SARS outbreak, thousands of people, mostly in the Toronto area, were quarantined at home for 10-day periods, the incubation period for SARS (Farquharson & Baguley, 2003). Although most people complied voluntarily during the SARS event, all provinces and territories have public health legislation that enforces compliance with a quarantine order. Owing to circumstances and the number of staff potentially infected with the virus, a special form of quarantine, called *work quarantine,* was used for health care workers during the SARS outbreak. This level of quarantine allowed health care workers who may have been exposed to SARS to continue working as long as they followed certain requirements, including wearing N95 respirators at work and on any public commute; home confinement when not at work; and self-monitoring for temperature and signs and symptoms of SARS.

Pandemic Planning

Pandemic influenza is a highly infectious outbreak of influenza that spreads rapidly around the world, with much more serious consequences than the usual effects of seasonal influenza. There are two primary routes by which the influenza virus exits the respiratory tract of an infected person: (1) expulsion of the virus into the air through sneezing (Figure 72-5), coughing, speaking, or breathing, or through aerosol-generating medical procedures and (2) by direct transfer of respiratory secretions to another person or surface. Coupled with the short incubation period (from 1 to 3 days) and the fact that the virus can be transmitted before an infected person is symptomatic, it is essential that nurses use appropriate infection control techniques to prevent the spread of influenza (see the "Evidence-Informed Practice" box, "Influenza Transmission and the Role of Personal Protective Respiratory Equipment").

Evidence-Informed Practice

Research Highlight

Influenza Transmission and the Role of Personal Protective Respiratory Equipment: An Assessment of the Evidence

The following are the consensus findings of the Expert Panel on Influenza and Personal Protective Respiratory Equipment (PPRE).

Conclusions on the Modes of Influenza Transmission

1. Ballistic-, nasopharyngeal-, tracheo-bronchial–, and alveolar-sized particles are all emitted from the human respiratory tract.
2. Evidence about the relative contributions of the different modes of transmission to the spread of influenza is sparse and inconclusive.
3. There is evidence that influenza is transmitted primarily at short range.
4. There is evidence that influenza can be transmitted via inhalation of tracheo-bronchial– and alveolar-sized particles at short range.

5. There is evidence that deposition of nasopharyngeal-sized particles in the upper respiratory tract can cause infection.
6. There is evidence that contact transmission can occur. The current weight of evidence suggests that transmission of influenza by inhalation is more probable than by indirect contact.
7. The evidence is lacking to determine whether long-range transmission of influenza occurs, but it cannot be ruled out.

Conclusions on Protective Measures Against Influenza Transmission

1. The primary elements of protection against influenza transmission are engineering and administrative controls. When exposure to an infected person is required or unavoidable, PPRE is the final layer of protection.
2. N95 respirators protect against the inhalation of nasopharyngeal-, tracheo-bronchial–, and alveolar-sized particles.
3. Surgical masks worn by an infected person may play a role in the prevention of influenza transmission by reducing the amount of infectious material that is expelled into the environment.
4. Both surgical masks and N95 respirators offer a physical barrier to contact with contaminated hands and ballistic trajectory particles.
5. The efficiency of the filters of surgical masks to block penetration of alveolar- and tracheo-bronchial–sized particles is highly variable. When combined with the inability of these masks to ensure a sealed fit, these factors suggest that surgical masks offer no significant protection against the inhalation of alveolar- and tracheo-bronchial–sized particles.
6. The efficiency of the filters of surgical masks to block penetration of nasopharyngeal-sized particles is unknown. The lack of a sealed fit on a surgical mask will allow for the inhalation of an unknown quantity of nasopharyngeal-sized particles.

Reference for Evidence

Council of Canadian Academies. *Influenza transmission and the role of personal protective respiratory equipment (PPRE): An assessment of the evidence*. Council of Canadian Academies: Ottawa; 2007:5–8 [Retrieved from] http://www.scienceadvice.ca/uploads/eng/assessments%20and%20publications%20and%20news%20releases/flu/(2007-12-19)_influenza_ppre_final_report.pdf.

In June 2009, the beginning of a global influenza pandemic was confirmed as the illness was identified across 74 countries, raising the WHO alert from a "5" (widespread human transmission) to a "6" (pandemic phase) (Slepski, 2010). The impact of pandemic influenza is vast and far-reaching. Owing to this concern and the need for vigilant monitoring of this illness in humans, the WHO monitors the risk as determined by its experts and an analysis of the situation in countries around the world. For further information about the current phase of pandemic influenza alert and a detailed explanation of the phases of pandemic alert, follow the WHO link in the Resources at the end of this chapter.

Faced with the demands of a novel H1N1 pandemic, in recent years, hospitals and communities have shifted much of their focus in emergency planning to pandemic planning. In the hospital setting, inpatient areas and critical services are key to an effective pandemic response (Hota, Fried, Burry, et al., 2010). The duration and acuity of patient illness, impact on hospital systems, and prior experiences with the H1N1 pandemic reflect a need for advanced surge capacity planning across clinical settings. H1N1 brings a surge in patient volume, affecting a younger population of individuals, many with severe lung injury as a result of the illness. Prolonged ventilation resulting in an extended surge situation has a significant impact on the health care system as a whole (Hota et al., 2010). With a pandemic wave that typically lasts 8 to 10 weeks, consideration of staff, patient triage, equipment and supplies, space to accommodate patients, and systems to respond to the pandemic event are key to preparedness and response activities (Hota et al., 2010).

Ethical Issues During a Disaster or Pandemic.

Either in connection with experiences with SARS or in anticipation of a major health disaster such as a pandemic, nurses have raised tough ethical questions. These include questions like, who gets access to critical care unit services, ventilators, and respiratory support in hospital and which sectors of the population should be given priority to receive vaccines and antivirals during a pandemic? During a disaster situation, the primary health focus shifts from obtaining the best possible health outcomes for the individual patient to protecting the health and safety of the population as a whole, which is both the moral and the legal mandate of public health (Gostin, Bayer, & Fairchild, 2003). Many of these ethical dilemmas are about balancing the best interests of the entire population, which is referred to as the "public good," with the rights of the individual. The duty to provide care, when care poses a risk to self and loved ones, highlights the ethical implications for all health care providers (see the "Ethical Dilemmas" box). Nurses and other health care workers have expressed the conflict they feel between their professional and legal obligations to their patients and their responsibilities to themselves and their families (CNA, 2017). Since the SARS outbreak, there have been a number of ethical frameworks, articles, and resources created to provide guidance for nurses, other health care workers, and decision makers in health care and government settings. Many of these resources can be found in the Resources list at the end of this chapter.

Ethical Dilemmas

Duty to Provide Care During a Pandemic

Situation

A senior undergraduate nursing student is in the last semester of her program. The Centre for Emergency Preparedness and Response, part of the Public Health Agency of Canada, has declared that areas in her province are in the midst of the initial wave of a pandemic influenza. Because the university she attends is in a city that has not yet had any reported cases of pandemic influenza, her university is open, and both her classes and her clinical practice placements are continuing. Her parents are worried about her safety and are urging her to return home to her rural community, 200 kilometres north of the city. She does not know what to do because she wants to finish her program.

Important Points for Consideration

There will be a massive need for health care workers during a pandemic owing to the number of people who are ill and in need of care; health care workers will also be ill. Many provincial and territorial pandemic influenza plans discuss the utilization of health science students in response to the overwhelming health human resource requirements. Universities are preparing pandemic influenza plans and have developed contingency plans for students who live in residence or cannot travel to their home communities during a pandemic. Nursing programs have begun developing specific guidelines and decision-making protocols for use during a pandemic because nursing students participate in the health care system.

Clinical Decision-Making Questions

1. What guidance is provided by the Canadian Nurses Association (CNA) *Code of Ethics* to help nurses address their ethical dilemmas about providing care during a pandemic?
2. The student is not yet a registered nurse. What are the legal obligations for her, as a student, during a pandemic?
3. What is the registered nurse's duty to provide care during a pandemic? What are the ethical considerations?

Vulnerable Individuals and Populations.

Special attention, in all the phases of a disaster or emergency, must be given to vulnerable individuals and marginalized groups. Failure to address the physical and psychological impact of a disaster in a timely and comprehensive manner can lead to long-term challenges and mental health issues. Individuals with pre-existing health conditions, disabilities, and mental health issues; women; people who are frail; people who are homeless; recent immigrants; children; and older adults are among the more vulnerable of the population and are at higher risk for the negative impacts of a disaster (WHO & ICN, 2009; Slepski, 2010). Where possible, these populations should be pre-identified as a part of emergency preparation, with the creation of specific plans to address their unique needs. Vulnerable populations often have limited resources, and their ability to recover is affected by their culture, support systems, and previous experiences. In the aftermath of a disaster, nurses are key to offering reassurance, education, and referral to needed resources to these

higher-risk populations. An understanding of stress and the impact of stress, while offering strategies to cope, is a key component of the nursing role.

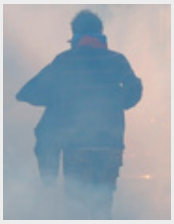
Disaster Nursing

With an increasing number of global disasters has come recognition of the need for increased health care preparedness. **Disaster nursing** involves the provision of nursing care, advocacy, and health promotion within the context of a disaster situation. Nurses, owing to their position and numbers, are essential in disaster mitigation, preparedness, response, and recovery (CNA, 2012; WHO & ICN, 2009). Nurses fill a variety of roles throughout the disaster management continuum. Eric Laroche, former WHO assistant director general for Health Action in Crises, states, "Nurses are often the first medical personnel on site after disaster strikes. In disaster situations, nurses are called upon to take roles as first responder, direct care provider, on-site coordinator of care, information provider or educator, mental health counsellor or triage officer" (WHO & ICN, 2009, pp. 5–6). Therefore, the need for nurses to develop competencies in this growing field is vital.

When disaster strikes, the demand for nurses is much greater than for other health care providers. Opportunities for nursing abroad in countries affected by disaster also exist through humanitarian networks and volunteer agencies. Disaster nursing, irrespective of the location of the disaster, requires application of basic nursing knowledge and skills in difficult environments with scarce resources, rapidly changing conditions, and large volumes of patients. Disaster nursing involves collaboration with other health care providers, first responders, and individuals not commonly worked with, requiring an ability to shift focus in care while working within the parameters of the laws in place in the area of work (WHO & ICN, 2009). The International Council of Nurses (ICN) has a mission to advance nurses and to bring nursing together worldwide (ICN, 2006; WHO & ICN, 2009). Recognizing the valuable role that nurses play in disaster responses, the ICN believes that "nurses with their technical skills and knowledge of epidemiology, physiology, pharmacology, cultural familial structures, and psychological issues can assist in disaster preparedness programs, as well as during disasters" (ICN, 2006, p. 2). The *ICN Framework of Disaster Nursing Competencies* (WHO & ICN, 2009) was created as an underpinning for the development of additional advanced competencies among nurses, globally. These competencies have been included in the Resources section at the end of this chapter.

Case Study

Pepper Spray



Source: thomas koch/Shutterstock.com.

Profile

It is 1636 hours on a Thursday in the month of May, in the emergency department of a downtown hospital in a major Canadian city. It has been an extremely busy day, and the triage nurse is working with the corridors fully occupied by patients, many of whom have been waiting a day or longer for inpatient beds. Several ambulances are waiting to off-load their patients from stretchers. The nurse receives a call from emergency medical services informing her of the need to be prepared for the potential arrival of patients from a nearby protest rally. She is told that the protesters breached the security fences and the police intervened by using significant amounts of pepper spray. On-site first responders (emergency medical services) have conducted some decontamination on site; however, many of the protesters fled on foot before decontamination.

Subjective Data

- Patients arrive within 6 minutes, with the following complaints:
    - Eye burning; some patients have temporary blindness
    - "Skin is burning"

Objective Data

- High levels of panic and anxiety
- Runny nose and watery eyes

- Severe coughing; some patients with shortness of breath

Collaborative Care

Decontamination shower and scrubbing are ordered before any medical intervention.

Discussion Questions

1. What risk factors do patients who require decontamination pose to an emergency department?
2. ***Priority decision:*** Identify priority actions the nurse will need to take in order to prepare for potential patient arrival.
3. Who should the nurse inform regarding the potential arrival of these patients?
4. What actions must be taken to manage patients who have been contaminated?
5. What equipment might be needed to care for contaminated patients?
6. ***Priority decision:*** What are the primary concerns of a triage nurse in this situation?
7. What information will the nurse need to obtain from contaminated patients?
8. What actions should the nurse take to ensure the safety of staff and patients currently in the emergency department?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. A chemical spill has occurred at a nearby industrial site. The first responders report that approximately 20 casualties need to be transported to the emergency department after decontamination at the site. What is this scenario an example of?
   a. An emergency
   b. A natural disaster or hazard
   c. A human-made or human-induced disaster
   d. An emergency response plan
2. Individuals and families must assume responsibility for taking appropriate steps to ensure they have the basics of what might be required following an emergency or disaster. Which list of items should be included in an individual emergency preparedness kit?
   a. Batteries, fresh fruits and vegetables, cups and plates
   b. Canned soups and stews, can opener, 2 L of water per day per person
   c. Fresh bread, frozen vegetables, lighter or matches
   d. 1 L of water per day per person, utensils, blankets, and sleeping bags
3. Which of the following statements *best* describes disaster nursing?
   a. Provision of nursing care, advocacy, and health promotion
   b. Provision of medical care and teaching
   c. Development and review of emergency operations plan and policy
   d. Provision of nursing care and coordination of health care interventions
4. Which of the following is a component of a comprehensive emergency operations plan?
   a. A closure strategy
   b. A documentation and data management strategy
   c. A pandemic plan
   d. A transfer policy
5. Which activity is correlated with the recovery and rehabilitation phase?
   a. Development of an emergency plan

b. Conducting emergency exercises and drills

c. Conducting critical incident debriefing with responders

d. Completing construction to build a flood-resistant emergency department

6. Which of the following statements best describes the Incident Management System (IMS)?

a. IMS is an administrative structure that can be used in large-scale emergency situations.

b. IMS involves a circular organizational structure where all participants are interlinked.

c. IMS involves a modular organizational structure that can be used in small- and large-scale situations.

d. IMS may be activated only by municipal or federal agencies.

7. Which of the following statements related to disaster triage in hospitals is correct?

a. Hospital and emergency department disaster triage is conducted by first responders.

b. The Canadian Triage and Acuity Scale was specifically designed for disaster triage.

c. Disaster triage should be done in 2 minutes or less.

d. Disaster triage involves a triage team composed of one to two nurses, a physician, a porter, and a registration clerk.

8. A nurse is assisting first responders during a mass casualty incident involving a bus rollover in an isolated rural community. Using the colour triage codes outlined in the START algorithm, place the following casualties in order of highest to lowest priority:

a. A 38-year-old female who is obese and dyspneic and has an upper thigh deformity

b. A 40-year-old male, minimally responsive, with shallow respirations, bleeding from the mouth

c. An older adult female, unresponsive, with a large scalp wound and a large amount of blood noted

d. A 14-year-old female, screaming, with lower back pain

e. An 8-year-old male, crying, with bloody gauze to the forehead

9. Which of the following is an example of a human-made disaster?

a. A terrorist attack
b. A pandemic
c. A hurricane
d. A severe ice storm

10. Which of the following biological agents of bioterrorism has no effective treatment?
a. Anthrax
b. Botulism
c. Smallpox
d. Hemorrhagic fever

11. Which of the following situations is an example of a chemical-biological-radiological-nuclear-explosive (CBRNE) event?
a. Dissemination of anthrax spores to a department in an office building
b. A train derailment
c. An outbreak of seasonal influenza
d. Forest fires

12. Which of the following examples meets the criteria for a pandemic?
a. A cluster of clients on an inpatient unit with diarrhea
b. Acquired immune deficiency syndrome (AIDS)
c. A school that has been closed as a result of flulike symptoms in children in three classrooms
d. Sudden acute respiratory syndrome (SARS) in Asia and Toronto

1. c; 2. b; 3. a; 4. b; 5. c; 6. c; 7. d; 8. b, c, a, e, d; 9. a. 10. d; 11. a; 12. b.

Appendices

OUTLINE

APPENDIX A

Nursing Diagnoses

Domain Label	Class Label	Diagnosis Code	Diagnosis Label
Health promotion	Health awareness	00097	Decreased diversional activity engagement
	Health awareness	00262	Readiness for enhanced health literacy
	Health awareness	00168	Sedentary lifestyle
	Health management	00257	Frail elderly syndrome
	Health management	00231	Risk for frail elderly syndrome
	Health management	00215	Deficient community health
	Health management	00188	Risk-prone health behaviour
	Health management	00099	Ineffective health maintenance
	Health management	00078	Ineffective health management
	Health management	00162	Readiness for enhanced health management
	Health management	00080	Ineffective family health management
	Health management	00043	Ineffective protection
Nutrition	Ingestion	00002	Imbalanced nutrition: less than body requirements
	Ingestion	00163	Readiness for enhanced nutrition
	Ingestion	00216	Insufficient breast milk production
	Ingestion	00104	Ineffective breastfeeding
	Ingestion	00105	Interrupted breastfeeding
	Ingestion	00106	Readiness for enhanced breastfeeding
	Ingestion	00269	Ineffective adolescent eating dynamics
	Ingestion	00270	Ineffective child eating dynamics
	Ingestion	00271	Ineffective infant feeding dynamics
	Ingestion	00107	Ineffective infant feeding pattern
	Ingestion	00232	Obesity
	Ingestion	00233	Overweight
	Ingestion	00234	Risk for overweight
	Ingestion	00103	Impaired swallowing
	Metabolism	00179	Risk for unstable blood glucose level
	Metabolism	00194	Neonatal hyperbilirubinemia
	Metabolism	00230	Risk for neonatal hyperbilirubinemia
	Metabolism	00178	Risk for impaired liver function
	Metabolism	00263	Risk for metabolic imbalance syndrome
	Hydration	00195	Risk for electrolyte imbalance
	Hydration	00025	Risk for imbalanced fluid volume
	Hydration	00027	Deficient fluid volume
	Hydration	00028	Risk for deficient fluid volume
	Hydration	00026	Excess fluid volume
Elimination and exchange	Urinary function	00016	Impaired urinary elimination
	Urinary function	00020	Functional urinary incontinence
	Urinary function	00176	Overflow urinary incontinence
	Urinary function	00018	Reflex urinary incontinence
	Urinary function	00017	Stress urinary incontinence
	Urinary function	00019	Urge urinary incontinence
	Urinary function	00022	Risk for urge urinary incontinence
	Urinary function	00023	Urinary retention
	Gastrointestinal function	00011	Constipation

Domain Label	Class Label	Diagnosis Code	Diagnosis Label
	Gastrointestinal function	00015	Risk for constipation
	Gastrointestinal function	00012	Perceived constipation
	Gastrointestinal function	00235	Chronic functional constipation
	Gastrointestinal function	00236	Risk for chronic functional constipation
	Gastrointestinal function	00013	Diarrhea
	Gastrointestinal function	00196	Dysfunctional gastrointestinal motility
	Gastrointestinal function	00197	Risk for dysfunctional gastrointestinal motility
	Gastrointestinal function	00014	Bowel incontinence
	Respiratory function	00030	Impaired gas exchange
Activity/rest	Sleep/rest	00095	Insomnia
	Sleep/rest	00096	Sleep deprivation
	Sleep/rest	00165	Readiness for enhanced sleep
	Sleep/rest	00198	Disturbed sleep pattern
	Activity/exercise	00040	Risk for disuse syndrome
	Activity/exercise	00091	Impaired bed mobility
	Activity/exercise	00085	Impaired physical mobility
	Activity/exercise	00089	Impaired wheelchair mobility
	Activity/exercise	00237	Impaired sitting
	Activity/exercise	00238	Impaired standing
	Activity/exercise	00090	Impaired transfer ability
	Activity/exercise	00088	Impaired walking
	Energy balance	00273	Imbalanced energy field
	Energy balance	00093	Fatigue
	Energy balance	00154	Wandering
	Cardiovascular/pulmonary responses	00092	Activity intolerance
	Cardiovascular/pulmonary responses	00094	Risk for activity intolerance
	Cardiovascular/pulmonary responses	00032	Ineffective breathing pattern
	Cardiovascular/pulmonary responses	00029	Decreased cardiac output
	Cardiovascular/pulmonary responses	00240	Risk for decreased cardiac output
	Cardiovascular/pulmonary responses	00033	Impaired spontaneous ventilation
	Cardiovascular/pulmonary responses	00267	Risk for unstable blood pressure
	Cardiovascular/pulmonary responses	00200	Risk for decreased cardiac tissue perfusion
	Cardiovascular/pulmonary responses	00201	Risk for ineffective cerebral tissue perfusion
	Cardiovascular/pulmonary responses	00204	Ineffective peripheral tissue perfusion
	Cardiovascular/pulmonary responses	00228	Risk for ineffective peripheral tissue perfusion
	Cardiovascular/pulmonary responses	00034	Dysfunctional ventilatory weaning response
	Self-care	00098	Impaired home maintenance

Domain Label	Class Label	Diagnosis Code	Diagnosis Label
	Self-care	00108	Bathing self-care deficit
	Self-care	00109	Dressing self-care deficit
	Self-care	00102	Feeding self-care deficit
	Self-care	00110	Toileting self-care deficit
	Self-care	00182	Readiness for enhanced self-care
	Self-care	00193	Self-neglect
Perception/cognition	Attention	00123	Unilateral neglect
	Cognition	00128	Acute confusion
	Cognition	00173	Risk for acute confusion
	Cognition	00129	Chronic confusion
	Cognition	00251	Labile emotional control
	Cognition	00222	Ineffective impulse control
	Cognition	00126	Deficient knowledge
	Cognition	00161	Readiness for enhanced knowledge
	Cognition	00131	Impaired memory
	Communication	00157	Readiness for enhanced communication
	Communication	00051	Impaired verbal communication
Self-perception	Self-concept	00124	Hopelessness
	Self-concept	00185	Readiness for enhanced hope
	Self-concept	00174	Risk for compromised human dignity
	Self-concept	00121	Disturbed personal identity
	Self-concept	00225	Risk for disturbed personal identity
	Self-concept	00167	Readiness for enhanced self-concept
	Self-esteem	00119	Chronic low self-esteem
	Self-esteem	00224	Risk for chronic low self-esteem
	Self-esteem	00120	Situational low self-esteem
	Self-esteem	00153	Risk for situational low self-esteem
	Body image	00118	Disturbed body image
Role relationship	Caregiving roles	00061	Caregiver role strain
	Caregiving roles	00062	Risk for caregiver role strain
	Caregiving roles	00056	Impaired parenting
	Caregiving roles	00057	Risk for impaired parenting
	Caregiving roles	00164	Readiness for enhanced parenting
	Family relationships	00058	Risk for impaired attachment
	Family relationships	00063	Dysfunctional family processes
	Family relationships	00060	Interrupted family processes
	Family relationships	00159	Readiness for enhanced family processes
	Role performance	00223	Ineffective relationship
	Role performance	00229	Risk for ineffective relationship
	Role performance	00207	Readiness for enhanced relationship
	Role performance	00064	Parental role conflict
	Role performance	00055	Ineffective role performance
	Role performance	00052	Impaired social interaction
Sexuality	Sexual function	00059	Sexual dysfunction
	Sexual function	00065	Ineffective sexuality pattern
	Reproduction	00221	Ineffective childbearing process
	Reproduction	00227	Risk for ineffective childbearing process

Domain Label	Class Label	Diagnosis Code	Diagnosis Label
	Reproduction	00208	Readiness for enhanced childbearing process
	Reproduction	00209	Risk for disturbed maternal-fetal dyad
Coping/stress tolerance	Post-trauma responses	00260	Risk for complicated immigration transition
	Post-trauma responses	00141	Post-trauma syndrome
	Post-trauma responses	00145	Risk for post-trauma syndrome
	Post-trauma responses	00142	Rape-trauma syndrome
	Post-trauma responses	00114	Relocation stress syndrome
	Post-trauma responses	00149	Risk for relocation stress syndrome
	Coping responses	00199	Ineffective activity planning
	Coping responses	00226	Risk for ineffective activity planning
	Coping responses	00146	Anxiety
	Coping responses	00071	Defensive coping
	Coping responses	00069	Ineffective coping
	Coping responses	00158	Readiness for enhanced coping
	Coping responses	00077	Ineffective community coping
	Coping responses	00076	Readiness for enhanced community coping
	Coping responses	00074	Compromised family coping
	Coping responses	00073	Disabled family coping
	Coping responses	00075	Readiness for enhanced family coping
	Coping responses	00147	Death anxiety
	Coping responses	00072	Ineffective denial
	Coping responses	00148	Fear
	Coping responses	00136	Grieving
	Coping responses	00135	Complicated grieving
	Coping responses	00172	Risk for complicated grieving
	Coping responses	00241	Impaired mood regulation
	Coping responses	00125	Powerlessness
	Coping responses	00152	Risk for powerlessness
	Coping responses	00187	Readiness for enhanced power
	Coping responses	00210	Impaired resilience
	Coping responses	00211	Risk for impaired resilience
	Coping responses	00212	Readiness for enhanced resilience
	Coping responses	00137	Chronic sorrow
	Coping responses	00177	Stress overload
	Neurobehavioural stress	00258	Acute substance withdrawal syndrome
	Neurobehavioural stress	00259	Risk for acute substance withdrawal syndrome
	Neurobehavioural stress	00009	Autonomic dysreflexia
	Neurobehavioural stress	00010	Risk for autonomic dysreflexia
	Neurobehavioural stress	00049	Decreased intracranial adaptive capacity
	Neurobehavioural stress	00264	Neonatal abstinence syndrome
	Neurobehavioural stress	00116	Disorganized infant behaviour
	Neurobehavioural stress	00115	Risk for disorganized infant behaviour
	Neurobehavioural stress	00117	Readiness for enhanced organized infant behaviour

APPENDIX B

Laboratory Values

Adapted by, Jana Lok

The tables in this appendix list some of the most common tests, their normal values, and possible etiologies of abnormal values. Laboratory values are expressed in the Système International d'Unités (SI) units, which are used in Canada. Conventional units, used in the United States, are presented after the SI units in parentheses. Laboratory values may vary with different techniques and in different laboratories. Possible etiologies are presented in alphabetical order. SI abbreviations and other symbols appearing in the tables are defined as follows:

<	=	less than
>	=	greater than
≥	=	greater than or equal to
≤	=	less than or equal to
AU	=	arbitrary unit
cm H_2O	=	centimetres of water
dL	=	decilitre
EU	=	Ehrlich unit
fL	=	femtolitre
g	=	gram
IU	=	international unit
kPa	=	kilopascal
kU	=	kilounit
L	=	litre
mcg	=	microgram (one millionth [10^{-6}] of a gram)
mcIU	=	micro–international unit (one millionth [10^{-6}] of an international unit)
mcL	=	microlitre
mcmol	=	micromole
mEq	=	milliequivalent
mg	=	milligram (one thousandth [10^{-3}] of a gram)
microkat	=	microkatal
microU	=	microunit
mL	=	millilitre
mm	=	millimetre
mm Hg	=	millimetre of mercury
mmol	=	millimole
mOsm	=	milliosmole
mU	=	milliunit (one hundredth [10^{-2}] of a unit)
nmol	=	nanomole (one billionth [10^{-9}] of a mole)
ng	=	nanogram (one billionth [10^{-9}] of a gram)
pg	=	picogram (one trillionth [10^{-12}] of a gram)
pmol	=	picomole (one trillionth [10^{-12}] of a mole)
U	=	unit

TABLE B-1
SERUM, PLASMA, AND WHOLE BLOOD CHEMISTRIES

Test	Normal Values (SI Units [Conventional Units])	Possible Etiology	
		Higher Values	Lower Values
Acetone		Diabetic ketoacidosis, high-fat diet, low-carbohydrate diet, starvation	—
• Quantitative	<200 mcmol/L (<1.16 mg/dL)		
• Qualitative	Negative (negative)		
Alanine aminotransferase (ALT; formerly known as serum glutamate pyruvate transferase [SGPT])	4–36 U/L (same as in SI units)	Liver disease, shock	—
Albumin	35–50 g/L (3.5–5 g/dL)	Dehydration	Burns, chronic liver disease, inflammatory disease, malabsorption, malnutrition, nephrotic syndrome, pregnancy
Aldolase	<8.0 mU/L (3–8.2 Sibley-Lehninger U/dL)	Infection, hepato-cellular disease, MI, muscle trauma, skeletal muscle disease	Hereditary fructose intolerance, late muscular dystrophy, renal disease
α_1-Antitrypsin	0.85–2.13 g/L (85–213 mg/dL)	Acute and chronic inflammation and infection, arthritis, malignancy, stress, thyroid infections	Chronic lung disease (early onset of emphysema), end-stage cancer, malnutrition, nephrotic syndrome
Alpha-fetoprotein	0–40 mcg/L (<40 ng/mL)	Cancers of testes, lymphoma, stomach, colon, breasts and ovaries; carcinoma of liver; fetal death; fetal distress or congenital abnormalities; neural tube defects or multiple pregnancies in pregnant women	In pregnant women, fetal trisomy 21 or fetal wastage
Ammonia	6–47 mcmol/L (10–80 mcg/dL)	GI bleeding, hepatic encephalopathy, portal hypertension, Reye syndrome, severe liver disease, severe heart failure or congestive hepatomegaly	Essential or malignant hypertension, hyperornithinemia
Amylase	100–300 U/L (60–120 Somogyi units/dL)	Acute and chronic pancreatitis, mumps (salivary gland disease), perforated ulcers	Acute alcoholism, cirrhosis of liver, extensive destruction of pancreas
Ascorbic acid	23–85 mcmol/L (0.4–1.5 mg/dL)	Excessive ingestion of vitamin C	Connective tissue disorders, hepatic disease, renal disease, rheumatic fever, vitamin C deficiency

Test	Normal Values (SI Units [Conventional Units])	Possible Etiology	
		Higher Values	Lower Values
Aspartate aminotransferase (AST) (formerly known as serum glutamic oxaloacetic transferase [SGOT])	0–35 U/L (same as SI units)	Acute hepatitis, liver disease, MI, pulmonary infarction, skeletal muscle disease	Acute renal disease, chronic renal dialysis, diabetic ketoacidosis, pregnancy
B-type (brain-type) natriuretic peptide	<100 mcg/L (<100 ng/mL)	Cor pulmonale, heart failure, hypertension, MI	—
Beta-carotene	1.4–4.7 mcmol/L (75–253 mcg/dL)	Cystic fibrosis, hypothyroidism, pancreatic insufficiency	Dietary deficiency, malabsorption disorders
Bicarbonate	21–28 mmol/L (21–28 mEq/L)	Chronic use of loop diuretics, compensated respiratory acidosis, metabolic alkalosis	Acute kidney injury, compensated respiratory alkalosis, diarrhea, metabolic acidosis
Bilirubin		Biliary obstruction, Dubin-Johnson syndrome, hemolytic anemia, hepatitis, impaired liver function, pernicious anemia, prolonged fasting, sickle cell anemia, sepsis	—
• Total	5.1–17 mcmol/L (0.3–1.0 mg/dL)		
• Indirect	3.4–12 mcmol/L (0.2–0.8 mg/dL)		
• Direct	1.7–5.1 mcmol/L (0.1–0.3 mg/dL)		
Blood gases*			
• Arterial pH	7.35–7.45 (same as SI units)	Alkalosis	Acidosis
• Venous pH	7.31–7.41 (same as SI units)	Alkalosis	Acidosis
• Partial pressure of carbon dioxide in arterial blood ($PaCO_2$)	35–45 mm Hg (same as SI units)	Compensated metabolic alkalosis, respiratory acidosis	Compensated metabolic acidosis, respiratory alkalosis
• Partial pressure of oxygen in arterial blood (PaO_2)	80–100 mm Hg (same as SI units)	Administration of high concentration of oxygen	Chronic lung disease, decreased cardiac output
• Partial pressure of oxygen in venous blood (PvO_2)	40–50 mm Hg (same as SI units)		
Calcium	2.25–2.75 mmol/L (9–10.5 mg/dL)	Acute osteoporosis, hyperparathyroidism, multiple myeloma, vitamin D intoxication	Acute pancreatitis, hypoparathyroidism, liver disease, malabsorption syndrome, renal failure, vitamin D deficiency
Calcium, ionized	1.05–1.30 mmol/L (4.5–5.6 mg/dL)	—	—
Carbon dioxide (CO_2 content)	21–28 mmol/L (21–28 mEq/L)	COPD, metabolic alkalosis, severe vomiting	Chronic use of loop diuretics, DKA, metabolic acidosis, renal failure, shock, starvation

Test	Normal Values (SI Units [Conventional Units])	Possible Etiology	
		Higher Values	Lower Values
Chloride	98–106 mmol/L (98–106 mEq/L)	Corticosteroid therapy, dehydration, excessive infusion of normal saline, metabolic acidosis, respiratory alkalosis, uremia	Addison's disease, diarrhea, heart failure, metabolic alkalosis, overhydration, respiratory acidosis, SIADH, vomiting
Cholesterol	<5 mmol/L (<200 mg/dL) age dependent	Biliary obstruction, cirrhosis hyperlipidemia, hypothyroidism, idiopathic hypercholesterolemia, renal disease, uncontrolled diabetes	Corticosteroid therapy, extensive liver disease, hyperthyroidism, malnutrition
• High-density lipoproteins (HDL)	>1.55 mmol/L (>60 mg/dL)		
• Low-density lipoproteins (LDL)	<2.59 mmol/L (<100 mg/dL)		
Cholinesterase (RBC)	5–10 U/L (same as SI units)	Exercise, sickle cell disease	Acute infections, insecticide intoxication, liver disease, muscular dystrophy
Copper	11–22 mcmol/L (70–140 mcg/dL)	Cirrhosis, contraceptive use by female patient	Wilson's disease
Cortisol		Adrenal adenoma, Cushing's syndrome, hyperthyroidism, pancreatitis, stress	Addison's disease, adrenal insufficiency, hypopituitary states, hypothyroidism, liver disease
• 0800 hours	138–635 nmol/L (5–23 mcg/dL)		
• 1600 hours	<83–359 nmol/L (3–13 mcg/dL)		
Creatine	15.3–76.3 mcmol/L (0.2–1.0 mg/dL)	Active rheumatoid arthritis, biliary obstruction, hyperthyroidism, renal disease, severe muscle disease	Diabetes mellitus
Creatine kinase (CK)		Brain damage, exercise, musculo-skeletal injury or disease, MI, numerous intramuscular injections, severe myocarditis	—
• Male	55–170 U/L (same as SI units)		
• Female	30–135 U/L (same as SI units)		
Creatine kinase isozyme of heart (CK-MB [CK-2])		Acute MI	—
• Male	2–6 mcg/L (2–6 ng/mL)		
• Female	2–5 mcg/L (2–5 ng/mL)		
Creatine kinase mass fraction	<5% fraction of total CK	—	—
Creatinine		Severe renal disease	Diseases with decreased muscle mass (e.g. muscular dystrophy, myasthenia gravis)
• Male	53–106 mcmol/L (0.6–1.2 mg/dL)		
• Female	44–97 mcmol/L (0.5–1.1 mg/dL)		
Ferritin (serum)		Anemia of chronic disease (infection, inflammation, liver disease), sideroblastic anemia	Iron-deficiency anemia, severe protein deficiency
• Male	26–674 pmol/L (12–300 ng/mL)		

Test	Normal Values (SI Units [Conventional Units])	Possible Etiology	
		Higher Values	Lower Values
• Female	22–337 pmol/L (10–150 ng/mL)		
Folic acid (folate)	11–57 mmol/L (5–25 ng/mL)	Hypothyroidism, pernicious anemia	Alcoholism, hemolytic anemia, inadequate diet, malabsorption syndrome, malnutrition, megaloblastic anemia
Gamma-glutamyltranspeptidase (GGT)		Cholestasis, cytomegalovirus infection, Epstein-Barr, liver disease, MI, pancreatitis	—
• Male	8–38 U/L (same as SI units)		
• Female	5–27 U/L (same as SI units)		
Glucose, fasting	4–6 mmol/L (70–110 mg/dL)	Acute stress, cerebral lesions, Cushing's syndrome, diabetes mellitus, hyperthyroidism, pancreatic insufficiency	Addison's disease, hepatic disease, hypothyroidism, insulin overdosage, pancreatic tumour, pituitary hypofunction, postdumping syndrome
Glucose, 2-hr oral glucose tolerance testing (OGTT)		Diabetes mellitus	Hyperinsulinism
• Fasting	4–6 mmol/L (70–110 mg/dL)		
• 1 hr	<11.1 mmol/L (<200 mg/dL)		
• 2 hr	<7.8 mmol/L (<140 mg/dL)		
Haptoglobin	0.5–2.2 g/L (50–220 mg/dL)	Acute MI, infectious and inflammatory processes, malignant neoplasms	Chronic liver disease, hemolytic anemia, mononucleosis, systemic lupus erythematosus, toxoplasmosis, transfusion reactions
Homocysteine		Cardiovascular disease, cerebrovascular disease, cystinuria, folate deficiency, malnutrition, peripheral vascular disease, vitamin B_6 or B_{12} deficiency	—
• 0–30 years	4.6–8.1 mcmol/L (same as SI units)		
• 30–59 years			
• Male	6.13–11.2 mcmol/L (same as SI units)		
• Female	4.5–7.9 mcmol/L (same as SI units)		
• >59 years	5.8–11.9 mcmol/L (same as SI units)		
Insulin	43–186 pmol/L (6–26 microU/mL)	Acromegaly, adenoma of islet cells, obesity, untreated mild case of type 2 diabetes mellitus	Diabetes mellitus, obesity
Iron		Excessive RBC destruction,	Anemia of chronic disease,

Test	Normal Values (SI Units [Conventional Units])	Possible Etiology	
		Higher Values	Lower Values
• Male	14–32 mcmol/L (80–180 mcg/dL)	hemochromatosis, massive transfusion	iron-deficiency anemia
• Female	11–29 mcmol/L (60–160 mcg/dL)		
Total iron-binding capacity (TIBC)	45–82 mcmol/L (250–460 mcg/dL)	Iron-deficiency state, oral contraceptive use, polycythemia	Cancer, chronic infections, pernicious anemia, uremia
Lactic acid (venous blood)	0.6–2.2 mmol/L (5–20 mg/dL)	Acidosis, heart failure, severe liver disease, shock, tissue ischemia	—
Lactic dehydrogenase (LDH)	100–190 U/L (same as SI units)	Heart failure, hemolytic disorders, hepatitis, metastatic cancer of liver, MI, pernicious anemia, pulmonary embolus and infarction, skeletal muscle damage	—
Lactic dehydrogenase isoenzymes			
• LDH_1	0.17–0.27 (17%–27%)	MI, pernicious anemia, strenuous exercise	—
• LDH_2	0.27–0.37 (27%–37%)	Exercise, pulmonary embolus, sickle cell crisis	—
• LDH_3	0.18–0.25 (18%–25%)	Malignant lymphoma, pulmonary embolus	—
• LDH_4	0.03–0.08 (3%–8%)	Systemic lupus erythematosus, pancreatitis, pulmonary infarction, renal disease	—
• LDH_5	0.0–0.05 (0%–5%)	Heart failure, hepatitis, pulmonary embolus and infarction, skeletal muscle damage, strenuous exercise	—
Lipase	0–160 U/L (same as SI units)	Acute and chronic pancreatitis, hepatic disorders, pancreatic disorder (cancer, pseudocyst), perforated peptic ulcer, salivary gland inflammation or tumour	—
Magnesium	0.74–1.07 mmol/L (1.8–2.6 mEq/L)	Addison's disease, hypothyroidism, renal failure	Chronic alcoholism, hyperparathyroidism, hyperthyroidism, hypoparathyroidism, malnutrition, severe malabsorption
Myoglobin	1.0–5.3 nmol/L (<90 ng/mL)	MI, myositis, malignant hyperthermia, muscular dystrophy, skeletal muscle ischemia or trauma, rhabdomyolysis, seizures	Polymyositis
Osmolality	280–300 mmol/kg (280–300 mOsm/kg)	Chronic renal disease, dehydration, diabetes mellitus, hypernatremia, shock	Addison's disease, diuretic therapy, hyponatremia, overhydration
Oxygen saturation		Increased inspired oxygen,	Anemia, cardiac

Test	Normal Values (SI Units [Conventional Units])	Possible Etiology	
		Higher Values	Lower Values
• Arterial	95%–100% (same as SI units)	polycythemia vera	decompensation, decreased inspired oxygen, respiratory disorders
• Venous	60%–80% (same as SI units)		
pH	*See* Blood gases		
Phenylalanine	0–121 mcmol/L (0–2 mg/dL)	Phenylketonuria	—
Phosphatase, acid	2.2–10.5 U/L (0.13–0.63 U/L)	Advanced Paget's disease, cancer of prostate, hyperparathyroidism	—
Phosphatase, alkaline (ALP)	35–120 U/L (0.5–2.0 mckat/L)	Bone diseases, cirrhosis, malignancy of liver/bone, marked hyperparathyroidism, obstruction of biliary system, rickets	Excessive vitamin D ingestion, hypothyroidism, milk-alkali syndrome
Phosphorus, phosphate	0.97–1.45 mmol/L (3.0–4.5 mg/dL)†	Bone metastasis, healing fractures, hypocalcemia, hypoparathyroidism, renal disease, vitamin D intoxication	Chronic alcoholism, diabetes mellitus, hypercalcemia, hyperparathyroidism, vitamin D deficiency
Potassium	3.5–5.0 mmol/L (3.5–5.0 mEq/L)	Acute or chronic renal failure, Addison's disease, dehydration, diabetic ketosis, excessive dietary or IV intake, massive tissue destruction, metabolic acidosis	Burns, Cushing's syndrome, deficient dietary or IV intake, diarrhea (severe), diuretic therapy, GI fistula, insulin administration, pyloric obstruction, starvation, vomiting
Prostate-specific antigen (PSA)	<4 mcg/L (<4 ng/mL)	Benign prostatic hypertrophy, prostate cancer, prostatitis	—
Proteins		Burns, cirrhosis (globulin fraction), dehydration	Congenital agammaglobulinemia, increased capillary permeability, inflammatory disease, liver disease, malabsorption, malnutrition
• Total	64–83 g/L (6.4–8.3 g/dL)		
• Albumin	35–50 g/L (3.5–5 g/dL)		
• Globulin	23–34 g/L (2.3–3.4 g/dL)		
• Albumin/globulin ratio	1.5 : 1–2.5 : 1 (same as SI units)	Multiple myeloma (globulin fraction), shock, vomiting	Malnutrition, nephrotic syndrome, proteinuria, renal disease, severe burns
Pseudocholinesterase (serum)	8–18 U/mL (same as SI units)	—	—
Renin		Renal hypertension, salt-losing GI disease (vomiting/diarrhea), volume decrease (e.g., hemorrhage)	Increased salt intake, primary aldosteronism
• Upright position	0.03–1.2 ng/L/sec (0.1–4.3 mg/mL/hr)		

Test	Normal Values (SI Units [Conventional Units])	Possible Etiology	
		Higher Values	Lower Values
Sodium	135–145 mmol/L (135–145 mEq/L)	Corticosteroid therapy, dehydration, impaired renal function, increased dietary or IV intake, primary aldosteronism	Addison's disease, decreased dietary or IV intake, diabetic ketoacidosis, diuretic therapy, excessive loss from GI tract, excessive perspiration, water intoxication
Testosterone		Adrenal hyperplasia, adrenal or pituitary tumours, testicular tumours	Hypofunction of testes
• Male	174–729 pmol/L (50–120 pg/mL)		
• Female	3.5–29.5 pmol/L (1.0–8.5 pg/mL)	Polycystic ovary, virilizing tumours	—
Thyroxine (T_4), total	64–154 nmol/L (5–12 mcg/dL)	Hyperthyroidism, thyroiditis	Cretinism, hypothyroidism, myxedema
Thyroxine (T_4), free	10–36 pmol/L (0.8–2.8 ng/dL)	Hyperthyroidism, metastatic neoplasms	Hypothyroidism, pregnancy
Thyroid-stimulating hormone (TSH)	2–10 mIU/L (2–10 mcIU/mL)	Graves' disease, myxedema, primary hypothyroidism	Secondary hypothyroidism
Triglycerides		Diabetes mellitus, hyperlipidemia, hypothyroidism, liver disease	Hyperthyroidism, malabsorption syndrome, malnutrition
• Male	0.45–1.81 mmol/L (40–160 mg/dL)		
• Female	0.40–1.52 mmol/L (35–135 mg/dL)		
Triiodothyronine (T_3) uptake	24–34 AU (24%–34%)	—	—
Triiodothyronine (T_3)	1.7-5.2 pmol/L (110.4–337.7 ng/dL)	Hyperthyroidism	Hypothyroidism
Troponin T (cTnT)	<0.1 mcg/L (<0.1 ng/mL)	Cardiac muscle damage (resulting from MI, myocarditis, or pericarditis), chronic renal failure, multiorgan failure, severe heart failure	—
Troponin I (cTnI)	<0.35 mcg/L (<0.35 ng/mL)		—
Urea nitrogen, blood (blood urea nitrogen [BUN], serum urea nitrogen)	3.6–7.1 mmol/L (10–20 mg/dL)	Burns, dehydration, GI bleeding, increase in protein catabolism (fever, stress), renal disease, shock, urinary tract infection	Fluid overload, malnutrition, severe liver damage, SIADH
Uric acid		Alcoholism, eclampsia, gout, gross tissue destruction, high-protein weight reduction diet, leukemia, multiple myeloma, renal failure	Administration of uricosuric drugs
• Male	240–501 mcmol/L (4.0–8.5 mg/dL)		
• Female	160–430 mcmol/L (2.7–7.3 mg/dL)		
Vitamin A	0.52–2.09 mcmol/L (15–60 mcg/dL)	Excess ingestion of vitamin A	Vitamin A deficiency

Test	Normal Values (SI Units [Conventional Units])	Possible Etiology	
		Higher Values	Lower Values
Vitamin B_{12}	118–701 pmol/L (160–950 pg/mL)	Chronic myeloid leukemia	Malabsorption syndrome, pernicious anemia, strict vegetarianism, total or partial gastrectomy
Zinc	11.5–18.5 mcmol/L (75–120 mcg/dL)	—	Alcoholic cirrhosis

*Because arterial blood gases are influenced by altitude, the values for $PaCO_2$, PaO_2, and PvO_2 decrease as altitude increases. The lower values are normal for an altitude of 1.6 km (1 mile).

†Values for older adults are significantly lower than those for younger adults.

COPD, chronic obstructive pulmonary disease; *DKA*, diabetic ketoacidosis; *GI,* gastro-intestinal; *IV,* intravenous; *MI,* myocardial infarction; *RBC,* red blood cell; *SIADH,* syndrome of inappropriate antidiuretic hormone.

TABLE B-2
HEMATOLOGY

Test	Normal Values (SI Units [Conventional Units])	Possible Etiology	
		Higher Values	Lower Values
Activated coagulation time or automated clotting time (ACT)	70–120 sec (same as SI units)	Same as for aPTT	—
Activated partial thromboplastin time (aPTT)	30–40 sec* (same as SI units)	Deficiency of one or more of the following: factor I, II, V, or VIII; factors IX and X; factor XI; and factor XII Hemophilia; heparin therapy; liver disease	—
Bleeding time (Ivy method)	1–9 min	Acetylsalicylic acid (ASA; Aspirin) ingestion, clotting factor deficiency, defective platelet function, thrombocytopenia, vascular disease, von Willebrand's disease	—
D-dimer	<3.0 mmol/L (<50 ng/mL)	Deep-vein thrombosis, DIC, myocardial infarction, unstable angina	—
Erythrocyte count† (RBC count [altitude dependent])		Dehydration, high altitudes, polycythemia vera, severe diarrhea	Anemia, leukemia, posthemorrhage
• Male	4.7–6.1 × 10^{12}/L		
• Female	4.2–5.4 × 10^{12}/L		
Erythrocyte sedimentation rate (ESR), Westergren Method		*Moderate increase:* acute hepatitis, myocardial infarction, rheumatoid arthritis *Marked increase:* acute and severe bacterial infections, malignancies, pelvic inflammatory disease	Malaria, severe liver disease, sickle cell anemia
• Male	≤15 mm/hr (same as SI units)		
• Female	≤20 mm/hr (same as SI units)		
Fibrin split (degradation) products	<10 mg/L (<10 mcg/mL)	Acute DIC, massive hemorrhage, massive trauma, primary fibrinolysis	—
Fibrinogen	2.0–5.0 g/L (60–100 mg/dL)	Burns (after first 36 hr), inflammatory disease	Burns (during first 36 hr), DIC, severe liver disease
Hematocrit (altitude dependent)†		Dehydration, high altitudes, polycythemia	Anemia, bone marrow failure, hemorrhage, leukemia, overhydration

Test	Normal Values (SI Units [Conventional Units])	Possible Etiology	
		Higher Values	Lower Values
• Male	0.42–0.52 volume fraction (42%–52%)		
• Female	0.37–0.47 volume fraction (37%–47%)		
Hemoglobin (altitude dependent)†		Chronic obstructive pulmonary disease, high altitudes, polycythemia	Anemia, hemorrhage
• Male	140–180 g/L (14–18 g/dL)		
• Female	120–160 g/L (12–16 g/dL)		
Hemoglobin, glycosylated or glycated (hemoglobin A_{1c} [HbA_{1c}])	<6% (adult without diabetes)	Nondiabetic hyperglycemia, poorly controlled diabetes mellitus	Chronic blood loss, chronic renal failure, pregnancy, sickle cell anemia
International normalized ratio (INR)	0.81–1.20 (same as SI units)	Same as for PT	—
Mean corpuscular hemoglobin (MCH) [Hb/RBC]	27–31 pg (same as SI units)	Macrocytic anemia	Microcytic anemia
Mean corpuscular hemoglobin concentration (MCHC) [Hb/Hct]	32–36 g/dL (32%–36%)	Intravascular hemolysis, spherocytosis	Hypochromic anemia
Mean corpuscular volume (MCV) [Hct/RBC]	80–95 fL (80–95 mm^3)	Folic acid and vitamin B_{12} deficiency, liver disease, macrocytic anemia	Microcytic anemia
Partial thromboplastin time (PTT)	60–70 sec (same as SI units)	Same as for aPTT	—
Platelet count (thrombocytes)	150–400 × 10^9/L (150,000–400,000/mm^3)	Acute infections, chronic granulocytic leukemia, chronic pancreatitis, cirrhosis, collagen disorders, polycythemia, post-splenectomy	Acute leukemia, cancer chemotherapy, DIC, hemorrhage, infection, systemic lupus erythematosus, thrombocytopenic purpura
Prothrombin time (PT; Protime)	11–12.5 sec* (same as SI units)	Deficiency of one or more of the following: factor I, II, V, VII, or X Liver disease; vitamin K deficiency; warfarin therapy	—

Test	Normal Values (SI Units [Conventional Units])	Possible Etiology	
		Higher Values	Lower Values
Red cell distribution width (RDW)	11%–14.5% (same as SI units)	—	Anisocytosis, macrocytic anemia, microcytic anemia
Reticulocyte count (manual)	0.5%–2% total number of RBC	Hemolytic anemia, polycythemia vera	Hypoproliferative anemia, macrocytic anemia, microcytic anemia
Sickle cell solubility	Negative (negative)	Sickle cell anemia	—
Thrombin time	8–12 sec (same as SI units)	DIC, increased tendency to bleed	—
WBC count†	5–10 × 10^9/L (5000–10,000/mm^3)	Inflammatory and infectious processes, leukemia	Aplastic anemia, autoimmune diseases, overwhelming infection, side effects of chemotherapy and irradiation
WBC differential			
• Band neutrophils	0–1 × 10^9/L (0%–9%)	Acute infections	—
• Basophils	0.02–0.05 × 10^9/L (15–50/mm^3; 0.5%–1%)	Hypothyroidism, myeloproliferative diseases, ulcerative colitis	Hyperthyroidism, stress
• Eosinophils	0.00–0.5 × 10^9/L (50–500/mm^3; 1%–4%)	Allergic reactions, eosinophilic and chronic granulocytic leukemia, Hodgkin's disease, parasitic disorders	Corticosteroid therapy
• Lymphocytes	1.0–4.0 × 10^9/L (1000–4000/mm^3; 20%–40%)	Chronic infections, lymphocytic leukemia, mononucleosis, viral infections	Corticosteroid therapy, whole body irradiation
• Monocytes	0.1–0.7 × 10^9/L (100–700/mm^3; 2%–8%)	Acute infections, chronic inflammatory disorders, Hodgkin's disease, malaria, monocytic leukemia	—
• Segmented neutrophils	2.5–7.5 × 10^9/L (62%–68%)	Bacterial infections, collagen diseases, Hodgkin's disease	Aplastic anemia, viral infections

*For patients receiving anticoagulant therapy, aPTT is 1.5–2.5 times control value in seconds; PT is 1.5–2.0 times control value in seconds.

†Components of complete blood count (CBC).

DIC, disseminated intravascular coagulation; *RBC,* red blood cell; *WBC,* white blood cell.

TABLE B-3
SEROLOGY–IMMUNOLOGY

Test	Normal Values (SI Units [Conventional Units])	Possible Etiology	
		Higher Values	Lower Values
Antinuclear antibody (ANA)	Negative at 1 : 40 dilution (same as SI units)	Chronic hepatitis, rheumatoid arthritis, scleroderma, systemic lupus erythematosus (SLE)	—
Anti-DNA antibody	Negative <70 U/mL (same as SI units)	SLE	—
Anti-RNP (ribonucleoprotein)	Negative (negative)	Mixed connective tissue disease, rheumatoid arthritis, scleroderma, Sjögren's syndrome, SLE	—
Anti-Sm (Smith)	Negative (negative)	SLE	—
Antistreptolysin-O (ASO)	≤160 Todd units/mL (same as SI units)	Acute glomerulo-nephritis, rheumatic fever, streptococcal infection	—
C-reactive protein (CRP)	<10 mg/L (<1.0 mg/dL)	Acute infections, any inflammatory condition (e.g., acute rheumatic fever/arthritis), widespread malignancy	—
Carcinoembryonic antigen (CEA)	<5 mcg/L (5 ng/mL)	Carcinomas of colon, liver, pancreas; chronic cigarette smoking; inflammatory bowel disease; other cancers	—
Complement assay components		—	Acute glomerulo-nephritis, rheumatoid arthritis, serum sickness, SLE, subacute bacterial endocarditis
• Total	75–160 kU/L (75–160 U/mL)		
• C3	0.55–1.2 g/L (55–120 mg/dL)		
• C4	0.2–0.5 g/L (20–50 mg/dL)		
Direct antihuman globulin test (DAT) or direct Coombs' test	Negative (negative) (no agglutination)	Acquired hemolytic anemia, drug reactions, hemolytic disease of the newborn, transfusion reactions	—
Fluorescent treponemal antibody absorption (FTAAbs)	Negative (nonreactive)	Syphilis	—
Hepatitis A antibody	Negative (negative)	Hepatitis A	—
Hepatitis B surface antigen (HBsAg)	Negative (negative)	Hepatitis B	—

Test	Normal Values (SI Units [Conventional Units])	Possible Etiology	
		Higher Values	Lower Values
Hepatitis C antibody	Negative (negative)	Hepatitis C	—
Immunoglobulins			
• IgA	0.85–3.85 g/L (85–385 mg/dL)	Autoimmune disorders, chronic infection, chronic liver disease, IgA myeloma, rheumatoid arthritis	Burns, hereditary telangiectasia, malabsorption syndromes
• IgD	Minimal	Chronic infection, connective tissue disease	—
• IgE	24–400 mcg/L	Anaphylactic shock, atopic disease (allergies), parasite infections	—
• IgG	5.65–17.65 g/L (565–1765 mg/dL)	Hepatitis, IgG monoclonal gammopathy, infections—acute and chronic, SLE	Acquired deficiencies, burns, congenital deficiencies, immuno-suppression, nephrotic syndromes
• IgM	0.55–3.75 g/L (55–375 mg/dL)	Acute infections, liver disease, rheumatoid arthritis	Congenital and acquired antibody deficiencies, lymphocytic leukemia, protein-losing enteropathies
Monospot or Mono-Test	Negative (<1 : 28 titre)	Infectious mononucleosis,	—
Rheumatoid factor (RA factor)	Negative or <60 IU/mL by nephelometric method	Rheumatoid arthritis, Sjögren's syndrome, SLE	—
RPR (rapid plasma reagin) test	Negative or nonreactive (same as SI units)	Febrile diseases, IV drug abuse, leprosy, malaria, rheumatoid arthritis, syphilis, SLE	—
VDRL (Venereal Disease Research Laboratory) test	Negative or nonreactive (same as SI units)	Syphilis	—
Thyroid antibodies	Titre <1 : 100 (same as SI units)	Early hypothyroidism, Graves' disease, Hashimoto's thyroiditis, pernicious anemia, SLE, thyroid carcinoma	—

IV, intravenous.

TABLE B-4
URINE CHEMISTRY

Test	Specimen	Normal Values (SI Units [Conventional Units])	Possible Etiology	
			Higher Values	Lower Values
Acetone (ketones)	Random	Negative (negative)	Diabetes mellitus, high-fat and low-carbohydrate diets, starvation states	—
Aldosterone	24 hr	17–70 nmol/24 hr (2–26 mcg/24 hr)	*Primary aldosteronism:* Adrenocortical tumours *Secondary aldosteronism:* Cardiac failure, cirrhosis, large dose of ACTH, salt depletion	Addison's disease, adrenocorticotrophic hormone (ACTH) deficiency, corticosteroid therapy
Amylase	24 hr	100–300 U/L (60–120 Somogyi units/dL)	Acute pancreatitis	—
Bence Jones protein	Random	Negative (negative)	Biliary duct obstruction, multiple myeloma	—
Bilirubin	Random	5.1–16 mcmol/L (0.3–1.0 mg/dL)	Gallstones, Dubin-Johnson syndrome, Rotor syndrome	—
Calcium	24 hr	2.25–2.75 mmol/day (9.0–10.5 mg/dL)	Bone tumour, hyperparathyroidism, milk-alkali syndrome, lymphoma, Addison's disease	Hypoparathyroidism, malabsorption of calcium and vitamin D, renal failure, pancreatitis
Catecholamines	24 hr		Heart failure, pheochromocytoma, progressive muscular dystrophy	
• Epinephrine		<109 nmol/day (<20 mcg/24 hr)		
• Norepinephrine		<590 nmol/day (<100 mcg/24 hr)		
Chloride	24 hr	110–250 mmol/day (110–250 mEq/day)	Dehydration, Cushing's syndrome, eclampsia, kidney dysfunction	Addison's disease, burns, diarrhea, excess perspiration, heart failure, menstruation, vomiting
Copper	24 hr	0.6 mcmol/day (<40 mcg/day)	Cirrhosis, Wilson's disease	—
Coproporphyrin	24 hr	<300 nmol/day (<200 mcg/day)	Lead poisoning, oral contraceptive use, poliomyelitis	—
Creatine	24 hr		Acromegaly, diabetic nephropathy, disease affecting renal function	Decrease muscle mass (e.g., muscular dystrophy, myasthenia gravis)
• Male		53–106 mcmol/day (0.6–1.2 mg/dL)		

Test	Specimen	Normal Values (SI Units [Conventional Units])	Possible Etiology	
			Higher Values	Lower Values
• Female		44–97 mcmol/L (0.6–1.2 mg/dL)		
Creatinine	24 hr		Anemia, leukemia, muscular atrophy, salmonellosis	Renal disease
• Male		53–106 mcmol/L (0.6–1.2 mg/dL)		
• Female		44–97 mcmol/L (0.5–1.1 mg/dL)		
Creatinine clearance	24 hr	1.42–2.25 mL/sec (85–135 mL/min)	—	Renal disease
• Male		1.78–2.32 mL/sec (107–139 mL/min)		
• Female		1.45–1.78 mL/sec (87–107 mL/min)		
Estriol	24 hr		Gonadal or adrenal tumour	
• Female				Agenesis of ovaries, endocrine disturbance, menopause, ovarian dysfunction
• Ovulatory phase		28–100 mcg/24 hr (104–370 nmol/L)		
• Luteal phase		22–80 mcg/24 hr (81–296 nmol/L)		
• Pregnancy		≤166,455 nmol/day (≤45,000 mcg/day)		
• Menopause		1.4–19.6 mcg/24 hr (5.2–72.5 nmol/L)		
• Male		5–18 mcg/24 hr (18–67 nmol/L)	—	—
Glucose	Random	Random: negative; 24-hour: <2.78 mmol/24 hr (<0.5 g/24 hr)	Diabetes mellitus, low renal threshold for glucose resorption, physiological stress, pituitary disorders	—
Hemoglobin	Random		Extensive burns, glomerulo-nephritis, hemolytic anemias, hemolytic transfusion reaction	—
• Male		140–180 mmol/L (14–18 g/dL)		
• Female		120–160 (12–16 g/dL)		
5-Hydroxyindole-acetic acid (5-HIAA)	24 hr	10–40 mcmol/day (2–8 mg/24 hr)	Malignant carcinoid syndrome	—

Test	Specimen	Normal Values (SI Units [Conventional Units])	Possible Etiology	
			Higher Values	Lower Values
Ketone bodies	Random	Negative (negative)	Alcoholism, fasting, high-protein diets, marked ketonuria, poorly controlled diabetes mellitus, starvation	—
Lead	24 hr	<0.40 mcmol/day (<80 mcg/day)	Lead poisoning	—
Metanephrine	24 hr	12–60 pg/mL	Pheochromocytoma	—
Myoglobin	Random	1.0–5.3 nmol/L (<90 ng/mL)	Crushing injuries, electric injuries, extreme physical exertion	—
pH	Random	4.6–8.0 (average, 6.0)	Chronic renal failure, compensatory phase of alkalosis, salicylate intoxication, vegetarian diet	Compensatory phase of acidosis, dehydration, emphysema
Phenylpyruvic acid	Random	Negative (negative)	Phenylketonuria	—
Phosphorus, inorganic	24 hr	0.97–1.45 mmol/L (3.0–4.5 mg/dL)	Fever, hypoparathyroidism, nervous exhaustion, rickets, tuberculosis	Acute infections, nephritis
Porphobilinogen	Random	Negative (negative)	Acute intermittent porphyria, liver disorders	—
	24 hr	0–6.6 mg/24 hr (0–2 mg/24 hr)		
Potassium	24 hr	25–100 mmol/day (25–100 mEq/L/day)	Alkalosis, chronic renal failure, Cushing's syndrome, diuretic therapy, hyperaldosteronism, starvation,	Acute kidney injury, Addison's disease, dehydration, diarrhea, malnutrition, reduced intake, vomiting
Protein (dipstick)	Random	Negative (negative)	Heart failure, nephritis, nephrosis, physiological stress	—
Protein (quantitative)	24 hr	<0.15 g/day (<150 mg/day)	Cardiac failure, inflammatory processes of urinary tract, nephritis, nephrosis, toxemia of pregnancy	—
• At rest		0.05–0.08 g/day (<50–80 mg/day)		
• During exercise		<0.25 g/day (<250 mg/day)		
Sodium	24 hr	40–250 mmol/day (40–250 mEq/day)	Acute tubular necrosis	Hyponatremia
Specific gravity	Random	1.005–1.030 (usually, 1.010–1.025)*	Albuminuria, dehydration, fever, GI losses (vomiting/diarrhea), glycosuria, SIADH	Diabetes insipidus, diuresis, overhydration

Test	Specimen	Normal Values (SI Units [Conventional Units])	Possible Etiology	
			Higher Values	Lower Values
Titratable acidity	24 hr	20–50 mEq/day (same as SI units)	Metabolic acidosis	Metabolic alkalosis
Uric acid	24 hr	1.48–4.43 mmol/day (250–750 mg/24 hr)	Gout, leukemia	Nephritis
Urobilinogen	24 hr	0.5–4.0 mg/24 hr (0.5–4.0 Ehrlich units/24 hr)	Hemolytic disease, hepatic parenchymal cell damage, liver disease	Complete obstruction of bile duct
Uroporphyrins	24 hr		Lead poisoning, liver disease, porphyria	—
• Male		10–53 nmol/24 hr (8–44 mcg/24 hr)		
• Female		10–26 nmol/24 hr (4–22 mcg/24 hr)		
Vanillylmandelic acid	24 hr	<35 mcmol/day (<6.8 mg/24 hr)	Pheochromocytoma, neuroblastomas	—

*Values decrease with age.

GI, gastro-intestinal; *SIADH*, syndrome of inappropriate antidiuretic hormone.

TABLE B-5
GASTRIC ANALYSIS

Test	Normal Values (SI Units [Conventional Units])	Possible Etiology	
		Higher Values	Lower Values
Basal			
Free hydrochloric acid	0.3 mmol/L (0.3 mEq/L)	Hypermotility of stomach	Pernicious anemia
Total acidity	15–45 mmol/L (15–45 mEq/L)	Gastric and duodenal ulcers, Zollinger-Ellison syndrome	Gastric carcinoma, severe gastritis
Post-stimulation			
Free hydrochloric acid	10–130 mmol/L (10–130 mEq/L)	—	—
Total acidity	20–150 mmol/L (20–150 mEq/L)	—	—

TABLE B-6
FECAL ANALYSIS

Test	Normal Values (SI Units [Conventional Units])	Possible Etiology	
		Higher Values	Lower Values
Blood*	Negative (negative)	Anal fissures, hemorrhoids, inflammatory bowel disease, malignant tumour, peptic ulcer	—
Colour			
• Brown		Various shades, depending on diet	—
• Clay		Biliary obstruction or presence of barium sulphate	—
• Tarry		More than 100 mL of blood in GI tract	—
• Red		Blood in large intestine	—
• Black		Blood in upper GI tract or iron medication	—
Fecal fat	7–21mmol/day (2–6 g/24 hr)	Chronic pancreatic disease, cystic fibrosis, malabsorption syndrome, obstruction of common bile duct, short gut syndrome	—
Mucus	Negative (negative)	Mucous colitis, spastic constipation	—
Pus	Negative (negative)	Chronic bacillary dysentery, chronic ulcerative colitis, localized abscesses	—
Urobilinogen	51–372 mcmol/100 g of stool (30–220 mg/100 g of stool)	Hemolytic anemias	Complete biliary obstruction

*Ingestion of meat may produce false-positive results. Patient may be placed on a meat-free diet for 3 days before the test.

GI, gastro-intestinal.

TABLE B-7
CEREBRO-SPINAL FLUID ANALYSIS

Test	Normal Values (SI Units [Conventional Units])	Possible Etiology	
		Higher Values	Lower Values
Blood	Negative (negative)	Intracranial hemorrhage	—
Cell count (age dependent)			
• White blood cells (WBCs)	0–5 × 10^6 WBCs/L (0–5 WBCs/mcL)	Inflammation or infections of CNS	—
• Red blood cells (RBCs)	Negative (negative)		—
Chloride	116–122 mmol/L of CSF (116–122 mEq/L of CSF)	Uremia	Bacterial infections of CNS (meningitis, encephalitis)
Glucose	2.8–4.2 mmol/L (50–75 mg/dL)	Diabetes mellitus, viral infections of CNS	Bacterial infections and tuberculosis of CNS
Protein			
• Lumbar	0.15–0.45 g/L (15–45 mg/dL)	Guillain-Barré syndrome, poliomyelitis, traumatic tap	—
• Cisternal	0.15–0.25 g/L (15–25 mg/dL)	Syphilis of CNS	—
• Ventricular	0.05–0.15 g/L (5–15 mg/dL)	Acute meningitis, brain tumour, chronic CNS infections, multiple sclerosis	—
Pressure	<20 cm H_2O (same as SI units)	Hemorrhage, intracranial tumour, meningitis	Head injury, spinal tumour, subdural hematoma

NB: All of the changes are based on the values presented in the Pagana & Pagana textbook.

CNS, central nervous system; *CSF*, cerebro-spinal fluid.

Glossary

A

abortion The loss or termination of a pregnancy before the fetus has developed to a state of viability. Ch. 56

absence seizure Type of seizure typically characterized by a brief staring spell that lasts only a few seconds; there may be an extremely brief loss of consciousness. Occurs most commonly in children and may cease altogether or evolve into another type of seizure as the child matures. Ch. 61

absorption Transfer of food products into circulation. Ch. 41

absorption atelectasis Absorption of oxygen into the bloodstream and collapse of the alveoli as a result of airway obstruction. Ch. 31

accommodation The convergence of the eyes and the constriction of the pupils when the eyes focus from a far to near object. Ch. 23

acculturation A multidimensional process in which individuals and groups undergo stages of adjustment, as well as changes in several domains, such as language, socioeconomic status, values, and attitudes, that result in increased similarity between two cultures. Ch. 2

achalasia Absence of peristalsis of the lower two-thirds smooth muscle of the esophagus. Ch. 44

acidosis A condition in which the blood pH drops below 7.35. Ch. 19

acne vulgaris An inflammatory disorder of the sebaceous glands most common in teenagers. Noninflammatory lesions include open comedones (blackheads) and closed comedones (whiteheads); inflammatory lesions include papules, pustules, and cysts. Ch. 26

acoustic neuroma A unilateral benign tumour that occurs where the vestibulo-cochlear nerve (cranial nerve [CN] VIII) enters the internal auditory canal. Ch. 24

acquired immune deficiency syndrome (AIDS) End stage of chronic HIV infection; a syndrome involving a defect in cell-mediated immunity that has a long incubation period and is manifested by various opportunistic infections and cancers. Ch. 17

acromegaly A condition caused by excessive secretion of growth hormone and characterized by an overgrowth of the bones and soft tissues in the hands, feet, and face; occurs most often as a result of a benign pituitary tumour (adenoma). Ch. 51

actinic keratosis Hyperkeratotic papules and plaques occurring on sun-exposed areas; also known as *solar keratosis*. Ch. 26

action potential The electrical impulse created and transported by the conduction system (specialized nerve tissue). Ch. 34

active transport A process requiring energy in which molecules move against the concentration gradient. Ch. 19

acupuncture The insertion of fine needles into the circulation of qi underneath the skin's surface to correct disruptions in the flow of qi. Ch. 12

acute arterial ischemia A sudden interruption in the arterial blood supply to a tissue, organ, or extremity that, if left untreated, can result in tissue death. Ch. 40

acute bronchitis An inflammation of the bronchi in the lower respiratory tract that is usually caused by infection. Ch. 30

acute coronary syndrome (ACS) Condition encompassing unstable angina, non–ST-segment elevation myocardial infarction, and ST-segment elevation myocardial infarction; develops when myocardial ischemia is prolonged and not immediately reversible. Ch. 36

acute illness Illness typically characterized by a sudden onset, with signs and symptoms related to the disease process itself. Ch. 5

acute kidney injury (AKI) An abrupt decline in kidney function, leading to a rise in serum creatinine or a reduction in urine output or both; the severity of dysfunction can range from a small increase in serum creatinine or reduction in urine output to the development of azotemia. (Previously known as *acute renal failure [ARF].*) Ch. 49

acute liver failure (ALF) A clinical condition characterized by rapid deterioration of liver function resulting in encephalopathy and coagulopathy in persons with no known history of liver disease. Ch. 46

acute pancreatitis An acute inflammation of the pancreas, ranging from mild edema to severe hemorrhagic necrosis. Ch. 46

acute renal failure (ARF) Former term for *acute kidney injury (AKI).* Ch. 49

acute respiratory distress syndrome (ARDS) A sudden and progressive form of acute respiratory failure in which the alveolar–capillary membrane becomes damaged and more permeable by intravascular fluid. Ch. 70

acute retroviral syndrome A flulike syndrome of fever, swollen lymph glands, sore throat, headache, malaise, nausea, muscle and joint pain, diarrhea, or a diffuse rash, or some combination of these. Ch. 21

acute rheumatic fever (ARF) A complication that occurs as a delayed sequela (usually after 2–3 wk) of group A streptococcal pharyngitis. Ch. 39

acute tubular necrosis (ATN) Necrosis of the renal tubular cells caused by ischemia, nephrotoxins, or sepsis; the most common intrarenal cause of AKI. Ch. 49

Addison's disease A disease that causes adrenocortical insufficiency (hypofunction of the adrenal cortex) and in which the supply of all three classes of adrenal corticosteroids (glucocorticoids, mineralocorticoids, and androgens) is reduced. Ch. 51

adhesions Bands of scar tissue that form between or around organs. Ch. 14

advance care planning A process of thinking about and sharing one's wishes for future health and personal care; a means by which an individual can tell others what would be important if he or she were ill and unable to communicate. Ch. 13

advance directives Legal documents specifying an individual's decisions regarding end-of-life care and specifying alternative decision makers as required. Ch. 13

advanced nursing practice Clinical nursing practice at a level that requires graduate education and attainment and advancement of in-depth nursing knowledge and expertise. Ch. 1

adventitious sounds Extra breath sounds that are abnormal. Ch. 28

adverse event An event that results in unintended harm to the patient and is related to the care and/or services provided to the patient rather than to the patient's underlying medical condition, p. 4

afterload The peripheral resistance against which the left ventricle must pump. Ch. 34

ageism Negative attitude based on age, leading to discrimination and disparities in the care of older people. Ch. 7

age-related macular degeneration (AMD) An eye disease that begins after age 60 that progressively destroys the macula (the central portion of the retina), causing irreversible central vision loss. Ch. 24

airway obstruction A blockage of the patient's airway, most commonly caused by the patient's tongue. Ch. 22

alarm reaction First stage of the stress response, in which the individual perceives a stressor physically or mentally and the fight-or-flight response is initiated. Ch. 8

aldosterone A potent mineralocorticoid that maintains extracellular fluid volume. Ch. 50

alkalosis A condition in which the blood pH is greater than 7.45. Ch. 19

allele One of two or more alternative forms of a gene that can occupy a particular chromosomal locus. Ch. 15

allergic rhinitis The reaction of the nasal mucosa to a specific allergen. Ch. 29

allostasis The process of achieving homeostasis in the presence of a challenge. Ch. 8

alopecia Partial or complete lack of hair resulting from normal aging, endocrine disorder, drug reaction, anticancer medication, or skin disease. Ch. 25

alternative therapies Therapies used as the primary treatment instead of traditional Western health practices. Ch. 12

alveolar hypoventilation A decrease in ventilation that results in an increase in partial pressure of arterial carbon dioxide ($PaCO_2$) and a consequent decrease in partial pressure of arterial oxygen (PaO_2). Ch. 70

Alzheimer's disease (AD) A chronic, progressive, degenerative disease of the brain. Ch. 62

amblyopia Reduced or no vision in an affected eye; also termed "lazy eye." Ch. 24

ambulatory surgery Also called *same-day surgery*; refers to surgery conducted in emergency departments, endoscopy clinics, doctors' offices, and outpatient surgery units in hospitals, after which the patient can be discharged on the same day. Ch. 20

amenorrhea Absence of menstruation. Chs. 53, 56

amniocentesis Transabdominal puncture of the amniotic sac under ultrasound guidance using a needle and syringe in order to remove amniotic fluid to detect genetic and biochemical disorders. Ch. 15

amyloid plaques Clusters of insoluble deposits of a protein called *beta-amyloid*, other proteins, remnants of neurons, non-nerve cells such as microglia (cells that surround and digest damaged cells or foreign substances), and other cells, such as astrocytes; present in abnormal quantities in the brains of persons with Alzheimer's disease. Ch. 62

amyotrophic lateral sclerosis (ALS) A rare, progressive neurological disorder characterized by loss of motor neurons and by weakness and atrophy of the muscles of the hands, the forearms, and the legs, spreading to involve most of the body and the face. Ch. 61

anaesthesia care team An anaesthesiologist-led care model in which anaesthesiologists practise among a team of other professionals such as nurse practitioners—anaesthesia, anaesthesia assistants, registered nurses, and respiratory therapists. Ch. 21

anaesthesiologist Physician who is an expert in administering potent drugs used to deliver general and regional anaesthesia and in ensuring absence of pain during surgery. Ch. 21

anal fissure A skin ulcer or a crack in the lining of the anal wall that is caused by trauma, local infection, or inflammation. Ch. 45

anal fistula An abnormal tunnel leading out from the anus or the rectum, which may extend to the outside of the skin, the vagina, or the buttocks. Ch. 45

analgesic ceiling A dosage at which no additional analgesia is produced regardless of further dosage increases. Ch. 10

anaphylactic shock An acute, life-threatening hypersensitivity (allergic) reaction to a sensitizing substance, such as a drug, chemical, vaccine, food, or insect venom. Ch. 69

anaplasia Cell differentiation to a more immature or embryonic form. Ch. 14

andragogy The theoretical basis of adult learning. Ch. 4

anemia A deficiency in the number of erythrocytes (red blood cells), the quantity or quality of hemoglobin, the volume of packed RBCs (hematocrit), or a combination of these. Ch. 33

anergy Immunodeficient condition characterized by lack of or diminished reaction to an antigen or a group of antigens. Ch. 16

aneurysm A permanent, localized outpouching or dilation of the blood vessel wall (either congenital or acquired). Chs. 40, 60

angina Chest pain that is the clinical manifestation of reversible myocardial ischemia. Ch. 36

anions Negatively charged ions. Ch. 19

ankylosing spondylitis (AS) A chronic inflammatory disease that affects primarily the axial skeleton, including the sacroiliac joints, intervertebral disc spaces, and costovertebral articulations. Ch. 67

ankylosis Stiffness or fixation of a joint, usually resulting from destruction of articular cartilage and subchondral bone with subsequent scarring. Ch. 64

anorexia nervosa A serious, often chronic, and life-threatening eating disorder characterized by self-imposed weight loss, endocrine dysfunction, and a distorted psychopathological attitude toward weight and eating. Ch. 42

antidiuretic hormone (ADH) A potent vasoconstrictor whose major physiological role is the regulation of fluid volume by stimulating reabsorption of water in the renal tubules; also called *vasopressin*. Ch. 50

antigen A substance that elicits an immune response. Ch. 16

aortic dissection Not a type of aneurysm; rather, a dissection that results from the creation of a false lumen (between the intima and

the media) through which blood flows. Ch. 40

aortic stenosis A narrowing or stricture of the aortic valve resulting in obstruction of the blood flow from the left ventricle to the aorta during systole; causes left ventricular hypertrophy and increased myocardial oxygen consumption. Ch. 39

aortic valve regurgitation (AR) Retrograde blood flow from the ascending aorta into the left ventricle when the valve should be closed, resulting in volume overload. Ch. 39

aphasia Total loss of comprehension and use of language or total inability to communicate. Ch. 60

apheresis A procedure in which components of the blood are separated and then one or more of those components is removed. Ch. 16

aplastic anemia A disease in which the patient has peripheral blood pancytopenia (decrease of all blood cell types—red blood cells, white blood cells, and platelets) and hypocellular bone marrow. Ch. 33

apoptosis Programmed cell death. Ch. 14

appendicitis An inflammation of the appendix. Ch. 45

aqueous humor A clear, watery fluid that fills the anterior and posterior chambers of the anterior cavity of the eye. Ch. 23

arterial blood pressure (BP) A measure of the pressure exerted by blood against the walls of the arterial system. Ch. 34

arterial pressure–based cardiac output (APCO) A technique for determining continuous cardiac output/continuous cardiac index, used to assess a patient's ability to respond to fluids by increasing stroke volume (preload responsiveness). Ch. 68

arteriovenous fistula (AVF) The preferred hemodialysis access, created by the surgical connection of a vein and an artery, usually in the forearm. Ch. 49

arteriovenous graft (AVG) A hemodialysis access created with a synthetic graft that is attached to an artery and vein; used for people who do not have suitable vessels for an AVF. Ch. 49

arthritis A type of rheumatic disease involving inflammation of a joint or joints; the most common types are osteoarthritis, rheumatoid arthritis, and gout. Ch. 67

arthrocentesis A procedure in which an incision or puncture is made in a joint capsule, usually to obtain samples of synovial fluid from within the joint cavity for a synovial fluid analysis. Ch. 64

arthrodesis The surgical fusion of a joint. Ch. 65

arthroplasty The reconstruction or replacement of a joint to relieve pain, improve or maintain range of motion, and correct deformity. Ch. 65

arthroscopy A procedure in which a small fibre-optic tube called an *arthroscope* is inserted into a joint and used to directly examine or to operate on the interior of the joint cavity. Ch. 64

Aschoff bodies Tiny, rounded or spindle-shaped nodules formed by a reaction to myocardial inflammation with accompanying swelling and fragmentation of collagen fibres. Ch. 39

ascites The accumulation of serous fluid in the peritoneal or the abdominal cavity. Ch. 46

assessment The collection of subjective and objective information about the patient. Ch. 1

assist-control ventilation (ACV) The ventilator delivery of a preset tidal volume at a preset frequency; when the patient initiates a spontaneous breath, the preset tidal volume is delivered. Ch. 68

assisted-living facilities (ALFs) Residential care facilities that provide housing and personal care. Ch. 7

asterixis Flapping tremors (liver flap) commonly affecting the arms and hands; a manifestation of hepatic encephalopathy. Ch. 46

asthma A chronic inflammatory disorder of the airways; inflammation causes varying degrees of obstruction, which leads to recurrent episodes of wheezing, breathlessness, chest tightness, and cough, particularly at night and in the early morning. Ch. 31

astigmatism A visual distortion caused by an unevenness in the cornea. Ch. 23

asystole The total absence of ventricular electrical activity. Ch. 38

atelectasis A complete or partial collapse of a lung or segment of a lung that occurs when the alveoli become deflated. Chs. 22, 30

atherosclerosis A disease characterized by deposits of lipids within the intima of the artery; major cause of coronary artery disease. Ch. 36

atrial fibrillation A cardiac dysrhythmia characterized by a total disorganization of atrial electrical activity resulting in loss of effective atrial contraction. Ch. 38

atrial flutter An atrial tachydysrhythmia identified by recurring, regular, sawtooth-shaped flutter waves. Ch. 38

atrophy Decrease in the size of a tissue or organ caused by a reduction in the number or size of the individual cells; characterized by decreased circumference and flabby appearance, leading to decreased function and tone. Ch. 14

aura Neurological symptoms such as visual field defects, tingling or burning sensations, paresthesias, motor dysfunction (e.g., weakness, paralysis), dizziness, confusion, and even loss of consciousness that usually precede the onset of migraine pain. Ch. 61

auscultation The act of listening for sounds produced by the body to assess normal conditions and deviations from normal;

particularly useful in evaluating the heart, lungs, abdomen, and vascular system. Ch. 3

autoimmunity An immune reaction to self-proteins: the immune system no longer differentiates self from nonself. Ch. 16

automated peritoneal dialysis (APD) A popular form of peritoneal dialysis that is done while the patient sleeps, using a device called a cycler. (Also called *continuous cycling peritoneal dialysis*.) Ch. 49

automatic external defibrillators (AEDs) Defibrillators that have rhythm detection capability and the ability to advise the operator to deliver a shock with hands-free defibrillator pads. Ch. 38

automaticity A property of specialized cells of the heart found in the sinoatrial (SA) node, parts of the atria, the atrioventricular (AV) node, and the His–Purkinje system that are able to discharge spontaneously. Ch. 38

autonomic dysreflexia A massive, life-threatening, uncompensated cardiovascular reaction mediated by the sympathetic nervous system that occurs in patients with spinal cord lesions in response to visceral stimulation. Ch. 63

autonomic nervous system (ANS) The division of the nervous system that governs involuntary functions of cardiac muscle, smooth (involuntary) muscle, and glands. Ch. 58

autosome Any chromosome that is not a sex chromosome. Ch. 15

avascular necrosis (AVN) Bone cell death as a result of inadequate blood supply. Ch. 65

azotemia An accumulation of nitrogen waste products (urea nitrogen, creatinine) in the blood. Ch. 49

B

bacteria One-celled microorganisms that are found virtually everywhere on earth and are involved in fermentation, putrefaction, infectious diseases, and nitrogen fixation. Ch. 17

bariatric surgery An invasive procedure used to treat morbid obesity. Ch. 43

baroreceptors Specialized nerve cells located in the carotid sinus and in the arch of the aorta that are sensitive to stretching and, when stimulated by an increase in blood pressure, send inhibitory impulses to the sympathetic vasomotor centre in the brain stem. Ch. 35

Barrett's esophagus A condition in which the normal squamous epithelium of the esophagus is replaced with columnar epithelium. Ch. 44

basal cell carcinoma (BCC) A locally invasive malignancy arising from epidermal basal cells; the most common type of skin cancer but the least deadly. Ch. 26

behavioural and psychological symptoms of dementia (BPSDs) The behavioural manifestations (e.g., appetite changes, slowed or excessive movements and speech, agitation, pacing, wandering) and psychological manifestations (e.g., anhedonia, worry, depressed mood, euphoria, fear) of dementia. Ch. 62

Bell's palsy A disorder characterized by the disruption of the motor branches of the facial nerve (cranial nerve VII) on one side of the face in the absence of any other disease. Ch. 63

benign neoplasms Well-differentiated tumours that are usually encapsulated, do not metastasize, have slight vascularity, and rarely recur. Ch. 18

benign paroxysmal positional vertigo (BPPV) A common cause of vertigo in which free-floating debris (“ear rocks”) in the

semicircular canal produces symptoms of dizziness, vertigo, lightheadedness, loss of balance, and nausea with specific head movements. Ch. 24

benign prostatic hyperplasia (BPH) A nonmalignant, noninflammatory enlargement of the prostate gland thought to be caused by an excessive accumulation of dihydroxytestosterone, stimulation by estrogen, or local growth hormone action. Ch. 57

bereavement The period after the death of a loved one during which grief is experienced and mourning occurs. Ch. 13

best buys Actions that should be undertaken immediately to produce accelerated results in terms of lives saved, diseases prevented, and heavy costs avoided. Ch. 5

bilirubin A pigment derived from the breakdown of aged red blood cells. Ch. 41

biological therapy Treatment involving the use of biological agents such as interferons, interleukins, monoclonal antibodies, and growth factors to modify the relationship between the host and the tumour. Ch. 18

bioterrorism The use of biological agents as the element of a terrorist attack; involves the deliberate spreading of microbes or toxins with the intent of causing disease or death in animals, plants, or humans. Ch. 72

blebs Air-filled alveolar dilations less than 1 cm in diameter on the edge of the lung at the apex of the upper lobe or superior segment of the lower lobe. Ch. 30

blood–brain barrier A physiological barrier between blood capillaries and brain tissue that protects the brain from certain potentially harmful agents while allowing nutrients and gases to enter. Ch. 58

blood pressure (BP) The force exerted by the blood against the walls of blood vessels; must be adequate for tissue perfusion to be maintained during activity and rest. Ch. 35

body mass index (BMI) A ratio of weight to height calculated by dividing weight (in kilograms) by height (in metres squared); higher ranges are associated with increased health risk. Ch. 43

bone marrow transplantation Life-saving procedure for a number of nonmalignant diseases; cells are allogeneic (from non-monozygotic twin donor), autologous (from self), or synegeneic (from healthy monozygotic twin). Ch. 18

botulism An acute neurological disorder that causes potentially life-threatening neuroparalysis due to a neurotoxin produced by *Clostridium botulinum*. Ch. 63

brachytherapy "Closed" radiation delivery system in which "radioactive materials are implanted or inserted directly into the tumour or close to the tumour." Ch. 18

brain abscess An accumulation of pus within the brain tissue that can result from a local or systemic infection. Ch. 59

brain reward system A system involving the mesolimbic and mesocortical pathways; responsible for creating the sensation of pleasure in reaction to certain behaviours that are required for survival of the human species. Ch. 11

breakthrough pain Moderate to severe pain that occurs despite treatment. Ch. 10

bronchiectasis A condition of the lungs characterized by permanent, abnormal dilation of one or more large bronchi. Ch. 30

bronchospasm The result of an increase in bronchial smooth muscle tone with resultant closure of small airways. Ch. 22

Brown-Séquard syndrome A syndrome resulting from damage to half of the spinal cord; characterized by a loss of motor function, sense of position, and sense of vibration on the same side as the lesion. Ch. 63

buffers Fast-acting regulatory mechanisms that act chemically to change strong acids into weaker acids or to bind acids to

neutralize their effect. Ch. 19

bulimia nervosa An eating disorder characterized by frequent binge eating, self-induced vomiting associated with loss of control over eating, and a persistent concern with body image. Ch. 42

burn An injury to the tissues of the body caused by heat, chemicals, electric current, or radiation. Ch. 27

bursitis Inflammation of a bursa. Ch. 65

C

calculus An abnormal stone formed in body tissues by an accumulation of mineral salts. Ch. 48

cancer A group of more than 200 diseases characterized by uncontrolled and unregulated growth of cells. Ch. 18

carcinogens Cancer-causing agents capable of producing cellular alterations. Ch. 18

carcinoma in situ A lesion with all the histological features of cancer except invasion; becomes invasive if left untreated. Ch. 18

carcinomas Malignant tumours that originate from embryonal ectoderm (skin and glands) and endoderm (mucous membrane linings of the respiratory, gastro-intestinal, and genito-urinary tracts). Ch. 18

cardiac index A measure of the cardiac output divided by the body mass index. Ch. 34

cardiac output (CO) The volume of blood ejected from the heart per minute; can be described as the stroke volume (SV, or amount of blood pumped out of the left ventricle per beat [~70 mL]) multiplied by the heart rate (HR) over 1 minute. Chs. 34, 35

cardiac pacemaker An electronic device used to pace the heart when the normal conduction pathway is damaged or diseased. Ch. 38

cardiac reserve The ability of the heart to respond to increased demands on the cardiovascular system by increasing cardiac output as much as three-fold or four-fold. Ch. 34

cardiac tamponade A condition that develops as fluid accumulates in the pericardial sac (pericardial effusion), causing an increase in intrapericardial pressure and producing compression of the heart. Ch. 39

cardiac transplantation Transfer of a heart from one person to another. Ch. 37

cardiogenic shock Shock occurring when either systolic or diastolic dysfunction of the pumping action of the heart results in compromised cardiac output. Ch. 69

cardiomyopathy A group of diseases that directly affect the structural or functional ability of the myocardium. Ch. 39

caregiver burden The overall physical, emotional, and financial costs of caregiving. Ch. 5

carpal tunnel syndrome (CTS) A condition caused by compression of the median nerve, which enters the hand through the narrow confines of the carpal tunnel, located in the wrist. Ch. 65

carrier An individual who carries a copy of a mutated gene for a recessive disorder. Ch. 15

cataplexy A brief and sudden loss of skeletal muscle tone or muscle weakness. Manifestations range from a brief episode of muscle weakness to complete postural collapse and falling to the ground. Ch. 9

cataract An area of opacity within the lens. Ch. 24

catecholamines Substances that are usually considered neurotransmitters but are hormones when secreted by the adrenal medulla; they include epinephrine, norepinephrine, and dopamine. Catecholamines are an essential part of the body's response to stress. Ch. 50

cations Positively charged ions. Ch. 19

CBRNE event Any situation in which weapons of a **c**hemical, **b**iological, **r**adiological, **n**uclear, or **e**xplosive nature are used with the goal of causing harm. Ch. 72

ceiling effect A phenomenon in which increasing the dose of a given medication beyond an upper limit provides no greater analgesia.

Ch. 10

celiac disease An autoimmune disease characterized by damage to the small intestinal mucosa from the ingestion of wheat, barley, and rye in genetically susceptible individuals. Ch. 45

cell-mediated immunity Immune responses that are initiated through specific antigen recognition by T cells. Ch. 16

cellulitis An inflammation of subcutaneous tissues. Ch. 26

central nervous system (CNS) The division of the nervous system that consists of the brain, the spinal cord, and cranial nerves I and II. Ch. 58

cerebral edema Increased accumulation of fluid in the extravascular spaces of brain tissue. Ch. 59

cerebro-spinal fluid (CSF) A clear, colourless fluid that provides cushioning for the brain and the spinal cord, allows fluid shifts from the cranial cavity to the spinal cavity, and carries nutrients. Ch. 58

cerebro-vascular accident (CVA) The medical term for *stroke*. Ch. 60

certification of death A written formal statement that the patient is dead, which is usually required within 24 hours of a death. Ch. 13

chancre A painless, indurated lesion found on the penis, vulva, lips, mouth, vagina, or rectum; a primary manifestation of syphilis. Ch. 55

chemical burns Burns that result from contact with acids, alkalis, and organic compounds. Ch. 27

chemoreceptor A receptor in the medulla that responds to a change in the chemical composition (partial pressure of arterial carbon dioxide [$PaCO_2$] and pH) of the fluid around it. Ch. 28

chest physiotherapy Airway clearance technique for reducing mucus; consists of percussion, vibration, and postural drainage. Ch. 31

Cheyne–Stokes respiration A pattern of breathing characterized by alternating periods of apnea and deep, rapid breathing. Ch. 13

chlamydial infections A superficial mucosal infection, caused by *Chlamydia trachomatis*, that can be transmitted during vaginal, anal, or oral sex; the most prevalent bacterial sexually transmitted infection in Canada today. Ch. 55

cholecystitis Inflammation of the gallbladder. Ch. 46

cholelithiasis Stones in the gallbladder. Ch. 46

chorionic villus sampling (CVS) Aspiration of fetal trophoblastic tissue (chorionic villi) by either transcervical or transabdominal approach for prenatal evaluation of the chromosomal, enzymatic, and DNA status of the fetus. Ch. 15

chronic bronchitis The presence of chronic productive cough for 3 months in 2 successive years. Ch. 31

chronic disease management The use of elements and tools within the health care system (e.g., information systems, decision support tools, self-management promotion, and realignment of health services) and within the community (e.g., a supportive environment, health policy, and strengthened community action) to help patients living with chronic diseases. Ch. 6

chronic illness Health problems that persist over extended periods and that are often (but not always) associated with participation and activity limitations (disability). Ch. 5

chronic kidney disease (CKD) The progressive, irreversible destruction of the nephrons in both kidneys, leading to loss of kidney function; classified at one of five stages, depending on level of severity based on glomerular filtration rate. Ch. 49

chronic kidney disease–mineral and bone disorder (CKD–MBD) A clinical syndrome with systemic components that include characteristic bone abnormalities, changes in mineral balance, and vascular and other soft tissue calcification. Ch. 49

chronic obstructive pulmonary disease (COPD) A preventable disease characterized by persistent airflow limitation that is usually progressive; associated with enhanced chronic inflammatory response in the airways and lungs, caused primarily by cigarette smoking and other noxious particles and gases. Ch. 31

chronic pancreatitis Progressive destruction of the pancreas as it is replaced with fibrotic tissues. Ch. 46

chronic stable angina Chest pain that occurs intermittently over a long period with the same pattern of onset, duration, and intensity of symptoms. Ch. 36

chronic venous insufficiency (CVI) A condition in which leg veins and valves fail to keep blood moving forward. Ch. 40

chylothorax Presence of lymphatic fluid in the pleural space caused by a leak in the thoracic duct. Ch. 30

circadian rhythms The biological rhythms of behaviour and physiology that fluctuate within a 24-hour period. Ch. 9

circadian rhythm sleep–wake disorders (CRSWDs) A group of sleep disorders that result in a person having good quality sleep at the wrong time of day. Ch. 9

circulating nurse A perioperative nurse who is not scrubbed, gowned, or gloved and remains in an unsterile field. Ch. 21

circulatory assist devices (CADs) Devices that are used to decrease cardiac work and improve organ perfusion in patients with heart failure. Ch. 68

cirrhosis The final stage of chronic liver disease; a diffuse pathological process characterized by fibrosis and conversion of normal liver architecture to abnormal nodules. Ch. 46

clinical (critical) pathway A plan outlining daily care goals for select health care problems; includes a nursing care plan, specific

interventions for each day of hospitalization, and a documentation tool. Ch. 1

clitoris Erectile tissue in women that lies anterior to the urethral meatus and the vaginal orifice and becomes engorged during sexual excitation. Ch. 53

cluster headaches A rare form of headache that involves repeated headaches that can occur for weeks to months at a time, followed by periods of remission; characterized by intense, stabbing pain that is ipsilateral in nature and lasts an average of 97 minutes per attack. Ch. 61

collaborative problems Potential or actual complications of disease or of treatment that nurses manage together with other health care providers. Ch. 1

collateral circulation Arterial connections within the coronary circulation; development depends on (a) the inherited predisposition to develop new blood vessels and (b) the presence of chronic ischemia. Ch. 36

colorectal cancer A malignant disease of the colon, the rectum, or both; the second-most common cause of cancer death in Canada. Ch. 45

coma A profound state of unconsciousness. Ch. 59

community-acquired pneumonia (CAP) A lower respiratory tract infection of the lung parenchyma with onset in the community or during the first 2 days of hospitalization. Ch. 30

comorbidity The presence of two or more chronic illnesses that are not directly related to each other in a person at the same time. Ch. 5

compartment syndrome A condition in which swelling and increased pressure within a limited space (a compartment) press on and compromise the function of blood vessels, nerves, and tendons that run through that compartment. Ch. 65

complementary therapies Therapies that accompany traditional Western health practices. Ch. 12

complete heart block A type of heart block in which no impulses from the atria are conducted to the ventricles; also called *third-degree AV heart block*. Ch. 38

compliance A measure of the elasticity of the lungs and thorax. Ch. 28

concussion A sudden, transient, mechanical head injury, with disruption of neural activity and a change in the level of consciousness; considered a mild brain injury. Ch. 59

Confusion Assessment Method A widely used, validated screening instrument and diagnostic aid that is effective in identifying the presence of delirium. Ch. 62

conjunctiva A transparent mucous membrane that covers the inner surfaces of the eyelids (the palpebral conjunctiva) and extends over the sclera (the bulbar conjunctiva), forming a "pocket" under each eyelid. Ch. 23

conjunctivitis An infection or inflammation of the conjunctiva caused by bacteria, viruses, allergies, or chemical irritants. Ch. 24

constipation A decrease in frequency of bowel movements from what is "normal" for the individual; hard, difficult-to-pass stools; a decrease in stool volume; and retention of feces in the rectum; or some combination of these symptoms. Ch. 45

continuing competence The ongoing ability to perform one's duties skillfully, safely, and ethically. Ch. 1

continuous ambulatory peritoneal dialysis (CAPD) A type of peritoneal dialysis that is done during the day and consists of a minimum of four exchanges of dialysis fluid over a 24-hour period. Ch. 49

continuous positive airway pressure (CPAP) A treatment for severe apnea or hypopnea in which a nasal mask attached to a high-flow

blower is applied to maintain pressure in the airway and prevent airway collapse. Ch. 9

continuous renal replacement therapy (CRRT) An alternative or adjunctive method for treating acute kidney injury that provides a means by which uremic toxins and fluids are removed from patients who are hemodynamically unstable, while acid–base status and electrolytes are adjusted slowly and continuously. Ch. 49

contracture An abnormal, usually permanent condition of a muscle or joint, characterized by flexion and fixation. Chs. 27, 64

contusion Bruising of the brain tissue within a focal area. Ch. 59

coping A person's cognitive and behavioural efforts to manage specific external or internal stressors that seem to exceed available resources. Ch. 8

coping resources Internal or external assets, characteristics, or actions that a person draws upon to manage stress. Ch. 8

cor pulmonale A hypertrophy of the right side of the heart, with or without heart failure, resulting from pulmonary hypertension. Diseases of the lung or thorax or changes in pulmonary circulation can lead to pulmonary hypertension. Chs. 30, 31

coronary angiography Imaging with left-sided heart catheterization in which the catheter is positioned at the origin of the coronary arteries and contrast medium is injected into the arteries; images identify the location and severity of any coronary blockages. Ch. 34

coronary artery disease (CAD) An abnormal condition that may affect the heart's arteries and produce various pathological effects, especially the reduced flow of oxygen and nutrients to the myocardium. Ch. 36

coronary revascularization An intervention that restores blood flow to the affected myocardium. Ch. 36

corticosteroid Any of the hormones synthesized by the adrenal cortex (excluding androgens). Ch. 50

cortisol The most abundant and potent glucocorticoid; one of its major functions is the regulation of blood glucose concentration. Ch. 50

costovertebral angle A physical examination landmark used to locate the kidneys, formed by the rib cage and the vertebral column. Ch. 47

cough variant asthma A type of asthma in which cough is the only symptom. Ch. 31

crackles Short, low-pitched sounds caused by the passage of air through an airway intermittently occluded by mucus, unstable bronchial wall, or fold of mucosa. Ch. 28

cranial nerves (CN) The 12 paired nerves composed of cell bodies with fibres that exit from the cranial cavity. Ch. 58

creatinine A waste product produced by protein breakdown (primarily body muscle mass); clearance of creatinine by the kidney approximates the glomerular filtration rate. Ch. 47

crepitation Crackling sound or grating sensation as a result of friction between bones, broken bone, or cartilage bits in joint. Ch. 64

CREST An acronym used to describe the clinical manifestations of systemic sclerosis (scleroderma): **c**alcinosis, **R**aynaud's phenomenon, **e**sophageal dysfunction, **s**clerodactyly, and **t**elangiectasia. Ch. 67

cretinism Hypothyroidism that develops in infancy, caused by thyroid hormone deficiencies during fetal or early neonatal life. Ch. 50

Creutzfeldt–Jakob disease (CJD) A very rare, fatal, infectious brain disorder thought to be caused by accumulation in the brain of an abnormally folded prion protein. Ch. 62

critical incident stress management (CISM) or debriefing A comprehensive approach to preventing and managing the emotional trauma that can be a result of involvement in a disaster response. Ch. 72

critical limb ischemia A condition characterized by chronic ischemic rest pain lasting more than 2 weeks, arterial leg ulcers, or gangrene of the leg as a result of peripheral artery disease. Ch. 40

critical thinking The art of analyzing and evaluating thinking with a view to improving it. Ch. 1

Crohn's disease A chronic, inflammatory bowel disease of unknown origin that can affect any part of the gastro-intestinal tract, from the mouth to the anus. Ch. 45

cross-tolerance The development of resistance to one or more effects of a drug as a result of tolerance developed to a similar drug. Ch. 11

cryosurgery The use of subfreezing temperatures to destroy epidermal lesions. Ch. 26

cultural competence The application of knowledge, attitudes, and skills that enhance cross-cultural communication and foster meaningful, respectful interactions with others. Ch. 2

cultural imposition The situation in which a person's own cultural beliefs and practices are, intentionally or unintentionally, imposed on another person or group of people. Ch. 2

cultural safety A concept that focuses on the power imbalances that lead to a disregard for health and illness beliefs of the Indigenous people and to a privileging of the dominant cultural values. Ch. 2

culture A way of life characterized by dimensions such as ethnicity, language, religion, sex, socioeconomic class, professional status, age, sexual orientation, group history, and life experiences. Ch. 2

cultured epithelial autograft Skin grafts grown from biopsy specimens obtained from the patient's own skin. Ch. 27

curettage The removal and scooping away of tissue using an instrument with a circular cutting edge attached to a handle. Ch. 26

Cushing's syndrome A spectrum of clinical abnormalities caused by excess levels of corticosteroids, particularly glucocorticoids; most common causes are iatrogenic administration of exogenous corticosteroids (e.g., prednisone) in large doses for several weeks or longer and excessive production of cortisol by the adrenal cortex. Ch. 51

cyst Palpable, fluid-filled mass. Ch. 54

cystic fibrosis An autosomal recessive, multisystem disease characterized by altered function of the exocrine glands, involving primarily the lungs, the pancreas, and the sweat glands. Ch. 31

cystitis An inflammatory condition of the urinary bladder, characterized by pain, urgency and frequency of urination, and hematuria. Ch. 48

cystocele Herniation or protrusion of the urinary bladder through the wall of the vagina; occurs when support between the vagina and the bladder is weakened; also known as *anterior wall prolapse*. Ch. 56

cystometrography A urodynamic study used to evaluate the compliance (elastic property) and stability of the detrusor muscle of the bladder and to evaluate bladder tone, sensations of filling, and bladder (detrusor) stability. Ch. 47

cystoscopy A radiological bladder procedure in which contrast material is instilled into the bladder to allow inspection of the interior of the bladder and evaluation of the vesico-ureteral reflux using a tubular lighted instrument called a cystoscope. Ch. 47

cytokines Soluble factors secreted by white blood cells and a variety of other cells in the body. Ch. 16

D

database All the health information about a patient, including the data from the nursing history and physical examination, the data from the medical history and physical examination, results of laboratory and diagnostic tests, and information contributed by other health care providers. Ch. 3

death The permanent loss of capacity for consciousness and all brain stem functions. Ch. 13

death rattle Noisy, wet-sounding respirations caused by mouth breathing and accumulation of mucus in the airways. Ch. 13

debridement Removal of necrotic tissue from a wound to prevent infection and promote healing. Ch. 27

decontamination The process of removing or neutralizing a hazardous agent from the environment, property, equipment, or a life form, through the use of water, cleansers, or neutralizers. Ch. 72

deep-vein thrombosis (DVT) A disorder involving a thrombus in a deep vein, most commonly the iliac and femoral veins. Ch. 40

defecation The discharge of feces from the rectum. Ch. 41

degenerative disc disease (DDD) Progressive degeneration that results in intervertebral discs' losing their elasticity, flexibility, and shock-absorbing capabilities; thinning of the discs also occurs. A normal process of aging. Ch. 66

deglutition The process of swallowing. Ch. 41

dehiscence Separation and disruption of previously joined wound edges. Ch. 14

delayed awakening Longer-than-expected duration of postoperative unconsciousness, usually caused by prolonged drug action or,

rarely, by neurological injury. Ch. 22

delayed sleep phase disorder (DSPD) Difficulty falling asleep (staying awake until 0100–0300 hours) and typically sleeping later into the morning. Ch. 9

delirium A state of acute mental confusion. Ch. 62

dementia A collection of symptoms caused by various diseases affecting the brain. Ch. 62

dementia with Lewy Bodies (DLB) A type of dementia characterized by the presence of Lewy bodies (deposits of alpha-synuclein protein) in the brain stem, amygdala, and cortex. Ch. 62

deoxyribonucleic acid (DNA) A nucleic acid that forms the chromosomes in human cells. Ch. 15

dermatomes Areas on the skin that are innervated primarily by a single spinal cord segment. Chs. 10, 58

dermatomyositis An inflammatory myopathy that presents with characteristic skin changes along with the symptoms of polymyositis (diffuse, idiopathic, inflammatory myopathies of the connective tissues, especially striated muscle, that produce bilateral weakness, usually most severe in the proximal or the limb-girdle muscles). Ch. 67

dermis Connective tissue below the epidermis. Ch. 25

determinants of health Factors that influence the health of individuals and groups. Ch. 1

deviated septum A deflection of the normally straight nasal septum. Ch. 29

diabetes insipidus (DI) A group of conditions associated with a deficiency of production or secretion of antidiuretic hormone (ADH) or with a decreased renal response to ADH; caused by injury to the neurohypophyseal system. Ch. 51

diabetes mellitus (DM) A multisystem disease related to abnormal insulin production, impaired insulin utilization, or both. Ch. 52

diabetic ketoacidosis (DKA) An acute metabolic complication of diabetes mellitus occurring when fats are metabolized in the absence of insulin; caused by a profound deficiency of insulin and characterized by hyperglycemia, ketosis, metabolic acidosis, and dehydration (volume depletion). Ch. 52

diabetic nephropathy A microvascular complication of diabetes mellitus associated with damage to the small blood vessels that supply the glomeruli of the kidney; the leading cause of end-stage renal disease in Canada. Ch. 52

diabetic neuropathy Nerve damage that occurs because of the metabolic derangements associated with diabetes mellitus. Ch. 52

dialysis A clinical technique, used to correct fluid and electrolyte imbalances and to remove waste products in renal failure, in which substances move from the blood through a semipermeable membrane (dialyzer/peritoneal membrane) and into a dialysis solution (dialysate). Ch. 49

diarrhea The frequent passage of loose, watery stools; a symptom, not a disease. Ch. 45

diastole Relaxation of the myocardium. Ch. 34

diastolic blood pressure (DBP) The residual pressure of the arterial system during ventricular relaxation. Ch. 34

diffuse axonal injury (DAI) Widespread axonal damage occurring after a mild, moderate, or severe traumatic brain injury. Ch. 59

diffusion The movement of molecules from an area of high concentration to one of low concentration. Ch. 19

diffusion limitation Decrease in gas exchange across the alveolar–capillary membrane caused by processes that thicken or destroy the membrane. Ch. 70

digestion The process by which food is broken down in the gastrointestinal tract in order to be converted into a substance suitable for absorption and assimilation into the body; involves both mechanical digestion (mastication) and chemical digestion. Ch. 41

dilated cardiomyopathy A disease characterized by a diffuse inflammation and rapid degeneration of myocardial fibres that result in ventricular dilation, impairment of systolic function, atrial enlargement, and stasis of blood in the left ventricle. Ch. 39

disability Any of a range of mental or physical impairments that limit one's functioning in society. Ch. 5

disaster The outcome of a natural hazard or event (e.g., hurricane, flood, earthquake) or a result of human action or error, whether malicious (e.g., terrorist attacks, use of biological warfare) or unintentional (e.g., an accidental chemical spill) that seriously disrupts the functioning of a community or society. Ch. 72

disaster nursing The provision of nursing care, advocacy, and health promotion within the context of a disaster situation. Ch. 72

disease A condition that a practitioner views from a pathophysiological model. Ch. 5

dislocation A severe injury of the ligamentous structures that surround a joint, resulting in the complete displacement of the bone from its normal position. Ch. 65

disseminated intravascular coagulation (DIC) A serious bleeding and thrombotic disorder resulting from the abnormally initiated and accelerated clotting and anticlotting processes that occur in response to disease or injury. Ch. 33

diversity Presence of persons with differences from the majority or dominant group that is assumed to be the norm. Ch. 2

diverticulum An outpouching of the mucosa through the circular smooth muscle of the intestinal wall; may occur at any point

within the gastro-intestinal tract but is most commonly found in the sigmoid colon. Ch. 45

domestic violence A pattern of coercive behaviour in a relationship that involves fear; humiliation; intimidation; neglect; intentional physical, emotional, financial, or sexual injury or assault; or a combination of these. Ch. 71

dry gangrene Necrosis of an appendage as a result of degenerative changes that occur with chronic diseases such as atherosclerosis or diabetes, when the blood supply to the lower extremities is gradually reduced. Ch. 14

ductus deferens (or vas deferens) A long, thick tube through which sperm exit the epididymis. Ch. 53

dysarthria A disturbance in the muscular control of speech. Ch. 60

dysmenorrhea Abdominal cramping pain or discomfort associated with menstrual flow. Ch. 56

dyspareunia Abnormal pain during sexual intercourse. Ch. 53

dysphagia Difficulty swallowing. Ch. 44

dysphasia Impaired ability to communicate; often used interchangeably with *aphasia*. Ch. 60

dysplasia Abnormal differentiation of dividing cells that results in changes in their size, shape, and appearance. Ch. 14

dysplastic nevi Atypical moles that are larger than usual and have irregular borders and various shades of colour. Ch. 26

dyspnea Shortness of breath. Ch. 28

dysrhythmias Abnormal cardiac rhythms. Ch. 38

E

ecchymosis Bruising. Ch. 32

ectopic pregnancy The implantation of the fertilized ovum anywhere outside the uterine cavity. Ch. 56

eHealth The use of communication and information technologies in order to support the delivery and integration of clinical care within and across settings. Ch. 1

ejection fraction (EF) The percentage of end-diastolic blood volume that is ejected during systole. Ch. 34

elastic recoil The tendency for the lungs to recoil after being stretched or expanded. Ch. 28

elder abuse A single or repeated act, or lack of appropriate action, occurring within a relationship in which there is an expectation of trust, which causes harm or distress to an older person. Ch. 7

elder mistreatment An act of commission (elder abuse) or omission (elder neglect) that harms or threatens to harm an older adult's health or welfare. Ch. 7

elder neglect An act of omission that harms or threatens to harm an older adult's health or welfare. Ch. 7

elective surgery Surgery that is planned. Ch. 20

electrical burns Burns that result from intense heat generated from an electric current. Ch. 27

electrocardiogram (ECG) A graphic tracing of the electrical impulses produced in the heart. Ch. 38

electrolytes Substances whose molecules dissociate or split into ions when placed in solution. Ch. 19

electronic health records (EHRs) Computerized records of patient information that are shared among all health care team members involved in a patient's care and that moves with the patient to other providers and across care settings. Ch. 1

embolic stroke A stroke that occurs when an embolus lodges in and occludes a cerebral artery, resulting in infarction and edema of the area supplied by the involved vessel. Ch. 60

emergence delirium A neurological alteration that occurs in some patients awakening from anaesthesia after surgery, manifesting as restlessness, agitation, disorientation, thrashing, and shouting; also called *violent emergence*. Ch. 22

emergency A present or imminent event that requires a rapid and skilled response to protect the health, safety, and wellness of individuals and to limit damage to property or the environment. Ch. 72

emergency management and disaster planning Advanced preparation for a variety of potential situations, including mass casualty incidents, natural or biological events, technological failures, human conflicts, and acts of terrorism. Ch. 72

emergency surgery Surgery that is unexpected and urgent. Ch. 20

emerging infectious disease An infectious disease whose incidence has recently increased or threatens to increase in the immediate future. Ch. 17

emotion-focused coping A coping strategy that concentrates on methods of managing the emotional response to a stressful event (e.g., discussing feelings with a friend, relaxing in a hot bath). Ch. 8

empathy The quality that allows one person to enter into the world of another so as not to judge, sympathize, or correct but to establish mutual understanding. Ch. 4

emphysema Destruction of the alveoli. Ch. 31

empirical therapy Therapy based on observation and experience, implemented when the condition's exact cause is not known. Ch. 30

empyema A pleural effusion that contains pus. Ch. 30

encephalitis Acute inflammation of the brain. Ch. 59

end-of-life care Care given during the last months, weeks, or days of a patient's life. Ch. 13

endometriosis The presence of endometrial epithelial cells in sites outside the uterine cavity. Ch. 56

endomyocardial biopsy (EMB) A technique that involves removing several small pieces of myocardial tissue percutaneously from the right ventricle and microscopically examining the samples. Ch. 39

endoscopy The direct visualization of a body structure through a lighted fibre-optic instrument (endoscope). Ch. 41

endotracheal (ET) intubation Insertion of a tube into the trachea, bypassing the upper airway and laryngeal structures, to create an artificial airway. Ch. 68

end-stage renal disease (ESRD) Advanced kidney disease with glomerular filtration rate <15 mL/min, when most patients with chronic kidney disease require some form of renal replacement therapy; also referred to as *stage 5 CKD*. Ch. 49

enteral nutrition (EN) Nutrition (e.g., a nutritionally balanced liquefied food or formula) delivered through the gastro-intestinal tract distal to the oral cavity via a tube, catheter, or stoma. Ch. 42

enucleation Removal of the eye. Ch. 24

epidemic An occurrence of the number of cases of a communicable disease exceeding the normal expected occurrence during a given period. Ch. 72

epidermis The thin avascular superficial layer of the skin; made up of an outer dead portion that serves as a protective barrier and a

deeper, living portion that folds into the dermis. Ch. 25

epididymis A comma-shaped structure located on posterior-superior aspect of each testis within the scrotum; transports the sperm as they mature. Ch. 53

epididymitis An inflammation of the epididymis, usually secondary to an infectious process and rarely as a result of trauma or urinary reflux down the vas deferens from the urethra. Ch. 57

epidural analgesia The infusion of pain-relieving medications through a catheter placed into the epidural space surrounding the spinal cord. Ch. 22

epidural block Injection of a local anaesthetic into the epidural (extradural) space via either a thoracic or a lumbar approach. Ch. 21

epidural hematoma A collection of blood that results from bleeding between the dura mater and the inner surface of the skull; produces compression of the dura mater and thus of the brain. Ch. 59

epilepsy A condition in which at least two spontaneous seizures occur more than 24 hours apart; caused by a chronic underlying pathology. Ch. 61

epispadias A congenital opening of the urethra on the dorsal surface of the penis; usually associated with other genito-urinary tract defects. Ch. 57

epistaxis Nosebleed. Ch. 29

equianalgesic dose A dose of one analgesic that produces pain-relieving effects equivalent to those of another analgesic. Ch. 10

erectile dysfunction (ED) The inability to attain or maintain an erect penis that allows satisfactory sexual performance. Ch. 57

erythema Skin redness occurring in patches of variable size and shape, caused by heat, certain drugs, alcohol, ultraviolet rays, and other problems. Ch. 25

erythropoiesis The process of red blood cell production. Ch. 32

escharotomy Scalpel or electrocautery incision into necrotic tissue from a severe burn; performed when circulation to extremities is compromised. Ch. 27

esophageal cancer A rare malignant neoplasm of the esophagus; the two main types are squamous cell carcinoma and adenocarcinoma. Ch. 44

esophageal diverticula Saclike outpouchings of one or more layers of the esophagus. Ch. 44

esophageal speech A method of swallowing air, trapping it in the esophagus, and releasing it to create sound. Ch. 29

esophageal varices Complexes of tortuous veins at the lower end of the esophagus; they are enlarged and swollen as a result of portal hypertension. Ch. 46

esophagitis Inflammation of the esophagus. Ch. 44

essential data Clinical and other information about a patient that must be included in the patient's records (e.g., level of distress). Ch. 13

ethnicity The common social, cultural, linguistic, or religious heritage of a group of people. Ch. 2

ethnocentrism A tendency of people to believe that their way of viewing and responding to the world is the most correct, natural, and superior one. Ch. 2

ethnogeriatrics A specialty area of culturally competent care for older people who are identified with a particular ethnic group. Ch. 7

eustress Stress associated with positive events such as the birth of a baby, going for a run, falling in love, or attending a much-anticipated event. Ch. 8

evaluation Process of determining whether identified outcomes have been met. Ch. 1

evidence-informed nursing Nursing that employs best practices as determined by the most current reliable research. Ch. 1

evisceration Protrusion of intestines through a wound when wound edges separate to a certain extent. Ch. 14

Ewing sarcoma family of tumours (ESFT) One of the most common primary malignant neoplasms of bone and soft tissue; characterized by rapid growth within the medullary cavity of long bones, especially the femur, humerus, pelvis, and tibia. Ch. 66

excision and grafting Procedure during which eschar is removed down to the subcutaneous tissue or fascia, depending on the degree of injury, and a graft is then placed on clean, viable tissue to achieve good adherence. Ch. 27

exophthalmos A protrusion of the eyeballs from the orbits; a type of infiltrative ophthalmopathy that results from impairment of venous drainage from the orbit, which causes increased fat deposits and fluid (edema) in the retro-orbital tissues. Ch. 51

expected patient outcomes Goals that articulate what is desired or expected as a result of care. Ch. 1

explanatory model Set of beliefs regarding what causes the disease or illness and the methods that would potentially best treat the condition. Ch. 2

external otitis Inflammation or infection of the epithelium of the auricle and ear canal. Ch. 24

extravasation The infiltration of drugs into tissues surrounding the infusion site. Ch. 18

F

facilitated diffusion Diffusion that involves the use of a protein carrier in the cell membrane (e.g., glucose transport into cell). Ch. 19

facilitator Someone who helps a group of people share insights about a common problem and keeps information moving among group members. Ch. 4

familial Alzheimer's disease Alzheimer's disease that develops in someone younger than 60 years old. Ch. 62

family-centred care An approach to nursing care that involves patients and families in the planning, delivery, and evaluation of health care and emphasizes dignity and respect, information sharing, participation, and collaboration. Ch. 6

family conference A meeting of the patient, caregivers, and members of the interdisciplinary health care team to identify needs for information and assistance with health care matters. Ch. 4

fat embolism syndrome (FES) A syndrome characterized by the presence of systemic fat globules that are distributed into tissues and organs after a traumatic skeletal injury involving fractures. Ch. 65

fatigue A subjective and complex condition that prevents functioning at normal capacity due to a feeling of exhaustion. Ch. 5

fecal impaction An accumulation of hardened feces in the rectum or the sigmoid colon that the individual is unable to move. Ch. 45

fecal incontinence The involuntary passage of stool. Ch. 45

fetor hepaticus A musty, sweet odour of the patient's breath resulting from the accumulation of digestive by-products that the

liver is unable to degrade. Ch. 46

fibrinolysis A means of maintaining blood in its fluid form; a continual process that results in the dissolution of fibrin and thus clots. Ch. 32

fibroadenoma A common cause of discrete benign breast lumps in young women; painless, round, well delineated, and very mobile. Ch 54

fibroblasts Immature connective tissue cells that migrate into the healing site and secrete collagen. Ch. 14

fibrocystic changes A benign condition of the breasts characterized by development of excess fibrous tissue, hyperplasia of the epithelial lining of the mammary ducts, proliferation of mammary ducts, and cyst formation. Ch. 54

fibromyalgia syndrome (FMS) A chronic disorder characterized by widespread, nonarticular musculo-skeletal pain and fatigue with multiple tender points. Ch. 67

fistula An abnormal passage that forms between organs or between a hollow organ and the skin. Ch. 14

flail chest A condition resulting from multiple rib fractures, causing instability of the chest wall. Ch. 30

fluid spacing Distribution of body water in different body compartments. Ch. 19

focal seizures One of the major classes of seizures; caused by electrical activity that is focal to a particular area of the brain, resulting in unilateral manifestations. (Previously known as *partial seizures*.) Ch 61

food security The ready availability of enough nutritious food to meet the daily requirements for health and well-being. Ch. 42

fracture A disruption or break in the continuity of the structure of bone. Ch. 65

frail older adults Older adults who, because of declining resources and physical health (e.g., as evidenced by unplanned weight loss, weakness, poor endurance and energy, slowness, or low activity), are most vulnerable to poor outcomes. Ch. 7

fremitus An abnormal, palpable vibration in the chest wall that is produced during vocalization and caused by the passage of air past thick bronchial mucus. Ch. 28

frontotemporal dementia (FTD) A type of dementia characterized by degeneration of the frontal lobe, temporal lobe, or both. Ch. 62

frostbite True tissue freezing, which results in the formation of ice crystals in the tissues and cells. Ch. 71

full-thickness burn Destruction of all skin elements and subcutaneous tissues, with possible involvement of muscles, tendons, and bones. Ch. 27

fulminant hepatitis An acute clinical syndrome that results in severe impairment or necrosis of liver cells and potential liver failure. Ch. 46

fungi Organisms similar to plants but lacking in chlorophyll. Ch. 17

G

galactorrhea A milky secretion from the nipple caused by inappropriate lactation. Ch. 54

gastric cancer Adenocarcinoma of the stomach wall; the second-most frequent cause of cancer death worldwide. Ch. 44

gastritis Inflammation of the gastric mucosa. Ch. 44

gastro-enteritis An inflammation of the mucosa of the stomach and the small intestine. Ch. 45

gastro-esophageal reflux disease (GERD) A syndrome presenting as any clinically significant symptomatic condition or histopathological alteration presumed to be secondary to reflux of gastric contents into the lower esophagus. Ch. 44

gene therapy An experimental technique that is used to replace or functionally repair defective or missing genes with normal genes. Ch. 15

general adaptation syndrome The three stages of physiological response pattern to stress proposed by Hans Selye: alarm reaction, stage of resistance, and stage of exhaustion. Ch. 8

general anaesthesia An altered physiological state characterized by reversible loss of consciousness, skeletal muscle relaxation, amnesia, and analgesia. Ch. 21

general survey statement Statement of the health care provider's general impression of a patient, including behavioural observations. Ch. 3

generalized seizures Seizures characterized by bilateral synchronous epileptic discharges in the brain from the onset, with no warning or aura; in most cases, the patient loses consciousness for a few seconds to several minutes. Ch. 61

genetics The study of inheritance. Ch. 15

genital herpes A sexually transmitted infection caused by the herpes simplex virus (HSV), usually HSV-2; results in painful genital or anal vesicular lesions. Ch. 55

genotype An individual's heritable collection of genetic material. Ch. 15

gerontological nursing A nursing specialty focused on the care of older adults. Ch. 7

Glasgow Coma Scale (GCS) A quick, practical, and standardized system for assessing the degree to which consciousness is impaired. Ch. 59

glaucoma A group of disorders characterized by elevated intraocular pressure and the consequences of elevated pressure, optic nerve atrophy, and peripheral visual field loss. Ch. 24

glial cells The cells in the nervous system that provide support, nourishment, and protection to neurons. Ch. 58

glomerular filtration rate (GFR) The amount of blood filtered by the glomeruli in a given time. Ch. 47

glomerulo-nephritis An immune-related inflammation of the glomeruli characterized by proteinuria, hematuria, decreased urine production, and edema. Ch. 48

glomerulus A capillary network within the kidneys that comprises up to 50 capillaries. Ch. 47

glucagon A hormone synthesized and released from pancreatic alpha cells in response to low levels of blood glucose, to protein ingestion, and to exercise; increases blood glucose levels by stimulating glycogenolysis, gluconeogenesis, and ketogenesis. Ch. 50

glycemic index (GI) The rise in blood glucose levels after a person has consumed carbohydrate-containing food. Ch. 52

goitre An enlarged thyroid gland; the thyroid cells are stimulated to grow, which may result in an overactive thyroid (hyperthyroidism) or an underactive one (hypothyroidism). Ch. 51

gonads The primary reproductive organs (i.e., ovaries in the female and testes in the male). Ch. 53

gonorrhea The second-most frequently occurring sexually transmitted infection, caused by *Neisseria gonorrhoeae*, which spreads by direct physical contact with an infected host, usually during sexual activity (vaginal, oral, or anal). Ch. 55

Goodpasture's syndrome An autoimmune disease characterized by the presence of circulating antibodies against the glomerular and alveolar basement membranes. Ch. 48

gout A type of recurring, acute arthritis characterized by the accumulation of uric acid crystals in one or more joints; characteristic deposits of sodium urate crystals occur in articular, periarticular, and subcutaneous tissues. Ch. 67

Graves' disease An autoimmune disease of unknown etiology marked by diffuse thyroid enlargement and excessive thyroid hormone secretion. Ch. 51

grief A normal reaction to loss that may manifest in both psychological and physiological ways. Ch. 13

growth hormone (GH) A hormone that affects the growth and development of skeletal muscles and long bones, thereby affecting a person's size and height; also has a role in the metabolism of protein, fat, and carbohydrate. Ch. 50

Guillain-Barré syndrome An acute, rapidly progressing, and potentially fatal form of polyneuritis believed to be caused by a cell-mediated immunological reaction directed at the peripheral nerves. Ch. 63

gummas Chronic, destructive lesions associated with late syphilis and affecting any organ of the body, especially the skin, bones, liver, and mucous membranes. Ch. 55

gynecomastia A transient, noninflammatory enlargement of one or both breasts in men. Ch. 54

H

hazards Anything that has the potential to cause harm or loss; can be substances, human activities, or physical events that may cause injury or loss of life, threaten the delivery of critical services, cause social and economic disruption, or cause property or environmental damage. Ch. 72

head injury Any trauma to the scalp, the skull, or the brain. Ch. 59

headache Probably the most common type of pain that humans experience. The majority of people have functional headaches, such as migraine or tension-type headaches; others have organic headaches caused by intracranial or extracranial disease. Ch. 61

healing touch A biofield therapy that encompasses a group of noninvasive techniques that use the hands to clear, energize, and balance the human and environmental energy fields. Ch. 12

health A state encompassing the biopsychosocial and spiritual aspects of well-being rather than one solely defined by the absence of disease. Ch. 5

health equity A situation in which all people have the opportunity to achieve their full health potential through fair and just access to resources for health. Ch. 2

health inequality Differences in the health status of individuals and groups as a result of factors such as biological and genetic makeup, physical environments, actions of the health care system, and broad social and economic issues. Ch. 2

health inequity Disparities in health that are a result of factors that are generally considered to be unfair or unjust and modifiable. Ch. 2

health literacy Ability to access, understand, and act on information regarding health. Ch. 2

health-related hardiness (HRH) A personality resource characterized by a sense of control, commitment, and challenge and an ability to withstand a high degree of stress without falling ill. Ch. 5

health-related quality of life (HRQL) At an individual level, perceptions of physical and mental health status; at a community level, resources, conditions, policies, and practices that influence a populations health perceptions and functional status. Ch. 5

heart failure (HF) An abnormal clinical syndrome involving impaired cardiac pumping or filling or both. Ch. 34

heart failure with preserved ejection fraction (HF-PEF) The inability of the ventricles to relax and fill during diastole; often referred to as diastolic HF. Ch. 37

heart failure with reduced ejection fraction (HF-REF) Heart failure that results from an inability of the heart to pump blood effectively; the most common form of HF. Ch. 37

heat cramps Severe cramps in large muscle groups fatigued by heavy work. Ch. 71

heat exhaustion A clinical syndrome characterized by fatigue, light-headedness, nausea, vomiting, diarrhea, and a sensation of impending doom, caused by prolonged exposure to heat over hours or days. Ch. 71

heatstroke The most serious form of heat stress, resulting from failure of the central thermoregulatory mechanisms. Ch. 71

heaves Sustained lifts of the chest wall in the precordial area that can be seen or palpated. Ch. 34

hematemesis Vomiting of blood, which indicates bleeding in the upper gastro-intestinal tract. Ch. 41

hematopoiesis Blood cell production. Ch. 32

hemochromatosis An iron overload disorder caused primarily by a genetic defect or occurring secondary to diseases such as sideroblastic anemia or liver disease. Ch. 33

hemodialysis (HD) A type of dialysis that uses a machine to remove waste products and excess fluid from the blood by pumping the blood through an artificial semipermeable membrane. Ch. 49

hemodynamic monitoring The measurement of pressure, flow, and oxygenation within the cardiovascular system. Ch. 68

hemoglobin A complex compound composed of heme (an iron compound) and globin (a simple protein) that binds with oxygen and carbon dioxide. Ch. 32

hemolysis Destruction of erythrocytes. Ch. 32

hemolytic anemia A condition caused by the destruction or hemolysis of red blood cells at a rate that exceeds production. Ch. 33

hemophilia An X-linked recessive genetic disorder caused by defective or deficient coagulation factor. Ch. 33

hemorrhagic stroke A stroke that results from bleeding into the brain tissue itself or into the subarachnoid space or the ventricles. Ch. 60

hemorrhoids Varicosities in the lower rectum or the anus caused by congestion in the veins of the hemorrhoidal plexus. Ch. 45

hemothorax An accumulation of blood in the intrapleural space. Ch. 30

hepatic encephalopathy A neuropsychiatric manifestation of advanced liver disease, resulting from ammonia crossing the blood–brain barrier; manifested as changes in neurological and mental responsiveness, ranging from sleep disturbances to deep coma. Ch. 46

hepatitis Inflammation of the liver. Ch. 46

hepatocytes Specialized hepatic cells. Ch. 41

hepatorenal syndrome (HRS) A serious complication of decompensated cirrhosis; a type of kidney failure with advancing azotemia, oliguria, and intractable ascites. Ch. 46

herbal therapy The use of individual herbs or combinations of herbs for therapeutic benefit to treat, prevent, or cure disease. Ch. 12

hernia A protrusion of a viscus through an abnormal opening or a weakened area in the wall of the cavity in which it is normally contained. Ch. 45

herniated intervertebral disc Herniation of nuclear material from the intervertebral disc that may compress or place tension on a cervical, lumbar, or sacral spinal nerve root, causing acute back pain; also called a *slipped disc*. Ch. 66

herpes zoster Varicella-zoster virus infection, characterized by an eruption of grouped vesicles on erythematous base; usually unilateral on trunk, face, and lumbosacral areas. Also called *shingles*. Ch. 26

heterozygous Having two different alleles for one given gene. Ch. 15

hiatal hernia Herniation of a portion of the stomach into the esophagus through an opening, or hiatus, in the diaphragm. Ch. 44

high-frequency oscillatory ventilation (HFOV) A ventilator that delivers a small tidal volume (usually 1 to 5 mL/kg of body weight) at a rapid respiratory rate (100 to 300 breaths/min) in an effort to recruit and maintain lung volume and reduce intrapulmonary shunting. Ch. 68

hirsutism Male-pattern distribution of hair in women, caused by an abnormality of ovaries or adrenal glands, decrease in estrogen level, or a familial trait. Ch. 25

histological grading A categorization of tumours in which the appearance of cells and the degree of differentiation are evaluated

pathologically. Ch. 18

Hodgkin's lymphoma A malignant condition characterized by proliferation of abnormal, giant, multinucleated cells, called *Reed–Sternberg cells*, which are located in lymph nodes. Ch. 33

holding area Also called the *preoperative holding area*; an admission and waiting area inside or adjacent to the surgical suite. Ch. 21

holistic nursing Nursing practice that incorporates mind–body–spirit principles into the development of a caring–healing relationship with patients. Ch. 12

home health nursing A specialized area of nursing practice rooted in community health nursing in which nursing care is delivered in the residence of the patient or where the patient works or attends school. Ch. 6

homeostasis The state of equilibrium in the internal environment of the body, naturally maintained by adaptive responses that promote healthy survival. Ch. 19

homozygous Having two identical alleles for one given gene. Ch. 15

hordeolum An infection of the sebaceous glands in the eyelid margin; commonly called a *sty*. Ch. 24

hormone A chemical substance synthesized and secreted by a specific organ or tissue; most hormones have common characteristics, including (a) secretion in small amounts at variable but predictable rates, (b) circulation through the blood, and (c) binding to specific cellular receptors either in the cell membrane or within the cell wall. Ch. 50

hospice A paradigm of care for patients with advanced malignant disease; end-of-life services. Ch. 13

hospice palliative care Care aimed at improving the quality of life of patients with life-threatening illness and of their families through the relief of pain and suffering. Chs. 6, 13

hospital-acquired pneumonia (HAP) Pneumonia occurring 48 hours or longer after hospital admission and not incubating at the time of hospitalization. Ch. 30

human immunodeficiency virus (HIV) Retrovirus that causes AIDS. Ch. 17

human leukocyte antigen (HLA) system A series of linked genes that occur together on the sixth chromosome in humans that plays an important part in the body's immune response to foreign substances. Ch. 16

humoral immunity Antibody-mediated immunity. Ch. 16

Huntington's disease (HD) A genetically transmitted, autosomal dominant disorder that affects both men and women of all races; characterized by chronic, devastating loss of all neurological function, resulting in a movement disorder and dementia. Ch. 61

hydrocele A nontender, fluid-filled mass that results from interference with lymphatic drainage of the scrotum and swelling of the tunica vaginalis that surrounds the testis. Ch. 57

hydronephrosis Dilation or enlargement of the renal pelvis and the calyces resulting from increased bladder pressure and backflow of urine to the kidney caused by obstruction in the lower urinary tract. Ch. 48

hydrostatic pressure The force within a fluid compartment. Ch. 19

hydroureter Dilation of the renal pelvis caused by backflow of urine. Ch. 48

hyperaldosteronism A condition characterized by excessive aldosterone secretion. Ch. 51

hypercapnia The presence of greater than normal amounts of carbon dioxide in the blood; also called *hypercarbia*. Ch. 70

hypercapnic respiratory failure A partial pressure of arterial carbon dioxide above normal (>45 mm Hg) in combination with acidemia

(arterial pH <7.35). Ch. 58

hyperopia A condition in which an affected person can see distant objects clearly (farsightedness) but close objects appear blurred. Ch. 23

hyperosmolar hyperglycemic state (HHS) A life-threatening syndrome that can occur in the patient with diabetes who is able to produce enough insulin to prevent diabetic ketoacidosis but not enough to prevent severe hyperglycemia, osmotic diuresis, and extracellular fluid depletion. Ch. 52

hyperparathyroidism A condition involving increased secretion of parathyroid hormone (PTH). Ch. 51

hyperplasia Multiplication of cells resulting from increased cellular division. Ch. 14

hypersensitivity reaction An overreactive immune response against foreign antigens or a reaction against one's own tissue that may result in tissue damage. Ch. 16

hypertension Sustained elevation of systemic arterial blood pressure; in adults, exists when systolic blood pressure (SBP) is equal to or greater than 140 mm Hg or diastolic blood pressure (DBP) is equal to or greater than 90 mm Hg. Ch. 35

hypertensive crisis A severe and abrupt elevation in blood pressure, arbitrarily defined as a diastolic blood pressure above 120 to 130 mm Hg. Ch. 35

hyperthyroidism Hyperactivity of the thyroid gland with sustained increase in synthesis and release of thyroid hormones. Ch.51

hypertonic Solutions in which solutes are more concentrated than they are in cells. Ch. 19

hypertrophic cardiomyopathy (HCM) Asymmetrical left ventricular hypertrophy without ventricular dilation. Ch. 39

hypertrophic scar Inappropriately large, red, raised, and hard scar. Ch. 14

hypertrophy Expansion in the size of cells, which results in increased tissue mass without cell division. Ch. 14

hypoparathyroidism An uncommon condition associated with inadequate levels of circulating parathyroid hormone (PTH); characterized by hypocalcemia that results from a lack of PTH to maintain serum calcium levels. Ch. 51

hypopituitarism A rare disorder that involves a decrease in one or more of the pituitary hormones. Ch. 51

hypospadias A urological abnormality in which the urethral meatus is located on the ventral surface of the penis anywhere from the corona to the perineum. Ch. 57

hypothermia A core temperature of less than 35°C; occurs when heat loss exceeds heat production. Chs. 22, 71

hypothyroidism Insufficient circulation of thyroid hormone as a result of various abnormalities; can be primary or secondary. Ch. 51

hypotonic Solutions in which solutes are less concentrated than they are in cells. Ch. 19

hypoventilation Deficient ventilation of the lungs, characterized by a decreased respiratory rate or effort, hypoxemia, and an increasing arterial partial pressure of carbon dioxide ($PaCO_2$). Ch. 22

hypovolemic shock Shock that occurs when intravascular fluid volume is lost, and the remaining volume is inadequate to fill the vascular space. Ch. 69

hypoxemia Low oxygen tension in the blood (partial pressure of oxygen in arterial blood [PaO_2] <60 mm Hg), characterized by a variety of nonspecific clinical signs and symptoms. Chs. 22, 70

hypoxemic respiratory failure A condition in which the partial pressure of oxygen in arterial blood (PaO_2) is 60 mm Hg or less

when the patient is receiving inspired oxygen at a fractional concentration (FiO_2) of 60% or greater. Ch. 70

hypoxia The condition in which the partial pressure of oxygen in arterial blood (PaO_2) has fallen sufficiently to cause signs and symptoms of inadequate oxygenation. Ch. 70

hysterectomy Surgical removal of the uterus. Ch. 56

I

ileal conduit Urinary diversion procedure; ureters are anastomosed into a segment of ileum that is converted into a conduit for urinary drainage; the other end of the bowel is brought out through the abdominal wall to form a stoma. Ch. 48

illness The human experience of symptoms and suffering; specifically, how the disease is perceived, lived with, and responded to by individuals and their families. Ch. 5

illness behaviour The varying ways individuals respond to physical symptoms: how they monitor internal states, define and interpret symptoms, make attributions, take remedial actions, and use various sources of informal and formal care. Ch. 5

illness trajectory A pathway along which the person with an illness progresses; it includes three phases: crisis phase, chronic phase, and terminal phase. Ch. 5

imagery The use of the mind to generate images that have a calming effect on the body. Ch. 8

immunity The body's ability to resist disease. Ch. 16

immuno-competence The ability of the body's immune system to identify and inactivate or destroy foreign substances. Ch. 16

immunodeficiency The inability of the immune system to protect the body adequately. Ch. 16

immunological surveillance The response of the immune system to antigens of the malignant cells. Ch.18

immuno-suppressive therapy Therapy with the goal of adequately suppressing the immune response to prevent rejection of a transplanted organ and yet maintain sufficient immunity to prevent overwhelming infection; also used to treat autoimmune disorders. Ch. 16

impetigo A condition caused by Group A β-hemolytic streptococci, staphylococci, or a combination of both and characterized by pruritus and an eruption of vesiculo-pustular lesions with a honey-coloured crust surrounded by erythema. Ch. 26

implementation The use of nursing interventions to carry out the nursing care plan. Ch. 1

infective endocarditis (IE) An infection of the heart valves or the endocardial surface of the heart; previously called *bacterial endocarditis*. Ch. 39

infertility The inability to achieve a pregnancy after at least 1 year of regular unprotected intercourse. Ch. 56

inflammatory bowel disease (IBD) An autoimmune disease characterized by idiopathic inflammation and ulceration; includes two disorders of the gastro-intestinal tract—Crohn's disease and ulcerative colitis. Ch. 45

inflammatory response A biological response to cell injury that neutralizes and dilutes the inflammatory agent, removes necrotic materials, and establishes an environment suitable for healing and repair. Ch. 14

informal caregiver A person who provides care without pay and who usually has personal ties to the care recipient. Ch. 5

information and communication technologies (ICT) The tools and applications that support the management of clinical data, information, and knowledge. Ch. 1

informed consent An active, shared decision-making process between the provider and the recipient of health care; this process protects the patient, the surgeon, the hospital, and its employees. Ch. 20

ingestion The intake of food. Ch. 41

insomnia Difficulty falling asleep, difficulty staying asleep, waking up too early, or poor quality of sleep. Ch. 9

inspection The visual examination of a part or region of the body to assess normal conditions or deviations. Ch. 3

insulin The principal regulator of the metabolism and storage of ingested carbohydrates, fats, and proteins; facilitates glucose transport across cell membranes in most tissues. Ch. 50

insulin resistance A condition in which body tissues do not respond to the action of insulin; caused by insulin receptors that are unresponsive to the action of insulin, insufficient in number, or both. Ch. 52

integrated palliative approach A approach to care that focuses on meeting a person's and family's full range of needs—physical, psychosocial, and spiritual—at all stages of illness, not just at the end of life. Ch. 13

integrins Cell receptors that mediate attachment between endothelial cells and surrounding tissues; involved in leukocyte extravasation during the immune response. Ch. 14

intermittent claudication An ischemic muscle ache or pain that is precipitated by a consistent level of exercise, resolves within 10 minutes or less with rest, and is reproducible. Ch. 40

intersectionality A framework for understanding how multiple social identities such as race, gender, sexual orientation, and economic status interact with each other to reflect interlocking systems of privilege and oppression. Ch. 2

interstitial cystitis (IC) A chronic, painful inflammatory disease of the bladder believed to be associated with an autoimmune or allergic response. Ch. 48

intertriginous Describing an area where opposing skin surfaces overlap and rub on each other, such as skin folds of groin, axilla, abdomen, or breast. Ch. 25

intestinal obstruction Partial or complete obstruction of the intestine, preventing intestinal contents from passing through the

gastro-intestinal tract; may be classified as mechanical or nonmechanical. Ch. 45

intra-aortic balloon pump Device that provides temporary circulatory assistance to the compromised heart by reducing afterload (via reduction in systolic pressure) and augmenting the aortic diastolic pressure. Ch. 68

intracerebral hemorrhage A type of hemorrhagic stroke in which bleeding occurs within the brain, caused by a rupture of a blood vessel. Ch. 60

intracranial pressure (ICP) Pressure exerted because of the combined total volume of the three components within the skull: brain tissue, blood, and cerebro-spinal fluid. Ch. 59

intraparenchymal or intracerebral hematoma A collection of blood within the parenchyma that results from bleeding within the brain tissue itself and occurs in approximately 16% of head injuries. Ch. 59

intravenous pyelography (IVP) A diagnostic study in which an intravenous contrast medium circulates in the blood and is excreted through the urinary system; used to evaluate the presence, position, size, and shape of the kidneys, ureters, and bladder. Ch. 47

ions Electrically charged atoms or molecules. Ch. 19

iron-deficiency anemia A microcytic hypochromic anemia caused by inadequate supplies of the iron needed to synthesize hemoglobin. Ch. 33

irritable bowel syndrome (IBS) A chronic functional disorder characterized by intermittent and recurrent abdominal pain associated with an alteration in bowel function (diarrhea, constipation, or both). Ch. 45

ischemic strokes Strokes that result from inadequate blood flow to the brain from partial or complete occlusion of an artery. Ch. 60

islets of Langerhans The hormone-secreting portion of the pancreas. Ch. 50

isolated systolic hypertension (ISH) A sustained elevation in systolic blood pressure equal to or greater than 140 mm Hg with a diastolic blood pressure less than 90 mm Hg. Ch. 35

isometric contractions Muscular contractions that increase tension within a muscle but do not produce movement. Ch. 64

isotonic State in which the fluid that surrounds a cell has the same osmolality as the cell interior. Ch. 19

isotonic contractions Muscular contraction that shortens a muscle to produce movement. Ch. 64

J

Janeway's lesions Flat, painless, small, red spots that may be found on the palms and the soles in patients with infective endocarditis. Ch. 39

jaundice A yellowish discoloration of body tissues resulting from an abnormal increase in the concentration of bilirubin in the blood. Ch. 46

jaw-thrust manoeuvre A technique for establishing a clear airway, in which the rescuer uses forearms to stabilize the patient's head (while avoiding neck hyperextension) and then applies pressure with the index fingers to push the patient's jaw forward. Ch. 71

K

keloid A protrusion of scar tissue that extends beyond the wound edges and may form tumour-like masses. Ch. 14

keratinocytes Cells synthesized from epidermal cells in the basal layer; they produce a fibrous protein, called *keratin*, which is vital to the skin's protective barrier function. Ch. 25

keratitis An inflammation or infection of the cornea that can be caused by a variety of microorganisms or by other factors. Ch. 24

Korotkoff sounds Sounds of turbulent blood flow through a compressed artery. Ch. 34

Korsakoff syndrome An irreversible form of amnesia caused by thiamine deficiency and characterized by loss of short-term memory and an inability to learn. Ch. 11

Kupffer cells A type of macrophage found in the liver that removes bacteria and toxins from the blood. Ch. 41

kyphosis Forward bending of thoracic spine: exaggerated thoracic curvature. Ch. 64

L

lactase deficiency A condition in which the lactase enzyme is deficient or absent. Ch. 45

lapses Very short periods of substance use followed by quick return to maintaining nonuse. Ch. 11

laryngeal mask airway (LMA) A supraglottic airway device that is easily placed and used as a method of elective ventilation. Ch. 21

learning A cognitive ability that is reflected by a change in behaviour (knowledge, attitudes, or skills or a combination of these) that can be observed and measured. Ch. 4

learning needs The new knowledge and skills that an individual must acquire to be able to meet an objective or a goal. Ch. 4

learning outcomes The competencies and the knowledge that the patient has achieved and can demonstrate successfully. Ch. 4

learning style The way in which each individual understands and responds to a learning situation; may be visual, auditory, or physical. Ch. 4

leiomyomas Benign smooth muscle tumours that occur most commonly within the uterus; also known as *uterine fibroids*. Ch. 56

lens A biconvex structure located behind the iris and supported in place by small fibres, collectively called the *suspensory ligament* (also called the *zonule*), that connect the lens to the ciliary body; the primary function of the lens is to bend light rays, which enables them to fall onto the retina. Ch. 23

lethal injury Irreversible cell injury that causes cell death. Ch. 14

leukemia A broad term given to a group of malignant diseases that affect the blood and blood-forming tissues of the bone marrow, lymph system, and spleen. Ch. 33

leukopenia An abnormal decrease in the total white blood cell count to less than 4×10^9/L. Ch. 32

leukoplakia A whitish precancerous lesion on the mucosa of the mouth or tongue that results from chronic irritation, especially from smoking. Ch. 44

lichenification A thickening of epidermis with exaggerated markings resembling a washboard, caused by chronic scratching or rubbing of the skin. Ch. 26

lifestyle The health choices made by individuals, which are influenced by social, economic, and environmental factors. Ch. 5

lipectomy Procedure performed to remove unsightly loose folds of adipose tissue for cosmetic reasons; also called *adipectomy*. Ch. 43

lipodystrophy A condition that produces lumps and dents in the skin—hypertrophy or atrophy of subcutaneous tissue; caused by repeated injection in the same spot. Ch. 52

lithotripsy The use of sound waves to break renal stones into small particles that can be eliminated from the urinary tract. Ch. 48

local anaesthesia The loss of sensation without loss of consciousness; induced topically or via intracutaneous or subcutaneous infiltration. Ch. 21

long-term care (LTC) facilities A placement alternative for adults who can no longer live alone, who need continuous supervision, who have three or more disabilities involving activities of daily living or who are frail. Ch. 7

lordosis Lumbar spinal deformity resulting in exaggerated lumbar curvature; also called *swayback*. Ch. 64

low back pain (LBP) A condition most often owing to a musculoskeletal problem caused by (a) acute lumbosacral strain, (b) instability of the lumbosacral bony mechanism, (c) osteoarthritis of the lumbosacral vertebrae, (d) degenerative disc disease, or (e) herniation of an intervertebral disc. Ch. 66

lower motor neurons (LMNs) The final common pathway through which descending motor tracts influence skeletal muscle, the effector organ for movement. Ch. 58

lumpectomy Breast-conserving surgery that involves the removal of the entire tumour along with a margin of normal surrounding tissue. Ch. 54

lung abscess A pus-containing lesion of the lung parenchyma that gives rise to a cavity. Ch. 30

Lyme disease A spirochetal infection caused by *Borrelia burgdorferi* and transmitted by the bite of an infected deer tick; the most characteristic clinical symptom of early localized disease is migrans, a skin lesion at the site of the tick bite that occurs within 3 to 30 days in 70% to 80% of people who are infected. Ch. 67

lymphedema Accumulation of lymph in soft tissue that results from the excision or irradiation of lymph nodes. Ch. 54

lymphomas Malignant neoplasms originating in the bone marrow and lymphatic structures resulting in the proliferation of lymphocytes. Ch. 33

M

malabsorption syndrome The impaired absorption of nutrients from the gastro-intestinal tract. Ch. 42

malignant hyperthermia A rare, potentially fatal metabolic disease characterized by hyperthermia with rigidity of skeletal muscles. Ch. 21

malignant melanoma A tumour arising in melanocytes, the cells producing melanin. Ch. 26

malignant neoplasms Tumours that have the ability to invade and metastasize; can be undifferentiated or well differentiated. Ch. 18

Mallory–Weiss tear A tear in the mucosa near the esophagogastric junction; usually caused by severe retching and vomiting. Ch. 44

malnutrition A deficit, excess, or imbalance of the essential components of a balanced diet. Ch. 42

mammoplasty Surgical change in the size or shape of the breast. Ch. 54

massage therapy Therapy involving the manipulation of soft tissues and joints of the body to improve health and promote healing. Ch. 12

mastalgia Breast pain; most common breast-related complaint in women. Ch. 54

mastectomy Surgical removal of all or a portion of a breast. Ch. 54

mastitis An inflammatory condition of the breast that occurs most frequently in lactating women; usually caused by staphylococcal infection. Ch. 54

mean arterial pressure A measurement related to BP; calculated by adding the diastolic pressure to one-third of the pulse pressure. Ch. 34

mechanical receptors Receptors located in the lungs, upper airways, chest wall, and diaphragm that are stimulated by a variety of physiological factors, such as irritants, muscle stretching, and alveolar wall distortion. Ch. 28

mechanical ventilation The process by which the fraction of inspired oxygen is moved in and out of the lungs by a machine. Ch. 68

medical-surgical nursing A type of nursing that involves caring for acutely ill adults experiencing complex variations in health. Ch. 1

megaloblastic anemias A group of disorders caused by impaired DNA synthesis and characterized by the presence of large RBCs. Ch. 33

melanocytes Cells contained in the deep, basal layer *(stratum germinativum)* of the epidermis that contain melanin, a pigment that gives colour to the skin and hair and protects the body from damaging ultraviolet sunlight. Ch. 25

melena Abnormal, black, tarry stool containing digested blood. Ch. 41

menarche The first episode of menstrual bleeding; indicates that a girl has reached puberty. Ch. 53

Ménière's disease A condition characterized by symptoms of inner ear disease, including episodic vertigo, tinnitus, fluctuating sensorineural hearing loss, and a sense of aural fullness; results in an excessive accumulation of endolymph in the membranous labyrinth; also called *endolymphatic hydrops*. Ch. 24

meninges Three layers of protective membranes that surround the brain and the spinal cord: dura mater, arachnoid, and pia mater. Ch. 58

meningitis An acute inflammation of meningeal tissues (the pia mater, arachnoid mater, and dura mater) surrounding the brain and the spinal cord. Ch. 59

menopause The physiological cessation of menses associated with declining ovarian function. Ch. 53, 56

menstrual cycle A monthly process mediated by the hormonal activity of the hypothalamus, the pituitary gland, and the ovaries (during which the major functions of the ovaries are ovulation and the secretion of hormones). Ch. 53

metabolic syndrome A collection of risk factors that increase an individual's chance of developing cardiovascular disease and diabetes mellitus. Ch. 43

metaplasia Transformation of one cell type into another in response to a change in physiological condition or to an external irritant. Ch. 14

metastasis Spread of the cancer to a distant site. Ch. 18

migraine headache A type of headache characterized by unilateral throbbing pain, a triggering event or factor, and manifestations associated with neurological and autonomic nervous system dysfunction; the effects of migraine headache pain are dramatic, often causing both physical and emotional disability. Ch. 61

mild cognitive impairment (MCI) A state of cognitive decline that is not severe enough to interfere with activities of daily living. Ch. 62

mitral valve prolapse (MVP) A structural abnormality of the mitral valve leaflets and the papillary muscles or chordae that allows the leaflets to prolapse, or buckle, back into the left atrium during ventricular systole. Ch. 39

modifiable risk factors Factors such as behaviour that can be changed to reduce the risk of developing an illness. Ch. 5

modulation The activation of descending pathways that exert inhibitory or facilitatory effects on the transmission of pain. Ch. 10

mole (nevus) Benign overgrowth of melanocytes, occurring as a defect of development; excessive numbers of large, irregular moles are often familial. Ch. 25

monoclonal antibodies Homogeneous populations of identical antibody molecules produced by specialized tissue cell culture lines. Ch. 16

mons pubis A fatty layer lying over the pubic bone that is covered in coarse hair after puberty (in a triangular pattern in women and a diamond pattern in men). Ch. 53

morbidity Rates of disease in a population. Ch. 5

morbidly obese Classification describing indi-viduals with a body mass index greater than 40 kg/m^2. Ch. 43

mortality Rates of death in a population. Ch. 5

motivational interviewing A collaborative, person-centred counselling approach aimed at changing a patient's ambivalence and, ultimately, the patient's behaviour. Ch. 11

multimorbidity The simultaneous occurrence of several chronic medical conditions in the same person. Ch. 5

multiple myeloma A condition in which neoplastic plasma cells infiltrate the bone marrow and destroy bone. Ch. 33

multiple-organ dysfunction syndrome (MODS) In a patient who is acutely ill, the failure of two or more organ systems to such a degree that homeostasis cannot be maintained without intervention. Ch. 69

multiple sclerosis (MS) A chronic, progressive, degenerative autoimmune disorder of the central nervous system characterized by disseminated demyelination of nerve fibres of the brain, the spinal cord, and the optic nerves. Ch. 61

murmurs Sounds produced by turbulent blood flow through the heart or the walls of large arteries. Ch. 34

mutation A change in the DNA sequence of a gene, affecting the original expression of the gene. Ch. 15

myasthenia gravis (MG) An autoimmune disease of the neuromuscular junction characterized by fluctuating weakness of certain skeletal muscle groups. Ch. 61

myasthenic crisis An acute exacerbation of muscle weakness triggered by infection, surgery, emotional distress, overdose of drugs, or inadequate drugs in a person with myasthenia gravis. Ch. 61

myelodysplastic syndrome (MDS) A group of related hematological disorders characterized by a change in the quantity and the quality of bone marrow elements. Ch. 33

myocardial infarction (MI) Irreversible myocardial cell death (necrosis) caused by sustained ischemia. Ch. 36

myocarditis A focal or diffuse inflammation of the myocardium. Ch. 39

myofascial pain syndrome A chronic form of muscle pain; characterized by musculo-skeletal pain and tenderness, typically in the chest, neck, shoulders, hips, and lower back. Ch. 67

myopia A condition in which an affected person can see near objects clearly (nearsightedness) but objects in the distance appear blurred. Ch. 23

myxedema The accumulation of hydrophilic mucopolysaccharides in the dermis and other tissues; causes the characteristic facies of hypothyroidism (i.e., puffiness, periorbital edema, and masklike affect). Ch. 51

myxedema coma A medical emergency in which the mental sluggishness, drowsiness, and lethargy of hypothyroidism progresses gradually or suddenly to a notable impairment of consciousness or coma. Ch. 51

nadir The lowest level of the peripheral blood cell counts that occurs secondary to bone marrow depression. Ch. 18

narcolepsy A chronic degenerative neurological disorder caused by the brain's inability to regulate sleep–wake cycles normally. Ch. 9

nasal polyps Benign mucous membrane masses that form slowly in response to repeated inflammation of the sinus or the nasal mucosa. Ch. 29

nausea A feeling of discomfort in the epigastrium with a conscious desire to vomit. Ch. 44

necrosis Tissue death that occurs as a result of a traumatic injury, infection, or exposure to a toxic chemical that causes a local inflammatory response. Ch. 14

negative feedback A highly specialized mechanism in the regulation of hormone levels; the most common type of feedback system, in which the gland responds by increasing or decreasing the secretion of a hormone on the basis of feedback from various factors. Ch. 50

negative-pressure ventilation Noninvasive ventilation (i.e., not requiring an artificial airway) delivered through the use of chambers that encase the chest or body and surround it with intermittent subatmospheric (or negative) pressure. Ch. 68

nephrolithiasis The formation of stones in the urinary tract. Ch. 48

nephron The functional unit of the kidney; each kidney has 800 000 to 1.2 million nephrons. Ch. 47

nephrosclerosis A vascular disease of the kidney characterized by sclerosis of the small arteries and arterioles of the kidney, resulting in renal tissue destruction. Ch. 48

nephrotic syndrome A clinical course associated with a number of disease conditions of the kidney; characterized by peripheral edema, massive proteinuria, dyslipidemia, and hypoalbuminemia. Ch. 48

neuraxial blocks Regional anaesthesia (epidural or spinal) that blocks pain transmission during surgery. Ch. 21

neurofibrillary tangles Abnormal collections of twisted protein threads inside nerve cells seen in the areas of the brain most affected by Alzheimer's disease. Ch. 62

neurogenic bladder A bladder dysfunction related to abnormal or absent bladder innervation. Ch. 63

neurogenic shock A hemodynamic syndrome of massive vasodilation without compensation that results from the loss of sympathetic nervous system vasoconstrictor tone caused by spinal cord injury; characterized by hypotension, bradycardia, and hypothermia. Chs. 63, 69

neurons The primary functional units of the nervous system; share three characteristics: excitability, conductivity, and the ability to influence other neurons, muscle cells, and glandular cells. Also called *nerve cells*. Ch. 58

neuropathic pain Pain caused by damage to nerve cells or changes in spinal cord processing, typically described as burning, shooting, stabbing, or electrical in nature. Ch. 10

neuro-syphilis An infection of any part of the nervous system by the organism *Treponema pallidum*. Ch. 63

neurotransmitter A chemical agent that affects the transmission of an impulse across the synaptic cleft. Ch. 58

neutropenia An abnormal reduction of the neutrophil count to less than 1×10^9/L to 1.5×10^9/L. Chs. 32, 33

nociception The activation of the primary afferent nociceptors with peripheral terminals (free nerve endings) that respond differently to noxious (tissue-damaging) stimuli. Ch. 10

nociceptive pain Pain caused by damage to somatic or visceral tissue. Ch. 10

nonalcoholic fatty liver disease (NAFLD) A spectrum of disease that ranges from simple fatty liver that causes no hepatic inflammation to severe liver scarring; characterized by accumulation of fat in hepatocytes not associated with alcohol. Ch. 46

nonalcoholic steatohepatitis (NASH) A condition characterized by the accumulation of fat in the liver cells, causing inflammation and liver cell injury; occurs in people who drink little or no alcohol. Ch. 46

non-Hodgkin's lymphomas (NHLs) A heterogeneous group of malignant neoplasms of primarily B-, T-, or natural killer cell origin that can affect people of all ages. Ch. 33

nonmodifiable risk factors Factors such as age and sex that contribute to the development of an illness but cannot be changed. Ch. 5

normal pressure hydrocephalus (NPH) An abnormal increase of cerebro-spinal fluid, characterized by an obstruction in the normal flow of cerebro-spinal fluid throughout the brain, spinal cord, and ventricles; a relatively uncommon disorder. Ch. 61

nuchal rigidity Resistance to flexion of the neck. Ch. 59

nulliparous Never pregnant. Ch. 53

nurse practitioners (NPs) Registered nurses with advanced education; NPs' scope of practice may include ordering and interpreting diagnostic tests, prescribing medications, and performing procedures beyond the scope of practice of registered nurses. Ch. 6

NurseONE A Web-based information portal for nurses that provides access to libraries and information related to evidence-informed practice and clinical practice issues. Ch. 1

nursing diagnosis The process of the nurse's identifying and labelling human responses to actual or potential health problems;

also, the product of this process as articulated in standard terminology. Ch. 1

nursing history Information used to determine the patient's strengths and responses to a health problem that is diagnosed and treated by nurses. Ch. 3

nursing informatics The integration of nursing science, computer science, and information technology to manage and communicate data, information, and knowledge in nursing practice. Ch. 1

nursing intervention Any treatment, based on clinical judgement and knowledge that a nurse performs to enhance patient outcomes. Ch. 1

nursing leadership An attitude and approach in which lifelong learning and a commitment to excellence in practice are valued. Ch. 1

nursing process An assertive, problem-solving approach to the identification and treatment of patient health problems; a framework to organize the knowledge, judgements, and actions that nurses supply in patient care. Ch. 1

nursing-sensitive outcomes Empirical-based indicators linking nursing interventions to problem or symptom resolution. Ch. 6

nutrition The process by which the body uses food for energy, growth, maintenance, and repair of body tissues. Ch. 42

nystagmus Abnormal eye movements that may be observed by other people as twitching of the eyeball or may be described by the patient as a blurring of vision with head or eye movement. Ch. 23

O

obese Classification used to describe individuals with body mass index value of 30 to 40 kg/m^2 or more. Ch. 43

obesity A complex, chronic, multifactorial disease that develops from the interaction between genetics and the environment; manifests as an abnormal increase in the proportion of fat cells in the body. Ch. 43

objective data Data relating to the patient's condition that can be observed and measured; also called *signs*. Ch. 3

obstructive sleep apnea (OSA) Partial or complete obstruction of the upper airway during sleep. Ch. 9

oliguria A urine output of less than 400 mL in 24 hours. Ch. 49

oncogenes Tumour-inducing genes that interfere with normal cell expression under some conditions, causing the cell to become malignant. Ch. 18

oncotic pressure Osmotic pressure exerted by colloids in solution. Ch. 19

operating room (OR) A unique acute care setting specially designed for surgery that, in a hospital, is usually adjacent to the postanaesthesia care unit and the surgical intensive care unit. Ch. 21

opiates Substances that are directly derived from the opium poppy, such as opium, morphine, and codeine. Ch. 11

opioids Umbrella term that includes both the opiates and the many semisynthetic and synthetic narcotic agents used as analgesics. Ch. 11

opportunistic diseases Infections and cancers that occur in immuno-suppressed patients that can lead to disability, disease, and death.

Ch. 17

optimal nutritional status State achieved when nutrients consumed meet daily requirements and metabolic demands. Ch. 42

oral hairy leukoplakia An Epstein-Barr virus infection that causes painless, white, raised lesions on the lateral aspect of the tongue. Ch. 17

orchitis An acute inflammation of the testis. Ch. 57

organ transplantation The transfer of a whole or partial organ from one individual to another for the purpose of replacing the recipient's damaged or failing organ with a working one from the donor. Ch. 16

orthostatic hypotension A decrease of 20 mm Hg (or more) in systolic blood pressure or a decrease of 10 mm Hg (or more) in diastolic blood pressure that occurs when an individual assumes a standing position. Ch. 35

Osler's nodes Painful, tender, red or purple, pea-size lesions that may be found on the fingertips or the toes in patients with infective endocarditis; last only 1 or 2 days. Ch. 39

osmolality A measure of the osmotic force of solute per unit of weight of solvent. Ch. 19

osmolarity A measure of the total milliosmoles of solute per unit of total volume of solution. Ch. 19

osmosis The movement of water between two compartments separated by a semipermeable membrane, one that allows the movement of water but not solute. Ch. 19

osmotic pressure The amount of pressure necessary to stop the osmotic flow of water. Ch. 19

osteoarthritis (OA) A slowly progressive, noninflammatory disorder of the diarthrodial (synovial) joints; the most common form of joint (articular) disease in North America. Ch. 67

osteoclastoma A destructive tumour that arises in the cancellous ends of long bones in young adults; also called a *giant-cell tumour*. Ch. 66

osteomyelitis A severe infection of the bone, bone marrow, and surrounding soft tissue, most commonly caused by *Staphylococcus aureus*. Ch. 66

osteoporosis A chronic, progressive metabolic bone disease characterized by low bone mass and structural deterioration of bone tissue, leading to increased bone fragility, which predisposes the individual to bone fractures at the hip, wrist, and spine. Ch. 66

osteosarcoma A malignant primary bone tumour that is extremely aggressive and is characterized by rapid growth and metastasis. Ch. 66

osteotomy Surgery to remove or add a wedge or slice of bone to change alignment (joint and vertebral) and to shift weight bearing, thereby correcting a deformity and relieving pain. Ch. 65

ostomy A surgical procedure in which an opening is made to allow passage of urine from the bladder, or intestinal contents from the bowel, to an incision or stoma surgically created in the wall of the abdomen. Ch. 45

otosclerosis A hereditary autosomal dominant disease in which spongy bone develops from the bony labyrinth, causing immobilization of the footplate of the stapes in the oval window; most common cause of hearing loss in young adults. Ch. 24

outbreak management Strategies used to prevent the spread of communicable disease among a cluster of people. Ch. 72

overnutrition A state that results from the consumption of nutrients —most frequently, calories, sodium, and fat—in excess of requirements. Ch. 42

overweight Classification used to describe individuals with a body mass index value of 25 to 29.9 kg/m^2. Ch. 43

oxygen toxicity A condition of oxygen overdosage. Ch. 31

P

Paget's disease of the bone A chronic skeletal bone disorder in which there is excessive bone resorption followed by replacement of normal marrow by vascular, fibrous connective tissue and new bone that is larger, disorganized, and structurally weaker; also called *osteitis deformans*. Ch. 66

Paget's disease of the breast A rare breast malignancy characterized by a persistent lesion of the nipple and areola with or without a palpable mass. Ch. 54.

pain A subjective and unpleasant sensation caused by actual or potential tissue damage. Ch. 10

pain perception Recognition of, definition of, and response to pain by the individual experiencing it. Ch. 10

paired organ donation An option for organ donation that allows a living donor to donate an organ (e.g., kidney) to a different compatible recipient, with the intent that another donor will donate to the first donor's designated recipient. Ch. 49

palliative Relieving pain without attempting to treat the cause; originates from the Latin word *palliaire*, which means “to cloak.” Ch. 13

palpation Examination of the body through the use of touch. Ch. 3

pancytopenia Marked decrease in the number of red blood cells, white blood cells, and platelets. Ch. 32

pandemic The occurrence of a communicable disease being widespread and affecting large numbers of people across several countries or continents or globally. Ch. 72

pandemic influenza A highly infectious outbreak of influenza that spreads rapidly around the world, with much more serious consequences than the usual effects of seasonal influenza. Ch. 72

paracentesis A needle puncture of the abdominal cavity performed to remove ascitic fluid or to test the fluid for infection. Ch. 46

paralytic ileus Impairment of intestinal motility (ileus that persists for more than 2 to 3 days) postoperatively. Ch. 22

paraphimosis Narrowing or edema of the retracted uncircumcised foreskin, preventing normal return over the glans and causing strangulation. Ch. 57

paraplegia Paralysis and loss of sensation in the lower limbs and the trunk. Ch. 63

parasomnias Unusual and often undesirable behaviours that occur during sleep or during arousal from sleep (e.g., abnormal movements; dream-related behaviours, emotions, and perceptions). Ch. 9

parenteral nutrition (PN) The administration of nutrients by a route other than the gastro-intestinal tract (e.g., the bloodstream). Ch. 42

Parkinson's disease (PD) A progressive neuro-degenerative disease of the central nervous system (basal ganglia) characterized by a slowing down in the initiation and the execution of movement (bradykinesia), increased muscle tone (rigidity), tremor at rest, and impaired postural reflexes. Ch. 61

paroxysmal nocturnal dyspnea A disorder that occurs when the patient is asleep; characterized by awakening in a panic with feelings of suffocation and a strong desire to sit or stand up; caused by the reabsorption of fluid from dependent body areas when the patient is flat. Ch. 37

partial-thickness burn Varying degrees of epidermal and dermal skin injury, with some skin elements remain viable for regeneration. Ch. 27

patient-centred approach An approach that focuses on the patient as a multifaceted person and not just on the condition. Ch. 1

patient-controlled analgesia (PCA) An infusion system that allows the patient to self-administer a dose of opioid through a pump when needed. Ch. 10

patient safety A cornerstone of nursing practice. Ch. 1

peer teaching Teaching that is conducted within the setting of a peer group, such as a self-help or support group. Ch. 4

pelvic inflammatory disease (PID) An infectious condition of the pelvic cavity that may involve the fallopian tubes *(salpingitis)*, ovaries *(oophoritis)*, and pelvic peritoneum *(peritonitis)*. Ch. 56

peptic ulcer disease (PUD) A condition characterized by erosion of the gastro-intestinal mucosa that results from the digestive action of hydrochloric acid and pepsin. Ch. 44

percussion Technique in physical examination of tapping the body directly or indirectly with the fingertips or fist to produce a sound and vibration to obtain information about the underlying area. Ch. 3

percutaneous coronary intervention (PCI) An intervention to treat coronary artery disease in which a catheter equipped with an inflatable balloon tip is inserted into a narrowed coronary artery and the balloon is inflated; common elective procedure and also used in emergent situations. Ch. 36

pericardial effusion An accumulation of excess fluid in the pericardium. Ch. 39

pericardial friction rub A scratching, grating, high-pitched sound believed to arise from friction between the roughened pericardial and the epicardial surfaces. Ch. 39

pericardiocentesis Procedure in which a 16- to 18-gauge needle is inserted into the pericardial space to remove fluid for analysis and to relieve cardiac pressure. Ch. 39

pericarditis A condition caused by inflammation of the pericardial sac. Ch. 39

perimenopause A normal life transition that begins with the first signs of change in menstrual cycles and ends after cessation of menses. Ch. 56

peripheral artery disease (PAD) A condition that involves thickening of artery walls, which results in a progressive narrowing of the arteries of the upper and lower extremities. Ch. 40

peripheral nervous system (PNS) The division of the nervous system that consists of cranial nerves III to XII, the spinal nerves, and the peripheral components of the autonomic nervous system. Ch. 58

peritoneal dialysis (PD) A type of dialysis that uses a natural semipermeable membrane, the peritoneum; dialysis fluid is infused into the peritoneal cavity, and excess fluid and waste products pass across the membrane into the fluid, which is then drained and discarded. Ch. 49

peritonitis A localized or generalized inflammatory process of the peritoneum. Ch. 45

pernicious anemia A disease in which the gastric mucosa does not secrete intrinsic factor (IF) because of either gastric mucosal atrophy or autoimmune destruction of parietal cells and possibly also because of IF itself. Ch. 33

PERRLA Acronym that stands for "**p**upils are **e**qual, **r**ound, and **r**eactive to **l**ight and **a**ccommodation" (a description of normal pupil function). Ch. 23

petechiae Small purplish-red lesions. Ch. 32

pH H^+ concentration, usually expressed as a negative logarithm. Ch. 19

phagocytosis A process by which white blood cells ingest or engulf an unwanted organism and then digest and kill it. Ch. 32

phantom limb sensation Phenomenon whereby the patient feels as though the amputated limb is still present after surgery to remove it; describes any sensation of the missing limb except pain. Ch. 65

pheochromocytoma A rare condition characterized by a tumour of the adrenal medulla that produces excessive amounts of catecholamines (epinephrine, norepinephrine), resulting in severe hypertension. Ch. 51

phimosis A constriction of the uncircumcised foreskin around the head of the penis, making retraction over the glans penis difficult. Ch. 57

phlebostatic axis A landmark used to establish the zero reference point at the level of the atria of the heart for positioning the stopcock nearest the transducer; located at the intersection of two imaginary lines, one through the fourth intercostal space at the sternum and one through midchest, halfway between the outermost anterior and the outermost posterior surfaces. Ch. 68

physical dependence Physiological adaptation to ongoing exposure to pharmacological agents such that use and cessation of use cause an expected physiological response. Ch. 10

physical examination The systematic assessment of a patient's physical status. Ch. 3

pilonidal sinus A small tract under the skin between the buttocks, in the sacrococcygeal area; may have several openings and is lined with epithelium and hair. Ch. 45

planning Setting goals and expected outcomes with the patient and, when feasible, the patient's family and determining strategies for accomplishing the goals. Ch. 1

pleural effusion A collection of fluid in the pleural space. Ch. 30

pleural friction rub A creaking or grating sound that occurs when roughened, inflamed surfaces of the pleura rub together; evident

during inspiration, expiration, or both; does not change with coughing. Ch. 28

pleurisy (pleuritis) Inflammation of the pleura. Ch. 30

pneumoconiosis A general term for lung diseases caused by the inhalation and retention of dust particles, literally meaning "dust in the lungs." Ch. 30

pneumonia Acute inflammation of the lung parenchyma caused by a microbial agent. Ch. 30

pneumothorax Presence of air in the pleural space. Ch. 30

poikilothermism The adjustment of the body temperature to the room temperature. Ch. 63

point of maximal impulse (PMI) The site of strongest pulsation; lies within the midclavicular line in the fifth intercostal space. Ch. 34

polycystic kidney disease (PKD) A genetic kidney disorder in which the cortex and the medulla are filled with thin-walled cysts that enlarge and destroy surrounding tissue by compression. Ch. 48

polycythemia An abnormal condition characterized by increased red blood cells. Chs. 32, 33

polymyositis Diffuse, idiopathic, inflammatory myopathies of the connective tissues, especially striated muscle, that produce bilateral weakness, usually most severe in the proximal or the limb-girdle muscles. Ch. 67

polypharmacy Use of multiple medications by a patient who has more than one health problem. Ch. 7

portal hypertension Hypertension characterized by increased venous pressure in the portal circulation, as well as by splenomegaly, large collateral veins, ascites, systemic hypertension, and esophageal varices. Ch. 46

positive end-expiratory pressure (PEEP) A ventilatory manoeuvre in which positive pressure is applied to the airway during exhalation. Ch. 68

positive feedback A second method of regulation of hormone secretion; increases the target organ action beyond normal. Ch. 50

positive-pressure ventilation (PPV) A ventilatory mode in which the ventilator pushes air into the lungs under positive pressure; the primary method used with acutely ill patients. Ch. 68

postmenopause The time in a woman's life after menopause. Ch. 56

postpolio syndrome (PPS) Recurrence of neuro-muscular symptoms of polio in disease survivors as they age. Ch. 63

post-thrombotic syndrome (PTS) A condition that results in chronic venous hypertension caused by valvular destruction (from inflammation and scarring); stiffness and noncompliance of vein walls; and persistent venous obstruction; occurs in 20% to 50% of patients with venous thrombo-embolism. Ch. 40

postural drainage An airway clearance technique in which gravity is used to assist in bronchial drainage. Ch. 31

potentiation A drug interaction causing a response greater than the sum of the individual responses to each drug. Ch. 11

prayer A form of communication or fellowship with a divine entity or the sacred. Ch. 12

prediabetes A condition in which a fasting or a 2-hour plasma glucose level is higher than normal but lower than that considered diagnostic for diabetes mellitus; places the individual at risk of developing diabetes mellitus and its complications. (Also known as *impaired glucose tolerance [IGT]* or *impaired fasting glucose [IFG])*. Ch. 52

preload The volume of blood in the ventricles at the end of diastole, before the next contraction. Ch. 34

premature atrial contraction (PAC) Contraction originating from an ectopic focus in the atrium in a location other than the sinus node. Ch. 38

premature ventricular contraction (PVC) A contraction originating in an ectopic focus in the ventricles. Ch. 38

premenstrual syndrome (PMS) A symptom complex related to the luteal phase of the menstrual cycle that resolves with menstruation. Ch. 56

presbycusis Hearing loss associated with aging; includes the loss of peripheral auditory sensitivity, a decline in word recognition ability, and associated psychological and communication issues. Ch. 24

presbyopia A form of hyperopia, or farsightedness, that occurs as a normal process of aging, usually beginning around age 40. Ch. 23

pressure injury A localized injury to the skin or underlying soft tissue, usually over a bony prominence or related to a medical or other device, as a result of pressure or pressure in combination with shear, friction, or both. Ch. 14

primary care A facet of primary health care that focuses on aspects of health care such as health promotion, illness prevention, diagnosis, and treatment. Ch. 6

primary (essential) hypertension Elevated blood pressure without an exact identified cause but considered to be due to a complex interaction between genes and the environment; accounts for about 90% to 95% of all cases of hypertension. Ch. 35

primary health care A philosophy and an approach to health care that focuses on a system-wide partnership between health, social services, housing, and the environment. Ch. 6

primary survey A systematic approach to emergency assessment that focuses on airway, breathing, circulation, and disability (ABCDs) and serves to identify life-threatening conditions. Ch. 71

Prinzmetal's angina Angina that occurs at rest, usually in response to spasm of a major coronary artery; also called *variant angina*. Ch. 36

problem-focused coping A cognitive approach that focuses on finding solutions to the problems causing stress (e.g., setting priorities, collecting information, seeking advice). Ch. 8

procedural sedation Mild depression of consciousness that results from administration of IV sedatives, analgesics, or both so patients can tolerate minor procedures yet still maintain airway control and protective airway reflexes. Ch. 21

prodrome Signs or symptoms that may precede a migraine headache, including psychic disturbances, gastro-intestinal upset, and changes in fluid balance. Ch. 61

pronouncement of death Verification of the absence of an apical pulse and respirations and that the pupils are fixed and dilated. Ch. 13

prostate-specific antigen (PSA) A glycoprotein found only in the epithelial cells of the prostate that, when elevated, indicates a pathological condition of the prostate, although not necessarily prostate cancer. Ch. 57

prostatitis An acute or chronic inflammatory condition affecting the prostate gland, usually as a result of infection. Ch. 57

protein–calorie malnutrition (PCM) The most common form of undernutrition. Ch. 42

proto-oncogenes Normal genes that are regulators of normal cellular processes; promote growth. Ch. 18

protozoa Single-cell, animal-like microorganisms that normally live in soil and bodies of water but, when introduced into the human body, can cause infection; include amoebas, ciliates, flagellates, and sporozoa. Ch. 17

pruritus Itching. Ch. 25

pseudocyst A cavity continuous with or surrounding the outside of the pancreas. Ch. 46

pseudo-obstruction An apparent mechanical obstruction of the intestine without demonstration of obstruction by radiological methods. Ch. 45

psoriasis A common inherited benign disorder that is characterized by the eruption of reddish, silver-scaled maculopapules, predominantly on the elbows, knees, scalp, and trunk. Ch. 26

psoriatic arthritis A progressive inflammatory disease that affects approximately 10% to 30% of people with psoriasis (a skin disorder); has a genetic link with the HLA antigens in many patients. Ch. 67

psychological dependence Emotional and mental reliance on a substance because of the pleasurable and reinforcing effects of the substance. Ch. 11

psychoneuroimmunology Interdisciplinary science in which investigators seek to understand the interactions among psychological, neurological, and immune responses. Ch. 8

public health nursing A specialized area of nursing practice in which the nurse combines knowledge from public health science, primary health care, nursing science, and the social sciences and focuses on promoting, protecting, and preserving the health of populations. Ch. 6

pulmonary edema An abnormal, life-threatening accumulation of fluid in the alveoli and the interstitial spaces of the lungs. Chs. 30, 37

pulmonary embolism (PE) The blockage of pulmonary arteries by a thrombus, fat or air embolus, or tumour tissue. Ch. 30

pulmonary hypertension Elevated pulmonary pressure resulting from an increase in pulmonary vascular resistance to blood flow through small arteries and arterioles. Ch. 30

pulse pressure The difference between the systolic blood pressure and the diastolic blood pressure. Ch. 34

purpura Purplish-red rash. Ch. 32

pursed-lip breathing A breathing exercise (breathing in through the nose and then breathing out through pursed lips); used to prolong exhalation, prevent bronchiolar collapse and air trapping, and assist with dyspnea. Ch. 31

pyelonephritis Inflammation (usually caused by infection) of the renal parenchyma and the collecting system. Ch. 48

pyrosis Heartburn; burning in epigastric or substernal area. Ch. 41

Q

quality of life A subjective evaluation of both the positive and negative aspects of life. Ch. 5

quarantine The isolation of people who have been exposed, or potentially exposed, to an infection or contagious disease but who are not yet sick or showing any signs of illness. Ch. 72

R

race A group characterized by specific biological and physical traits, such as skin colour, bone structure, or blood group. Ch. 2

racialization Social processes of categorization or differentiation of groups according to race. Ch. 2

radiation The emission and distribution of energy through space or a material medium. Ch. 18

radical prostatectomy Surgical removal of the entire prostate gland, the seminal vesicles, and part of the bladder neck (ampulla). Ch. 57

rapid-sequence intubation The preferred procedure for securing an unprotected airway; the patient is given a sedative and a neuromuscular blocking agent to facilitate intubation and minimize the risk for aspiration and airway trauma. Ch. 71

Raynaud's phenomenon An episodic vasospastic disorder of small cutaneous arteries, most frequently involving the fingers and toes. Ch. 40

recessive allele An allele that has no noticeable effect on the phenotype in a heterozygous individual. Ch. 15

rectocele Herniation or protrusion of the rectum through the wall of the vagina; occurs when support between the vagina and the rectum is weakened; also known as *posterior wall prolapse*. Ch. 56

reflex An involuntary response to a stimulus. Ch. 58

refractive error A defect in which light rays focus either in front of or behind the eye, causing images to be out of focus. Ch. 24

refractory hypoxemia Hypoxemia unresponsive to increasing concentrations of oxygen. Ch. 70

regeneration Replacement of lost cells and tissues with cells of the same type. Ch. 14

regional anaesthesia Reversible loss of sensation to a region of the body without loss of consciousness, achieved by blocking nerve fibres with the administration of a local anaesthetic. Ch. 21

regulated health care providers Paid workers who meet certain requirements that allow them to legally use a specific title and to undertake a specific type of work. Ch. 1

regurgitation Incomplete closure of the valve leaflets, resulting in the backward flow of blood. Ch. 39

relapse A return to substance use after a period of abstinence. Ch. 11

relief craving The intense desire for a substance, usually experienced after decreased use, resulting from the memory aspect related to the brain reward pathway. Ch. 11

renal arteriography A radiological study performed by injecting contrast material into the renal artery via a catheter inserted into the femoral artery; the purpose is to visualize renal blood vessels. Ch. 47

renal artery stenosis A partial occlusion of one or both renal arteries and their major branches; a major cause of abrupt-onset hypertension. Ch. 48

renal biopsy Procedure to obtain renal tissue for examination to establish a diagnosis or to follow progress of renal disease; may be an open biopsy or, more commonly, a skin (percutaneous) biopsy conducted through needle insertion into the lower lobe of the kidney. Ch. 47

renal osteodystrophy A disorder of the bones associated with chronic kidney disease that includes a number of skeletal disorders: osteitis fibrosa, osteomalacia, adynamic bone disorder, and mixed osteodystrophy. Ch. 49

renal replacement therapy (RRT) All forms of life-supporting therapies for renal failure, including hemodialysis, peritoneal dialysis, hemofiltration, and renal transplantation. Ch. 49

renal vein thrombosis An embolus occurring in the renal vein. Ch. 48

repair Healing as a result of lost cells' being replaced by connective tissue. Ch. 14

repetitive strain injury (RSI) Injury resulting from prolonged force or repetitive movements and awkward postures; also called *cumulative trauma disorder*, *repetitive trauma disorder*, *nontraumatic musculo-skeletal injury*, *overuse syndrome* (sports medicine), *regional musculo-skeletal disorder*, and *work-related musculo-skeletal disorder*. Ch. 65

resilience The ability to be resourceful, be flexible, and recover from stressful situations and return to prior levels of functioning. Ch. 8

responsive behaviours In patients with dementia, behaviours that are responses to something in the patient's environment. Ch. 62

restless legs syndrome (RLS) Syndrome characterized by unpleasant sensory (paresthesias) and motor abnormalities of one or both legs; also known as *Willis–Ekbom disease*. Ch. 61

retina The innermost layer of the eye that extends and gives rise to the optic nerve; responsible for converting images into a form that the brain can understand and process as vision. Ch. 23

retinal detachment A separation of the sensory retina and the underlying pigment epithelium, with fluid accumulation between the two layers. Ch. 24

retinopathy The process of microvascular damage to the retina. Ch. 24

retrograde pyelography Radiographic visualization of the kidneys, the ureter, and the bladder after direct injection of a contrast material into the kidney. Ch. 47

retroviruses Viruses that replicate in a "backward" manner (transcribing their RNA and DNA after entering a cell). Ch. 17

reverse transcriptase An enzyme made by HIV and other retroviruses that helps transcribe viral RNA into a double strand of viral DNA. Ch. 17

reward craving A craving that occurs when in the presence of people, places, or things that were previously associated with taking the substance. Ch. 11

rheumatic fever A disease that causes inflammation in connective tissues; commonly affects the heart, the brain, the joints, or the skin. Ch. 39

rheumatic heart disease A chronic condition resulting from rheumatic fever that is characterized by scarring and deformity of the heart valves. Ch. 39

rheumatoid arthritis (RA) A chronic, systemic autoimmune disease characterized by inflammation of connective tissue in the diarthrodial (synovial) joints, typically with periods of remission and exacerbation. Ch. 67

rhinoplasty Surgical reconstruction of the nose, performed for cosmetic reasons or to improve airway function when trauma or developmental deformities result in nasal obstruction. Ch. 29

ribonucleic acid (RNA) A single-stranded nucleic acid that translates DNA genetic information into protein. Ch. 15

S

same-day admission Admission to hospital on the day that surgery will take place. Ch. 20

sarcoma A malignant tumour in the connective tissue of the body (fat, muscles, blood vessels, nerves, bones, or cartilage). Chs. 18, 66

SBAR (situation, background, assessment, and recommendation) A means for members of the health care team to talk about a patient's condition in a predictable, structured manner. Ch. 1

sclera The bulbar conjunctiva, composed of collagen fibres meshed together to form an opaque structure commonly referred to as the "white" of the eye; helps protect the intraocular structures. Ch. 23

scleroderma A disorder of connective tissue characterized by fibrotic, degenerative, and occasionally inflammatory changes in skin, blood vessels, synovium, skeletal muscle, and internal organs; also called *systemic sclerosis*. Ch. 67

scoliosis A deformity resulting from lateral S-shaped curvature of the thoracic and lumbar spine. Ch. 64

scrub nurse A perioperative nurse who performs surgical hand asepsis, is gowned and gloved in sterile attire, and remains in the sterile field assisting the surgical team. Ch. 21

sebaceous glands Oil-producing glands that secrete sebum, which waterproofs and lubricates the skin and hair. Ch. 25

secondary hypertension Elevated blood pressure with a specific cause that often can be identified and corrected; accounts for about 5% to 10% of hypertension in adults and more than 80% of hypertension in children. Ch. 35

secondary survey A brief, systematic process that is aimed at identifying all injuries (follows primary survey and life-saving interventions). Ch. 71

seizure A transient uncontrolled electrical discharge of neurons in the brain that interrupts normal function. Often, seizures are symptoms of an underlying illness. Ch. 61

selectins Cell surface carbohydrate-binding proteins that mediate cell adhesion; involved in leukocyte extravasation during the immune response. Ch. 14

self-efficacy A person's sense of confidence in his or her ability to perform a set of actions. Ch. 4

self-management A person's ability to manage symptoms, treatments, and the various consequences of an illness. Ch. 5

self-protective behaviours In patients with dementia, behaviours that are responses to a perceived threat. Ch. 62

sense of coherence An optimistic view of the world and perceived ability to function optimally in that world. Ch. 8

sepsis A systemic inflammatory response to a documented or suspected infection. Ch. 69

septic arthritis An infection caused by microorganisms that invade the joint cavity; also called *infectious* or *bacterial arthritis*. Ch. 67

septic shock A condition in which hypotension cannot be reversed with fluid resuscitation; tissue perfusion abnormalities are present. Ch. 69

severe sepsis Sepsis complicated by organ dysfunction, hypoperfusion, or hypertension. Ch. 69

sex-linked gene A gene located on a sex chromosome. Ch. 15

sexual assault The legal term used to refer to any form of sexual contact imposed on another person without that person's voluntary consent. Ch. 71

sexually transmitted infections (STIs) Infectious diseases that are commonly acquired through sexual contact but may also be contracted by other routes, such as through blood, blood products, perinatal transmission, and autoinoculation; can be bacterial, viral, or both. Ch. 55

shared decision making A decision-making process engaged in jointly by patients and their health care providers. Ch. 5

shearing force Pressure exerted on the skin when it adheres to the bed and the underlying skin layers slide in the direction of body movement. Ch. 14

shift work sleep disorder Insomnia, sleepiness, and fatigue often experienced by people who work a permanent night shift or rapidly rotating shifts. Ch. 9

shock A syndrome characterized by decreased tissue perfusion and impaired cellular metabolism that results in an imbalance between the supply of and the demand for oxygen and nutrients. Ch. 69

short bowel syndrome (SBS) Syndrome resulting from extensive resection of the small intestine and characterized by rapid intestinal transit, impaired digestive and absorption processes, and fluid and electrolyte losses. Ch. 45

sickle cell disease (SCD) A group of inherited, autosomal recessive disorders characterized by the presence of an abnormal form of hemoglobin in the red blood cell. Ch. 33

signs Objective manifestations of a condition. Ch. 5

silent ischemia Ischemia that occurs in the absence of clinical symptoms such as chest pain. Ch. 36

Sjögren syndrome A relatively uncommon autoimmune disease that targets moisture-producing exocrine glands, leading to the common symptoms of xerostomia (dry mouth) and kerato-conjunctivitis sicca (dry eyes). Ch. 67

sleep A state during which an individual lacks conscious awareness of environmental surroundings and from which the individual can be easily aroused. Ch. 9

sleep disorder A condition that specifically affects the quality of sleep and wake behaviour. Ch. 9

sleep-disordered breathing Abnormal respiratory patterns associated with sleep, such as snoring, apnea, and hypopnea, characterized by increased respiratory effort that leads to frequent arousals. Ch. 9

sleep disturbances Situations of poor quality sleep. Ch. 9

sleep hygiene A variety of different practices that are important for normal, quality nighttime sleep and daytime alertness. Ch. 9

sleep terrors A sudden awakening from sleep along with a loud cry and signs of panic; includes an intense autonomic response, including increased heart rate, increased respiration, and diaphoresis. Ch. 9

smoke and inhalation injuries Damage to the tissues of the respiratory tract as a result of the inhalation of hot air or noxious chemicals. Ch. 27

Somogyi effect An effect characterized by wide differences in early-morning (low) and fasting (high) glucose levels. Usually occurs during the hours of sleep and produces a decline in blood glucose level in response to too much insulin; counter-regulatory hormones are released, stimulating lipolysis, gluconeogenesis, and glycogenolysis, which in turn produce rebound hyperglycemia and ketosis. Ch. 52

spermatocele A firm, sperm-containing, painless cyst of the epididymis. Ch. 57

spermatogenesis The process of sperm production. Ch. 53

spider angiomas Small, dilated blood vessels of the skin that have a bright-red centre and spider-like branches; occur on nose, cheeks,

upper trunk, neck, and shoulders. Ch. 46

spinal anaesthesia The injection of a local anaesthetic into the cerebro-spinal fluid found in the subarachnoid space, usually below the level of L2. Ch. 21

spinal shock A temporary neurological syndrome experienced after spinal cord injury and characterized by decreased reflexes, loss of sensation, and flaccid paralysis below the level of the injury. Ch. 63

spirituality Beliefs, values, and practices that relate to the search for existential meaning and purpose; may or may not include belief in a higher power. Ch. 13

spondyloarthropathies A group of interrelated, multisystem inflammatory disorders that affect the spine, the peripheral joints, and the periarticular structures. Ch. 67

sprain An injury related to the ligamentous structures surrounding a joint, usually caused by a wrenching or twisting motion. Ch. 65

squamous cell carcinoma (SCC) A malignant neoplasm of keratinizing epidermal cells that frequently occurs on sun-exposed skin. Ch. 26

stage of exhaustion Final stage of general adaptation syndrome, which occurs when all of the energy for adaptation has been expended; usually results in illness and can result in death without external sources of adaptive energy, such as medication or psychotherapy. Ch. 8

stage of resistance Second stage of general adaptation syndrome, in which physiological reserves are mobilized to increase the resistance to stress. Ch. 8

stages of behavioural change The six stages of change identified by Prochaska and Velicer (1997) in their transtheoretical model of behaviour change: precontemplation, contemplation, preparation, action, maintenance, and termination. Ch. 4

staging Classifying the extent and spread of disease. Ch. 18

standard of practice An authoritative statement outlining the legal and professional foundation for nursing practice and the expected level of performance. Ch. 1

status epilepticus A state of continuous seizure activity, in which seizures recur in rapid succession without the person returning to consciousness between seizures. It is a neurological emergency and can involve any type of seizure. Ch. 61

steatorrhea Passage of large amounts of fat as bulky, fatty, frothy, foul-smelling, yellow-grey, greasy stools with putty-like consistency; results from failure to digest and absorb the fat. Ch. 41

stem cell An immature blood cell that is able to self-renew and to differentiate into hematopoietic progenitor cells. Ch. 32

stereotyping The assumption that members of a specific culture, race, or ethnic group have certain characteristics associated with that group, without further exploration of what the individuals are actually like. Ch. 2

stigmatization Being regarded by others as unworthy or disgraceful. Ch. 5

strabismus A condition in which the patient cannot consistently focus both eyes simultaneously on the same object. Ch. 24

strain An excessive stretching of a muscle, a muscle's fascial sheath, or a tendon; most occur in the foot, leg (typically hamstring), or back. Ch. 65

stress The inability to cope with perceived (real or imagined) demands or threats to an individual's mental, emotional, or spiritual well-being. Ch. 8

stressors Stress-inducing demands on a person. Ch. 8

stricture An abnormal temporary or permanent narrowing of the lumen of a hollow organ such as the ureter or the urethra. Ch. 48

stroke Death of brain cells as a result of ischemia to a part of the brain or hemorrhage into the brain. Ch. 60

subarachnoid hemorrhage (SAH) A stroke resulting from intracranial bleeding into the cerebro-spinal fluid–filled space between the arachnoid and the pia mater membranes on the surface of the brain. Ch. 60

subdural hematoma A collection of blood that results from bleeding between the dura mater and arachnoid layer of the meningeal covering of the brain; usually results from injury to the brain substance and its parenchymal vessels. Ch. 59

subjective data What the person tells the nurse either spontaneously or in response to a direct question; also called *symptoms*. Ch. 3

sublethal injury Cell injury that alters function without causing cell destruction. Ch. 14

subluxation A partial or incomplete displacement of the joint surface. Ch. 65

submersion injury Injury resulting when a person becomes hypoxic as a result of submersion in a substance, usually water. Ch. 71

substance use disorder Problematic use of a substance resulting from the prolonged effects of the substance on the brain. Ch. 11

sudden cardiac death (SCD) Unexpected death resulting from various causes, including cardiac arrest. Ch. 36

suffering Distress that occurs when stressors threaten the biopsychosocial integrity of an individual. Ch. 10

sun protection factor (SPF) A method of measuring the effectiveness of a sunscreen in filtering and absorbing ultraviolet B light (UVB) radiation. Ch. 26

sundowning A pattern of behavioural disturbance that occurs in the late afternoon. Ch. 62

superficial vein thrombosis (SVT) The formation of a thrombus in a superficial vein, usually the greater or lesser saphenous vein. Ch. 40

surfactant A lipoprotein that lowers the surface tension in the alveoli, reduces the amount of pressure needed to inflate the alveoli, and decreases the tendency of the alveoli to collapse. Ch. 28

surgeon A physician who performs surgical procedures. Ch. 21

surgical suite A controlled environment designed to maximize infection control and provide a seamless flow of patients, personnel, and operative instruments, equipment, and supplies; it is divided into unrestricted, semirestricted, and restricted areas. Ch. 21

symptoms The subjective reports of the patient. Ch. 5

synapse The structural and functional junction between two neurons; the point at which the nerve impulse is transmitted from one neuron to another or from a neuron to glands or muscles. Ch. 58

syncope Fainting that may occur with decreased cardiac output, fluid deficits, or defects in cerebral perfusion. Ch. 22

syndrome of inappropriate antidiuretic hormone (SIADH) A condition in which there is overproduction or oversecretion of antidiuretic hormone; characterized by fluid retention, serum hypo-osmolality, dilutional hyponatremia, hypochloremia, concentrated urine in the presence of normal or increased intravascular volume, and normal renal function. Ch. 51

synovectomy Removal of the synovial membrane; used as a prophylactic measure or as a palliative treatment for rheumatoid arthritis. Ch. 65

syphilis A sexually transmitted infection caused by *Treponema pallidum*; may also be spread through contact with infectious lesions and sharing of needles among people who use intravenous drugs. Ch. 55

systemic exertion intolerance disease (SEID) A serious, complex, multisystem disease in which exertion of any sort (physical, emotional, cognitive) can adversely affect multiple organs in a person; also known as *chronic fatigue syndrome (CFS)*. Ch. 67

systemic inflammatory response syndrome (SIRS) A systemic inflammatory response to a variety of insults, including infection, ischemia, infarct, and injury; characterized by at least two of the following: fever, edema, hypotension, tachycardia, impaired oxygenation, and elevated white blood cell count. Ch. 69

systemic lupus erythematosus (SLE) A multisystem, inflammatory disease that typically affects the skin, the joints, and the serous membranes (pleura, pericardium), along with the renal, hematological, and neurological systems. Ch. 67

systemic vascular resistance (SVR) The force opposing the movement of blood within the blood vessels; the radius of the small arteries and arterioles is the principal factor determining vascular resistance. Ch. 35

systole Contraction of the myocardium. Ch. 34

systolic blood pressure (SBP) The peak pressure exerted against the arteries when the heart contracts. Ch. 34

T

teaching A process of deliberately planning experiences and sharing knowledge to meet learner outcomes in the cognitive, affective, and psychomotor domains. Ch. 4

teaching plan A learner-centred approach for action to achieve the goals and learning outcomes agreed upon by the patient and nurse. Ch. 4

teaching process The development and implementation of a plan that includes assessment, diagnosis, the setting of patient outcomes or objectives, intervention, and evaluation. Ch. 4

tenesmus Spasmodic contraction of the anal sphincter with pain and persistent desire to empty the bowel; painful and ineffective straining at stool. Ch. 41

tension pneumothorax A pneumothorax with rapid accumulation of air in the pleural space, causing severely high intrapleural pressures with resultant tension on the heart and great vessels. Ch. 30

tension-type headache The most common type of primary headache, characterized by bilateral location and pressing or tightening quality; usually of mild or moderate intensity and lasting from minutes to days. (Also called *stress headache*.) Ch. 61

terrorism Intentional and overt actions that are committed to cause fear, panic, destruction, injury, and death in service of political, religious, or ideological goals. Ch. 72

testicular torsion A condition involving a twisting of the spermatic cord that supplies blood to the testes and epididymis, causing an interruption to the blood supply. Ch. 57

tetanus An extremely severe polyradiculitis and polyneuritis affecting spinal and cranial nerves that results from the effects of

a potent neurotoxin released by the anaerobic bacillus *Clostridium tetani*; also called *lockjaw*. Ch. 63

tetany Condition of sustained muscle contraction. Ch. 19

tetraplegia Paralysis of the arms, the legs, and the trunk occurring with spinal cord damage at the eighth cervical (C8) vertebra or above; formerly called *quadriplegia*. Ch. 63

thalassemia A group of diseases involving inadequate production of normal hemoglobin; caused by an absent or reduced globulin protein. Ch. 33

therapeutic touch A method of detecting, balancing, and repatterning the human energy field. Ch. 12

thermal burns Burns caused by flame, flash fire, scald, or contact with hot objects. Ch. 27

thoracentesis A procedure to remove fluid from the pleural space. Ch. 30

thoracotomy Surgical opening into the thoracic cavity. Ch. 30

thromboangiitis obliterans (Buerger's disease) A nonatherosclerotic, segmental, recurrent inflammatory disorder of the small and medium-sized arteries and veins of the upper and lower extremities. Ch. 40

thrombo-cytopenia A reduction of platelets to an amount below 150 $\times 10^9$/L. Chs. 32, 33

thrombo-cytosis A condition characterized by excessive levels of platelets; a disorder that occurs with inflammation and some malignant diseases. Ch. 32

thrombotic stroke A stroke resulting from the formation of a blood clot in a diseased and narrowed blood vessel in the brain. Ch. 60

thyroiditis An inflammation of the thyroid gland; can have several causes. Ch. 51

thyrotoxicosis The clinical syndrome of hypermetabolism caused by excess circulating levels of thyroxine, triiodothyronine, or both. Ch. 51

thyroxine (T_4) The most abundant hormone produced by the thyroid gland and the precursor to triiodothyronine. Ch. 50

tidal volume Volume of air exchanged with each breath. Ch. 28

tinnitus The perception of ringing in the ears. Ch. 23

titration Dosage adjustment based on assessment of the adequacy of analgesic effect versus the adverse effects produced. Ch. 10

tolerance The need for a larger dose of a drug to obtain the original euphoria. Ch. 11

tonic–clonic seizure The most common type of generalized seizure, characterized by loss of consciousness and falling to the ground if the patient is upright, followed by stiffening of the body (tonic phase) for 10 to 20 seconds and subsequent jerking of the extremities (clonic phase) for another 30 to 40 seconds. Ch. 61

tracheostomy A stoma (opening) that results from a tracheotomy. Ch. 29

tracheotomy A surgical incision into the trachea for the purpose of establishing an airway. Ch. 29

traction The application of a pulling force to an injured or diseased part of the body or extremity while counter-traction pulls in the opposite direction. Ch. 65

traditional Chinese medicine (TCM) A group of treatment modalities used to replenish and smooth the flow of qi, or the fundamental life force; interventions include acupressure, acupuncture, Chinese massage, cupping, moxibustion, nutrition counselling, and meditative physical exercise. Ch. 12

transcription The process through which RNA is synthesized from the DNA template. Ch. 15

transduction The conversion of a mechanical, thermal, or chemical stimulus to a neuronal action potential. Ch. 10

transient ischemic attack (TIA) A temporary episode of neurological dysfunction caused by focal brain, spinal cord, or retinal ischemia but without acute infarction of the brain. Ch. 60

translation The process through which the codon sequence is converted into amino acids. Ch. 15

transmission The movement of pain impulses from the site of transduction to the brain. Ch. 10

transtheoretical model of change A framework of behaviour change that provides a contextual approach for clinicians; the stages of change include precontemplation, contemplation, preparation, action, maintenance, and termination, Ch. 11

transurethral resection of the prostate (TURP) A surgical procedure involving the removal of prostate tissue using a resectoscope inserted through the urethra. Ch. 57

triage The sorting or ranking of casualties to prioritize health care needs and to allocate resources. Ch. 72

trigeminal neuralgia (TN) Uncommon cranial nerve disorder affecting cranial nerve V; characterized by paroxysms of flashing, stabbing pain radiating along the course of a branch of the trigeminal facial nerve from the angle of the jaw; also called *tic douloureux*. Ch. 63

trigger point A circumscribed hypersensitive area within a tight band of muscle that is caused by acute or persistent muscle strain. Ch. 10

triiodothyronine (T_3) A potent hormone produced by the thyroid gland that regulates the metabolic rate of all cells and processes of cell growth and tissue differentiation. Ch. 50

tropic hormones Several hormones secreted by the anterior pituitary gland that control the secretion of hormones by other glands. Ch.

tuberculosis An infectious disease caused by *Mycobacterium tuberculosis*; usually involves the lungs but also occurs in the larynx, the kidneys, the bones, the adrenal glands, the lymph nodes, and the meninges and can be disseminated throughout the body. Ch. 30

tumour angiogenesis The process of the formation of blood vessels within the tumour itself. Ch. 18

tumour-associated antigens Cell surface antigens on some cancer cells that have changes as a result of malignant transformation. Ch. 18

tumour suppressor genes Normal genes that are regulators of normal cellular processes; suppress growth. Ch. 18

U

ulcerative colitis (UC) A chronic inflammatory bowel disease characterized by inflammation and ulceration of the rectum and colon. Ch. 45

unconsciousness An abnormal state of complete or partial unawareness of self or environment. Ch. 59

undernutrition A state that occurs when nutritional reserves become depleted or when nutrient intake is inadequate to meet daily requirements or metabolic demands. Ch. 42

unregulated care providers Paid employees who are not licensed or registered by a regulatory body, who have no legally defined scope of practice, who may or may not have mandatory education or practice standards, who provide care under the direct or indirect supervision of a nurse, and who are accountable for their own actions and decisions. Ch. 1

unstable angina (UA) Angina that is new in onset, occurs at rest, or has a worsening pattern. Ch. 36

upper motor neurons (UMNs) The classification of motor pathways that originate in the cerebral cortex and project downward; the cortico-bulbar tract ends in the brain stem, and the cortico-spinal tract descends into the spinal cord. Ch. 58

uremia A constellation of signs and symptoms resulting from the buildup of waste products and excess fluid associated with kidney failure; these signs and symptoms may include but are not limited to elevated serum creatinine and blood urea nitrogen, abnormal electrolytes, acidosis, anemia, fluid volume excess, nausea, loss of appetite, fatigue, decreased cognition, pruritus, and neuropathy. Ch. 49

urethritis Inflammation of the urethra. Ch. 48

urinalysis A general examination of urine for routine and microscopic findings; may establish baseline information, provide information about possible abnormalities, indicate what further studies need to be done, and supply information on the progression of a diagnosed disorder. Ch. 47

urinary incontinence (UI) An uncontrolled leakage loss of urine that is of sufficient magnitude to be a problem, p. 1315. Ch. 48

urinary retention The inability to empty the bladder despite micturition, or the accumulation of urine in the bladder because of an inability to urinate. Ch. 48

urodynamics testing A set of studies designed to measure urinary tract function—the storage of urine within the bladder and the flow of urine through the urinary tract to the outside of the body. Ch. 47

urticaria An eruption of spontaneously occurring, raised or irregularly shaped wheals; usually allergic phenomenon. Ch. 26

uterine prolapse The downward displacement of the uterus into the vaginal canal as a result of impaired pelvic support. Ch. 56

V

valence The electrical charge of an ion. Ch. 19

Valsalva manoeuvre A manoeuvre that involves contraction of the chest muscles on a closed glottis with simultaneous contraction of the abdominal muscles; used during straining. Ch. 41

varicocele A dilation of the veins that drain the testes. Ch. 57

varicose veins Dilated, tortuous subcutaneous veins most commonly found in the saphenous vein system. Ch. 40

vascular dementia A form of dementia that results from ischemic, ischemic–hypoxic, or hemorrhagic brain damage caused by cardiovascular disease; also called *multi-infarct dementia*. Ch. 62

vasectomy The bilateral surgical ligation or resection of the vas deferens performed for the purpose of sterilization. Ch. 57

venous thrombo-embolism (VTE) Condition in which a thrombus forms in association with inflammation of the vein. Ch. 40

ventilation Inspiration (movement of air into the lungs) and expiration (movement of air out of the lungs). Ch. 28

ventricular assist device (VAD) An internally implanted or externally positioned device that provides short- and long-term support for the failing heart; inserted into the path of flowing blood to augment or replace the action of the ventricle. Ch. 68

ventricular fibrillation A severe derangement of the heart rhythm characterized by irregular undulations of varying shapes and amplitude on the ECG. Ch. 38

ventricular tachycardia (VT) The occurrence of three or more PVCs in succession; occurs when an ectopic focus or foci fire repetitively and the ventricle takes control as the pacemaker. Ch. 38

vertigo A sense that the person or objects around the person are moving or spinning; usually stimulated by movement of the head. Ch. 23

vesicants Drugs that cause severe local tissue breakdown and necrosis when accidentally infiltrated into the skin. Ch. 18

villi Minute, finger-like projections in the mucous membrane of the small intestine, containing goblet cells that secrete mucus and epithelial cells that produce the intestinal digestive enzymes. Ch. 41

viral load The number of HIV (or other virus) particles in the blood. Ch. 17

Virchow's triad Three important factors in the etiology of venous thrombosis: (a) venous stasis, (b) damage of the endothelium (inner lining of the vein), and (c) hypercoagulability of the blood. Ch. 40

viremia Large amounts of virus in the blood. Ch. 17

viruses Infectious agents consisting of either RNA or DNA and a protein envelope; can reproduce only in the cells of a living organism. Ch. 17

vitiligo Complete absence of melanin (pigment) resulting in a chalky white patch of skin. Ch. 25

volume ventilation A predetermined tidal volume is delivered to the patient with each inspiration, and the amount of pressure needed to deliver the breath varies. Ch. 68

vomiting The forceful ejection of partially digested food and secretions *(emesis)* from the upper gastro-intestinal tract. Ch. 44

W

waist-to-hip ratio (WHR) A method of describing the distribution of both subcutaneous and visceral adipose tissue; calculated by dividing the waist measurement by the hip measuremen. Ch. 43

wake behaviour Behaviour associated with an activated cortical brain wave (EEG) pattern. Ch. 9

weaning The process of reducing ventilator support and resuming spontaneous ventilation. Ch. 68

Wernicke's encephalopathy An inflammatory, hemorrhagic, degenerative condition of the brain associated with long-term alcohol abuse. Ch. 11

wet gangrene Ischemic necrosis of an appendage as a result of a sudden, rapid elimination of blood flow, such as that seen in a severe burn or traumatic crash injury. Ch. 14

wheezes Continuous high-pitched squeaking sounds caused by rapid vibration of bronchial walls. Ch. 28

window period The time between exposure to HIV infection and when the test yields an accurate result. Ch. 17

windup A pain process that results in an increase in the firing of specialized dorsal horn neurons and that is dependent on the activation of N-methyl-D-aspartate receptors. Ch. 10

withdrawal Constellation of physiological and psychological responses that occur upon abrupt cessation or reduced intake of a substance on which an individual is dependent. Ch. 11

withdrawal management Interventions and processes aimed at addressing the physiological and psychological symptoms that occur in response to stopping a substance on which physiological and psychological dependence has developed. Ch. 11

world view A paradigm or a set of assumptions, values, concepts, and practices that influences how people perceive, interpret, and relate to the world around them. Ch. 2

α_1-antitrypsin (AAT) deficiency The only known genetic abnormality that leads to chronic obstructive pulmonary disease; AAT, the major antiprotease in plasma, inhibits neutrophil elastase and the action of proteolytic enzymes from neutrophils and macrophages. Ch. 31

PATIENT & CAREGIVER TEACHING GUIDES

Endsheet 7

Situation–Background–Assessment–Recommendation (SBAR) or Identification-Situation–Background–Assessment–Recommendation-Read Back (I-SBAR-R) Technique

Nurses communicate information about patients to all team members so that they can make appropriate decisions about the patients' care. Any verbal report must be timely, accurate, and relevant. Many Canadian hospitals use the **situation–background–assessment–recommendation (SBAR)** or **identification-situation–background–assessment–recommendation-read back (I-SBAR-R)** communication technique to provide a common and predictable template for communication between members of the health care team about a patient's care. The SBAR/I-SBAR-R technique is an attempt to align ways of communicating important information that often necessitates immediate attention, and it fosters a culture of patient safety. This technique can be incorporated into a variety of ways of reporting (e.g., a nurse's report to a physician about a critically ill patient, change-of-shift-reports about individual patients, incident reports) and can be adapted for use with or by other health care professionals.

The Identification–Situation–Background–Assessment–Recommendation–Read Back (I–SBAR–R) Technique

When calling the physician or communicating with another member of the health care team, follow the I–SBAR–R process as follows:

Identification: Who is calling and who are you calling about?

- Identify yourself and your role
- Identify the unit, the patient, and the room number

Situation: What is the situation you are calling about?

- Briefly state the problem: what it is, when it started, and the severity

Background: Provide background information related to the situation, including the all or some of the following information:

- Admission diagnosis, date of admission and pertinent medical history
- List of current medications, allergies, intravenous fluids, and laboratory tests
- Laboratory results (date and time each test was performed and results of previous tests for comparison)
- Other clinical information

- Code status

Assessment: What is your assessment of the situation?
Examples include the following:

- Most recent vital signs
- Changes in vital signs or assessment from previous assessments

Recommendations: What is your recommendation or what do you want?
Examples include the following:

- Patient to be admitted or transferred
- New medication or further tests
- Patient to be seen now
- Order to be changed

Repeat Back:

- Repeat back orders that have been given
- Clarify any questions

Source: Adapted from: Joint Commission on Accreditation of Healthcare Organizations. (2005, February). The SBAR technique: Improves communication, enhances patient safety. *Joint Commission Perspectives on Patient Safety, 5*(2), 2; Enlow, M., Shanks, L., Guhde, J. & Perkins, M. (2010). Incorporating interprofessional communication skills (ISBARR) into an undergraduate nursing curriculum. *Nurse Educator, 35*(4), 176-180; and Grbach, W., Struth, D., & Vincent, I. Sample I-SBAR-R Report From a Nurse to a Physician About a Critical Situation

Identification

Hello Dr. Khan. My name is Mei Lin. I am the nurse caring for Mrs. Reddy on 17 North Rm 1072.

Situation

I am calling about her respiratory status. She started to get short of breath about 30 minutes ago.

Background

Mrs. Reddy had a left knee replacement 2 days ago. She is 78 years old. She has no history of heart problems or COPD. She is alert and complaining of sudden onset shortness of breath.

Assessment

Her oxygen saturation is 88%; BP = 140/90; P = 96; RR = 32. She was started on oxygen by nasal prongs at 2 L/min 15 minutes ago with no change in her vital signs. She has no chest pain and is distressed about her breathing problems. I wonder if she might have a pulmonary embolism.

Recommendations

I would like you to order a portable chest x-ray and oxygen by mask. Her condition is unstable and I would like you to examine her as soon as possible.

Repeat Back

Let me repeat back what you have said:

- Oxygen by facemask to keep oxygen saturation about 92%
- Chest x-ray stat
- You will be up to see the patient within 10 minutes
