- Its toxic effects are dose related. Ingestion of more than 10 g/day leads to acute liver failure.
- Combining the drug with alcohol increases risk for liver injury.

The pathophysiological changes in the liver and the clinical manifestations of toxic and drug-induced hepatitis are similar to those of viral hepatitis. The usual presenting clinical findings are anorexia, nausea, vomiting, hepatomegaly, splenomegaly, and abnormal results of liver function studies. Treatment is largely supportive, as in acute viral hepatitis. Recovery may be rapid if the hepatotoxin is identified and removed. Liver transplantation may be necessary in cases with severe liver injuries.

Autoimmune and Genetic Liver Diseases

Autoimmune Hepatitis

Autoimmune hepatitis (AIH) is a chronic inflammatory disorder of the liver that occurs when the body's immune system attacks its own liver cells. The cause is unknown, but its occurrence may be related to genetic and environmental factors or to drug, virus, or toxin exposure that triggers the activation of the immune system. However, the immune system remains activated after the trigger is removed. The majority (70% to 80%) of patients with AIH are women, and many affected patients have other autoimmune diseases such as celiac disease or hypothyroidism.

The course of AIH is variable. Some patients have no symptoms, whereas others have an acute presentation with symptoms similar to those of acute viral hepatitis. Symptoms include fatigue, arthralgia, abdominal pain, and occasionally jaundice. Diagnosis is usually based on the presence of autoantibodies (i.e., antinuclear antibodies [ANA] and anti–smooth muscle antibodies [ASMA]), high levels of serum immunoglobulins, and elevated liver enzymes. Liver cancer develops in approximately 6% of patients with AIH.

Treatment with prednisone alone or in combination with azathioprine (Imuran) induces remission in approximately 80% of patients. If these

drugs are not effective, other immuno-suppressive therapies (e.g., cyclosporine, tacrolimus [Prograf], or mycophenolate mofetil [CellCept]) are administered. Many patients who stop treatment experience relapse; therefore, treatment is usually lifelong to maintain remission. The most common cause of relapse is failure to adhere to the treatment regimen. Patients who do adhere and respond do not have a shortened life expectancy. However, liver transplantation is indicated for those with liver failure.

Wilson's Disease

Wilson's disease is an autosomal recessive gene disorder of copper metabolism that affects mainly the liver but also the brain, eyes, and kidneys. It is associated with increased storage of copper. Mutations in the affected gene, *ATP7,* lead to decreased biliary excretion of copper and result in its accumulation in the liver, which causes liver cell injury. Wilson's disease has an average worldwide prevalence of 1 per 30 000.

The hallmark of the disease is corneal Kayser–Fleischer rings, which are brownish-red rings seen in the cornea near the limbus. In addition to liver disease, many affected patients also have neurological dysfunction, including movement disorders (tremor, involuntary movements), drooling, dysarthria, rigid dystonia, seizures, migraine headaches, and insomnia.

Diagnosis is based on clinical findings, including the corneal rings and neurological symptoms. Serum ALT and AST levels are elevated, serum ceruloplasmin levels are low, serum uric acid levels are decreased, and urinary copper excretion levels are increased. Measurable copper concentrations from liver biopsy samples can also be present.

The mainstay initial treatment of symptomatic patients or those with active disease is with chelating agents such as D-penicillamine or high-dose zinc that promote the excretion. Treatment is lifelong. Liver transplantation is reserved for acute liver failures or for treatment failures.

Hereditary Hemochromatosis

Hereditary hemochromatosis (HH) is a genetic disorder that affects the liver, heart, pancreas, and endocrine system. It is an inherited condition that is related to the mutation in the *HFE* gene, causing an increase and inappropriate absorption of dietary iron. Prolonged increased iron absorption can lead to complications such as cirrhosis, hepato-cellular

carcinoma, diabetes, and heart disease. (Hemochromatosis is discussed further in Chapter 33.)

Primary Biliary Cholangitis

Until 2015, *primary biliary cholangitis (PBC)* was termed *primary biliary cirrhosis* (Beuers, Gershwin, Gish, et al., 2015). It is a chronic and slowly progressive disease caused by inflammation and destruction of small bile ducts in the liver. A T-cell–mediated attack on the small bile duct epithelial cells results in the loss of bile ducts and ultimately in *cholestasis* (blockage of bile flow). Over time, cholangitis, along with the associated inflammation and destruction of the bile ducts, leads to liver fibrosis and cirrhosis. Although the etiology of PBC is not completely understood, it appears that both genetic and environmental factors such as chemical exposure and infection may play a role.

Most patients (95%) diagnosed with PBC are women between ages 30 and 60. The disease is associated with other autoimmune disorders such as rheumatoid arthritis, Sjögren syndrome, and scleroderma.

In the early stages, patients may have no symptoms and may present with generalized pruritus, hepatomegaly, hyperpigmentation of the skin, and fatigue. Jaundice is a sign of late-stage disease. Osteoporosis is also found in a significant number of patients with PBC, and they may also have signs of fat malabsorption, including low levels of fat-soluble vitamins, which occur because of decreased bile secretion. Levels of serum alkaline phosphatase, antimitochondrial antibodies, antinuclear antibodies, and serum lipid levels are also elevated in patients with PBC. Histological evidence of disease is found on liver biopsy.

The goals of treatment are suppression of ongoing liver damage, prevention of complications, and symptom management. The only drug approved for treatment of PBC in Canada is ursodiol (Urso). This drug increases the rate of bile acid secretion and appears to have a cytoprotective effect. Management focuses on malabsorption, skin disorders such as pruritus and xanthomas (cholesterol deposits in the skin), hyperlipidemia, vitamin deficiencies, anemia, and fatigue. Cholestyramine is administered to treat pruritus. Patients are monitored for progression to cirrhosis. Liver transplantation is a treatment option for end-stage liver disease in patients with PBC.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is a disease of unknown etiology characterized by chronic inflammation, fibrosis, and strictures (narrowing) of the medium and large bile ducts. The majority of patients with PSC also have ulcerative colitis. Complications of PSC can include cholangitis, cholestasis with jaundice, cholangiocarcinoma (bile duct cancer), and cirrhosis.

Drug therapy has not been beneficial. Treatment is directed at reducing the incidence of biliary complications and at screening for bile duct and colorectal cancer, which is related to the high incidence of ulcerative colitis. Patients with advanced liver disease may require liver transplantation.

Cirrhosis of the Liver

Cirrhosis is a diffuse pathological process, characterized by fibrosis (scar tissue) and conversion of normal liver architecture to abnormal nodules (Figure 46-5). Fibrosis occurs when the liver cells attempt to regenerate after liver injuries but the regenerative process is disorganized. The overgrowth of new and fibrous connective tissue distorts the normal lobular structure, resulting in lobules of irregular size and shape with impeded blood flow. Eventually, irregular and disorganized regeneration, poor cellular nutrition, and hypoxia caused by inadequate blood flow and scar tissue result in decreased functioning of the liver. Cirrhosis is the final stage of chronic liver disease.

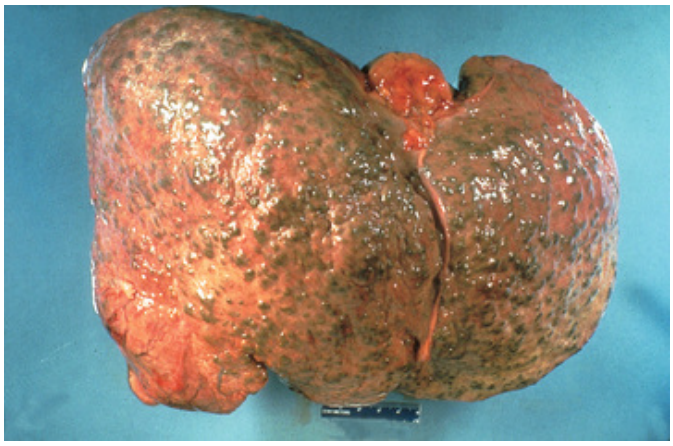

FIGURE 46-5 Cirrhosis that developed secondary to alcoholism. The characteristic diffuse nodularity of the surface is caused by the combination of regeneration and scarring of the liver. Source: Kumar, V., Abbas, A. K., Fausto, J. N., et al. (2010). *Robbins and Cotran pathologic basis of disease* (8th ed., p. 858). Philadelphia: W. B. Saunders.

Cirrhosis is a significant cause of morbidity and mortality. It is ranked as the tenth leading cause of death in Canadians (Statistics Canada, 2017); the incidence is highest between ages 40 and 60. It is twice as common in men as in women.

Etiology

Any chronic liver disease—including chronic viral hepatitis, NAFLD, and autoimmune hepatitis—as well as excessive alcohol intake can cause cirrhosis. However, excessive alcohol ingestion remains one of the most common causes of cirrhosis. Alcohol has a direct hepatotoxic effect, and it causes cell necrosis and fatty infiltration in the liver. Some controversy continues as to whether the cause of cirrhosis is alcohol or the malnutrition that frequently coexists with chronic ingestion of alcohol. A common problem in people with alcohol use disorder is protein malnutrition. Cases of nutrition-related cirrhosis have resulted from extreme dieting, malabsorption, and obesity.

Approximately 20% of patients with chronic hepatitis C and 25% of those with chronic hepatitis B develop cirrhosis. Chronic inflammation and cell necrosis result in fibrosis and, ultimately, cirrhosis. The combination of chronic hepatitis and excessive alcohol use exacerbates the degree of liver damage.

Biliary causes of cirrhosis include PBC and PSC (both described above).

Cardiac cirrhosis includes a spectrum of hepatic derangements that result from longstanding, severe right-sided heart failure. The treatment is aimed

at managing the underlying heart failure.

Clinical Manifestations

Cirrhosis can be classified as *compensated* or *decompensated*. In well-compensated cirrhosis, the liver is able to continue to function normally despite severe hepatic cell injury. Results of liver function tests—including albumin level, bilirubin level, and prothrombin time—are normal. In decompensated cirrhosis, one or more of the complications from cirrhosis (discussed in the following section) occurs.

The onset of cirrhosis is usually insidious. Most patients with early compensated cirrhosis have no specific physical symptoms. Some patients may complain of abdominal pain, described as a dull, heavy feeling in the right upper quadrant or epigastrium. The pain may be caused by swelling and stretching of the liver capsule, spasm of the biliary ducts, intermittent vascular spasm, or a combination of these. Other early manifestations are nonspecific, including lassitude, fatigue, slight weight loss, and enlargement of the liver and the spleen.

Early symptoms of decompensated cirrhosis that leads to liver failure can be abrupt. Symptoms may include anorexia, dyspepsia, nausea and vomiting, weakness, muscle loss, and diarrhea or constipation. These symptoms occur as a result of the liver's altered metabolism of carbohydrates, fats, and proteins.

Manifestations of Advanced Cirrhosis.

Late symptoms result from the complications of portal hypertension and liver failure. Jaundice, peripheral edema, and ascites develop gradually as the liver's synthesis function deteriorates. Other late symptoms include skin lesions, hematological disorders, endocrine disturbances, and peripheral neuropathies (Figure 46-6). In the advanced stages, the liver becomes small and nodular and feels firm on palpation.

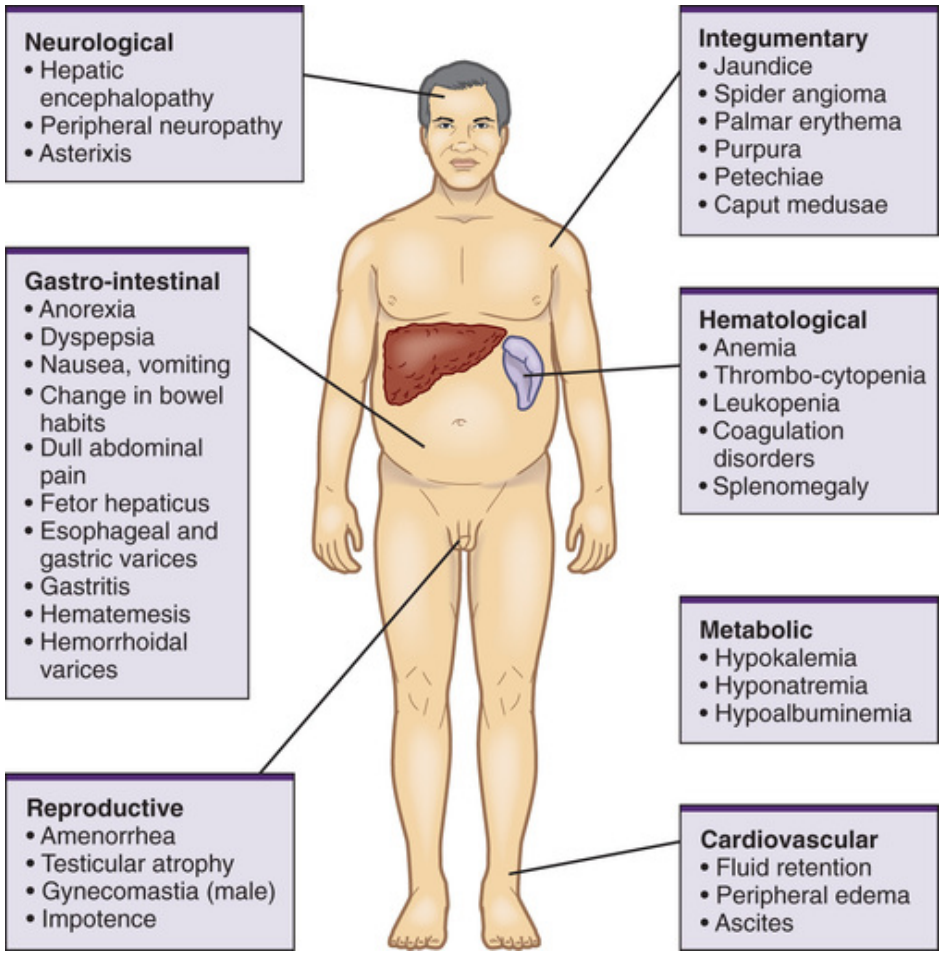

FIGURE 46-6 Systemic clinical manifestations of advanced liver cirrhosis.

Jaundice.

Jaundice occurs as a result of the liver's decreased ability to excrete conjugated bilirubin (hepatic jaundice). The jaundice may be minimal or severe, depending on the degree of liver damage. If obstruction of the biliary tract occurs, obstructive jaundice may also occur and is usually accompanied by pruritus. The pruritus is caused by an accumulation of bile salts underneath the skin.

Skin Lesions.

Various skin manifestations are commonly seen in cirrhosis. **Spider angiomas** *(telangiectasia* or *spider nevi)* are small, dilated blood vessels with a bright-red centre and spider-like branches. They occur on nose, cheeks, upper trunk, neck, and shoulders. *Palmar erythema* (a red area that blanches with pressure) appears on the palms of the hands. Both of these

abnormalities are attributed to an increase in circulating estrogen as a result of the damaged liver's inability to metabolize steroid hormones.

Hematological Problems.

Hematological problems include thrombo-cytopenia, leukopenia, anemia, and coagulation disorders. Thrombo-cytopenia is the strongest indicator of cirrhosis. Thrombo-cytopenia, leukopenia, and anemia are probably caused by splenomegaly, which results from backup of blood from the portal vein into the spleen. Overactivity of the enlarged spleen results in increased removal of blood cells, particularly the platelets, from circulation. The anemia also results from inadequate red blood cell production and survival. Other factors involved in the anemia are related to poor diet, poor absorption of folic acid, and bleeding from varices (enlarged veins).

The coagulation problems result from the liver's inability to produce prothrombin and other factors essential for blood clotting. Coagulation problems are manifested by hemorrhagic phenomena or bleeding tendencies, such as epistaxis, purpura, petechiae, easy bruising, gingival bleeding, and heavy menstrual bleeding.

Endocrine Disturbances.

Normally, the liver metabolizes hormones including adrenocortical hormones, estrogen, and testosterone. When the damaged liver is unable to do so, various manifestations occur. In men, gynecomastia, loss of axillary and pubic hair, testicular atrophy, and impotence with loss of libido may occur as a result of estrogen accumulation. Younger women with cirrhosis may develop amenorrhea, and older women may have vaginal bleeding. The liver fails to metabolize aldosterone adequately, which results in hyperaldosteronism with subsequent sodium retention, water retention, and potassium loss.

Peripheral Neuropathy.

Peripheral neuropathy is a common finding in alcoholic cirrhosis and is probably caused by a dietary deficiency of thiamine, folic acid, and cobalamin (vitamin B_{12}). The neuropathy usually results in mixed neurological symptoms, but sensory symptoms may predominate (see Figure 46-6).

Complications

Major complications of cirrhosis are portal hypertension with resultant esophageal or gastric varices or both, peripheral edema and ascites, hepatic encephalopathy (mental status changes including coma), and hepato-renal syndrome. One or more of these complications are suggestive of disease decompensation.

Portal Hypertension and Esophageal and Gastric Varices.

Because of the structural changes in the liver as a result of the cirrhotic process, the portal and hepatic veins and sinusoids are compressed and damaged. These changes result in obstruction to the normal flow of blood through the portal system, which causes portal hypertension.

Portal hypertension is characterized by increased venous pressure in the portal circulation, as well as by splenomegaly, large collateral veins, ascites, systemic hypertension, and esophageal varices. Collateral circulation develops in an attempt both to reduce this high portal pressure and to reduce the increased plasma volume and lymphatic flow. The collateral channels are commonly formed in the lower esophagus (the anastomosis of the left gastric vein and the azygos veins), anterior abdominal wall, parietal peritoneum, and rectum. Varicosities may develop in areas where the collateral and systemic circulations communicate, resulting in esophageal and gastric varices, *caput medusae* (ring of varices around the umbilicus), and hemorrhoids.

Esophageal varices are complexes of tortuous veins located at the lower end of the esophagus. They are enlarged and swollen as a result of portal hypertension. Gastric varices are located in the upper portion (fundus) of the stomach. These collateral vessels contain little elastic tissue and are quite fragile. They tolerate the high pressure poorly, and therefore bleed easily. Large varices are more likely to bleed.

Bleeding esophageal varices are the most life-threatening complication of cirrhosis. The patient may have melena or hematemesis. Hemorrhage may be slow and oozing or massive. Massive hemorrhage is a medical emergency.

Peripheral Edema and Ascites.

Peripheral edema sometimes precedes ascites, but in some patients, its development coincides with or occurs after ascites. Edema is caused by decreased colloidal oncotic pressure as a result of impaired liver synthesis of albumin and by increased portacaval pressure from portal hypertension. Peripheral edema manifests as ankle and presacral edema.

Ascites is the accumulation of serous fluid in the peritoneal or the abdominal cavity. When the portal pressure is elevated in the liver, as occurs in cirrhosis, proteins shift from the blood vessels via the larger pores of the sinusoids (capillaries) into the lymph space (Figure 46-7). When the lymphatic system is unable to carry off the excess proteins and water, they leak through the liver capsule into the peritoneal cavity. The osmotic pressure of the proteins pulls additional fluid into the peritoneal cavity (Table 46-11).

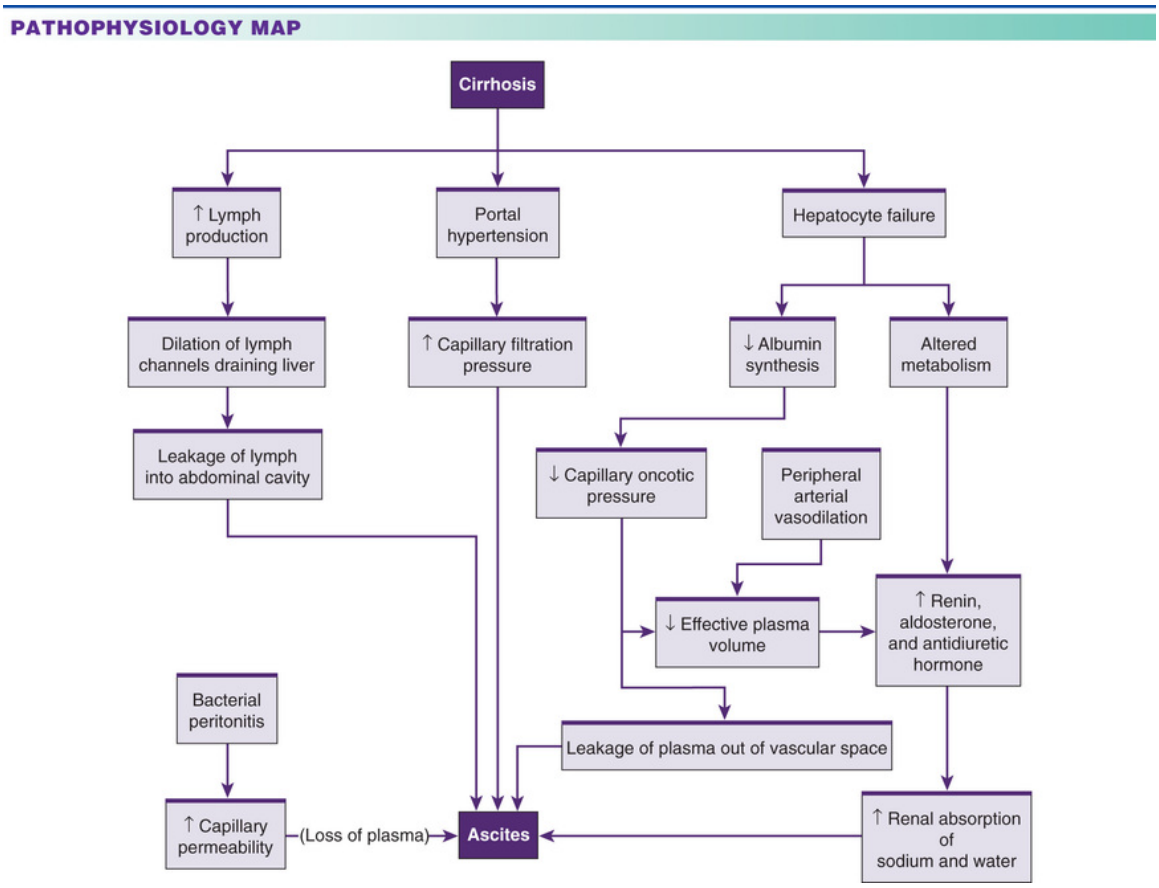

FIGURE 46-7 Mechanisms for development of ascites. Source: Adapted from McCance, K. L., & Huether, S. E. (2014). *Pathophysiology: The biologic basis for disease in adults and children* (7th ed., p. 1454). St. Louis: Mosby.

TABLE 46-11

FACTORS INVOLVED IN THE DEVELOPMENT OF ASCITES

Factor	Mechanism
Portal hypertension	Increase in resistance of blood flow through liver
Increased flow of hepatic lymph	Leaking of protein-rich lymph from surface of cirrhotic liver; intrahepatic blockage of lymph channels
Decreased serum colloidal oncotic pressure	Impairment of liver synthesis of albumin; loss of albumin into peritoneal cavity
Hyperaldosteronism	Increase in aldosterone secretion, stimulated by decreased renal blood flow; decreased liver metabolism of aldosterone
Impaired water excretion	Reduction in renal vascular flow and excessive serum levels of antidiuretic hormone

A second mechanism of ascites formation is hypoalbuminemia, which results from the inability of the liver to synthesize albumin. The hypoalbuminemia results in decreased colloidal oncotic pressure. A third mechanism of ascites, hyperaldosteronism, results when aldosterone is not metabolized by damaged hepatocytes. The increased level of aldosterone causes an increase in sodium reabsorption by the renal tubules. This retention of sodium, as well as an increase in antidiuretic hormone, causes additional water retention in affected patients. Because of edema formation, intravascular volume and, subsequently, renal blood flow and glomerular filtration are decreased.

Ascites is manifested by abdominal distension with weight gain (Figure 46-8). If the ascites is severe, the umbilicus may be everted. Abdominal striae with distended abdominal wall veins may be present. Urinary output is decreased, and signs of dehydration (e.g., dry tongue and skin, sunken eyeballs, muscle weakness) are manifested. Hypokalemia is common and results from an excessive loss of potassium caused by the increased aldosterone. Lowering of potassium levels can also result from diuretic therapy administered to treat the ascites.

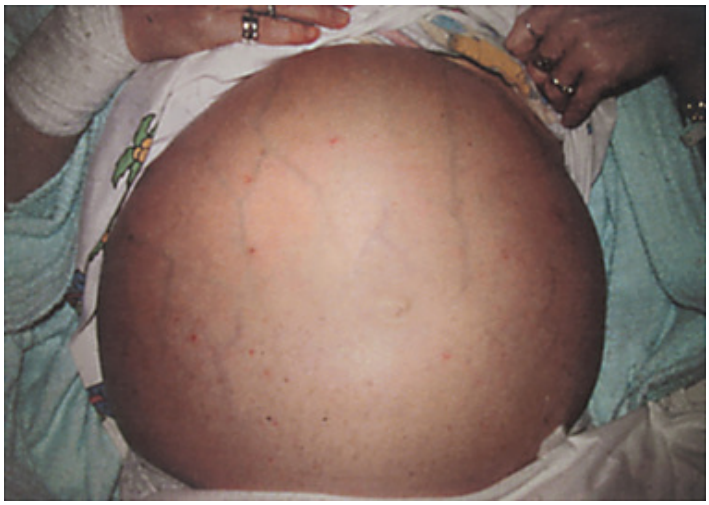

FIGURE 46-8 Gross ascites. Source: Butcher, G. P. (2004). *Gastroenterology: An illustrated colour text.* London: Churchill Livingstone.

Hepatic Encephalopathy.

Hepatic encephalopathy is a neuropsychiatric manifestation of advanced liver disease. The pathogenesis of hepatic encephalopathy is multifactorial and includes the neurotoxic effects of ammonia, abnormal neurotransmission, astrocyte swelling, and inflammatory cytokines. A major source of ammonia is the bacterial and enzymatic deamination of amino acids in the intestines. The ammonia that results from this deamination process normally goes to the liver via the portal circulation and is converted to urea, which is then excreted by the kidneys. When the blood is shunted past the liver via the collateral anastomoses, or when the liver is unable to convert ammonia to urea, ammonia levels in the systemic circulation rise. The ammonia crosses the blood–brain barrier and produces neurotoxic manifestations. Factors that increase ammonia in circulation may precipitate hepatic encephalopathy (Table 46-12). Hepatic encephalopathy can also occur after placement of transjugular intrahepatic portosystemic shunt (TIPS), which is used to treat portal hypertension (Riggio, Nardelli, Moscucci, et al., 2012).

TABLE 46-12

FACTORS PRECIPITATING HEPATIC ENCEPHALOPATHY

Factor	Mechanism
Cerebral depressants (e.g., opioids)	Decrease in drug metabolism by liver, which causes higher drug levels and cerebral depression
Constipation	Increase in ammonia from bacterial action on feces
Dehydration	Potentiation of ammonia toxicity
GI hemorrhage	Increase in ammonia in GI tract
Hypokalemia	Potassium ions are needed by brain to metabolize ammonia
Hypovolemia	Increase in blood ammonia, caused by hepatic hypoxia; impairment of cerebral, hepatic, and renal function because of decreased blood flow
Increased metabolism	Increase in workload of liver
Infection	Increase in catabolism; increase in cerebral sensitivity to toxins
Metabolic alkalosis	Facilitation of transport of ammonia across blood–brain barrier; increase in renal production of ammonia
Paracentesis	Loss of sodium and potassium ions; decrease in blood volume
Uremia (kidney failure)	Retention of nitrogenous metabolites

GI, gastro-intestinal.

Clinical manifestations of encephalopathy are changes in neurological and mental responsiveness, ranging from sleep disturbances to lethargy to deep coma. Changes may occur suddenly because of an increase in ammonia in response to bleeding varices, or they may occur gradually as blood ammonia levels slowly increase. A grading system is used to classify the stages of hepatic encephalopathy (Table 46-13). A characteristic symptom of hepatic encephalopathy is **asterixis** (flapping tremors) involving the arms and hands. When asked to stretch out the arms and hands, the patient is unable to hold this position, and the hands exhibit a series of rapid flexion and extension movements. Impairments in writing involve difficulty in moving the pen or pencil from left to right and *constructional apraxia* (the inability to construct simple figures). Other signs include hyperventilation, hypothermia, and grimacing and grasping reflexes.

TABLE 46-13
GRADING SCALE FOR HEPATIC ENCEPHALOPATHY

Grade	Level of Consciousness	Intellectual Function	Neurological Findings
0	Insomnia, sleep disturbances	Subtle change in computational skills	Impaired handwriting, tremor
1	Lack of awareness, personality change	Short attention span, mild confusion, depression	Incoordination, asterixis
2	Lethargy, drowsiness, inappropriate behaviour	Disorientation	Asterixis, abnormal reflexes
3	Asleep, rousable	Loss of meaningful conversation, marked confusion, incomprehensible speech	Asterixis, abnormal reflexes
4	Not rousable	Absent	Decerebrate May be responsive to painful stimuli

Fetor hepaticus—a musty, sweet odour of the patient's breath—occurs in some patients with encephalopathy. This odour results from the accumulation of digestive by-products that the liver is unable to degrade.

Hepato-Renal Syndrome.

Hepato-renal syndrome (HRS) is a serious complication of decompensated cirrhosis. It is a type of kidney failure with advancing azotemia, oliguria, and intractable ascites. In this syndrome, the kidneys have no structural abnormality. The etiology is complex, but the final common pathway is likely to be portal hypertension along with liver decompensation that results in splanchnic and systemic vasodilation and decreased arterial blood volume. As a result, renal vasoconstriction occurs, leading to kidney failure. This kidney failure can be reversed by liver transplantation. In patients with cirrhosis, HRS frequently follows diuretic therapy, GI hemorrhage, or paracentesis.

Diagnostic Studies

In patients with decompensated cirrhosis, most of the liver function studies (see Table 46-7 for tests) will be abnormal.

Enzymes levels including AST, ALT, alkaline phosphatase, and γ-glutamyl transpeptidase are elevated because of their release from damaged liver cells and bile ducts. However, in end-stage liver disease, AST and ALT levels may be normal. Patients with cirrhosis have decreased total protein, decreased albumin, increased serum bilirubin, and increased globulin levels. Fat metabolism abnormalities are reflected by decreased

cholesterol levels. The prothrombin time or INR is prolonged, and bilirubin metabolism is altered.

Liver Biopsy.

Liver biopsy may be done to confirm the underlying causes of the liver disease. Liver biopsy is unnecessary to confirm cirrhosis if cirrhosis is clinically evident (e.g., nodular appearance of the liver on ultrasonography, presence of thrombo-cytopenia).

Liver biopsy is normally performed percutaneously. In patients with abnormal coagulation, biopsy must be performed via the transjugular vein. The most common risk of liver biopsy is bleeding.

Noninvasive Fibrosis Markers.

Transient elastography (FibroScan) is a noninvasive imaging technique by which the degree of hepatic fibrosis is measured. Its use in Canada was approved in 2010. It is an ultrasonography-based imaging technique for detecting liver stiffness. It has excellent diagnostic accuracy for the diagnosis of cirrhosis, regardless of the underlying causes of the liver disease (Wilder, & Patel, 2014).

Models of serum markers (e.g., FibroTest) are also noninvasive tests that can be performed with blood samples. FibroTest is most commonly used in Canada. In this model, five parameters are used (bilirubin, γ-glutamyl transpeptidase, haptoglobin, apolipoprotein, and α_2-macroglobulin), in addition to patient's age and sex, to calculate a fibrosis score for predicting the degree of liver fibrosis.

Collaborative Care in Advanced Cirrhosis of the Liver

The goal of therapy for patients with cirrhosis is to slow the disease progression and to treat symptoms associated with decompensation. Collaborative care measures are listed in Table 46-14. Management of specific complications related to decompensated cirrhosis is described next.

TABLE 46-14

COLLABORATIVE CARE
Advanced Cirrhosis of the Liver

Diagnostic
• History and physical examination • CBC • Computed tomography • Endoscopy (esophago-gastro-duodenoscopy) • Liver biopsy (if indicated) • Liver enzyme measurements (AST, ALT, ALP, GGT) • Liver function studies (albumin, bilirubin, INR) • Liver stiffness measurement (FibroScan) • Liver ultrasonography • Magnetic resonance imaging • Serum electrolyte measurements • Serum fibrosis markers (FibroTest)
Collaborative Therapy
Conservative Therapy
• Avoidance of alcohol, acetylsalicylic acid (Aspirin), sedatives, and nonsteroidal anti-inflammatory drugs • Rest (in decompensated cirrhosis)
Ascites
• Diuretics • Low-sodium diet • Paracentesis (if indicated) • TIPS
Esophageal and Gastric Varices

• Balloon tamponade
• Drugs
  • Nonselective β-blockers (e.g., nadolol)
  • Octreotide (Sandostatin)
  • Vasopressin
• Endoscopic sclerotherapy or band ligation
• TIPS

Hepatic Encephalopathy
• Antibiotics (rifaximin [Zaxine]) • Lactulose

ALP, alkaline phosphatase; *ALT,* alanine aminotransferase; *AST,* aspartate aminotransferase; *CBC,* complete blood cell count; *GGT,* γ-glutamyl transpeptidase; *INR,* international normalized ratio; *TIPS,* transjugular intrahepatic portosystemic shunt.

Ascites.

The presence of ascites indicates disease decompensation. Management is focused on sodium restriction, diuretics, and fluid removal. Affected patients are encouraged to limit sodium intake to 2 g (88 mmol) per day. More stringent sodium restriction is no longer recommended because it can result in reduced nutritional intake and subsequent malnutrition problems. Fluid restriction is usually not necessary unless severe ascites develops. Fluid and electrolyte balance should be accurately assessed and controlled. Albumin infusions are used to help maintain intravascular

volume and adequate urinary output by increasing plasma colloid osmotic pressure.

Diuretic therapy is an important part of ascites management. A combination of drugs that work at multiple sites in the nephron is often more effective. Spironolactone (Aldactone) is an effective diuretic. It is an antagonist of aldosterone and is potassium sparing. Other potassium-sparing diuretics include amiloride (Apo-Amilzide) and triamterene (Teva-Triamterene). A high-potency loop diuretic, such as furosemide (Lasix), is frequently administered in combination with a potassium-sparing drug. Hydrochlorothiazide is rarely administered because it is not as potent as the loop diuretics.

Paracentesis (needle puncture of the abdominal cavity) may be performed to remove ascitic fluid or to test the fluid for infection (spontaneous bacterial peritonitis). However, it is indicated only when the diuretic therapy fails and to relieve symptoms such as abdominal pain or difficulty breathing. The relief provided by paracentesis is only temporary because the fluid reaccumulates.

TIPS (discussed later in this section) is used to alleviate ascites that does not respond to diuretics.

Esophageal and Gastric Varices.

The main therapeutic goal for esophageal and gastric varices is prevention of bleeding. All patients with cirrhosis should have an upper endoscopy (esophago-gastro-duodenoscopy [EGD]) to screen for varices (Garcia-Tsao, Sanyal, Grace, et al., 2007). Risk factors for esophageal bleeding include variceal size (the largest varices are at highest risk of bleeding), decreased wall thickness, and degree of liver dysfunction (associated with increased portal hypertension). Patients who have esophageal varices should avoid ingesting alcohol, acetylsalicylic acid (ASA; Aspirin), and nonsteroidal anti-inflammatory drugs (NSAIDs). For patients who have esophageal varices that have not bled, prophylactic treatment with nonselective beta blockers (e.g., propranolol or nadolol) has been shown to reduce the risk of bleeding, as well as the number of bleeding-related deaths. Nonselective beta blockers reduce portal venous pressure by decreasing cardiac output and possibly by constricting splanchnic vessels.

When variceal bleeding occurs, the first step is to stabilize the patient and manage the airway. IV therapy is initiated and may include administration of blood products. Variceal bleeding is diagnosed on endoscopic examination. Management that involves a combination of drug

therapy and endoscopic therapy is more successful than either approach alone.

Drug therapy may include octreotide (Sandostatin), vasopressin, and β-adrenergic blockers. The main goal of drug therapy is to stop the bleeding. IV administration of vasopressin produces vasoconstriction of the splanchnic arterial bed, decreases portal blood flow, and decreases portal hypertension. Because vasopressin has adverse effects (including decreased coronary blood flow and heart rate and increased blood pressure), nitroglycerin is often administered in combination with vasopressin for reducing the detrimental effects of the vasopressin while enhancing its beneficial effect. Vasopressin should be avoided or administered cautiously in older adults because of the risk of cardiac ischemia.

Endoscopic therapies include sclerotherapy and ligation of varices. Endoscopic sclerotherapy involves injecting a sclerosing agent into the varices to thrombose and obliterate the distended veins. Endoscopic ligation or banding of the varices is performed by placing a small rubber band (elastic O-ring) around the base of the varix. Endoscopic ligation is as effective as endoscopic sclerotherapy with fewer complications.

Balloon tamponade may be used in patients with brisk esophageal or gastric variceal hemorrhage that cannot be controlled on initial endoscopy. Balloon tamponade controls the hemorrhage by mechanical compression of the varices. Either the Minnesota or Sengstaken–Blakemore tube (Figure 46-9) is used for this purpose. These tubes have two balloons, one gastric and one esophageal. The Sengstaken–Blakemore tube has three lumens: one for the gastric balloon, one for the esophageal balloon, and one for gastric aspiration. The Minnesota tube has an esophageal aspiration port. When inflated, the gastric and esophageal balloons put mechanical compression on the varices. The gastric balloon anchors the tube in position and also applies pressure to any bleeding gastric varices.

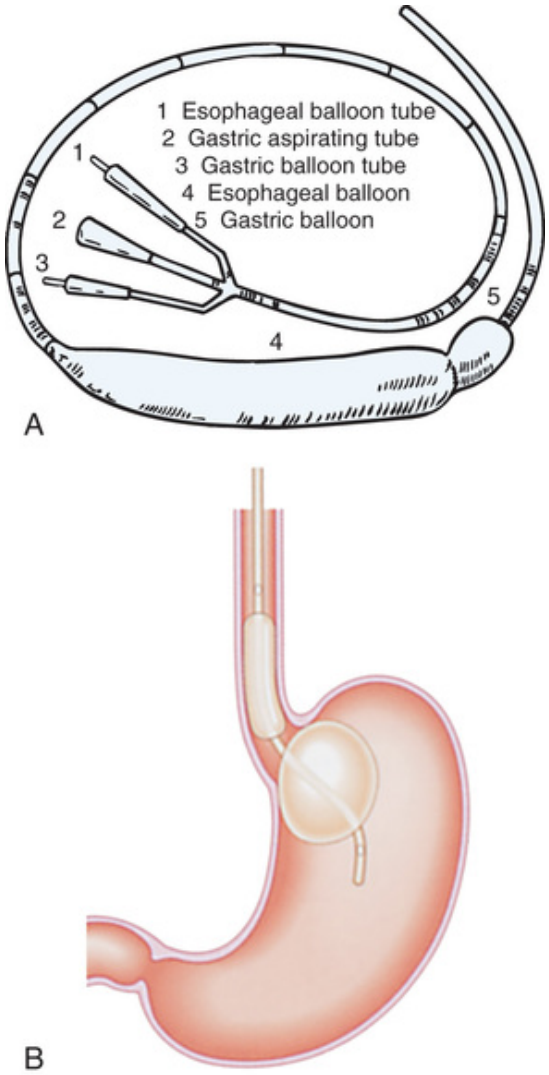

FIGURE 46-9 **A,** Diagram of Sengstaken–Blakemore tube. **B,** Diagram of tube inserted into esophagus and stomach.

Supportive measures during an acute variceal bleed include administration of fresh-frozen plasma and packed red blood cells, vitamin K, and proton pump inhibitors. Lactulose may be administered to prevent hepatic encephalopathy from breakdown of blood and the release of ammonia in the intestine. Antibiotics such as norfloxacin are given prophylactically to prevent bacterial infections.

Long-Term Management.

Because of the high incidence of recurrent bleeding and the mortality risk with each bleeding episode, continued therapy is necessary. Long-term management of patients who have had an episode of bleeding includes the

use of nonselective beta blockers, repeated endoscopic ligation, and portosystemic shunts.

Shunting Procedures.

Surgical and nonsurgical methods of shunting blood away from the esophageal varices are available. Shunting procedures tend to be used more after a second major bleeding episode than after an initial bleeding episode. In TIPS, a tract (shunt) between the systemic and portal venous systems is nonsurgically created to redirect portal blood flow (Figure 46-10).

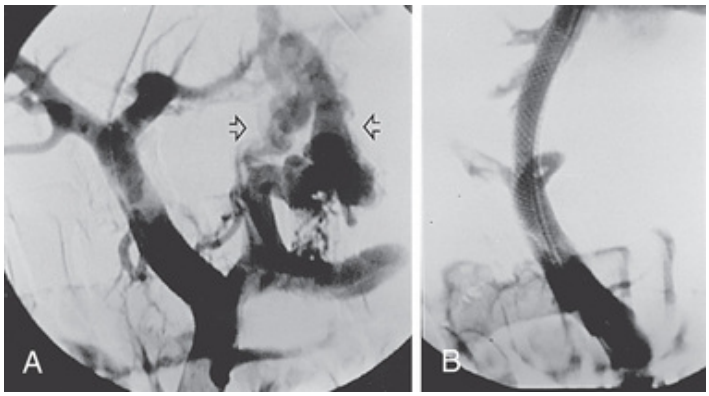

FIGURE 46-10 Total portal diversion after insertion of a transjugular intrahepatic portosystemic shunt (TIPS). **A,** Portal venogram before TIPS insertion shows filling of large esophageal varices *(arrows).* **B,** After TIPS insertion, flow to varices is eliminated. The direction of intrahepatic portal vein flow is now reversed, toward the TIPS. Source: Reprinted from *Journal of Vascular Surgery,* Volume 16(2), Jeanne M. LaBerge, Ernest J. Ring, John R. Lake, Linda D. Ferrell, Margaret M. Doherty, Roy L. Gordon, John P. Roberts, Marc Y. Peltzer, Nancy L. Ascher, "Transjugular intrahepatic portosystemic shunts: Preliminary results in 25 patients," pp. 258–267, Copyright 1992, with permission from Elsevier.

Under radiological guidance, the catheter is placed in the jugular vein and then threaded through the superior and inferior venae cavae to the hepatic vein. The wall of the hepatic vein is punctured, and the catheter is directed to the portal vein. Stents are positioned along the passageway, overlapping in the liver tissue and extending into both veins.

This procedure reduces portal venous pressure and decompresses the varices, thus controlling bleeding. This procedure does not interfere with future liver transplantation. Limitations of the TIPS procedure include the increased risk for hepatic encephalopathy and stenosis of the stent. TIPS is

contraindicated in patients with severe hepatic encephalopathy, hepatocellular carcinoma, severe hepato-renal syndrome, and portal vein thrombosis. Various surgical shunting procedures are no longer in common use but may be used to decrease portal hypertension by diverting some of the portal blood flow and simultaneously allowing adequate liver perfusion. The surgical shunts still in use are the portacaval shunt and the distal splenorenal shunt (Figure 46-11). Surgical shunts are more likely to be used in emergency situations. Although a prophylactic portacaval shunt decreases bleeding episodes, it does not prolong life. Patients can develop hepatic encephalopathy as a result of the diversion of the ammonia past the liver and into the systemic circulation.

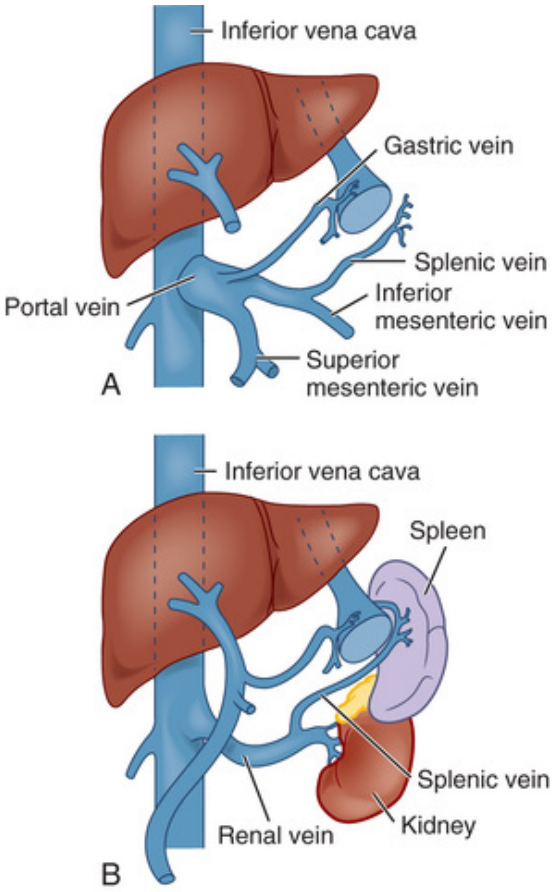

FIGURE 46-11 Portosystemic shunts. **A,** Portacaval shunt. The portal vein is anastomosed to the inferior vena cava, diverting blood from the portal vein to the systemic circulation. **B,** Distal splenorenal shunt. The splenic vein is anastomosed to the renal vein. The portal venous flow remains intact, and esophageal varices are selectively decompressed (by decompression of the short gastric veins). The spleen conducts blood from the high pressure of the esophageal and gastric varices to the low-pressure renal vein.

Hepatic Encephalopathy.

The goal of the management of hepatic encephalopathy is the reduction of ammonia formation. Ammonia formation in the intestines is reduced with lactulose, a drug that traps the ammonia in the gut. The laxative effect of lactulose expels the ammonia from the colon. It is usually administered orally to prevent encephalopathy but can be given as an enema or via a nasogastric (NG) tube.

Antibiotics such as rifaximin (Zaxine) may also be given concomitantly in patients who do not respond to lactulose alone. Constipation should be prevented.

Control of hepatic encephalopathy also involves treatment of precipitating causes (see Table 46-12). One strategy involves controlling GI hemorrhage and removing the blood from the GI tract to decrease the protein in the intestine. Electrolyte disorders, acid–base imbalances, and infections should also be treated.

Liver transplantation may be considered in patients with recurring hepatic encephalopathy and end-stage liver disease. The decision to perform liver transplantation depends on a number of factors, including the cause of the cirrhosis and other systemic medical problems.

Drug Therapy.

There is no specific drug therapy for cirrhosis. However, a number of drugs are used to treat symptoms and complications of advanced liver disease (Table 46-15).

TABLE 46-15
DRUG THERAPY
Advanced Cirrhosis

Drug	Mechanism of Action
Diuretics	
• Spironolactone (Aldactone)	Blocking action of aldosterone; potassium sparing
• Amiloride (Apo-Amilzide)	Inhibition of reabsorption of sodium and secretion of potassium
• Furosemide (Lasix)	Rapid action on distal tubule and loop of Henle to prevent reabsorption of sodium and water
• Triamterene (Teva-Triamterene)	Inhibition of reabsorption of sodium and secretion of potassium
Lactulose	Acidification of feces in bowel and trapping of ammonia, causing its elimination in feces
Propranolol (Inderal) or nadolol	Reduction of portal venous pressure
Proton pump inhibitors (e.g., pantoprazole [Pantoloc])	Decrease in gastric acidity
Rifaximin (Zaxine) Neomycin sulphate	Decrease in bacterial flora, decrease in formation of ammonia
Vasopressin Octreotide (Sandostatin)	Hemostasis and control of bleeding in esophageal varices; constriction of splanchnic arterial bed
Vitamin K	Correction of clotting abnormalities

Nutritional Therapy.

The diet for a patient with cirrhosis without complications is high in calories (3 000 kcal/day) with high carbohydrate content and moderate to low fat levels. Protein restriction may be appropriate in some patients immediately after a severe flare of symptoms (i.e., episodic hepatic encephalopathy). However, protein restriction is rarely justified in patients with cirrhosis and persistent hepatic encephalopathy. Indeed, malnutrition

is a more serious clinical problem than hepatic encephalopathy for many of these patients.

Many patients with alcoholic cirrhosis have protein–calorie malnutrition and may benefit from receiving enteral formulas containing protein from branched-chain amino acids that are metabolized by the muscles. They provide protein that is more easily metabolized by the liver. Total parenteral nutrition or tube feedings may be required.

In patients with ascites and edema, diet must be low in sodium. The degree of sodium restriction depends on the patient's condition. Table salt is a common, well-known source of sodium, but sodium is also present in baking soda and baking powder. Other foods that are high in sodium content include canned soups and vegetables, salted snacks such as potato chips, nuts, smoked meats and fish, crackers, breads, olives, pickles, ketchup, and beer. Sodium is also present in many OTC drugs (e.g., antacids); however, most antacids now have a lower sodium content than they did in the past. Carbonated beverages tend to be high in sodium, but low-sodium and sodium-free carbonated drinks are also available. Patients should be advised to read food labels; foods high in protein usually have large amounts of sodium. Alternative protein supplements that are low in sodium may have to be administered. Food can be made more palatable by the use of seasonings such as garlic, parsley, onion, lemon juice, and spices.

Nursing Management Cirrhosis

Nursing Assessment

Subjective and objective data that should be obtained from an individual with cirrhosis are presented in Table 46-16.

TABLE 46-16

NURSING ASSESSMENT
Cirrhosis

Subjective Data
Important Health Information
Past health history: Previous viral, toxic, or idiopathic hepatitis; chronic biliary obstruction and infection; severe right-sided heart failure; chronic alcohol use disorder *Medications:* Adverse reaction to any medication; use of anticoagulants, acetylsalicylic acid (Aspirin), nonsteroidal anti-inflammatory drugs, acetaminophen (Tylenol)
Symptoms
• Weakness, fatigue, difficulty with concentration • Change in sleep–wake pattern • Anorexia, muscle loss • Gum bleeding • Yellow sclera or skin; pruritus; easy bruising • Dull pain in right upper quadrant or epigastric region • Erectile dysfunction; amenorrhea
Objective Data
General
Fever, cachexia, muscle wasting
Integumentary
Icteric sclera, jaundice, petechiae, ecchymoses, spider angiomas, palmar erythema, alopecia, clubbing, peripheral edema
Respiratory
Shallow, rapid respirations, epistaxis
Gastro-Intestinal
Abdominal distension, ascites, distended abdominal wall veins, palpable liver and spleen, foul breath; hematemesis; black, tarry stools; hemorrhoids, fetor hepaticus
Neurological
Confusion, asterixis
Reproductive
Gynecomastia and testicular atrophy (men), erectile dysfunction (men), loss of libido (men and women), amenorrhea or heavy menstrual bleeding (women)
Possible Findings
Anemia, thrombo-cytopenia; leukopenia; ↓ serum albumin level; abnormal liver function studies; ↑ INR and bilirubin levels; abnormal abdominal ultrasound or MRI results

INR, international normalized ratio; *MRI*, magnetic resonance imaging.

Nursing Diagnoses

Nursing diagnoses for the patient with advanced cirrhosis include but are not limited to the following:

- *Imbalanced nutrition: less than body requirements* related to *insufficient dietary intake* (anorexia, nausea, impaired utilization and storage of nutrients)
- *Impaired skin integrity* related to *moisture, pressure over bony prominence* (peripheral edema, ascites, pruritus)
- *Excess fluid volume* related to *compromised regulatory mechanism* (portal hypertension and hyperaldosteronism)
- *Ineffective health maintenance* related to *ineffective coping strategies* (alcohol use)

Additional information on nursing diagnoses for the patient with cirrhosis is presented in NCP 46-2, available on the Evolve website.

Planning

The overall goals are that the patient with cirrhosis will (a) have relief of discomfort, (b) have minimal to no complications (ascites, esophageal varices, hepatic encephalopathy), and (c) maintain as normal a lifestyle as possible.

Nursing Implementation

Health Promotion.

The common causes of cirrhosis are alcohol, viral hepatitis, biliary obstruction, obesity, and right-sided heart failure. Prevention and early treatment of cirrhosis must focus on eliminating the primary cause. Alcohol use disorder must be treated. Patients should be urged to avoid alcohol ingestion, and their efforts should be supported. Adequate nutrition, especially for those at risk for cirrhosis, is essential to prevent muscle loss. Acute and chronic viral hepatitis must be identified and treated early so that it does not progress to cirrhosis or liver failure. Biliary disease should be treated to avoid biliary obstruction and infection. The underlying cause (e.g., chronic lung disease) of right-sided heart failure must be treated so that the heart failure does not lead to cirrhosis.

Acute Intervention.

The focus of nursing care for a patient with advanced cirrhosis is on conserving the patient's energy and strength (see NCP 46-2). Patients should be provided rest periods for recovery but be allowed to engage in activities as tolerated. The nurse should modify the patient's activity and rest schedule according to signs of clinical improvement (e.g., decreasing jaundice, improvement in results of liver function studies).

Anorexia, nausea and vomiting, pressure from ascites, and poor eating habits create problems in maintaining adequate nutrition. Oral hygiene before meals may improve the patient's taste sensation. Between-meal nourishments should be available at times when the patient can best tolerate them. Foods the patient prefers should also be available whenever possible. The nurse should explain to the patient and caregivers the reason for any dietary restrictions.

Nursing assessment and care should include the patient's physiological response to cirrhosis. If jaundice is present, the nurse should document where it is observed—sclera, skin, hard palate. If the jaundice is accompanied by pruritus, cholestyramine may be ordered to help relieve the pruritus. Other measures to help alleviate pruritus include baking soda baths, lotions containing antihistamines and calamine, the use of soft linens, and control of extreme hot and cold temperatures. The patient's nails should be kept short and clean.

The colour of the urine and stools should be noted. When jaundice is present, the urine is often dark brown and foamy when shaken. The stool is grey or tan.

Edema and ascites are frequent manifestations of decompensated cirrhosis and necessitate nursing assessment and interventions. Accurate calculation and recordings of intake and output, as well as daily body weights, help in the ongoing assessment of the location and the extent of the edema.

When paracentesis is required, the patient should void immediately before the procedure to prevent puncture of the bladder. After the procedure, the nurse should monitor vital signs for hypovolemia and check the dressing for bleeding and leakage from the puncture site.

Dyspnea is a frequent problem for patients with ascites, which can often lead to pleural effusion. A semi-Fowler's or Fowler's position allows for maximal respiratory efficiency. Pillows can be used to support the arms and the chest and may increase the patient's comfort and ability to breathe.

Meticulous skin care is essential because the edematous tissues are prone to breakdown. An alternating–air pressure mattress or other special

mattress should be used, if possible. A turning schedule (minimum of every 2 hours) must be adhered to rigidly. The patient's abdomen should be supported with pillows. If the abdomen is taut, cleansing must be done very gently. Patients with ascites tend to move very little because of the abdominal discomfort and dyspnea, so range-of-motion, deep-breathing, and coughing exercises are helpful in preventing respiratory problems. The lower extremities may be elevated. If scrotal edema is present, a scrotal support provides some comfort.

When the patient is taking diuretics, monitor serum levels of sodium, potassium, chloride, bicarbonate, and creatinine, especially with any changes in the diuretic dosage. The nurse should observe for signs of fluid and electrolyte imbalance. Hypokalemia may be manifested by cardiac dysrhythmias, hypotension, tachycardia, and generalized muscle weakness. Water excess is manifested by muscle cramping, weakness, lethargy, and confusion.

Observations and nursing care in relation to hematological disorders (bleeding tendencies, anemia, increased susceptibility to infection) are the same as for patients with advanced liver disease (see NCP 46-2 on the Evolve website).

The nurse must assess the patient's response to altered body image resulting from jaundice, spider angiomas, palmar erythema, ascites, and gynecomastia. The patient may experience anxiety and embarrassment regarding these changes. The nurse should explain these phenomena and be a supportive listener. Nursing care with concern and warmth helps the patient maintain self-esteem.

Bleeding Esophageal Varices.

If the patient has esophageal or gastric varices, the nurse should observe for signs of bleeding from the varices, such as hematemesis and melena. If hematemesis occurs, the nurse must call the physician and be ready to assist with treatment used to control the bleeding. The patient may be admitted to the critical care unit. The patient's airway must be maintained.

To stop the bleeding, the physician may perform sclerotherapy or ligation procedures. Balloon tamponade may be used in cases of refractory bleeding that is unresponsive to sclerotherapy or ligation. When balloon tamponade is used, the initial nursing task is to explain to the patient the use of the tube and how it will be inserted. The balloons should be checked for patency. It is usually the physician's responsibility to insert the tube via the nose or the mouth (see Figure 46-9). Then the gastric balloon is inflated with approximately 250 mL of air, and the tube is retracted until

resistance (gastro-esophageal junction) is felt. The tube is secured by placing a piece of sponge or foam rubber at the nostrils (nasal cuff). For continued bleeding, the esophageal balloon is then inflated. A sphygmomanometer is used to measure and maintain the desired pressure at 20 to 40 mm Hg. The positions of the balloons are verified radiologically.

Nursing care includes monitoring for complications of rupture or erosion of the esophagus, regurgitation and aspiration of gastric contents, and occlusion of the airway by the balloon. If the gastric balloon breaks or is deflated, the esophageal balloon will slip upward, obstructing the airway and causing asphyxiation. If this happens, the nurse must cut the tube or deflate the esophageal balloon; thus scissors should be kept at the patient's bedside. Regurgitation is minimized by oral and pharyngeal suctioning and by keeping the patient in a semi-Fowler's position.

The patient is unable to swallow saliva because the esophagus is occluded by the inflated esophageal balloon. The patient should be encouraged to expectorate, and an emesis basin and tissues should be provided. Frequent oral and nasal care provides relief from the taste of blood and irritation from mouth breathing.

Hepatic Encephalopathy.

The focus of nursing care of the patient with hepatic encephalopathy is on maintaining a safe environment, sustaining life, and assisting with measures to reduce episodes of drowsiness. The nurse should assess (a) the patient's level of responsiveness (e.g., reflexes, pupillary reactions, orientation), (b) sensory and motor abnormalities (e.g., hyper-reflexia, asterixis, motor coordination), (c) fluid and electrolyte imbalances, (d) acid–base imbalances, and (e) the effect of treatment measures.

Assessment of the neurological status should be performed at least every 2 hours and should include an exact description of the patient's behaviour. The care of the patient with neurological problems is based on the severity of the encephalopathy.

Constipation, which is a common precipitating factor for encephalopathy, should be prevented. Drugs, laxatives, and enemas should be given as ordered. Any GI bleeding may worsen encephalopathy. Patients who are taking lactulose for diarrhea and excessive fluid and electrolyte losses must be evaluated. It is desirable for the patient to have two to three loose bowel movements per day to promote elimination of toxins.

Ambulatory and Home Care.

The patient with advanced cirrhosis may face a prolonged course and the possibility of serious, life-threatening problems and complications. The patient and the caregivers need to understand the importance of continuous health care and medical supervision and ways to reduce mortality risk (Table 46-17).

TABLE 46-17

PATIENT & CAREGIVER TEACHING GUIDE
Cirrhosis in Ambulatory and Home Care Setting

The following guidelines should be included when teaching the patient and caregiver. The nurse should:

1. Explain the importance of continuous medical care with the goal of prolonging survival and avoiding disease complications.
2. Teach patients and caregivers the symptoms of complications (e.g., black stools, confusion) and when to seek medical attention to enable prompt treatment of complications.
3. Teach about the importance of a low-sodium diet and how to make food more palatable by using herbs and spices.
4. Teach patients to avoid certain drugs:
    - ASA (Aspirin): increases risk of bleeding
    - NSAIDs: increase risk of bleeding, edema
    - ASA, NSAIDs, aminoglycoside: increase risk of renal impairment
    - ACE inhibitors: cause fluid retention
    - Sleeping pills, sedatives, and cough syrups that contain opioids may cause confusion
5. Encourage complete abstinence from alcohol because alcohol can further injure the liver.
6. Teach patients to seek medical attention promptly for any type of infections to avoid complications.
7. Teach patients to avoid heavy lifting (e.g., Valsalva manoeuvre), which increases portal pressure and heightens risk of hemorrhage.
8. Encourage patients to receive hepatitis A and B vaccine, if the patient is not immune, to prevent risk for fulminant hepatitis when exposed to these viruses.
9. Ensure that patients undergo ultrasound surveillance every 6 months for early detection of liver cancer.

ACE, angiotensin-converting enzyme; *ASA*, acetylsalicylic acid; *NSAID*, nonsteroidal anti-inflammatory drug.

Patients with cirrhosis should receive vaccination for hepatitis A and B if they are not already immune. Infection with these viruses in patients with cirrhosis can lead to fulminant hepatitis. Patients should avoid ASA, NSAIDs, and aminoglycosides, which can cause bleeding, edema, and renal complications. Patients should also avoid sleeping pills or sedatives that contain codeine because they can lead to encephalopathy. Total abstinence from alcohol is mandatory. A low-sodium diet should be followed at home. Patients with cirrhosis have higher risks for infection and surgical complications, and so any infections must be promptly treated, and surgical procedures that necessitate general anaesthesia must first be discussed with the liver specialist. Patients with cirrhosis are at high risk for hepato-cellular carcinoma. The current recommendation is

hepatoma surveillance with abdominal ultrasonography every 6 months. Hepato-cellular carcinoma, when small, is curable.

Cirrhosis is a chronic disorder. The patient is affected not only physically but also psychologically, socially, and economically. Major lifestyle changes may be required, especially if alcohol use is the primary cause. The nurse should provide information regarding community support programs, such as Alcoholics Anonymous, for help with alcohol use disorder. Other health teaching should include information about early signs of disease decompensation such as black stools and abdominal swelling. Counselling information regarding sexual problems may be needed. The emphasis of home care for patients with cirrhosis should focus on helping patients maintain the highest level of wellness possible and initiate and maintain necessary lifestyle changes.

Evaluation

Expected outcomes for patients with advanced cirrhosis are addressed in NCP 46-2, available on the Evolve website.

Acute Liver Failure

Acute liver failure is a clinical condition characterized by rapid deterioration of liver function resulting in encephalopathy and coagulopathy in persons with no known history of liver disease. It is a broad term that encompasses *fulminant hepatic failure,* which describes development of encephalopathy within 8 weeks of the onset of the illness. In general, the disease runs its course over 8 weeks, but it can last as long as 26 weeks. Depending on the cause, survival rates range from 10% to 40% with intensive support.

The most common cause of acute liver failure is drugs, usually acetaminophen, in combination with alcohol (Lee, Larson, Stravitz, et al., 2011). People with alcohol use disorder are particularly susceptible to the detrimental effects of acetaminophen on the liver. Other drugs that can cause acute liver failure include isoniazid, halothane, sulpha-containing drugs, and NSAIDs. Drugs can cause liver cell failure by disrupting essential intracellular processes or causing an accumulation of toxic metabolic products.

Hepatic failure may also occur rarely with HAV infection. Mushroom poisoning is also associated with fulminant liver failure. The majority of mushroom poisonings occur with *Amanita phalloides* (also known as “death cap”).

Clinical Manifestations and Diagnostic Studies

Manifestations of acute liver failure include jaundice, coagulation abnormalities, and encephalopathy; changes in mentation are the first clinical sign. Patients with acute liver failure are susceptible to a wide variety of complications, including cerebral edema, renal failure, hypoglycemia, metabolic acidosis, sepsis, and multiorgan failure.

Acute liver failure is identified in most patients by abnormalities in laboratory values and clinical manifestations resulting from hepatic necrosis and fibrosis. Most often, serum bilirubin levels are elevated and the prothrombin time is prolonged. Liver enzyme levels (AST, ALT) are often markedly elevated. Additional laboratory tests include blood chemistry evaluation (especially glucose because hypoglycemia may be present and require correction); complete blood cell counts (CBCs); screening for acetaminophen and other drugs and toxins; viral hepatitis serological testing (especially for HAV and HBV); and measurements of serum ceruloplasmin (enzyme synthesized in liver) levels, α_1-antitrypsin levels, iron levels, and autoantibodies (ANA and ASMA). Plasma ammonia levels may also be measured.

Liver biopsy may be performed via the transjugular route because of coagulopathy, when a condition such as autoimmune hepatitis, metastatic liver disease, or lymphoma is suspected. In addition, ultrasonography, CT, or magnetic resonance imaging (MRI) is helpful in providing information about the liver size and contour, presence of ascites, presence of tumours, and patency of the blood vessels.

Nursing and Collaborative Management Acute Liver Failure

Because acute liver failure may progress rapidly, with hour-by-hour changes in consciousness, early transfer to the critical care unit is preferred once the diagnosis is made. Planning for transfer to a transplantation centre should begin in patients with grade 1 or 2 encephalopathy because the condition may worsen rapidly. Early transfer is important because the risks involved with patient transport may increase or even preclude transfer once stage 3 or 4 encephalopathy develops (see Table 46-13).

Renal failure is a frequent complication in patients with liver failure and may be caused by dehydration, hepato-renal syndrome, or acute tubular necrosis. The probability of renal failure may be even greater with acetaminophen overdose or other toxins, in which direct renal toxicity occurs. Although few patients die of renal failure alone, it often contributes to mortality risk and may worsen the prognosis.

The nurse should protect a patient's renal function by maintaining adequate fluid balance, withholding nephrotoxic agents (e.g., aminoglycosides, NSAIDs), and promptly identifying and treating infection. Liver transplantation is the treatment of choice for acute liver failure. Cerebral edema, cerebellar herniation, and brain stem compression are the most common causes of death. (Treatment of cerebral edema is described in Chapter 59.)

The nurse checks a patient's mental status frequently if the level of consciousness declines. To minimize agitation, the patient's environment should be kept quiet. Additional measures include padding bedrails to avoid injury from possible seizures, observing the patient closely to avoid injuries, monitoring intake and output for renal function, and providing good skin and oral care to avoid breakdown and infection.

Monitoring and management of hemodynamic and renal parameters, glucose levels, electrolyte levels, and acid–base status are critical. The nurse should conduct frequent neurological evaluations for signs of elevated intracranial pressure. The patient should be positioned with the head elevated at 30 degrees. Stimulation of the patient should be avoided. Manoeuvres that cause straining, or Valsalva-like movements, may increase intracranial pressure. The use of any sedatives should be avoided because of their effects on mental status, and the use of benzodiazepines because of the increased risk of encephalopathy.

Alterations in level of consciousness may compromise nutritional intake. Factors such as coagulation problems may influence whether enteral nutrition is initiated. An NG tube may irritate the nasal and esophageal mucosa and thus cause bleeding.

Liver Cancer

Hepato-cellular carcinoma (HCC), the primary liver cancer, is the third most common cancer in the world. It is also the fifth most common cause of cancer-related death in men and the seventh in women (Sherman, Burak, Maroun, et al., 2011). The Multidisciplinary Canadian Consensus for the Management and Treatment of Hepatocellular Carcinoma reported that the incidence rate among men 40 to 84 years old was 15.4 per 100 000 in the years 2006 to 2010. The incidence rate for women is four to eight times lower but has also shown an increasing trend (Sherman, Burak, Maroun, et al., 2011).

About 80% to 90% of people with HCC have cirrhosis of the liver. Cirrhosis is therefore a major risk factor regardless of the cause of cirrhosis. In North America, chronic HCV infection is the major underlying cause of HCC. Among those with chronic HBV infection, the risk for HCC is further increased if they are male, are older, have a family history of HCC, or are infected with HBV genotype C. NAFLD is also a well-established risk factor for HCC although to a lesser extent than HBV and HCV infections.

In liver cancer, hemorrhage and necrosis in the liver are common. Single or multiple tumours can occur; they can be well defined or diffusely spread over the entire liver. Some tumours infiltrate other organs, such as the gallbladder, or move to the peritoneum or the diaphragm. The liver is a common site of metastatic growth because of its high rate of blood flow and extensive capillary network. Cancer cells in other parts of the body are commonly carried to the liver via the portal circulation (Figure 46-12). Primary liver tumours commonly metastasize to the lungs.

FIGURE 46-12 Multiple hepatic metastases from a primary colon cancer. Source: Kumar, V., Abbas, A. K., & Fausto, N. (2005). *Robbins and Cotran pathologic basis of disease* (7th ed.). Philadelphia: W. B. Saunders.

Clinical Manifestations and Diagnostic Studies

Liver cancers usually produce no symptoms until they become very large. Diagnosing small liver cancers in the presence of cirrhosis is sometimes a challenge when the liver is nodular and severely scarred. Clinical manifestations in later stages of cancer include weight loss, epigastric or right upper quadrant pain, anorexia, nausea and vomiting, weakness, and jaundice. More severe clinical symptoms such as ascites, peripheral edema, encephalopathy, and variceal bleeding occur in the setting of decompensated liver disease. A hemorrhagic tumour can cause blood clots to form, leading to pulmonary emboli as a complication.

Liver cancer can be diagnosed with ultrasound, CT, and MRI. A percutaneous biopsy is performed when the results of diagnostic imaging studies are inconclusive or tissue is needed to guide treatment. Risks of biopsy include bleeding and potential tumour cell spread. Serum alpha-fetoprotein (AFP) levels are elevated in approximately 60% of patients with HCC. The level of elevation may not correlate with the clinical features of HCC (e.g., stage or prognosis). (Alpha-fetoprotein is discussed in Chapter 18.)

Nursing and Collaborative Management Liver Cancer

Treatment of liver cancer depends on the size and number of tumours, presence of spread beyond of the liver, and the age and overall health of the patient. Surgical resection (partial hepatectomy) is performed when there is no evidence of invasion of hepatic blood vessels. Hepatectomy offers the best chance for cure of liver cancer. Liver transplantation can be an option when the tumour is localized. Other treatment options are radiofrequency ablation (RFA), chemoembolization, and chemotherapies.

RFA has become the most frequently used modality for treating tumours that are less than 2 to 3 cm in diameter. The overall survival rates are 100% and 98% at 1 and 2 years, but the 5-year recurrence rates are as high as 70% (El-Serag, 2011). In RFA, a thin needle is inserted into the core of the tumour. Electrical energy is then used to create heat in a specific location for a limited time. The end result is destruction of tumour cells. Complications are uncommon but can include infection, bleeding, dysrhythmias, and skin burn.

Chemoembolization (sometimes called *transarterial chemoembolization [TACE]*) is a minimally invasive procedure performed in the interventional radiology department. A catheter is placed in the arteries to the tumour, and an embolic agent is administered, mixed with one or more chemotherapeutic agents. The embolic agent reduces the blood supply to the tumour, thus allowing greater exposure of liver cells to the chemotherapy drugs. A postembolization syndrome of fever and abdominal pain related to liver ischemia occurs in up to 50% of patients receiving chemoembolization.

Systemic chemotherapy is not used for patients with HCC because of the poor response rates. Sorafenib (Nexavar), a targeted therapy, is now used to treat HCC. It is taken orally and works by inhibiting new blood vessels' growth to tumours. It has many adverse effects, including rash on the hands and feet, diarrhea, and fatigue.

Nurses play a very important role in health promotion and health teaching for prevention of HCC. HBV vaccination for people at high risk for HBV infection can drastically reduce the occurrence of liver cancer. Early treatment for chronic hepatitis B and C viral infections before the establishment of cirrhosis also helps decrease risk for liver cancer. For patients at risk of developing HCC (e.g., those with cirrhosis), cancer

surveillance with ultrasound every 6 months is a recommended clinical practice as small cancers are potentially curable (Sherman, Burak, Maroun, et al., 2011).

The prognosis for patients with liver cancer depends on how early the tumour is detected. Nursing interventions for patients with liver cancer focus on keeping patients as comfortable as possible. (See Chapter 18 for care of patients with cancer.)

Liver Transplantation

Canada's first liver transplantation was performed in Montreal in 1970. In 2015, 533 liver transplantations were performed in Canada (Canadian Institute for Health Information, 2017), up to 35% of which were for hepatitis C–related liver disease.

Liver transplantation has become an acceptable therapeutic option for many people with end-stage liver disease or localized and recurrent HCC. It improves overall health and quality of life. Liver transplantation is contraindicated in patients with widespread malignant disease. Among recipients, 1-year survival rates are 85% to 95%, and 5-year survival rates are 75% (Haque, Scudamore, Steinbrecher, et al., 2010).

Liver transplant candidates undergo a rigorous pretransplantation assessment to confirm the diagnosis of end-stage liver disease and to assess for other comorbid conditions (e.g., cardiovascular disease, chronic kidney disease) that may affect the patient's surgical outcome. The evaluation includes physical examination, laboratory tests (CBC, liver function tests), cardiac and pulmonary evaluations, endoscopy, CT scan, and psychological testing. Contraindications for liver transplantation include severe extrahepatic disease, advanced hepato-cellular carcinoma or other cancer, ongoing drug or alcohol use, and inability to comprehend or comply with the rigorous post-transplantation course.

Liver transplantation is performed using either a deceased- (cadaver) or living-donor liver (see Chapter 49 for a general discussion of organ transplants). For a living-donor liver transplantation, a living person donates a portion of his or her liver to another. However, live liver donation poses potential risks to the donor, including biliary problems, hepatic artery thrombosis, wound infection, postoperative ileus, and pneumothorax.

Postoperative complications of liver transplantation include bleeding, infection, and rejection. Rejection is the most feared but the most easily treated complication. It often necessitates only adjustment of immuno-

suppressive drug dosages. Cyclosporine, the original immuno-suppressant drug, improved the rates of success of liver transplantation. Tacrolimus (Prograf) is currently the first-line immuno-suppressive drug in most programs. Both these drugs are calcineurin inhibitors. The mechanism of action and adverse effects of cyclosporine are discussed in Chapter 16 and Table 16-16. Other immuno-suppressants used include mycophenolate mofetil (CellCept), azathioprine (Imuran), corticosteroids, and sirolimus (Rapamune) (see Chapter 16, Table 16-16). The interleukin-2 receptor antagonist basiliximab (Simulect) and polyclonal antilymphocyte antibodies, such as thymoglobulin, may be administered to patients at high risk for complications.

Almost all liver diseases may recur after transplantation. Because of the effective antiviral agents for HBV infection and the concurrent use of hepatitis B immune globulin, HBV reinfection is rare. Patients with HCV have lower survival rates than do other patient groups. Factors that may contribute to recurrent HCV include the donor's advanced age, HCV genotype 1, high HCV RNA levels before the transplantation, and co-infection with other viruses (e.g., cytomegalovirus). Although the recurrence of HCV is nearly universal after liver transplantation, avoidance of changes in immuno-suppressive regimen helps to prevent clinically aggressive disease. Antiviral therapy for HCV after transplantation is initiated on an individual basis. Overall, liver transplantation provides good long-term survival.

The patient who has undergone liver transplantation requires highly skilled nursing care, either in the intensive care unit or in a dedicated transplantation unit. Common respiratory problems are pneumonia, atelectasis, and pleural effusions, so measures such as coughing, deep breathing, incentive spirometry, and repositioning are needed to prevent complications. Drainage from the Jackson-Pratt drain, the NG tube, and the T-tube should be measured, and the colour and the consistency of drainage noted. Postoperative nursing care also includes assessing neurological status; monitoring for signs of hemorrhage; preventing pulmonary complications; assessing drainage, electrolyte levels, and urine output; and monitoring for signs and symptoms of infection and rejection.

Monitoring for infection is a critical aspect of nursing care after liver transplantation because infection is the most common cause of mortality and morbidity. Infections can be viral, fungal, or bacterial. Fever may be the only sign of infection. Nutrition, physiotherapy, and patient education focused on medication regimens, signs and symptoms of infection, and lifestyle practices are all key to lifelong success in transplant recipients.

Emotional support for the patient and family is also essential for successful transplantation outcomes.

Age-Related Considerations

Liver Disease in Older Adults

The incidence of liver disease increases with age. With aging, the liver size decreases, drug metabolism slows, and hepato-biliary function is altered. The liver's ability to respond to injury, particularly to regenerate after injury, decreases (Carrion & Martin, 2012). As well, transplanted livers take longer to regenerate in older adults than in younger adults.

Older patients are particularly vulnerable to drug-induced hepatitis. This vulnerability is due to several factors, including decline in body weight and increased use of prescription and OTC drugs, which can lead to drug interactions and potential drug toxicity. Age-related decreases in liver function caused by decreased liver blood flow and enzyme activity result in decreased drug metabolism. In addition, with aging, the liver's ability to recover from drug-induced injury is reduced.

A growing number of older adults have chronic hepatitis C and subsequent cirrhosis. The presence of HCV and elevated liver enzyme levels are often found during a routine health assessment. Because older adults have more comorbid conditions, liver transplantation may not be an option in the case of liver failure.

Lifetime health behaviours may also influence the development of chronic liver disease in the older adult. Chronic alcohol use and obesity can contribute to alcoholic cirrhosis, NASH, and subsequent liver failure. Older adults with comorbid cardiovascular and pulmonary diseases are less able to tolerate variceal bleeding. In older adults with liver disease, hepatic encephalopathy may be misdiagnosed as dementia.

Disorders of the Pancreas

Acute Pancreatitis

Acute pancreatitis is an acute inflammation of the pancreas. The degree of inflammation varies from mild edema to severe hemorrhagic necrosis. Acute pancreatitis is most common in middle-aged men and women.

Etiology and Pathophysiology

Many factors can cause injury to the pancreas. In Canada, the most common cause is gallbladder disease (gallstones), followed by alcohol use disorder. Acute pancreatitis attacks are also associated with hypertriglyceridemia (serum triglyceride level >11 mmol/L). Less common causes include trauma (postsurgical, abdominal), viral infections (mumps, coxsackievirus), penetrating duodenal ulcer, cysts, abscesses, cystic fibrosis, certain drugs (azathioprine, corticosteroids, thiazides, estrogens, sulphonamides, HIV medications, anti-inflammatory drugs), metabolic disorders (hyperparathyroidism, renal failure), and vascular disease. Pancreatitis may occur after surgical procedures on the pancreas, stomach, duodenum, or biliary tract. Pancreatitis can also develop following endoscopic retrograde cholangiopancreatography (ERCP). In some cases, the cause is unknown (idiopathic).

The most common pathogenic mechanism is believed to be autodigestion of the pancreas (Figure 46-13). Injury to pancreatic cells or activation of the pancreatic enzymes is caused in the pancreas rather than in the intestine. The activation of pancreatic enzymes may be due to reflux of bile acids into the pancreatic ducts through an open or distended sphincter of Oddi. This reflux may result from blockage created by gallstones. Obstruction of a pancreatic duct results in pancreatic ischemia.

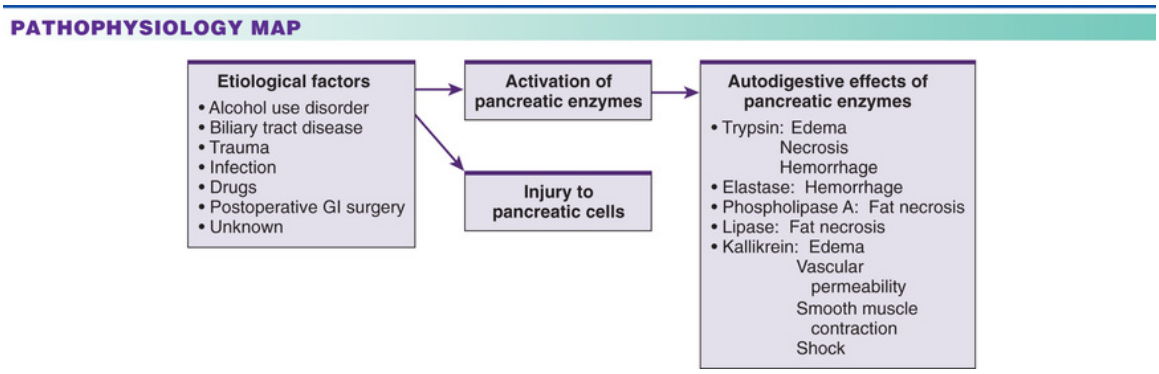

FIGURE 46-13 Pathogenic process of acute pancreatitis. *GI*, gastro-intestinal.

Trypsinogen is an inactive proteolytic enzyme produced by the pancreas. It is released into the small intestine via the pancreatic duct. In the intestine, it is activated to trypsin by enterokinase. Normally, trypsin inhibitors in the pancreas and the plasma bind and inactivate any trypsin that is inadvertently produced. In pancreatitis, activated trypsin is present in the pancreas and can digest the pancreas and produce bleeding.

It is not entirely clear how chronic alcohol use causes acute pancreatitis. It is thought that alcohol increases the production of digestive enzymes in the pancreas. However, because only 5% to 10% of people with alcohol use disorder develop pancreatitis, it is believed that other factors such as environment (high-fat diet, smoking) and genetics also contribute to the cause.

The pathophysiological involvement of acute pancreatitis ranges from mild (*edematous* or *interstitial pancreatitis*) to severe (*necrotizing pancreatitis;* Figure 46-14). In mild pancreatitis, the functions of the gland return to normal upon recovery. In severe pancreatitis, approximately half of patients have a permanent decrease in endocrine and exocrine function. Such patients are also at risk of developing pancreatic necrosis, organ failure, septic complications, or a combination of these, all of which are associated with higher mortality rates (Tenner, Baillie, DeWitt, et al., 2013).

FIGURE 46-14 In acute pancreatitis, the pancreas appears edematous and is commonly hemorrhagic (*H*). Source: Stevens, A., & Lowe, J. (2000). *Pathology: Illustrated review in colour* (2nd ed.). London: Mosby.

Clinical Manifestations

Abdominal pain is the predominant symptom of acute pancreatitis. The pain is caused by distension of the pancreas, peritoneal irritation, and obstruction of the biliary tract.

The pain is usually located in the left upper quadrant, but it may be in the midepigastrium. It commonly radiates to the back because of the retroperitoneal location of the pancreas. The pain has a sudden onset and is described as severe, deep, piercing, and continuous or steady. It is aggravated by eating and frequently occurs when the patient is recumbent. It is not relieved by vomiting. The pain may be accompanied by flushing, cyanosis, and dyspnea. The patient may assume various positions involving flexion of the spine in an attempt to relieve the severe pain.

Other manifestations of acute pancreatitis include nausea and vomiting, low-grade fever, leukocytosis, hypotension, tachycardia, and jaundice. Abdominal tenderness with muscle guarding is common. Bowel sounds may be decreased or absent. Paralytic ileus may occur and causes marked abdominal distension. The lungs are frequently involved, with crackles present. Intravascular damage from circulating trypsin may cause areas of cyanosis or greenish to yellow-brown discoloration of the abdominal wall. Other areas of ecchymoses are the flanks (*Grey Turner's spots* or *sign,* a bluish flank discoloration) and the periumbilical area (*Cullen's sign*, a bluish periumbilical discoloration). These ecchymoses may occur in severe cases as a result of seepage of blood-stained exudate from the pancreas.

Shock is possible as a result of hemorrhage into the pancreas, toxemia from the activated pancreatic enzymes, or hypovolemia as a result of

massive shift of exudates of blood and plasma proteins into the retroperitoneal space.

Complications

The severity of the disease varies according to the extent of pancreatic destruction. Some patients recover completely, some have recurring attacks, and some develop chronic pancreatitis. Acute pancreatitis can be life-threatening.

Two significant local complications of acute pancreatitis are pseudocyst and abscess. A pancreatic **pseudocyst** is a cavity continuous with or surrounding the outside of the pancreas. It is filled with necrotic products, plasma, pancreatic enzymes, and inflammatory exudates. Manifestations of pseudocyst are abdominal pain, palpable epigastric mass, nausea, vomiting, and anorexia. The serum amylase level frequently remains elevated. These cysts usually resolve spontaneously within a few weeks, but they may perforate, causing peritonitis, or they may rupture into the stomach or duodenum. Treatment consists of an internal drainage procedure with an anastomosis between the pancreatic duct and the jejunum.

A pancreatic abscess is a large collection of pus within the pancreas. It results from extensive necrosis in the pancreas. It may become infected or perforate into adjacent organs. Manifestations of an abscess include upper abdominal pain, abdominal mass, high fever, and leukocytosis. Pancreatic abscesses require prompt surgical drainage to prevent sepsis.

The main systemic complications of acute pancreatitis are pulmonary (pleural effusion, atelectasis, and pneumonia), cardiovascular (hypotension), and tetany caused by hypocalcemia. The pulmonary complications are likely caused by the passage of exudate containing pancreatic enzymes from the peritoneal cavity through transdiaphragmatic lymph channels. Enzyme-induced inflammation of the diaphragm reduces diaphragm movement, which leads to atelectasis. Trypsin can activate prothrombin and plasminogen, increasing the patient's risk for intravascular thrombi, pulmonary emboli, and disseminated intravascular coagulation. Hypocalcemia is a sign of severe disease, caused in part by the combining of calcium and fatty acids during fat necrosis. The exact mechanisms of how or why hypocalcemia occurs are not well understood.

Diagnostic Studies

The primary diagnostic tests for acute pancreatitis are measurements of serum amylase and lipase. The serum amylase level is usually elevated early and remains so for 24 to 72 hours. The serum lipase level is also elevated and is an important test for differentiating acute pancreatitis from other disorders such as mumps and cerebral trauma. Other abnormal findings include an increase in liver enzymes, triglycerides, glucose, and bilirubin and a decrease in calcium.

Abdominal ultrasound, radiograph, or CT scan can be used to identify pancreatic problems. Contrast-enhanced CT and magnetic resonance cholangiopancreatography (MRCP) are used for detecting pancreatitis-related complications such as pseudocysts and abscesses. MRCP often replaces the use of ERCP, which itself can cause acute pancreatitis.

Collaborative Care

Objectives of collaborative care for acute pancreatitis include (a) relief of pain; (b) prevention or alleviation of shock; (c) reduction of pancreatic secretions; (d) control of fluid and electrolyte imbalance; (e) prevention or treatment of infections; and (f) removal of the precipitating cause, if possible (Table 46-18).

TABLE 46-18

COLLABORATIVE CARE
Acute Pancreatitis

Diagnostic	Collaborative Therapy
• History and physical examination • Abdominal ultrasound • Blood glucose • Chest radiograph • Contrast-enhanced CT • Endoscopic ultrasound • ERCP • Flat-plate radiograph of the abdomen • MRCP • Serum amylase • Serum calcium • Serum lipase • Triglycerides	• Albumin (if shock is present) • Antibiotics (if necrotizing pancreatitis is present) • IV calcium gluconate, 10% (if tetany is present) • Lactated Ringer's solution • NPO with NG tube to suction • Pain medication (e.g., morphine) • Proton pump inhibitors (e.g., omeprazole [Losec])

CT, computed tomography; *ERCP,* endoscopic retrograde cholangiopancreatography; *IV,* intravenous; *MRCP,* magnetic resonance cholangiopancreatography; *NG,* nasogastric; *NPO,* nothing by mouth.

Conservative Therapy.

Treatment is primarily focused on supportive care, including aggressive hydration, pain management, management of metabolic complications, and minimization of pancreatic stimulation. Relief and control of pain are very important. IV morphine may be administered. Pain medications may be combined with an antispasmodic agent. However, atropine-like drugs should be avoided when paralytic ileus is present because they may decrease GI motility and further contribute to the problem. Other medications that relax smooth muscles (spasmolytics), such as nitroglycerin or papaverine, may be used.

If shock is present, plasma or plasma volume expanders such as dextran or albumin may be given. Fluid and electrolyte imbalances are corrected with lactated Ringer's solution. Central venous pressure readings may be used to assist in determining requirements to increase systemic vascular resistance in patients with ongoing hypotension.

Pancreatic enzyme secretion must be reduced or suppressed in order to decrease stimulation of the pancreas and allow it to rest. Suppression of pancreatic secretion is accomplished by keeping the patient on nothing-by-mouth (NPO) and by using NG suction to reduce vomiting and gastric distension and to prevent gastric acidic contents from entering the duodenum. Certain drugs may also be administered for this purpose (Table 46-19). With resolution of the pancreatitis, the patient resumes oral intake. For the patient with severe acute pancreatitis who does not resume oral intake, enteral nutrition support may be initiated.

TABLE 46-19

DRUG THERAPY
Acute and Chronic Pancreatitis

Drug	Mechanism of Action or Rationale
Acute Pancreatitis	
Antacids	Neutralization of gastric HCl secretion and subsequent decrease in secretin, which stimulates production and secretion of pancreatic secretions
Antispasmodics (e.g., dicyclomine [Bentylol]*	Decrease of vagal stimulation, motility, and pancreatic outflow (through inhibition of volume and concentration of bicarbonate and enzymatic secretion)
Carbonic anhydrase inhibitor (acetazolamide)	Reduction in volume and bicarbonate concentration of pancreatic secretion
Morphine, meperidine (Demerol)	Relief of pain
Nitroglycerin or papaverine	Relaxation of smooth muscles and relief of pain
Proton pump inhibitors (omeprazole [Losec])	Decrease in HCl secretion (HCl stimulates pancreatic activity)
Chronic Pancreatitis	
Insulin	Treatment for diabetes mellitus, if it occurs, or for hyperglycemia
Pancreatin, pancrelipase	Replacement therapy for pancreatic enzymes

*Contraindicated in patients with paralytic ileus.

HCl, Hydrochloric acid.

The inflamed and necrotic pancreatic tissue is a good medium for bacterial growth. In patients with acute necrotizing pancreatitis, infection is the leading cause of morbidity and mortality. Therefore, it is important to prevent infections. The prophylactic use of antibiotics is somewhat controversial. The patient should be monitored closely so that antibiotic therapy can be instituted early if infection occurs.

Surgical Therapy.

When the acute pancreatitis is related to gallstones, urgent ERCP and endoscopic sphincterotomy may be performed and followed by laparoscopic cholecystectomy to reduce the potential for recurrence. Surgical intervention may also be indicated when the diagnosis is uncertain and for patients who do not respond to conservative therapy. Patients with severe acute pancreatitis may require drainage of necrotic fluid collections. Drainage can be accomplished either surgically under CT guidance or endoscopically. A pseudocyst can be drained percutaneously, and a drainage tube is left in place.

Drug Therapy.

Several different drugs are used to treat problems associated with pancreatitis (see Table 46-19). Currently there are no drugs that cure

pancreatitis.

Nutritional Therapy.

Initially, patients with acute pancreatitis are kept on NPO status to reduce pancreatic secretion. In cases of moderate to severe pancreatitis, the patient may require enteral feeding via a jejunal feeding tube. When food is allowed, small, frequent feedings are given. The diet is usually high in carbohydrate content because that is the least stimulating to the exocrine portion of the pancreas. Intolerance to oral foods should be suspected if a patient reports pain, has increasing abdominal girth, or has elevated amylase and lipase levels. The patient needs to abstain from alcohol. Supplemental fat-soluble vitamins may be administered (see Chapter 42).

Nursing Management Acute Pancreatitis

Nursing Assessment

Subjective and objective data that should be obtained from a person with acute pancreatitis are presented in Table 46-20.

TABLE 46-20

NURSING ASSESSMENT
Acute Pancreatitis

Subjective Data
Important Health Information
Past health history: Biliary tract disease, alcohol use, abdominal trauma, duodenal ulcers, infection, metabolic disorders *Medications:* Thiazides, anti-inflammatory drugs *Surgery or other treatments:* Surgical procedures on the pancreas, stomach, duodenum, or biliary tract; ERCP
Symptoms
• Dyspnea • Nausea, vomiting, or both; anorexia • Severe abdominal pain that may radiate to the back and is aggravated by food, alcohol, or both • Weakness or lassitude
Objective Data
General
Restlessness, anxiety, low-grade fever
Integumentary
Flushing, diaphoresis, discoloration of abdomen and flanks, cyanosis, jaundice; decreased skin turgor; dry mucous membranes
Respiratory
Tachypnea, basilar crackles
Cardiovascular
Tachycardia, hypotension
Gastro-Intestinal
Abdominal distension, tenderness, and muscle guarding; diminished bowel sounds
Possible Findings
↑ Serum amylase and lipase levels, leukocytosis, hyperglycemia, dyslipidemia, hypocalcemia, abnormal findings on ultrasound and CT scan of pancreas, abnormal findings on ERCP or MRCP

CT, computed tomographic; *ERCP,* endoscopic retrograde cholangiopancreatography; *MRCP*, magnetic resonance cholangiopancreatography.

Nursing Diagnoses

Nursing diagnoses for patients with acute pancreatitis may include but are not limited to the following:

- *Acute pain* related to *biological injury agent* (distention of pancreas, peritoneal irritation, obstruction of biliary tract)
- *Deficient fluid volume* related to *insufficient fluid intake* (vomiting, restricted oral intake, fluid shift into the retroperitoneal space)
- *Imbalanced nutrition: less than body requirements* related to *insufficient dietary intake* (anorexia, dietary restrictions, nausea)
- *Ineffective health management* related to *insufficient knowledge of therapeutic regimen* (diet restrictions), *ineffective coping strategies* (alcohol intake)

Additional information on nursing diagnoses for the patient with pancreatitis is presented in NCP 46-3, available on the Evolve website for this chapter.

Planning

The overall goals are that patients with acute pancreatitis will have (a) relief of pain, (b) normal fluid and electrolyte balance, (c) minimal to no complications, and (d) no recurrent attacks.

Nursing Implementation

Health Promotion.

Health promotion is focused on the assessment of the predisposing and etiological factors of pancreatitis and on encouragement of early intervention to prevent occurrence of acute pancreatitis. The patient should be advised to eliminate alcohol intake, especially if there have been any previous episodes of pancreatitis. Attacks of pancreatitis become milder or disappear when alcohol use is discontinued.

Acute Intervention.

During the acute phase, it is important to monitor vital signs. Hemodynamic stability may be compromised by hypotension, fever, and

tachypnea. A vital part of the nursing care plan for patients with acute pancreatitis is monitoring for electrolyte imbalances and response to IV fluids. Frequent vomiting, along with gastric suction, may cause electrolyte levels to decrease. Respiratory failure may develop in patients with severe acute pancreatitis. It is important to assess respiratory function (e.g., breath sounds, oxygen saturation levels). If acute respiratory distress syndrome develops, the patient may require intubation and mechanical ventilatory support. Because hypocalcemia can also occur, the nurse must observe for symptoms of tetany, such as jerking, irritability, and muscular twitching. Numbness or tingling around the lips and in the fingers is an early indicator of hypocalcemia. The patient should be assessed for a positive Chvostek's or Trousseau's sign (see Chapter 19). Calcium gluconate (as ordered) should be given to treat symptomatic hypocalcemia. In addition, hypomagnesemia may develop, necessitating the observation of serum magnesium levels.

Because abdominal pain is a prominent symptom of pancreatitis, a major focus of nursing care is the relief of pain (see NCP 46-3). Pain and restlessness can increase body metabolism and subsequent stimulation of pancreatic secretions. Morphine or meperidine (Demerol) may be used for pain relief. The nurse should assess and document the duration of pain relief. Measures such as comfortable positioning, frequent changes in position, and relief of nausea and vomiting assist in reducing the restlessness that usually accompanies the pain. Assuming positions that flex the trunk and draw the knees up to the abdomen may decrease pain. A side-lying position with the head elevated 45 degrees decreases tension on the abdomen and may also help ease the pain.

Nursing measures for the patient who is kept NPO or has an NG tube should include frequent oral and nasal care to relieve the dryness of the mouth and nose. Oral care is essential to prevent parotitis. If the patient is taking anticholinergics to decrease GI secretions, dryness of the mouth is exacerbated. If antacids are taken to neutralize gastric acid secretions, they should be sipped slowly or administered through the NG tube. The patient with acute pancreatitis is susceptible to infections. The nurse should monitor for fever and other manifestations of infection. Respiratory infections are common because the retroperitoneal fluid raises the diaphragm, which causes the patient to take shallow, guarded abdominal breaths. Measures to prevent respiratory tract infections include frequent turning, coughing, deep breathing, and assuming a semi-Fowler's position. Other important assessments are for signs of paralytic ileus, renal failure,

and mental changes. The blood glucose level should be monitored to assess damage to the beta cells of the islets of Langerhans in the pancreas.

After pancreatic surgery, the patient may require special wound care for an anastomotic leak or a fistula. To prevent skin irritation, measures such as skin barriers (Stomahesive or Karaya paste), pouching, and drains should be used. In addition to protecting the skin, pouching also provides a more accurate determination of fluid and electrolyte losses and increases patient comfort.

Ambulatory and Home Care.

After acute pancreatitis, most patients may need home care follow-up to prevent infection, monitor pain, and detect complications. Physiotherapy may be needed if the patient has lost physical reserve and muscle strength. Patient counselling should include that directed toward alcohol abstinence and cigarette smoking cessation. Abstinence from alcohol prevents future pancreatitis attacks. Because tobacco can stimulate the pancreatic enzyme secretions, smoking should be avoided. Counselling recommendations and strategies for smoking cessation, including resources, can be referenced from the *Integrating Smoking Cessation Into Daily Nursing Practice* best practice guideline by the Registered Nurses' Association of Ontario, listed in the Resources at the end of this chapter.

Dietary teaching should include restriction of fats because they stimulate the secretion of cholecystokinin, which then stimulates the pancreas. Carbohydrates are less stimulating to the pancreas. The patient should be advised to avoid crash dieting and bingeing because they can precipitate attacks. The patient and the caregivers should be taught the symptoms of infection, diabetes mellitus, and steatorrhea (foul-smelling, frothy stools). These changes indicate possible ongoing destruction of pancreatic tissue. The patient and the caregivers should also be educated about the prescribed regimen, including the importance of taking the required medications and following the recommended diet.

Evaluation

Expected outcomes for patients with acute pancreatitis are presented in NCP 46-3, available on the Evolve website.

Chronic Pancreatitis

Chronic pancreatitis is a continuous, prolonged inflammatory and fibrosing process of the pancreas. The pancreas becomes progressively destroyed as it is replaced with fibrotic tissues. Strictures and calcifications may also occur in the pancreas.

Etiology and Pathophysiology

In Western countries, 70% of cases of chronic pancreatitis are associated with alcohol use disorder. However, not all people who overuse alcohol develop chronic pancreatitis, which suggests that affected people have cofactors that predispose them to the direct toxic effect of the alcohol on the pancreas. In some patients, an identifiable cause may not be found *(idiopathic pancreatitis).* Chronic pancreatitis may follow acute pancreatitis, but it may also occur in the absence of any history of acute episodes.

Chronic pancreatitis can be classified into *obstructive* and *nonobstructive.* In nonobstructive pancreatitis, there is inflammation and sclerosis, mainly in the head of the pancreas and around the pancreatic duct. The ducts are obstructed with protein precipitates. These precipitates block the pancreatic duct and eventually calcify. This process is followed by fibrosis and glandular atrophy. Pseudocysts and abscesses commonly develop. Alcohol use disorder is the most common cause of nonobstructive calcifying pancreatitis.

Obstructive pancreatitis is associated with biliary disease. The most common cause is inflammation of the sphincter of Oddi associated with cholelithiasis. Cancer of the ampulla of Vater, the duodenum, or the pancreas can also cause this type of chronic pancreatitis.

Clinical Manifestations

As with acute pancreatitis, a major manifestation of chronic pancreatitis is abdominal pain. The patient may have episodes of acute pain, but it usually is chronic (recurrent attacks at intervals of months or years). The attacks may become more and more frequent until they are almost constant, or they may diminish as pancreatic fibrosis develops. The pain is located in the same areas as in acute pancreatitis but is usually described as a heavy, gnawing feeling or sometimes as burning and cramplike. The pain is not relieved with food or antacids.

Other clinical manifestations are symptoms of pancreatic insufficiency, including malabsorption with weight loss, constipation, mild jaundice with dark urine, steatorrhea, and diabetes mellitus. The steatorrhea may become severe, with voluminous, foul-smelling, fatty stools. Urine and

stool may be frothy. Some abdominal tenderness may be present. Chronic pancreatitis is also associated with a variety of complications, including pseudocyst formation, bile duct or duodenal obstruction, diabetes mellitus, pancreatic ascites or pleural effusion, splenic vein thrombosis, pseudoaneurysms, and pancreatic cancer.

Diagnostic Studies

The diagnosis is based on the patient's signs and symptoms, laboratory studies, and imaging. In chronic pancreatitis, the levels of serum amylase and lipase may be elevated slightly or not at all, depending on the degree of pancreatic fibrosis. Serum bilirubin and alkaline phosphatase levels may be increased. Mild leukocytosis is usually present, and the sedimentation rate is usually elevated.

Stool samples are examined for fecal fat content. Deficiencies of fat-soluble vitamins and cobalamin, glucose intolerance, and possibly diabetes may also be found in patients with chronic pancreatitis. ERCP is used to visualize the pancreatic and common bile ducts, as well as changes in the pancreatic ductal system, such as gross dilation and microcysts. Other imaging studies such as CT, MRI, MRCP, transabdominal ultrasound, and endoscopic ultrasound are useful in patients with chronic pancreatitis. These tests show a variety of changes, including calcifications, ductal dilation, pseudocysts, and pancreatic enlargement. The secretin stimulation test, although not widely used, may help to assess pancreatic function.

Collaborative Care

When a patient with chronic pancreatitis experiences an acute attack, the therapy is identical to that for acute pancreatitis. At other times, the focus is on prevention of further attacks, relief of pain, and control of pancreatic exocrine and endocrine insufficiency. Sometimes, doses of analgesics must be large and frequent to relieve the pain.

Diet, pancreatic enzyme replacement, and control of diabetes are measures used to control the pancreatic insufficiency. The diet should be bland and low in fat. Small, frequent meals should be encouraged. Fatty, rich, and stimulating foods should be avoided in order to decrease pancreatic secretions. Alcohol must be totally eliminated from the diet. Smoking should be stopped as it is associated with accelerated progression of chronic pancreatitis.

Pancreatic enzyme products (e.g., pancreatin and pancrelipase) containing amylase, lipase, and trypsin are administered to replace the deficient pancreatic enzymes. They are usually enteric coated to prevent their breakdown or inactivation by gastric hydrochloric acid. Bile salts are sometimes administered to facilitate the absorption of the fat-soluble vitamins (A, D, E, and K) and to prevent further fat loss. If diabetes develops, it is controlled with insulin or oral hypoglycemic agents. Acid-neutralizing (e.g., antacids) and acid-inhibiting drugs (e.g., proton pump inhibitors) may be administered to decrease hydrochloric acid levels, but they have little overall effect on the outcome of the disease.

When biliary disease is present or if obstruction or pseudocyst develops, surgery may be indicated. Surgical procedures can divert bile flow or relieve ductal obstruction. A choledochojejunostomy diverts bile around the ampulla of Vater, where spasm or hypertrophy of the sphincter may be present. In this procedure, the common bile duct is anastomosed into the jejunum. One type is the Roux-en-Y pancreatojejunostomy, in which the pancreatic duct is opened and an anastomosis is made with the jejunum. Pancreatic drainage procedures relieve ductal obstruction. Some patients may undergo ERCP with either sphincterotomy or stent placement at the site of obstruction, or both. These patients require follow-up ERCP to either exchange or remove the stent.

Nursing Management Chronic Pancreatitis

Except during an acute episode, the focus of nursing management is on chronic care and health promotion. Patients must be instructed to take measures to prevent further attacks. Dietary control, along with adherence to pancreatic enzyme treatment regimens, is essential. The pancreatic enzymes are taken with meals or snacks. Patients' stools should be examined for steatorrhea to help determine the effectiveness of the enzyme treatment. Patients and caregivers must be given clear instructions on stool assessment.

If diabetes has developed, patients need instruction about testing of blood glucose levels and medications (see Chapter 52). Patients who are taking antisecretory agents must take them as ordered to control gastric acidity. Antacids should be taken after meals and at bedtime.

Alcohol must be avoided. Patients who have developed a dependence on alcohol may need referral to other agencies or resources to help with this problem (see Chapter 11).

Pancreatic Cancer

Pancreatic cancer is a disease with a dismal outcome. In Canada, it was estimated that 1 in 79 Canadians will have pancreatic cancer, making it the twelfth most common fatal disease (Kanji & Gallinger, 2013). Pancreatic cancer affects older people; the incidence peaks among those 65 to 75 years of age. The prognosis of pancreatic cancer is poor. The majority of patients die within 5 to 12 months of the initial diagnosis, and the overall 5-year survival rate is about 6%.

Etiology and Pathophysiology

The cause of pancreatic cancer remains unknown. Cigarette smoking is the most established environmental risk factor for pancreatic cancer (Kanji & Gallinger, 2013). Active smokers are twice as likely as nonsmokers to develop pancreatic cancer. The risk is related to both duration and number of cigarettes smoked. Other risk factors are obesity (BMI >35), heavy alcohol use, and genetic dispositions.

Most pancreatic tumours are adenocarcinomas originating from the epithelium of the ductal system. More than half the tumours occur in the

head of the pancreas. As the tumour grows, the common bile duct becomes obstructed, and obstructive jaundice develops. Tumours starting in the body or the tail often do not produce symptoms until their growth is advanced. The majority of cancers have metastasized at the time of diagnosis. Metastases to the lymph nodes are common.

Clinical Manifestations

Common manifestations of pancreatic cancer include abdominal pain (dull, aching), anorexia, nausea, and rapid and progressive weight loss. Jaundice occurs when the cancer is in the head of the pancreas because of the ductal obstruction. Pruritus may accompany obstructive jaundice.

Pain is common and is related to the location of malignancy. Extreme, unrelenting pain is related to extension of the cancer into the retroperitoneal tissues and nerve plexuses. The pain is frequently located in the upper abdomen or the left hypochondrium and often radiates to the back. Its onset is commonly related to eating, and it also occurs at night. Weight loss results from poor digestion and absorption caused by lack of digestive enzymes from the pancreas.

Diagnostic Studies

Endoscopic ultrasonography, CT scan, ERCP, MRI, and MRCP are the most commonly used imaging techniques for diagnosing pancreatic diseases, including cancer. Endoscopic ultrasonography involves imaging the pancreas with the use of an endoscope positioned in the stomach and duodenum. It also allows for fine-needle aspiration of the tumour. CT scan is often the initial study and provides information on metastasis and vascular involvement. ERCP allows visualization of the pancreatic duct and the biliary system. When ERCP is used, pancreatic secretions and tissue can be collected for analysis of different tumour markers. MRI and MRCP can also be used for diagnosing and staging the cancer.

Tumour markers are used both for establishing the diagnosis of pancreatic adenocarcinoma and for monitoring the response to treatment. Cancer-associated antigen (CA-19-9) is elevated in pancreatic cancer and is the most commonly used tumour marker.

Collaborative Care

Surgery is the most effective treatment for cancer of the pancreas. Only 15% to 20% of affected patients have resectable tumours. The classic

surgical procedure is a *radical pancreatico-duodenectomy,* or *Whipple procedure* (Figure 46-15). This procedure involves resection of the proximal pancreas (proximal pancreatectomy), the adjoining duodenum (duodenectomy), the distal portion of the stomach (partial gastrectomy), and the distal segment of the common bile duct, and removal of the gallbladder. An anastomosis of the pancreatic duct, the common bile duct, and the stomach to the jejunum is created. A total pancreatectomy is performed in some institutions. Sometimes, a simple bypass procedure, such as a cholecystojejunostomy to relieve biliary obstruction, may be used as a palliative measure. Some surgeons suggest a more radical resection, such as a total pancreatico-duodenectomy with splenectomy. Biliary stents can be used as a palliative measure when tumours compress the bile duct. Common postsurgical complications include delayed gastric emptying and pancreatic anastomotic leaks.

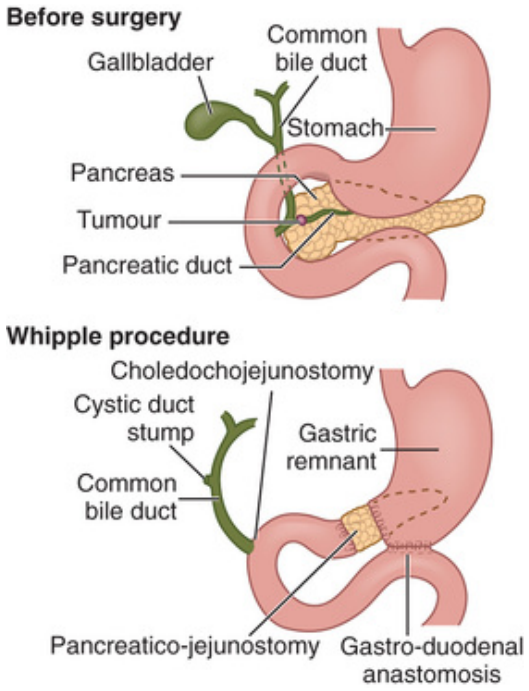

FIGURE 46-15 Whipple procedure, or radical pancreatico-duodenectomy. This surgical procedure involves resection of the proximal pancreas, adjoining duodenum, distal portion of the stomach, and distal segment of the common bile duct, and the removal of the gallbladder. An anastomosis of the pancreatic duct, common bile duct, and stomach to the jejunum is created.

Adjuvant treatment with chemotherapy or radiotherapy is often used postsurgery. Chemotherapy usually consists of 5-fluorouracil (5-FU) and gemcitabine, either alone or in combination with agents such as capecitabine (Xeloda) or erlotinib (Tarceva). Erlotinib is a targeted therapy.

Nursing Management Pancreatic Cancer

Because patients with pancreatic cancer have many of the same problems as patients with pancreatitis, nursing care includes the same measures (see NCP 46-3, Patient With Acute Pancreatitis, available on the Evolve website for this chapter). The nurse should provide symptomatic and supportive nursing care and administer analgesics and comfort measures to relieve pain. Psychological support to both the patient and the family is essential, especially during times of anxiety or depression.

Adequate nutrition is an important part of the nursing care plan. Frequent and supplemental feedings may be necessary. Measures to stimulate the appetite and to overcome anorexia, nausea, and vomiting should be included in nursing care. Because bleeding can result from impaired vitamin K production, the nurse should assess for bleeding from body orifices and mucous membranes. If a patient is undergoing radiation therapy, the nurse should observe for adverse reactions, such as anorexia, nausea, vomiting, and skin irritation. The prognosis for patients with pancreatic cancer is poor. A significant component of the nursing care is helping the patient and the family or significant others through the grieving process.

Disorders of the Biliary Tract

Cholelithiasis and Cholecystitis

The most common disorder of the biliary system is **cholelithiasis** (stones in the gallbladder) (Figures 46-16 and 46-17). The stones may be lodged in the neck of the gallbladder or in the cystic duct. **Cholecystitis** (inflammation of the gallbladder) is usually associated with cholelithiasis. Cholecystitis may be acute or chronic.

FIGURE 46-16 Cholesterol gallstones in a gallbladder that was removed. Source: Kumar, V., Abbas, A. K., Aster, J. C., et al. (2010). *Robbins and Cotran pathologic basis of disease* (8th ed.). Philadelphia: W. B. Saunders.

FIGURE 46-17 Radiograph of a gallbladder with gallstones.

Cholelithiasis occurs in 10% to 15% of adults in developed countries. The prevalence is highest in Indigenous populations, affecting about 64% of women and 30% of men in certain communities (Stinton & Shaffer, 2012). *Cholecystectomy* (removal of the gallbladder) ranks among the most common surgical procedures. Although gallstones are common, more than 80% of affected patients have no symptoms. The incidence of cholelithiasis is higher in women, particularly multiparous women, and in people older than 40 years. Postmenopausal women on estrogen therapy are at somewhat greater risk than are women who are taking birth control pills. Oral contraceptives alter the character of bile, resulting in increased cholesterol saturation. Other factors that increase the occurrence of gallbladder disease are a sedentary lifestyle, a familial tendency, and obesity. Obesity causes increased secretion of cholesterol in bile. The incidence of gallstones in industrialized and developing societies will probably escalate because of the increase in dietary fat and carbohydrate intake coupled with reductions in dietary fibre intake.

Etiology and Pathophysiology

Cholelithiasis.

The cause of gallstones is unknown. Gallstones develop when the balance that keeps cholesterol, bile salts, and calcium in solution is altered so that these substances precipitate. Conditions that upset this balance include infection and disturbances in the metabolism of cholesterol. When the bile secreted by the liver is supersaturated with cholesterol (lithogenic bile), the bile in the gallbladder also becomes supersaturated with cholesterol.

When that happens, precipitation of cholesterol occurs. The cholesterol type of gallstone accounts for 90% of all gallstones. Risk factors for developing cholesterol gallstones can be genetic, dietary, and medication related.

Black pigment gallstones account for 2% of gallstones, and they consist of polymerized calcium bilirubinate. Patients with hemolytic anemia, cirrhosis, and ileal diseases are at highest risk for developing black pigment stones.

Brown pigment gallstones are infrequent and usually form in the bile ducts as a result of stasis of bile and infection. These stones consist of unconjugated bilirubin and calcium salts. People at risk include those with duodenal diverticula, bile duct strictures, or parasitic diseases.

The stones may remain in the gallbladder or migrate to the cystic duct or to the common bile duct. They cause pain as they pass through the ducts, and they may lodge in the ducts and produce an obstruction. Small stones are more likely to move into a duct and cause obstruction. Table 46-21 lists the changes and the manifestations that occur when the stones obstruct the common bile duct. If the blockage occurs in the cystic duct, the bile can continue to flow into the duodenum directly from the liver. However, when the bile in the gallbladder cannot escape, this stasis of bile may lead to cholecystitis.

TABLE 46-21

CLINICAL MANIFESTATIONS CAUSED BY OBSTRUCTED BILE FLOW

Clinical Manifestation	Etiology
Bleeding tendencies	Lack of or decreased absorption of vitamin K, resulting in decreased production of prothrombin
Clay-coloured stools	Blockage of flow of bile salts out of the liver
Dark amber urine, which foams when shaken	Soluble bilirubin in urine
Intolerance of fatty foods (nausea, sensation of fullness, anorexia)	No bile in small intestine for fat digestion
No urobilinogen in urine	No bilirubin reaching small intestine to be converted to urobilinogen
Obstructive jaundice	No bile flow into duodenum
Pruritus	Deposition of bile salts in skin tissues
Steatorrhea	No bile salts in duodenum, preventing fat emulsion and digestion

Cholecystitis.

Cholecystitis is most commonly associated with obstruction caused by gallstones or biliary sludge. Cholecystitis in the absence of obstruction (acalculous cholecystitis) occurs most commonly in older adults and in patients who have trauma or extensive burns or have recently undergone

surgery. Acalculous cholecystitis can also occur as a result of prolonged immobility and fasting, prolonged total parenteral nutrition, and diabetes mellitus. Bacteria (reaching the gallbladder via the vascular or the lymphatic route) or chemical irritants in the bile can also produce cholecystitis. *Escherichia coli, Streptococci,* and *Salmonellae* are common causative bacteria.

Inflammation is the major pathophysiological process in cholecystitis; it may be confined to the mucous lining, or it may involve the entire wall of the gallbladder. During an acute attack of cholecystitis, the gallbladder is edematous and hyperemic. It may be distended with bile or pus. The cystic duct is also involved and may become occluded. The wall of the gallbladder becomes scarred after an acute attack. Functioning decreases if large amounts of tissue undergo fibrosis.

Clinical Manifestations

Cholelithiasis may produce severe symptoms or none at all *(silent cholelithiasis).* The severity of symptoms depends on whether the stones are stationary or mobile and whether obstruction is present. When a stone is lodged in the ducts or when stones are moving through the ducts, spasms may result. The gallbladder spasms occur in response to the stone. The spasms sometimes produce severe pain, which is termed *biliary colic* even though the pain is rarely colicky; it is more often steady. The pain can be excruciating and accompanied by tachycardia, diaphoresis, and prostration. The severe pain may last up to an hour, and when it subsides, there is residual tenderness in the right upper quadrant. The attacks of pain frequently occur 3 to 6 hours after a high-fat meal or when the patient lies down. When total obstruction occurs, symptoms related to bile duct blockage manifest (see Table 46-21).

Manifestations of cholecystitis vary from indigestion to moderate to severe pain, fever, and jaundice. Initial symptoms of acute cholecystitis include pain and tenderness in the right upper quadrant (which may be referred to the right shoulder and scapula) and indigestion. The pain may be acute and be accompanied by nausea and vomiting, restlessness, and diaphoresis. Manifestations of inflammation include leukocytosis and fever. Physical findings include a positive Murphy sign, a manoeuvre that elicits a painful response when the right subcostal region is palpated. The manoeuvre may cause a sudden stop of inspiration as the inflamed gallbladder reaches the examiner's fingers (inspiratory arrest). Symptoms

of chronic cholecystitis include fat intolerance, dyspepsia, heartburn, and flatulence.

Complications

Complications of cholelithiasis and cholecystitis include gangrenous cholecystitis, subphrenic abscess, acute pancreatitis, *cholangitis* (inflammation of bile ducts), biliary cirrhosis, fistulas, and rupture of the gallbladder, which can cause bile peritonitis. In older patients and those with diabetes, gangrenous cholecystitis and bile peritonitis are the most common complications of cholecystitis. *Choledocholithiasis* (stone in the common bile duct) may occur, producing symptoms of obstruction.

Diagnostic Studies

Ultrasound is 90% to 95% accurate in detecting stones. It is especially useful for patients who are allergic to contrast medium. ERCP allows for visualization of the gallbladder, the cystic duct, the common hepatic duct, and the common bile duct. Bile samples taken during ERCP are sent for culture to identify possibly infecting organisms. Laboratory tests may reveal elevations in some liver enzymes, such as alkaline phosphatase, ALT, and AST. The white blood cell (WBC) count is increased as a result of inflammation. Both the direct and indirect bilirubin levels are elevated, as is the urinary bilirubin level if an obstructive process is present. If the common bile duct is obstructed, no bilirubin reaches the small intestine to be converted to urobilinogen. The serum amylase is increased if the pancreas is involved.

Collaborative Care

Once gallstones become symptomatic, definitive surgical intervention with cholescystectomy is usually indicated. However, in some cases, conservative therapy may be considered.

Conservative Therapy

Cholelithiasis.

The treatment of gallstones depends on the stage of the disease. Bile acids (cholesterol solvents) such as ursodeoxycholic acid are administered to dissolve stones. However, the gallstones may recur. Gallstones are not

usually treated with drugs because of the high use and success of laparoscopic cholecystectomy.

Standard ERCP clears stones from the common bile duct in approximately 90% of patients (Figure 46-18). This procedure allows for visualization of the biliary system, placement of stents, and sphincterotomy (papillotomy) if warranted. In this procedure, the endoscope is passed through the duodenum. With an electrodiathermy knife attached to the endoscope, the sphincter of Oddi is widened (sphincterotomy). A basket is used to retrieve the stone. The stone may be removed in the basket, but more commonly it is left in the duodenum and will be passed naturally in the stool.

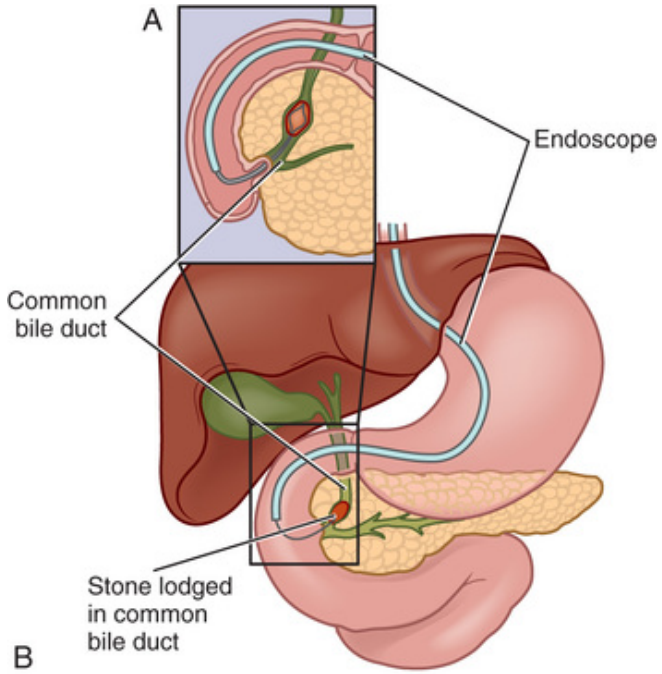

FIGURE 46-18 Standard endoscopic retrograde cholangiopancreatography (ERCP). **A,** During endoscopic sphincterotomy, an endoscope is advanced through the mouth and stomach until its tip sits in the duodenum opposite the common bile duct. **B,** After widening the duct mouth by incising the sphincter muscle, the physician advances a basket attachment into the duct and snags the stone.

Extracorporeal shock-wave lithotripsy (ESWL) is another nonsurgical treatment for gallstones. In ESWL, a lithotripter uses high-energy shock waves to disintegrate gallstones once they have been located by ultrasound. It usually takes 1 to 2 hours to disintegrate the stones. After

they are broken up, the fragments pass through the common bile duct and into the small intestine. Usually ESWL and oral dissolution therapy are used together.

Cholecystitis.

During an acute episode of cholecystitis, the focus of treatment is on control of pain, control of possible infection with antibiotics, and maintenance of fluid and electrolyte balance (Table 46-22). If nausea and vomiting are severe, an NG tube may be inserted, and gastric decompression may be used to prevent further gallbladder stimulation. Anticholinergics are administered to decrease secretion and counteract smooth muscle spasms. Analgesics are given for pain relief.

TABLE 46-22

COLLABORATIVE CARE
Cholelithiasis and Acute Cholecystitis

Diagnostic	• ERCP with sphincterotomy (papillotomy)
• History and physical examination	• Extracorporeal shock-wave lithotripsy
• ERCP	• Fat-soluble vitamins (A, D, E, and K)
• Liver enzyme measurements	• IV fluids
• Serum bilirubin	• NPO with NG tube, later progressing to low-fat diet
• Ultrasound	***Dissolution Therapy***
• WBC count	• Ursodeoxycholic acid
Collaborative Therapy	***Surgical Therapy****
Conservative Therapy	• Incisional cholecystectomy
• Analgesics	• Laparoscopic cholecystectomy
• Antiemetics	
• Antibiotics (for secondary infection)	
• Anticholinergics (antispasmodics)	

*See Table 46-23.

ERCP, endoscopic retrograde cholangiopancreatography; *IV,* intravenous; *NG,* nasogastric; *NPO,* nothing by mouth; *WBC,* white blood cell.

Surgical Therapy.

Laparoscopic cholecystectomy is the treatment of choice for symptomatic cholelithiasis. Approximately 92% of all cholecystectomies are performed laparoscopically. In this procedure, the gallbladder is removed through one to four small punctures in the abdomen. A 1-cm puncture is made slightly above the umbilicus, and the surgeon inflates the abdominal cavity with 3 to 4 L of CO_2 to improve visibility. A laparoscope that has a camera attached is inserted into the abdomen. Two additional punctures made just below the ribs are used for insertion of grasping forceps. A

dissection laser is inserted into the fourth puncture. (The incision sites may vary.) Using closed-circuit monitors to view the abdominal cavity, the surgeon retracts and dissects the gallbladder and removes it with grasping forceps.

This procedure is relatively minor and entails few complications. Most patients have minimal postoperative pain and are discharged the day of or the day after surgery. In most cases, patients are able to resume normal activities and return to work within 1 week. The main complication is injury to the common bile duct. The few contraindications to laparoscopic cholecystectomy include peritonitis, cholangitis, gangrene or perforation of the gallbladder, portal hypertension, and serious bleeding disorders.

On select patients, an incisional (open) cholecystectomy may be performed. This procedure involves removal of the gallbladder through a right subcostal incision. A T-tube is inserted into the common bile duct during surgery when a common bile duct exploration is part of the surgical procedure (Figure 46-19). This ensures patency of the duct until the edema produced by the trauma of exploring and probing the duct has subsided. It also allows the excess bile to drain while the small intestine is adjusting to receiving a continuous flow of bile.

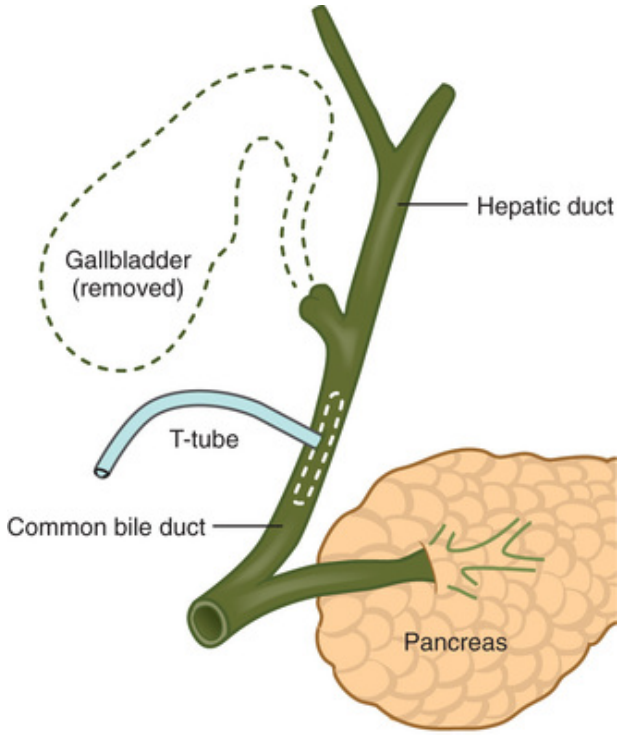

FIGURE 46-19 Placement of T-tube during cholecystectomy. *Dotted lines* indicate parts removed.

Transhepatic Biliary Catheter.

The transhepatic biliary catheter can be used preoperatively in biliary obstruction and in hepatic dysfunction secondary to obstructive jaundice. It can also be inserted for palliative care when inoperable carcinoma of the liver, pancreatic duct, or bile duct obstructs bile flow. Under fluoroscopic guidance, the catheter is percutaneously inserted across the liver parenchyma into the common bile duct and duodenum. It decompresses obstructed extrahepatic bile ducts so that bile can flow freely. After insertion, the catheter is connected to a drainage bag. The skin around the catheter insertion site has to be cleansed daily with an antiseptic. It is important to observe for bile leakage at the insertion site. Depending on the reason for the catheter, the patient may be discharged with it in place.

Drug Therapy.

The most common drugs used in the treatment of gallbladder disease are analgesics, anticholinergics (antispasmodics), fat-soluble vitamins, and bile salts. Morphine or meperidine (Demerol) may be administered for pain management. Anticholinergics such as atropine and other antispasmodics may be administered to relax the smooth muscle and decrease ductal tone.

If a patient has chronic gallbladder disease or any biliary tract obstruction, fat-soluble vitamins (A, D, E, and K) will probably be given. Bile salts may be administered to facilitate digestion and vitamin absorption. For treatment of pruritus, cholestyramine may provide relief. Cholestyramine is a resin that binds bile salts in the intestine, increasing their excretion in the feces. It is administered in powder form and should be mixed with milk or juice. Adverse effects include nausea, vomiting, diarrhea or constipation, and skin reactions.

Nutritional Therapy.

Many patients have fewer problems if they eat smaller, more frequent meals, with some fat at each meal to promote gallbladder emptying. If obesity is a problem, a reduced-calorie diet is indicated. The diet should be low in saturated fats (e.g., butter, shortening) and high in fibre and calcium. Rapid weight loss should be avoided because it can promote gallstone formation. After a laparoscopic cholecystectomy, the patient should have liquids for the rest of the day and eat light meals for a few days. If an incisional cholecystectomy is performed, the patient may progress from liquids to a bland diet once bowel sounds have returned. The amount of fat in the postoperative diet depends on the patient's tolerance of fat. A low-fat diet may be helpful if the flow of bile is reduced (usually only in the early postoperative period) or if the patient is overweight. Some patients need to restrict fats for 4 to 6 weeks. Otherwise, no special dietary instructions are needed other than to eat nutritious meals and avoid excessive fat intake.

Nursing Management Gallbladder Disease

Nursing Assessment

Subjective and objective data that should be obtained from a person with gallbladder disease are presented in Table 46-23.

TABLE 46-23

NURSING ASSESSMENT
Cholecystitis or Cholelithiasis

Subjective Data
Important Health Information
Past health history: Obesity, multiparity, infection, cancer, extensive fasting, pregnancy; positive family history; sedentary lifestyle *Medications:* estrogen or oral contraceptives *Surgery or other treatments:* Previous abdominal surgery
Symptoms
• Clay-coloured stools, steatorrhea, flatulence; dark urine • Moderate to severe pain in right upper quadrant that may radiate to the back or scapula • Positive Murphy sign • Pruritus • Weight loss, anorexia; indigestion, fat intolerance, nausea and vomiting, dyspepsia; chills
Objective Data
General
Fever, restlessness
Integumentary
Jaundice, icteric sclera; diaphoresis
Respiratory
Tachypnea, splinting during respirations
Cardiovascular
Tachycardia
Gastro-Intestinal
Palpable gallbladder, abdominal guarding and distension
Possible Findings
↑ Serum liver enzymes and bilirubin; absence of urobilinogen in urine; ↑ urinary bilirubin; leukocytosis; abnormal ultrasound findings

Nursing Diagnoses

Nursing diagnoses for patients with gallbladder disease treated surgically include but are not limited to the following:

- *Acute pain* related to physical injury agent (surgical procedure)
- *Ineffective health management* related to *insufficient resources* (lack of knowledge of diet and postoperative management)

Planning

The overall goals are that the patient with gallbladder disease will have (a) relief of pain and discomfort, (b) no complications postoperatively, and (c) no recurrent attacks of cholecystitis or cholelithiasis.

Nursing Implementation

Health Promotion.

The nurse should recognize the predisposing factors for gallbladder disease in general health screening. Patients at risk should be taught initial clinical manifestations and be instructed to seek medical care if these manifestations occur. Patients with chronic cholecystitis do not have acute symptoms and may not seek help until jaundice and biliary obstruction occur. Earlier detection in these patients is beneficial so that the condition can be managed with lifestyle modifications (e.g., a low-fat diet).

Acute Intervention.

Nursing objectives for the patient undergoing conservative therapy include managing pain, relieving nausea and vomiting, providing comfort and emotional support, maintaining fluid and electrolyte balance, maintaining nutrition, making accurate assessments of effectiveness of treatment, and observing for complications.

Many patients with acute cholecystitis or cholelithiasis have severe pain. The medications ordered to relieve the pain should be administered as required by patients and before the pain becomes more severe. The nurse should determine what medications relieve the pain and how much medication is required. The nurse must also observe for adverse effects of the medications. Nursing comfort measures, such as a clean bed, comfortable positioning, and oral care, are appropriate.

For patients who have severe nausea and vomiting, insertion of an NG tube and gastric decompression may be necessary. Eliminating food and

fluid intake also prevents further stimulation of the gallbladder. Oral hygiene, care of nares, accurate intake and output measurements, and maintenance of suction should be a part of the nursing care plan for such patients. For patients with less severe nausea and vomiting, antiemetics are usually adequate. When a patient is vomiting, comfort measures such as frequent mouth rinses should be provided. Any vomitus must be removed immediately from the patient's view.

If pruritus occurs with jaundice, measures to relieve itching include baking soda or oatmeal baths; lotions, such as those containing calamine; antihistamines; soft, old linen; and control of the temperature (not too hot and not too cold). The patient's nails should be kept short and clean. Patients should be taught to rub with their knuckles rather than scratch with their nails when they cannot resist scratching.

The nursing care plan for such patients also includes assessment of progression of the symptoms and development of complications. The nurse should observe for signs of bile duct obstructions: jaundice; clay-coloured stools; dark, foamy urine; steatorrhea; fever; and increased WBC count.

When symptoms of obstruction are present (see Table 46-21), the nurse must be aware of possible bleeding as a result of decreased prothrombin production. Common sites to observe for bleeding are the mucous membranes of the mouth, the nose, the gingivae, and injection sites. If injections are given, a small-gauge needle should be used and gentle pressure applied after the injection. The nurse should know the patient's prothrombin time and use this as a guide in the assessment process.

Assessment for infections includes monitoring of vital signs. Fever with chills and jaundice may indicate choledocholithiasis. Nursing care of the patient after ERCP with papillotomy includes assessment to detect complications such as pancreatitis, perforation, infection, and bleeding. Abdominal pain and fever may indicate pancreatitis. The patient should be rested for several hours and ingest nothing by mouth until the gag reflex returns.

Postoperative Care.

Postoperative nursing care after a laparoscopic cholecystectomy includes monitoring for complications such as bleeding, making the patient comfortable, and preparing the patient for discharge. A common postoperative problem is referred pain to the shoulder because of the carbon dioxide (CO_2) that is used to inflate the abdominal cavity during surgery. CO_2 may not be released or absorbed by the body. The CO_2 can

irritate the phrenic nerve and the diaphragm, causing some difficulty breathing. Placing the patient in a Sims position (left side with right knee flexed) helps move the gas pocket away from the diaphragm. Deep breathing and early ambulation should be encouraged. Severe pain can be relieved by opioid analgesics such as oxycodone or codeine. The patient is allowed clear liquids and can walk to the bathroom to void. Many patients go home the same day as the procedure.

Postoperative nursing care for incisional cholecystectomy is the same as general postoperative nursing care (see Chapter 22). The goal is to prevent postoperative complications. If the patient has a T-tube (see Figure 46-19), the nursing care plan should focus on maintaining bile drainage and observing for the T-tube functioning and drainage. The T-tube is connected to a closed gravity drainage system. If the Penrose or Jackson-Pratt drain or the T-tube is draining large amounts, a sterile pouching system should be used to protect the skin.

Ambulatory and Home Care.

For patients who have conservative therapy, long-term nursing management depends on symptoms and on whether surgical intervention is planned. Dietary teaching is usually necessary. The food should be low in fat. A weight-reduction program should be recommended for patients with obesity. Patients may need to take fat-soluble vitamin supplements. The nurse should instruct patients about symptoms that indicate obstruction (stool and urine changes, jaundice, and pruritus). The nurse should explain the importance of continued follow-up care. Patients who undergo a laparoscopic cholecystectomy are discharged soon after the surgery; therefore, home care is important. Teaching is essential; a teaching guide is presented in Table 46-24.

TABLE 46-24

PATIENT & CAREGIVER TEACHING GUIDE
Laparoscopic Cholecystectomy: Postoperative Care

The following guidelines should be included when teaching the patient and caregiver about postoperative care following laparoscopic cholecystectomy.
1. Remove the bandages on the puncture site the day after surgery, and bathe or shower. 2. Notify the surgeon of any of the following signs and symptoms: • Redness; swelling; bile-coloured drainage or pus from any incision • Severe abdominal pain, nausea, vomiting, fever, chills 3. Resume normal activities gradually. 4. Return to work within 1 week of surgery if no complications ensue. 5. Resume normal diet; a low-fat diet, however, is usually better tolerated for several weeks after surgery.

After an incisional cholecystectomy, the patient is usually discharged in 2 to 3 days. The patient must avoid heavy lifting for 4 to 6 weeks. Usual sexual activities, including intercourse, can be resumed as soon as the patient feels ready, unless the physician instructs otherwise. If the patient is required to remain on a low-fat diet for 4 to 6 weeks, a dietary teaching plan is necessary. A weight-reduction program may be helpful if the patient is overweight. Most patients tolerate a regular diet with no difficulties but should avoid excessive fats.

Evaluation

The overall expected outcomes are that the patient with gallbladder disease will (a) be comfortable and free of pain and (b) will verbalize understanding of activity level and dietary restrictions.

Gallbladder Cancer

Primary cancer of the gallbladder is uncommon. The majority of gallbladder carcinomas are adenocarcinomas. A relationship exists between cancer of the gallbladder and chronic cholecystitis and cholelithiasis. The early symptoms of carcinoma of the gallbladder are insidious and are similar to those of chronic cholecystitis and cholelithiasis, which makes diagnosis difficult. Later symptoms are usually those of biliary obstruction.

Diagnosis and staging of gallbladder cancer are done using endoscopic ultrasound, transabdominal ultrasound, CT, MRI, MRCP, or a combination of these methodologies. Unfortunately, gallbladder cancer often is not detected until the advanced stage. When it is found early, surgery can be curative. Several factors influence successful surgical outcomes, including the depth of cancer invasion, extent of liver involvement, presence of

venous or lymphatic invasion, and lymph node metastasis. Extended cholecystectomy with lymph node dissection has improved the outcomes for patients with gallbladder cancer.

When surgery is not an option, endoscopic implantation of stents in the biliary tree to reduce obstructive jaundice can be done. Adjuvant therapies, including radiation therapy and chemotherapy, may be used, depending on the disease state. Overall, cancer of the gallbladder has a poor prognosis.

Nursing management involves supportive care with special attention to nutrition, hydration, skin care, and pain relief. Many of the nursing care measures used for patients with cholecystitis and cholelithiasis are frequently applied, as are nursing care measures for patients with cancer (see Chapter 18).

Case Study

Cirrhosis of the Liver

Source: triocean/Shutterstock.com.

Patient Profile

Mr. Arnold Bisson is a 55-year-old man admitted with a diagnosis of an upper GI bleed secondary to cirrhosis of the liver.

Subjective Data

- Has been vomiting for 2 days, noticed blood in the toilet when he vomits
- Was informed 10 years ago that he had cirrhosis
- Had a blood transfusion 25 years ago after a car accident

- Acknowledges that he has been drinking heavily for more than 30 years
- Complains of anorexia, nausea, and abdominal discomfort

Objective Data

Physical Examination

- Is thin and malnourished
- Has moderate ascites
- Has jaundice of sclera and skin
- Has 4+ pitting edema of the lower extremities
- Has palpable liver and spleen

Laboratory Values

- Total bilirubin: 150 mcmol/L
- Albumin: 26 g/L
- AST: 210 U/L
- ALT: 190 U/L
- Hb 60 g/L and Hct of 20%
- Platelet count: 75×10^9/L
- INR: 2.1
- Anti-HCV (antibody to hepatitis C) positive and HCV RNA negative
- HBsAg (hepatitis B surface antigen) negative and anti-HBs (antibody to hepatitis B surface antigen) positive

Discussion Questions

1. What are the possible causes of cirrhosis? What is the most likely etiology responsible for Mr. Bisson's cirrhosis?
2. Describe the pathophysiological changes that occur in the liver as cirrhosis develops.
3. List Mr. Bisson's clinical manifestations of liver failure. For each manifestation, explain the pathophysiological basis.
4. Explain the significance of the results of his laboratory values.

5. If Mr. Bisson begins to manifest signs and symptoms of hepatic encephalopathy, what would the nurse monitor? What measures should be instituted to control or decrease encephalopathy?
6. Mr. Bisson was being closely observed for the possibility of gastro-intestinal bleeding. Why is this considered a possible complication?
7. ***Priority decision:*** On the basis of the assessment data presented, what are the nursing diagnoses? Are there any collaborative problems?
8. ***Priority decision:*** What are the priority nursing interventions for the patient at this stage of his illness?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. During assessment of a client with posthepatic (cholestatic) jaundice, which of the following would the nurse expect to find?
   a. Clay-coloured stools
   b. Dark urine and stools
   c. Pyrexia and severe pruritus
   d. Elevated urinary urobilinogen level
2. A client with hepatitis A is in the acute phase. Which of the following should the nurse's plan of care consider?
   a. Pruritus is a common problem with jaundice in this phase.
   b. The client is most likely to transmit the disease during this phase.
   c. Gastro-intestinal symptoms are not as severe in hepatitis A as they are in hepatitis B.
   d. Extrahepatic manifestations of glomerulonephritis and polyarteritis are common in this phase.
3. A client with acute hepatitis B is being discharged in 2 days. Which of the following instructions should the nurse include in the discharge teaching plan?
   a. Resume alcohol as soon as he is symptom free.
   b. Use a condom during sexual intercourse.
   c. Have family members get an injection of immune globulin.
   d. Follow a low-protein, moderate-carbohydrate, moderate-fat diet.
4. A client with advanced cirrhosis asks the nurse why his abdomen is so swollen. The nurse's response is based on the knowledge of which of the following?
   a. A lack of clotting factors promotes the collection of blood in the abdominal cavity.
   b. Portal hypertension and hypoalbuminemia cause a fluid shift into the peritoneal space.
   c. Decreased peristalsis in the gastro-intestinal tract contributes to gas formation and distension of the bowel.

d. Bile salts in the blood irritate the peritoneal membranes, causing edema and pocketing of fluid.

5. A client has been told that she has elevated liver enzyme caused by NAFLD. Which of the following instructions should the nurse's teaching plan include?
   a. Have genetic testing performed.
   b. Follow a heart-healthy diet and regular exercise program.
   c. Lose weight quickly within the next 4 weeks.
   d. Avoid alcohol until the liver enzyme levels return to normal.
6. In caring for a client with metastatic liver cancer, which of the following should the nurse perform?
   a. Focus primarily on symptomatic and comfort measures
   b. Reassure the client that chemotherapy offers a good prognosis for recovery
   c. Promote the client's confidence that surgical excision of the tumour will be successful
   d. Provide information necessary for the client to make decisions regarding liver transplantation
7. Nursing management of a client with acute pancreatitis includes which of the following? *(Select all that apply)*
   a. Checking for signs of hypocalcemia
   b. Observing stools for signs of steatorrhea
   c. Providing a diet low in carbohydrates with moderate fat
   d. Giving insulin based on a sliding scale
   e. Monitoring for infection, particularly respiratory tract infection
8. A client with pancreatic cancer is admitted to the hospital for evaluation for treatment. The client asks the nurse to describe Whipple procedure, which the surgeon has planned. Which of the following would the nurse include in her explanation?
   a. Creation of a bypass around the obstruction caused by the tumour by joining the gallbladder to the jejunum
   b. Resection of the entire pancreas and the distal portion of the stomach, with anastomosis of the common bile duct and the stomach into the duodenum

c. Removal of part of the pancreas, part of the stomach, the duodenum, and the gallbladder, with joining of the pancreatic duct, the common bile duct, and the stomach to the jejunum

d. Radical removal of pancreas, duodenum, and spleen, and attachment of the stomach to the jejunum, which requires oral supplementation of pancreatic digestive enzymes and insulin replacement therapy

9. The nursing management of a client with cholecystitis in association with cholelithiasis should include which of the following?

a. Recommendation of a diet low in saturated fat

b. Information that gallstones once removed tend not to recur

c. Avoidance of morphine in the management of pain

d. Treatment with oral bile salts that dissolve gallstones

10. What information should be included in teaching about home management after a laparoscopic cholecystectomy?

a. Keeping the bandages on the puncture sites for 48 hours

b. Reporting any bile-coloured drainage or pus from any incision

c. Using over-the-counter antiemetics if nausea and vomiting occur

d. Emptying and measuring the contents of the bile bag from the T-tube every day

1. a; 2. b; 3. b; 4. b; 5. b; 6. a; 7. a, e; 8. c; 9. a; 10. b.

CHAPTER 47

Nursing Assessment

Urinary System

Written by:, Suzanne Teresa Parsell

Adapted by:, Kathleen Rodger, Lynn Jansen

LEARNING OBJECTIVES

1. Describe the anatomical location and functions of the kidneys, the ureters, the bladder, and the urethra.
2. Explain the physiological events involved in the formation and passage of urine, from glomerular filtration to voiding.
3. Identify relevant subjective patient information and objective data that should be collected to determine health history, health status, and clinical manifestations of patients with urinary disorders.
4. Describe age-related changes in the urinary system.
5. Describe the appropriate techniques used in the physical assessment of the urinary system.
6. Differentiate normal from common abnormal findings of a physical assessment of the urinary system.
7. Describe the range of tests performed in the analysis of urine.
8. Describe the normal physical and chemical characteristics of urine.

"Bones can break, muscles can atrophy, glands can loaf, even the brain can go to sleep without immediate danger to survival. But should the kidneys fail … neither bone, muscle, gland, nor brain could carry on" (Smith, 1953). This statement underlines the importance of kidneys to our lives. Adequate functioning of the kidneys is essential to the maintenance of a healthy body. If the kidneys fail completely and treatment is not given, death is inevitable.

The primary functions of the kidneys are (a) to filter waste products from the bloodstream, (b) to maintain fluid and electrolyte and acid–base balance in the body, and (c) to excrete metabolic waste products. The two kidneys perform the primary physiological functions. Secondary functions of the kidneys are to regulate (a) blood pressure, (b) bone density, and (c) erythropoiesis. The kidneys are connected to two narrow tubules, the ureters, which reabsorb 99% of filtered products and transport urine from the kidney to the bladder. Urine flows from the bladder and from the body through the urethra (Figure 47-1).

Structures and Functions of the Urinary System

Kidneys

Macrostructure.

The paired kidneys are bean-shaped organs that are retroperitoneal (behind the peritoneum), on either side of the vertebral column at about the level of the twelfth thoracic (T12) vertebra to the third lumbar (L3) vertebra. Each kidney weighs 115 to 175 g and is about 12 cm long. With the liver above it, the right kidney is at the level of the twelfth rib, lower than the left kidney. An adrenal gland lies on top of each kidney.

Each kidney is surrounded by a considerable amount of fat and connective tissue that serve to support and maintain its position. The surface of the kidney is covered by a thin, smooth layer of fibrous membrane called the *capsule.* These structures protect the kidney and serve as a shock absorber should the kidney be subjected to a sudden force from a blunt object striking the abdomen or back. The *hilus* on the medial side of the kidney serves as the entry site for the renal artery and nerves, as well as the exit site for the renal vein and the ureter.

On a longitudinal section of the kidney (Figure 47-2), the parenchyma (actual tissue) of the kidney can be visualized. The outer layer is termed the *cortex,* and the inner layer is called the *medulla.* The medulla consists of a number of pyramids. The apices of these pyramids are called *papillae,* and urine passes through the papillae to enter the calyces. The minor calyces widen and merge to form major calyces, which form a funnel-shaped sac called the *renal pelvis.* The minor and major calyces transport urine to the renal pelvis in preparation for transportation to the bladder via the ureter. The renal pelvis can store a small volume of urine (3 to 5 mL).

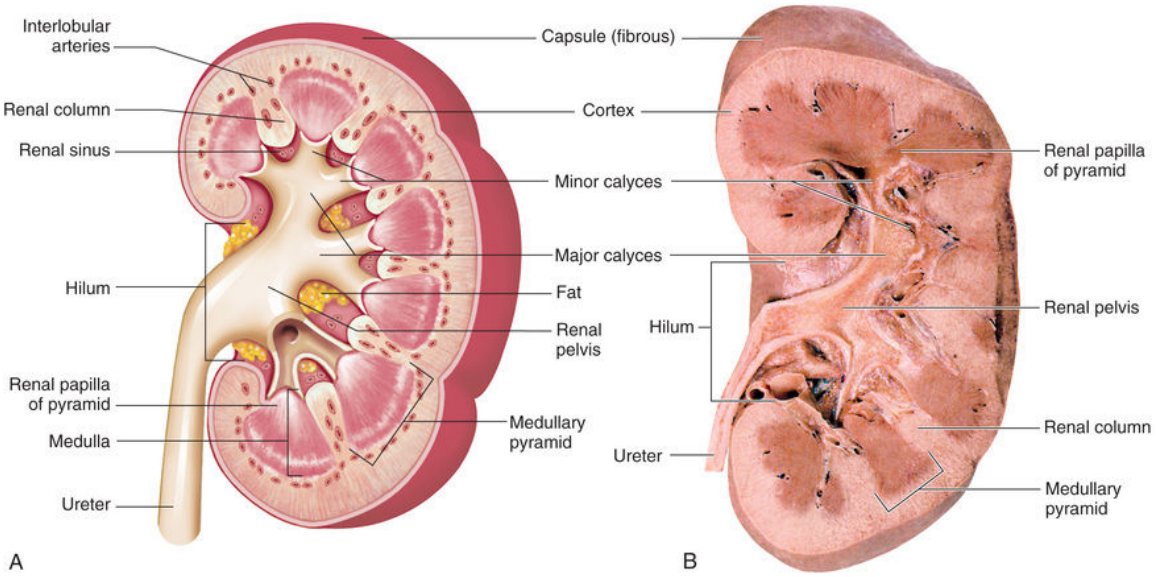

FIGURE 47-2 Illustration of a longitudinal section of the kidney.

Microstructure.

The functional unit of the kidney is the **nephron.** Each kidney has about 1 million nephrons. A nephron is composed of a glomerulus, Bowman capsule, and the tubular system. The tubular system consists of the proximal convoluted tubule, the loop of Henle, and the distal convoluted tubule (Figure 47-3). The glomeruli, Bowman capsule, the proximal tubule, and the distal tubule are located in the cortex of the kidney. The loop of Henle and the collecting ducts are located in the medulla (Figure 47-4; see also Figure 47-2). Several nephrons converge into a collecting duct, which eventually merges into a pyramid and empties via the papilla into a minor calyx (see Figures 47-2 and 47-4).

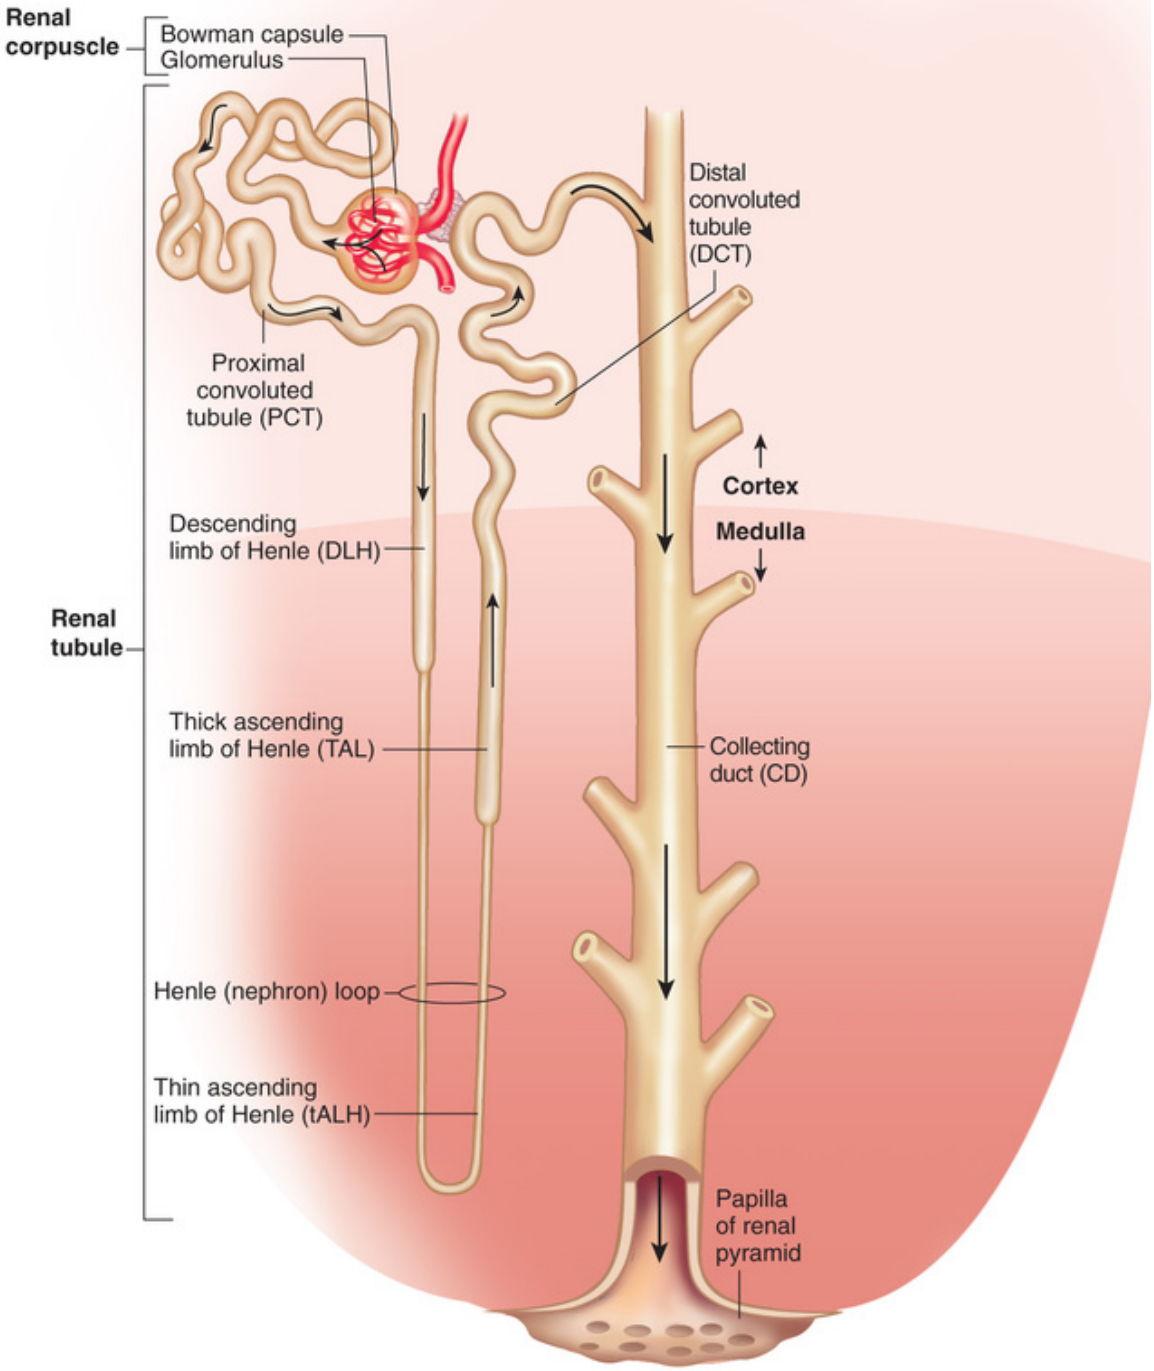

FIGURE 47-3 The nephron is the basic functional unit of the kidney. This illustration of a single nephron unit also shows the surrounding blood vessels. Source: From Patton, K. T., & Thibodeau, G. A., (2015). *Anatomy and physiology* (9th ed., p. 971, Figure 42-10). St. Louis: Mosby.

Blood Supply.

A blood supply of about 1200 mL/min, which is 20% to 25% of total cardiac output, flows to the two kidneys. Blood reaches the kidneys via the renal artery, which arises from the aorta and enters the kidney through the hilus. The renal artery divides into secondary branches and then into still smaller branches, each of which eventually forms an afferent arteriole. The afferent arteriole divides into a capillary network termed the *glomerulus,* which is a tuft of up to 50 capillaries. The capillaries of the glomerulus eventually unite in the efferent arteriole (Figure 47-5). This arteriole splits to form a capillary network called the *peritubular capillaries,* which, as the name suggests, surround the tubular system. All peritubular capillaries eventually drain into the venous system. The renal vein empties into the inferior vena cava.

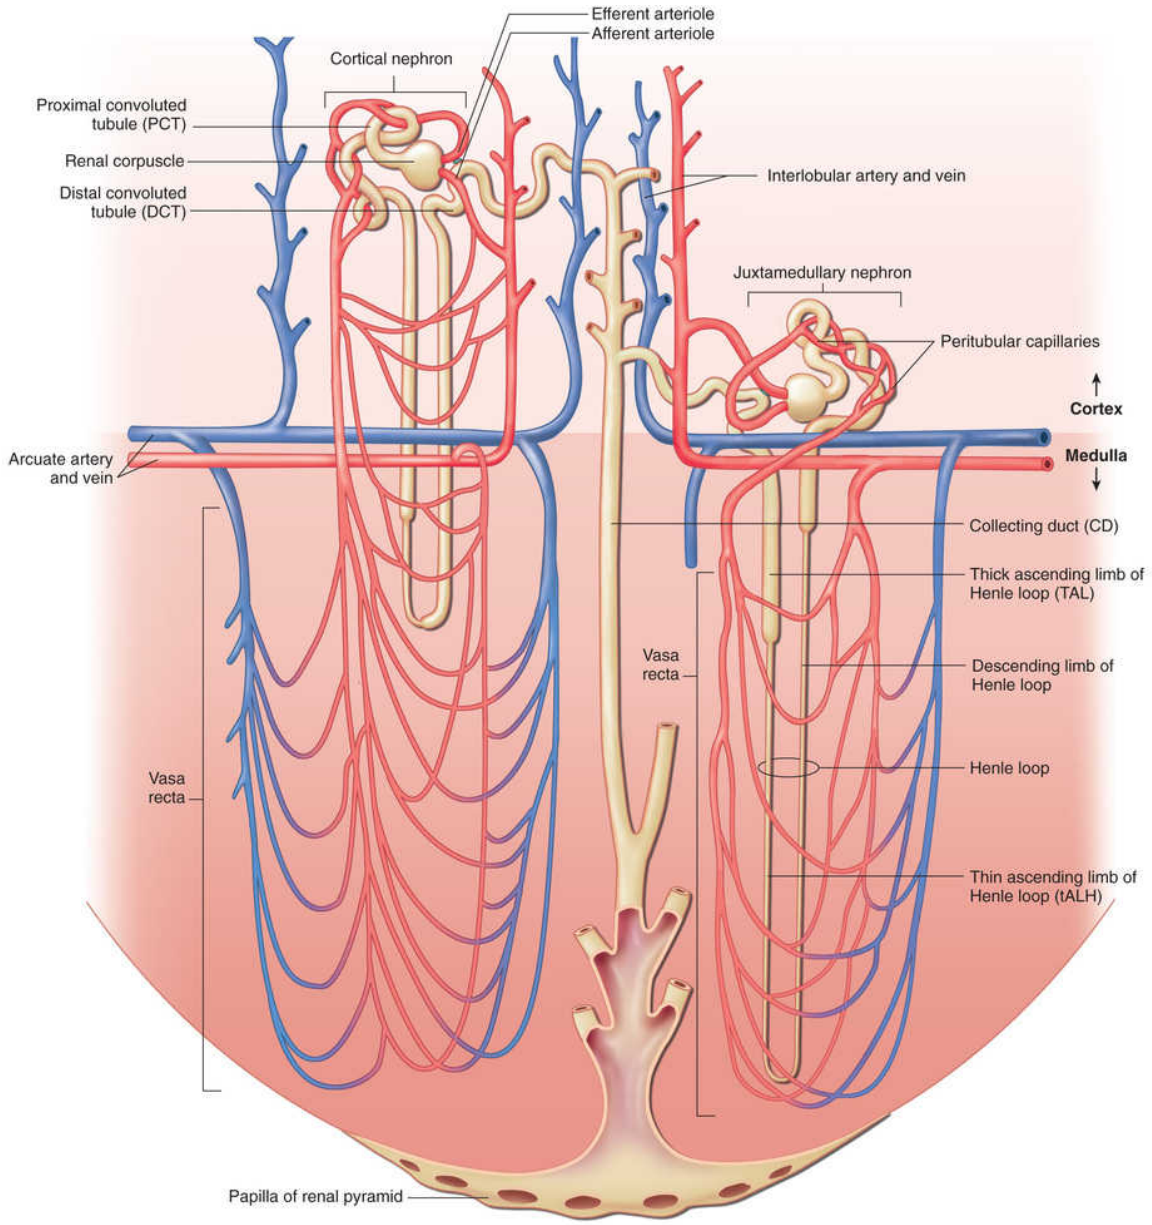

FIGURE 47-5 Blood supply of nephrons. In this illustration, two types of nephrons (cortical and juxtaglomerular) are shown surrounded by the peritubular blood supply. Source: From Patton, K. T., & Thibodeau, G. A. (2013). *Anatomy and physiology* (8th ed., p. 981, Figure 31-17). St. Louis: Mosby.

Physiology of Urine Formation.

The process of urine formation is extremely complex. It represents the outcome of a multistep process of filtration, reabsorption, secretion, and excretion of water, electrolytes, and metabolic waste products. Although

urine formation is the result of this process, the primary function of the kidneys is to filter the blood and maintain the body's internal homeostasis.

Glomerular Function.

Urine formation starts at the glomerulus, where blood is filtered. The **glomerulus,** a capillary network within the kidneys that comprises up to 50 capillaries, is a semipermeable membrane and so allows for filtration (see Figure 47-3). The hydrostatic pressure of the blood within the glomerular capillaries causes a portion of blood to be filtered across the semipermeable membrane into Bowman capsule, where the filtered portion of the blood, called the *glomerular filtrate,* begins to pass down to the tubule. Filtration is more rapid in the glomerulus than in ordinary tissue capillaries because of the porosity of the glomerular membrane. The ultrafiltrate is similar in composition to blood except that it lacks blood cells, platelets, and large plasma proteins. Under normal conditions, the capillary pores are too small to allow the loss of these large blood components. Capillary permeability is increased in many renal diseases, enabling plasma proteins to pass into the urine.

The amount of blood filtered by the glomeruli in a given time is termed the **glomerular filtration rate (GFR).** The normal GFR is about 125 mL/min (Grossman & Porth, 2014). However, on average, only 1 mL is excreted as urine per minute because the peritubular capillary network reabsorbs most glomerular filtrate before it reaches the end of the collecting duct.

Tubular Function.

Because the glomerular membrane is a selective filtration membrane that filters primarily by size, provision is made for the reabsorption of essential materials and the excretion of nonessential ones (Table 47-1).

TABLE 47-1

FUNCTIONS OF THE SEGMENTS OF THE NEPHRON

Component	Function
Glomerulus	Selective filtration of water and solutes from the blood
Proximal tubule	Reabsorption of 80% of electrolytes and water; reabsorption of all glucose and amino acids; reabsorption of HCO_3^-; secretion of H^+ and creatinine
Loop of Henle	Reabsorption of Na^+ and Cl^- in ascending limb; reabsorption of water in descending loop; concentration of filtrate
Distal tubule	Secretion of K^+, H^+, and ammonia; reabsorption of water (regulated by ADH); reabsorption of HCO_3^-; regulation of Ca^{2+} and PO_4^{2-} by parathyroid hormone, regulation of Na^+ and K^+ by aldosterone
Collecting duct	Reabsorption of water (ADH required)

ADH, antidiuretic hormone; Ca^{2+}, calcium; Cl^-, chloride; H^+, hydrogen; HCO_3^-, bicarbonate; K^+, potassium; Na^+, sodium; PO_4^{2-}, phosphate.

In the proximal convoluted tubule, about 80% of the electrolytes are reabsorbed. Normally, all the glucose, amino acids, and small proteins are reabsorbed. For the most part, reabsorption occurs by active transport. Hydrogen ions (H^+) and creatinine are secreted into the filtrate (Grossman & Porth, 2014).

The loop of Henle is important in conserving water and thus concentrating the filtrate. Reabsorption continues in the loop of Henle. The descending loop is permeable to water and moderately permeable to sodium, urea, and other solutes. In the ascending limb, chloride ions (Cl^-) are actively reabsorbed, followed passively by sodium ions (Na^+). About 25% of the filtered sodium is reabsorbed in the ascending limb.

Two important functions of the distal convoluted tubules are final regulation of water balance and acid–base balance (Grossman & Porth, 2014). Antidiuretic hormone (ADH), released by the posterior portion of the pituitary gland, is required for water reabsorption. The stimuli for ADH release are increased serum osmolality and decreased blood volume. ADH makes the distal convoluted tubules and the collecting ducts permeable to water, allowing it to be reabsorbed into the peritubular capillaries and to be eventually returned to circulation. In the absence of ADH, the tubules are practically impermeable to water, and any water in the tubules leaves the body as urine.

In the presence of aldosterone (released from the adrenal cortex) acting on the distal tubule, reabsorption of Na^+ and water occurs. In exchange, potassium ions (K^+) are excreted. The secretion of aldosterone is influenced

by both circulating blood volume and plasma concentrations of Na^+ and K^+.

Acid–base regulation involves reabsorbing and conserving most of the bicarbonate (HCO_3^-) and secreting excess H^+. The distal tubule functions in different ways to maintain the pH of extracellular fluid (ECF) volume within a range of 7.35 to 7.45 (see Chapter 19).

Atrial natriuretic factor (ANF) is a hormone secreted from cells in the right atrium when right atrial blood pressure increases. ANF inhibits the secretion and effect of ADH and results in a large volume of dilute urine.

Parathyroid hormone is released from the parathyroid gland in response to low serum calcium levels. It causes increased tubular reabsorption of calcium ions (Ca^{2+}) and decreased tubular reabsorption of phosphate ions (PO_4^{2-}). Therefore, serum Ca^{2+} levels are increased.

The basic function of nephrons is to cleanse or clear blood plasma of unnecessary substances. After the glomerulus has filtered the blood, the tubules separate the portions of tubular fluid that are useful to the body from those that are not. The necessary portions are returned to the blood, and the unnecessary portions pass into urine as waste.

Other Functions of the Kidney.

In addition to their function of regulating the volume and the composition of ECF, the kidneys have other vital functions, including the production of erythropoietin, activation of vitamin D, and production and secretion of renin.

Production of Erythropoietin.

Erythropoietin is a hormone produced by the kidney and released in response to hypoxia and decreased renal blood flow. Erythropoietin stimulates the production of red blood cells (RBCs) in the bone marrow. A deficiency of erythropoietin in renal failure leads to anemia.

Activation of Vitamin D.

Vitamin D is a hormone that can be obtained in the diet or synthesized by the action of ultraviolet radiation on cholesterol in the skin. These forms of vitamin D are inactive and require two more steps to become metabolically active. The first step in activation occurs in the liver; the second step occurs in the kidneys. Active vitamin D is essential for the absorption of calcium from the gastro-intestinal (GI) tract. The patient with kidney failure (also called *renal failure*) has a deficiency of the active

metabolite of vitamin D and manifests as problems of altered calcium and phosphate balance.

Production and Secretion of Renin.

Renin, an enzyme, is important in the regulation of blood pressure and is the first step in the RAA (renin–angiotensin–aldosterone) pathway. Renin is released from the *juxtaglomerular apparatus* of the nephron (Figure 47-6) in response to decreased arterial blood pressure, renal ischemia, ECF depletion, increased norepinephrine, and increased urinary Na^+ concentration. Renin catalyzes the splitting of the plasma protein angiotensinogen (from the liver) into angiotensin I, which is subsequently converted to angiotensin II by a converting enzyme made in the lungs. Angiotensin II stimulates the release of aldosterone from the adrenal cortex, which causes retention of Na^+ and water, leading to an increase in ECF. Angiotensin II also causes increases in peripheral vasoconstriction. The increases in ECF and vasoconstriction cause an elevation in blood pressure, which inhibits renin release. Excessive renin production caused by impaired renal perfusion may be a contributing factor in hypertension (see Chapters 35 and 49).

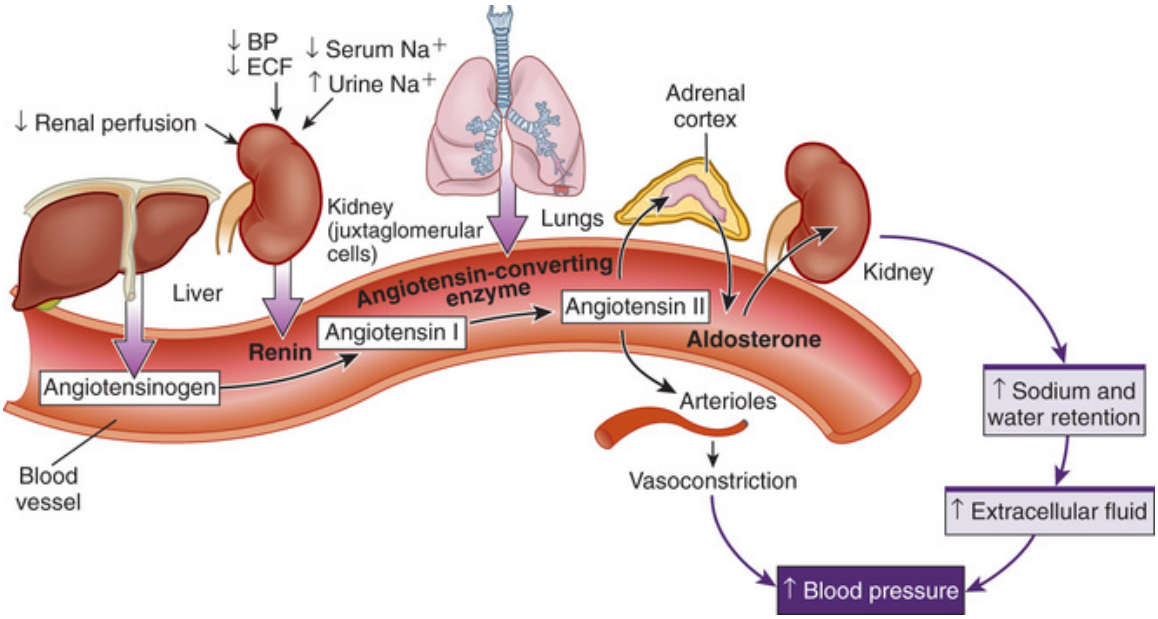

FIGURE 47-6 Renin–angiotensin–aldosterone system. Source: Adapted from Herlihy, B. (2014). *The human body in health and illness* (5th ed., p. 466, Figure 24-3). Philadelphia: W. B. Saunders.

ANF acts directly on the medullary collecting ducts and indirectly on other tubular segments (by inhibiting several steps in the RAA pathway) to inhibit sodium reabsorption. It inhibits secretion of renin and aldosterone and causes an increase in GFR (through its effects on the renal arterioles), all of which increase excretion of sodium and water. Angiotensin converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are commonly used drugs to help control blood pressure in patients with hypertension. Since the mechanism of action works directly on RAA pathway, these drugs are also understood to cause adverse effects that can directly impact kidney function, such as proteinuria, increased serum creatinine, nephrotic syndrome, and renal failure (McCance & Huether, 2014).

Prostaglandins (PGs) are important regulators of cellular function. In the kidney, PG synthesis (primarily PGE_2 and PGI_2) occurs primarily in the medulla. These PGs have a vasodilating action in addition to increasing renal blood flow and promoting Na^+ excretion. They also counteract the vasoconstrictor effect of substances such as angiotensin and norepinephrine. Renal PGs may have a systemic effect in lowering blood pressure by decreasing systemic vascular resistance (McCance & Huether, 2014). In addition, they are associated with hypertension that develops in renal failure. When there is a loss of functioning tissue, these renal vasodilators are also lost (see Chapter 49).

Ureters

The ureters are tubes approximately 25 to 35 cm long and 2 to 8 mm in diameter that carry urine from the renal pelvis to the bladder (see Figure 47-1). The narrow area where the ureter joins the renal pelvis is termed the *uretero-pelvic junction.* After coursing down along the psoas muscle, the ureter crosses over the pelvic brim and the iliac artery and inserts into the base of the bladder at the *uretero-vesical junction* (UVJ). The ureteral lumen is narrowest at these junctions; consequently, they are often the sites of urinary stone (calculus) obstruction. Because the lumen of the ureter is narrow, it can be easily occluded internally (e.g., by calculi) or externally (e.g., by tumours, adhesions, or inflammation).

Sympathetic and parasympathetic nerves, along with the vascular supply, surround the mucosal lining of the ureter. Circular and longitudinal smooth muscle fibres are arranged in a meshlike outer layer and contract to promote the peristaltic one-way flow of urine. These muscle contractions can be affected by distension as well as by

neurological, endocrine, and pharmacological factors. Stimulation of these nerves during passage of a stone or clot may cause acute, severe pain, termed *renal colic.*

Because the renal pelvis holds only 3 to 5 mL of urine, kidney damage can result from a backflow of more than that amount of urine. The UVJ relies on the ureter's angle of bladder penetration and muscle fibre attachments with the bladder to prevent the backflow of urine (reflux) and ascending infection. The distal ureter entering the bladder has more longitudinal muscle fibres than the upper ureter. This segment enters the bladder laterally at its base, courses along obliquely through the bladder wall for about 1.5 cm, and intermingles with muscle fibres of the bladder base. Circular and longitudinal bladder muscle fibres adjacent to the embedded ureter help secure it. When bladder pressure rises (e.g., during voiding or coughing), muscle fibres that the ureter shares with the bladder base contract first to help promote urethral lumen closure. The bladder then contracts against its base to further close the UVJ and prevent urine from moving back through the junction.

Bladder

The urinary bladder is a distensible organ positioned behind the symphysis pubis and is anterior to the vagina and the rectum. (Figure 47-7 shows the male urinary bladder.) Its primary functions are to serve as a reservoir for urine and to help the body eliminate waste products. Normal adult urine output is approximately 1 500 mL/day, which varies with food and fluid intake. The volume of urine produced at night is less than half of that formed during the day because of hormonal influences (e.g., ADH). This diurnal pattern of urination is normal. Most people urinate five to six times during the day and only occasionally at night.

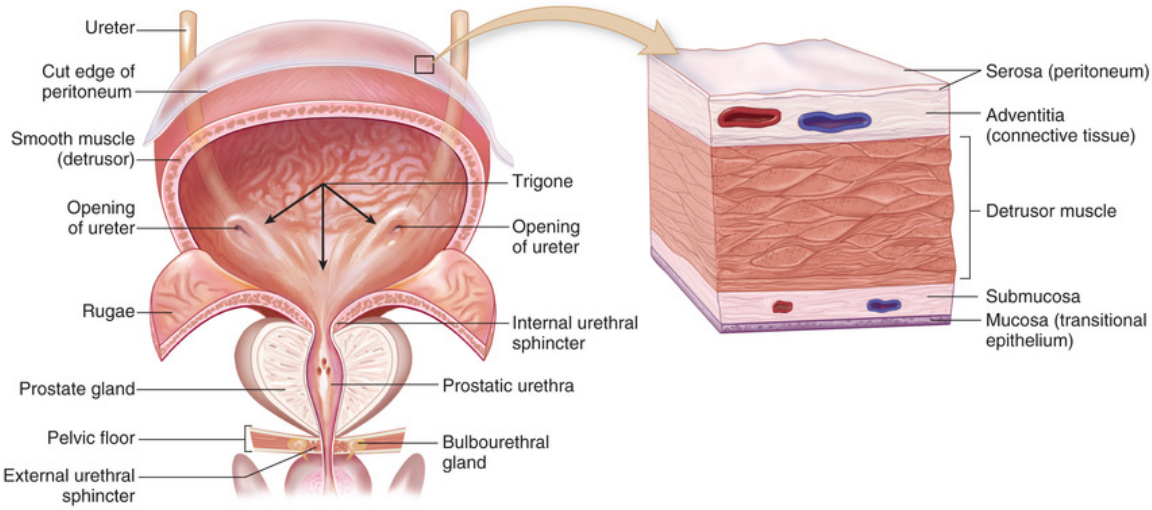

FIGURE 47-7 Illustration of the male urinary bladder. Source: Patton, K. T., & Thibodeau, G. A. (2013). *Anatomy and physiology* (8th ed., p. 974, Figure 31-5). St. Louis: Mosby.

The triangular area formed by the two ureteral openings and the bladder neck at the base of the bladder is the *trigone.* It is affixed to the pelvis by many ligaments, and it does not change its shape during bladder filling or emptying. The bladder muscle, the *detrusor,* is composed of layers of intertwined smooth muscle fibres and is capable of considerable distension during bladder filling and contraction during emptying. It is affixed to the abdominal wall by an umbilical ligament. As the bladder fills, it rises toward the umbilicus. The dome, anterior, and lateral aspects of the bladder expand and contract. When the bladder is empty, it appears as multiple folds within the pelvis.

On average, 200 to 250 mL of urine in the bladder causes moderate distension and the urge to urinate. When the quantity of urine reaches about 400 to 600 mL, the person feels uncomfortable. Bladder capacity varies with the individual, usually ranging from 600 to 1 000 mL. Evacuation of urine is termed *urination, micturition,* or *voiding.*

The lining of the bladder is identical to that of the renal pelvis, the ureter, and the bladder neck. It is called *transitional cell epithelium* or *urothelium* and is unique to the urinary tract. Transitional cell epithelium is resistant to absorption of urine. Therefore, urinary wastes produced by the kidneys do not leak out of the urinary system after they leave the kidneys. Microscopically, transitional cell epithelium is several cells deep. These cells stretch out in the bladder so that the epithelium is only a few cells deep as it accommodates filling. As the bladder empties, the epithelium resumes its multicellular layer formation.

Because the linings of these organs are similar, transitional cell tumours that occur in one section of the urinary tract can easily metastasize to other urinary tract areas. Malignant cells may move down from upper urinary tract tumours and become established in the bladder, or large bladder tumours can invade the ureter. Tumour recurrence within the bladder is common.

Urethra

The urethra is a small muscular tube that leads from the bladder neck to the external meatus. Its primary function is to serve as a conduit for urine to the bladder and then to the outside of the body.

The urothelium and submucosal layers are the same as those of the bladder. Smooth muscle fibres extend from the bladder neck down into the urethra and are further supported by circular smooth muscle fibres around the urethra. Special C-shaped striated muscle fibres (the rhabdo-sphincter or external sphincter) surround a portion of the urethra and, when bladder pressure increases, voluntarily contract and prevent leaking.

The female urethra is 3 to 5 cm long and lies behind the symphysis pubis but anterior to the vagina (see Figure 47-1, *B*). The rhabdo-sphincter encircles the middle third of the urethra. The shortness of the urethra is a contributing factor to the increased incidence of urinary tract infections in women.

The male urethra, which is about 20 to 25 cm long, originates at the bladder neck and extends the length of the penis (see Figure 47-1, *B*). It is often viewed as consisting of three parts. The prostatic urethra extends from the bladder neck through the prostate to the urogenital diaphragm. The membranous urethra passes through the urogenital diaphragm. The rhabdo-sphincter encircles this portion. Because of the concentrated muscular support, this short portion is not very expandable. As a consequence, stricture formation in this area after instrumentation is common. The penile urethra continues through the corpus spongiosum, a cavernous penile body, through the urogenital diaphragm to a distal dilated area, the fossa navicularis, before terminating at the meatus.

Urethro-Vesical Unit Function

Together, the bladder, the urethra, and the pelvic floor muscles form the *urethro-vesical unit.* Normal voluntary control of this unit is defined as *continence.* Various areas of the brain send stimulating and inhibiting impulses to the thoraco-lumbar (T11–L2) and sacral (S2–S4) areas of the

spinal cord to control voiding. Distension of the bladder stimulates stretch receptors within the bladder wall. Impulses are transmitted to the sacral spinal cord and then to the brain, causing a desire to urinate. If the time is not appropriate for voiding, inhibitor impulses in the brain are stimulated and transmitted back to the thoraco-lumbar and sacral nerves innervating the bladder. In a coordinated manner, the detrusor accommodates to the pressure (does not contract), while the sphincter and pelvic floor muscles tighten to resist bladder pressure. If the time is appropriate for voiding, cerebral inhibition is voluntarily suppressed, and impulses are transmitted via the spinal cord for the bladder neck, the sphincter, and the pelvic floor muscles to relax and for the bladder to contract. The sphincter closes, and the detrusor muscle relaxes when the bladder is empty.

Any disease or trauma that affects function of the brain, the spinal cord, or the nerves that directly innervate the bladder, the bladder neck, the external sphincter, or the pelvic floor can affect bladder function. These conditions include diabetes mellitus, paraplegia, and tetraplegia (quadriplegia). Drugs affecting nerve transmission also can affect bladder function.

Age-Related Considerations

Effects of Aging on the Urinary System

Anatomical changes in the aging kidney include a 20% to 30% decrease in size and weight between the ages of 30 and 90 years. This loss in renal mass is predominantly in the cortex. The aging nephron fails as a unit because glomerular and tubular function appears to decrease at the same rate. By the seventh decade of life, 30% to 50% of glomeruli have lost their function. Despite losing this original kidney volume, older individuals maintain body fluid homeostasis unless they encounter diseases or other physiological stressors (Nguyen & Goldfarb, 2012).

Blood flow to and within the kidneys also decreases with age. There is no evidence, however, that atherosclerotic vascular disease is primarily responsible for the age-related changes in the kidneys.

Physiological changes in the aging kidney include a decrease in renal blood flow; a decrease in GFR; and decreases in the abilities to conserve Na^+, dilute or concentrate urine, and excrete an acid load. Under normal conditions, the aging kidney is able to maintain homeostasis, but after abrupt changes in blood volume, acid load, or other insults, the kidney may not be able to function effectively because much of its renal reserve has been lost (McCance & Huether, 2014).

Physiological changes also occur in the aging bladder and urethra. Estrogen receptors exist in the female urethra, bladder, vagina, and pelvic floor. As estrogen levels decrease with age, tissues become less elastic, thin, and less vascular. Estrogen replacement may be prescribed to minimize these changes. Periurethral striated muscle fibres and muscles supporting the bladder relax. Consequently, older women are more prone to urethral irritation, urinary incontinence, and urethral and bladder infections (Eriksson, Olofsson, Gustafson, et al., 2014). Although urinary incontinence in older women has long been associated with diminished estrogen levels, the incidence of incontinence has been found to be higher in menopausal women who use hormone therapy. These findings may promote changes in therapy for postmenopausal urinary incontinence.

Eriksson, Olofsson, Gustafson, and colleagues (2015) report that approximately one-third of older women suffer from urinary tract infections each year. In a qualitative descriptive study, they found that these women struggled with activities of daily life and felt miserable and restricted when the urinary tract infection was acute. Many of these

women were identified as having other health conditions and were frail and thus vulnerable to disease. It is important to adapt supportive nursing strategies to both assess and intervene with this population.

Men's prostates enlarge as they age, and because the prostate surrounds the proximal urethra, increasing prostate size may affect urinary patterns in men, causing hesitancy, retention, slow stream, and bladder infections. Constipation, a complaint often expressed by older adults, can also affect urination. Partial urethral obstruction may occur because of the rectum's close proximity to the urethra (Registered Nurses' Association of Ontario, 2011).

A summary of age-related changes in the urinary system and differences in assessment findings is presented in Table 47-2.

TABLE 47-2
AGE-RELATED DIFFERENCES
Urinary System

Changes	Differences in Assessment Findings
Kidney	
↓ Amount of renal tissue	Less palpable
↓ Number of nephrons and renal blood vessels; thickened basement membrane of Bowman capsule and glomeruli	↓ Creatinine clearance, ↑ BUN level
↓ Function of loop of Henle and tubules	Alterations in drug excretion; nocturia; loss of normal diurnal excretory pattern because of ↓ ability to concentrate urine; less concentrated urine
Ureter, Bladder, and Urethra	
↓ Elasticity and muscle tone	Palpable bladder after urination because of retention
Weakening of urinary sphincter	Stress incontinence (especially during Valsalva manoeuvre), dribbling of urine after urination
↓ Bladder capacity and sensory receptors	Frequency, urgency, nocturia, overflow incontinence
Estrogen deficiency, leading to thinning and dryness of vaginal tissue	Stress or overactive bladder, dysuria
↑ Prevalence of unstable bladder contractions	Overactive bladder
Prostatic enlargement	Hesitancy, frequency, urgency, nocturia, straining to urinate, retention, dribbling

BUN, blood urea nitrogen.

Assessment of the Urinary System

Subjective Data

Important Health Information

Past Health History.

The patient should be questioned about the presence or history of diseases that are known to be related to renal or other urological problems. Some of these diseases are hypertension, diabetes mellitus, gout and other metabolic problems, connective tissue disorders (e.g., systemic lupus erythematosus, systemic sclerosis [scleroderma]), skin or upper respiratory infections of streptococcal origin, tuberculosis, viral hepatitis, congenital disorders, neurological conditions (e.g., stroke, back injury), and trauma. Specific urinary problems such as cancer, infections, benign prostatic hyperplasia, and calculi should be noted.

Medications.

An assessment of the patient's current and past use of medications is important. This list should include over-the-counter drugs, prescription medications, and herbs. Drugs affect the urinary tract in several ways. Many drugs are known to be nephrotoxic (Table 47-3). Certain drugs may alter the quantity and the character of urine output (e.g., diuretics). Numerous drugs, such as nitrofurantoin, change urine colour. Anticoagulants may cause hematuria. Many antidepressants, calcium channel blockers, antihistamines, and drugs used to treat neurological and musculo-skeletal disorders affect the ability of the bladder or the sphincter to contract or relax normally.

TABLE 47-3
POTENTIALLY NEPHROTOXIC AGENTS

Antibiotics	Other Agents
• Amikacin • Amphotericin B • Bacitracin • Cephalosporins • Gentamicin • Neomycin • Polymyxin B • Streptomycin • Sulphonamides • Tobramycin • Vancomycin	• Anaesthetics • Acetylsalicylic acid (ASA; Aspirin) • Captopril • Cimetidine • Cisplatin • Cocaine • Contrast medium • Cyclosporin (Neoral, Sandimmune) • Ethylene glycol • Gold • Heavy metals • Heroin • Lithium • Methotrexate • Nonsteroidal anti-inflammatory drugs (e.g., ibuprofen, indomethacin, naproxen) • Quinine • Rifampin • Salicylate (large quantities)

Surgery and Other Treatments.

The patient should also be questioned about any previous hospitalizations related to renal or urological diseases, and women should be asked about all urinary problems during past pregnancies. The duration, the severity, and the patient's perception of any problem and its treatment should be sought. Past surgical procedures, particularly pelvic surgery, and urinary tract instrumentation should be documented. Information should be obtained from the patient about any radiation or chemotherapy treatment for cancer.

Key Questions.

Nurses must convey sensitivity and understanding while asking urinary health assessment questions to maintain the patient's physical and emotional comfort. Key questions to ask a patient with problems related to the urinary system are listed in Table 47-4.

TABLE 47-4

HEALTH HISTORY
Urinary System: Questions for Obtaining Subjective Data

Health History
• How is your energy level compared to how it was a year ago? • Have you ever smoked? If yes, how many packs per day? • What occupations or work positions have you held? • Do you have any history of kidney disease, kidney stones, urinary tract infections?* • Have you had any tests or surgical procedures on your kidney, bladder, or [in men] prostate?* • Do certain activities aggravate any urinary problems you might have?* • Have urinary problems caused you to alter or stop any activity or exercise?* • How do you move or get to the bathroom?* • What medications are you currently taking?* • Do you take vitamin or mineral supplements?*
Nutritional Assessment
• How much and what kinds of fluids do you drink daily? Describe when fluid intake occurs over a day. • Do you drink coffee? Colas? Alcohol? How often? How much? • Do you eat chocolate? How often? How much? • Do you spice your food heavily?*
Elimination Assessment
• Do you ever have difficulty holding your urine (water) long enough to get to the toilet? (or) How long can you hold your urine after you first feel the need to go to the bathroom? • Do you ever leak urine? If so, what causes urine leakage? Do you leak when you cough or sneeze, laugh, walk, run, or lift a heavy object? Do you leak when you touch a doorknob or attempt to open the bathroom door or if you are unable to reach a toilet right away? When did the leaking begin? • What have you done to manage the problem of leaking? (Have you cut down on the amount of fluids that you drink? Do you empty your bladder as a precautionary measure?) • Are there certain things that make the problem worse or better? • Does it happen all of the time, or just at certain times? • Are you able to sit through a 2-hour meeting or ride in a car for 2 hours without urinating? • Do you ever leak urine at night? If so, how often and how much do you leak? (If the response is affirmative, the nurse should try to differentiate between this symptom and the habit of going to the bathroom after waking up for some other reason.) • Do you ever find that you have leaked without awareness of doing so?
• Do you use special devices or supplies for urine elimination or control? If so, (a) What types of devices or supplies do you use? (b) How often do you use these devices or supplies? (c) How many of these devices or supplies do you use on a daily basis? • Immediately after urinating (passing your water), does it feel as if you have not emptied your bladder completely? Do you experience any hesitancy and straining? A weakened force of stream? Any dribbling? • Do you have to exert pressure during urination to feel as if your bladder is being completely emptied? • [Men] When you urinate (pass water), do you have any difficulty starting the stream or keeping the stream going? • Do you ever notice blood in your urine?* If so, at what point in the urination does it occur? • How often do you move your bowels? Do you ever experience constipation (hardened stools that are difficult to pass or a sensation that you are unable to completely evacuate your bowels)?
Activity Assessment
• Have you changed any of your activities because you need to stay near a toilet? • Do you avoid going to certain places because of difficulty holding your urine (water)?
Pain Assessment
• Do you ever have pain when you urinate?* If so, where is the pain? • [Women] Do you feel any pressure in your pelvic area?
Self-Concept Assessment
• How does the urinary problem make you feel about yourself? • Have you been perceiving your body differently since the urinary problem developed? • Does the urinary problem interfere with your relationships with family or friends?* • Has the urinary problem caused a change in your job status or affected your ability to carry out job-related responsibilities?*

Sexuality Assessment
• Has the urinary problem caused any change in your sexual pleasure or performance?* • Do you ever notice any blood or red-tinged urine when you urinate after intercourse?
Coping Assessment
• Have you ever sought help or talked to a primary care provider or other health care professional about this problem? • Do you feel able to manage the problems associated with your urinary problem? If not, explain. • What strategies are you using to cope with your urinary problem?

*Describe.

Source: Adapted from Jarvis, C., Browne, A. J., MacDonald-Jenkins, J., et al. (Eds.). (2014). *Physical examination and health assessment* (1st Canadian ed., pp. 749–751). Toronto: Elsevier Canada; and Miller, C. A. (2009). Urinary function. In C. A. Miller (Ed.), *Nursing for wellness in older adults* (5th ed., pp. 390–416). Philadelphia: Lippincott Williams & Wilkins.

Health History.

The nurse should ask about the patient's general health, particularly when disease affecting the kidneys is suspected. Sometimes responses such as "feeling tired all the time"; changes in weight or appetite; excess thirst; fluid retention; and complaints of headache, pruritus, or blurred vision may be related to abnormal kidney function. Similarly, in older patients, malaise and nonlocalized abdominal discomfort may be the only symptoms of a urinary tract infection (Wagner & Hardin-Pearce, 2014).

An occupational history should be taken. Exposure to certain chemicals can affect the kidneys and the urinary tract system. Phenol and ethylene glycol are examples of nephrotoxic chemicals. Aromatic amines and certain organic chemicals may increase the risk for bladder cancers. Textile workers, painters, hairdressers, and industrial workers have a higher incidence of bladder tumours.

A smoking history should be obtained. Cigarette smoking is a major factor in the risk for bladder cancer. Bladder tumours occur four times more frequently in cigarette smokers than in nonsmokers.

Places where a patient has lived may affect the incidence and prevalence of renal disease. Higher mineral content of the soil and water may be a contributing factor. People living in Middle Eastern countries or Africa can acquire certain parasites that can cause cystitis or bladder cancer.

A family history of certain renal or urological problems increases the likelihood that similar problems will occur in the patient. The nurse should ask about family members who have had any of the diseases referred to in the past health history, as well as polycystic renal disease and congenital urinary tract abnormalities such as Alport syndrome (congenital nephritis).

Nutritional Assessment.

The usual quantity and types of fluid that a patient drinks are important information in relation to urinary tract disease. Dehydration may contribute to urinary infections, calculi formation, and renal failure. Large intake of particular foods, such as dairy products or foods high in proteins, may also lead to calculi formation. Asparagus may cause the urine to smell musty, and redness of urine caused by beet ingestion may be mistaken for blood. Coffee, alcohol, carbonated beverages, or spicy foods often aggravate urinary inflammatory diseases. An unexplained weight gain may be the result of fluid retention secondary to a renal problem. Anorexia, nausea, and vomiting can dramatically affect fluid status and require careful assessment. Information on vitamin and mineral supplements and herbal therapies should be obtained. The patient may not think of these supplements and therapies when listing over-the-counter drugs; supplements are often considered part of nutritional intake.

Elimination Assessment.

Questions about urine elimination patterns are the cornerstone of the health history in patients with a lower urinary tract disorder. This line of inquiry begins with a question about how patients manage urine elimination. The majority of patients eliminate urine by spontaneous voiding, and they should be asked about daytime (diurnal) voiding frequency and the frequency of nocturia. Patients should also be queried about additional bothersome lower urinary tract symptoms, including urgency, incontinence, or urinary retention. Table 47-5 lists some of the common clinical manifestations of urinary tract disorders. Changes in the colour and the appearance of urine are often significant and should be evaluated. If blood is visible in the urine, it should be determined whether it occurs at the beginning, throughout, or at the end of urination.

TABLE 47-5

CLINICAL MANIFESTATIONS OF DISORDERS OF THE URINARY SYSTEM

General Manifestations	• Incontinence
• Anorexia	• Nocturia
• Blurred vision	• Overactive bladder
• Chills	• Retention
• Change in body weight	• Stress incontinence
• Change in mentation	• Urgency
• Excess thirst	***Changes in Urine Output***
• Fatigue	• Anuria
• Headaches	• Oliguria
• Hypertension	• Polyuria
• Itching	***Changes in Urine Composition***
• Nausea and vomiting	• Colour (red, brown, yellowish-green)
Urinary System Symptoms	• Increased concentration
Pain	• Dilution
• Dysuria	• Hematuria
• Flank or costovertebral angle	• Pyuria
• Groin	***Edema***
• Suprapubic	• Anasarca
Changes in Patterns of Urination	• Ankle
• Change in stream	• Ascites
• Dribbling	• Facial (periorbital)
• Dysuria	• Sacral
• Frequency	
• Hesitancy of stream	

Bowel function should also be investigated. Problems with fecal incontinence may signal neurological causes of bladder problems because of shared nerve pathways. Constipation and fecal impaction can partially obstruct the urethra, causing inadequate bladder emptying, overflow incontinence, and infection.

The nurse should find out patients' methods of handling a urinary problem. A patient may already be using a catheter or collection device. Sometimes a patient has to assume a particular position to urinate or must perform such manoeuvres as pressing on the lower abdomen (Credé method), straining (Valsalva manoeuvre), or stretching the rectum to empty the bladder.

Case Study

Patient Introduction

Source: Jean-Philippe Menard/Shutterstock.com.

Amal Malcolm is a 28-yr-old man who comes to the emergency department (ED) in acute distress, with complaints of severe abdominal pain. The pain began about 6 hr ago after he finished a 10-mile (16K) run as part of his training for a marathon. He says that the pain has steadily increased, he is nauseated, and his urine is a dark, smoky colour.

Critical Thinking

Throughout this assessment chapter, think about Mr. Malcolm's symptoms with the following questions in mind:

1. What are the possible causes of Mr. Malcolm's abdominal pain, nausea, and urine colour?
2. What would be the priority assessment of Mr. Malcolm?
3. What questions should be asked of Mr. Malcolm?
4. What should be included in the physical assessment? What should be looked for?
5. What diagnostic studies should be ordered?

Mr. Malcolm and his condition will be followed throughout this assessment chapter. See pp. 1152 and 1154 for more information on Mr. Malcolm.

Activity Assessment.

The patient's level of activity should be assessed. A sedentary person is more likely than an active individual to have stasis of urine, which can predispose to infection and calculi. Demineralization of bones in a person with limited physical activity causes increased urine calcium precipitation.

An active person may find that increasing activity aggravates a urinary problem. A patient who has had prostate surgery or who has weakened pelvic floor muscles may leak urine when attempting particular activities such as running. Some men may develop chronic inflammatory prostatitis or epididymitis after heavy lifting or long-distance driving.

Nocturia is a common and a particularly bothersome lower urinary tract symptom that often leads to sleep deprivation, daytime sleepiness, and fatigue. It occurs in multiple disorders affecting the lower urinary tract, including urinary incontinence, urinary retention, and interstitial cystitis. Nocturia also may be attributable to polyuria from renal disease, poorly controlled diabetes mellitus, alcoholism, excessive fluid intake, or obstructive sleep apnea. When the nurse asks the patient about nocturia, it is helpful to determine whether the desire to urinate is what causes the patient to arise from sleep or whether pain or some other symptom interrupts sleep and the person urinates as a matter of habit before returning to bed. Up to one episode of nocturia is considered normal in younger adults, and up to two episodes are considered acceptable among adults age 65 years or older. Sleep problems associated with a urinary disorder should be documented. Older adults may awaken several times during the night to urinate and may need to be assured that this may be normal. However, a complete assessment should be made to rule out any problem.

Pain Assessment.

Pain is a frequent symptom of urinary tract disease. Types of pain associated with renal and urological problems include dysuria, groin pain, costovertebral pain, and suprapubic pain. If pain is present, the location, the character, and the duration should be assessed. The absence of pain when other urinary symptoms exist is also significant. Many urinary tract tumours are painless in the early stages.

Self-Concept Assessment.

Problems associated with the urinary system—such as incontinence, urinary diversion procedures, and chronic fatigue—can result in loss of self-esteem and a negative body image. Sensitive questioning may elicit cues to problems in this area.

Relationship and Sexuality Assessment.

Urinary problems can affect many aspects of a person's life, including the ability to work and relationships with others. These factors have important implications for future treatment and management. The nurse must be alert to cues from the patient.

Urinary system problems may be serious enough to cause problems in job-related and social situations. Chronic dialysis therapy often makes regular employment or full-time homemaking difficult. Also, concurrent

poor health and negative body image can seriously alter existing roles. The nurse should assess this area to plan appropriate interventions.

The nurse should ask about the effect of a renal or urological problem on the patient's sexual patterns and satisfaction. Problems related to personal hygiene and fatigue can seriously affect a sexual relationship. Although urinary incontinence is not directly associated with sexual dysfunction, it often has a devastating effect on self-esteem and on social and intimate relationships. Counselling of both the patient and the partner may be indicated.

Case Study

Subjective Data

Source: Jean-Philippe Menard/Shutterstock.com.

A focused subjective assessment of Amal Malcolm revealed the following information.

Past Medical History: History of one isolated incidence of possible gout 6 yr ago. He stopped drinking alcohol with no further occurrence. Appendectomy 12 yr ago.

Medications: None.

Overall Health Management: Mr. Malcolm states that he is usually healthy. He does not smoke or drink alcohol. He believes he is able to monitor self and maintain healthy lifestyle. He has never experienced this type of pain before. Describes the pain as being sharp and colicky (coming in waves). Rates the pain as 9 on a scale of 0 to 10.

Functional Assessment

Nutrition and Metabolic History: Mr. Malcolm is currently on a high-protein diet as he trains for the marathon. He eats a lot of chicken, beef, and seafood. He drinks milk-based protein shakes and water after exercising but admits that he thinks he does not drink enough to replace fluid loss in perspiration. He drinks coffee for energy but denies eating chocolate or other sweets. He also avoids sodas.

Elimination: He denies any history of difficulty or pain upon urination. No identified constipation or diarrhea. This is the first time he has ever noticed a change of colour in his urine.

Self-Care History: Prides himself in his ability to exercise and run without difficulty.

Coping and Stress Management: Worried that this pain may interfere with his marathon training.

See pp. 1151 and 1154 for more information on Mr. Malcolm.

Objective Data

Physical Examination

Inspection.

The nurse should assess for changes in the following:

Skin: Pallor, yellow-grey cast, excoriations, changes in turgor, bruises, texture (e.g., rough, dry skin)

Mouth: Stomatitis, ammonia breath odour

Face and extremities: Generalized edema, peripheral edema, bladder distension, masses, enlarged kidneys

Abdomen: Skin changes described earlier, as well as striae, abdominal contour for midline mass in lower abdomen (may indicate urinary retention) or unilateral mass (occasionally observed in adults, indicating enlargement of one or both kidneys from large tumour or polycystic kidney)

Weight: Weight gain secondary to edema; weight loss and muscle wasting in renal failure.

General state of health: Fatigue, lethargy, and diminished alertness

Palpation.

The kidneys are posterior organs protected by the abdominal organs, the ribs, and the heavy back muscles. A landmark useful in locating the kidneys is the **costovertebral angle** (CVA) formed by the rib cage and the vertebral column. The normal-sized left kidney is rarely palpable because the spleen lies directly on top of it. On occasion, the lower pole of the right kidney is palpable.

To palpate the right kidney, the examiner's left hand is placed behind and supports the patient's right side between the rib cage and the iliac crest (Figure 47-8). The patient's right flank is elevated with the examiner's left hand, and the examiner's right hand is used to palpate deeply for the patient's right kidney. The lower pole of the right kidney may feel like a smooth, rounded mass that descends on inspiration. If the kidney is palpable, its size, contour, and tenderness should be noted. Kidney enlargement is suggestive of neoplasm or other serious renal pathological conditions.

FIGURE 47-8 Palpating the right kidney. Source: From Brundage, D. J. (1992). *Renal disorders.* St. Louis: Mosby.

The urinary bladder is normally not palpable unless it is distended with urine. If the bladder is full, it may feel like a smooth, round, firm organ and is sensitive to palpation.

Percussion.

Tenderness in the flank area may be detected by fist percussion. This technique is performed by striking the fist (kidney punch) of one hand

against the dorsal surface of the other hand, which is placed flat on the patient along the posterior CVA margin. Normally, a firm blow in the flank area should not elicit pain. Tenderness and pain at the CVA may indicate a kidney infection or polycystic kidney disease.

Normally, a bladder is not percussible until it contains at least 150 mL of urine. If the bladder is full, dullness is heard above the symphysis pubis. A distended bladder may be percussed as high as the umbilicus.

Auscultation.

The diaphragm of the stethoscope may be used to auscultate over both CVAs and in the upper abdominal quadrants. With this technique, the abdominal aorta and the renal arteries are auscultated for a bruit (an abnormal murmur), which indicates impaired blood flow to the kidneys.

Table 47-6 lists the normal physical assessment findings in the urinary system. Table 47-7 lists common assessment abnormalities of the urinary system. Variations in assessment findings may be normal in older adults. Table 47-2 shows the age-related changes in the urinary system and differences in assessment findings. The nurse should use a focused assessment to evaluate the status of previously identified urinary system problems and to monitor for signs of new problems. A focused assessment of the urinary system is presented in the "Focused Assessment: Urinary System" box.

TABLE 47-6
EVIDENCE OF NORMAL PHYSICAL FINDINGS

• No costovertebral angle tenderness • Nonpalpable kidney and bladder • No palpable masses

TABLE 47-7

ASSESSMENT ABNORMALITIES
Urinary System

Finding	Description	Possible Etiology and Significance
Anuria	Technically no urination (24-hr urine output of <100 mL)	Acute renal failure, end-stage renal disease, bilateral ureteral obstruction
Burning on urination	Stinging pain in urethral area	Urethral irritation, urinary tract infection
Dysuria	Painful or difficult urination	Sign of urinary tract infection, interstitial cystitis, and a wide variety of pathological conditions
Enuresis	Involuntary nocturnal urinating	Symptom of lower urinary tract disorder
Frequency	Increased incidence of urinating	Acutely inflamed bladder, retention with overflow, excess fluid intake
Hematuria	Blood in the urine	Cancer of genito-urinary tract, blood dyscrasias, renal disease, urinary tract infection, stones in kidney or ureter, medications (anticoagulants)
Hesitancy	Delay or difficulty in initiating urination	Partial urethral obstruction
Incontinence	Inability to voluntarily control discharge of urine	Neurogenic bladder, bladder infection, injury to external sphincter
Nocturia	Frequency of urination at night	Renal disease with impaired concentrating ability, bladder obstruction, heart failure, diabetes mellitus May occur after renal transplantation
Oliguria	Diminished amount of urine in a given time (24-hr urine output of 100–400 mL)	Severe dehydration, shock, transfusion reaction, kidney disease, end-stage renal disease
Pain	Presence of pain over suprapubic area (related to bladder), urethral pain (irritation of bladder neck), flank (CVA) pain	Infection, urinary retention, foreign body in urinary tract, urethritis, pyelonephritis, renal colic or stones
Pneumaturia	Passage of urine containing gas	Fistula connections between bowel and bladder, gas-forming urinary tract infections
Polyuria	Large volume of urine in a given time	Diabetes mellitus, diabetes insipidus, chronic renal failure, diuretics, excess fluid intake
Retention	Inability to urinate, even though bladder contains excessive amount of urine	Urethral stricture or obstruction; neurogenic bladder; postanaesthesia status May occur after pelvic surgery, childbirth, catheter removal
Stress incontinence	Involuntary urination with increased pressure (sneezing or coughing)	Weakness of sphincter control
Urgency	Strong desire to urinate	Inflammatory lesions in bladder or urethra, acute bacterial infections

CVA, costovertebral angle.

Focused Assessment

Urinary System

Use this checklist to ensure that the key assessment steps have been performed.

Subjective

Ask the patient about experiencing any of the following, and note responses.

Painful urination	Y	N
Changes in colour of urine (blood, cloudy)	Y	N
Change in characteristics of urination (diminished, excessive)	Y	N
Problems with frequent nighttime urination (nocturia)	Y	N

Objective: Diagnostic

Check the following laboratory results for critical values

Blood urea nitrogen	✓
Serum creatinine	✓
Urinalysis	✓
Urine culture and sensitivity	✓

Objective: Physical Examination

Inspect

Abdomen	✓
Urinary meatus for inflammation or discharge	✓

Palpate

Abdomen for bladder distention, masses, or tenderness	✓

Percuss

Costovertebral angle for tenderness	✓

Auscultate

Renal arteries for bruits	✓

Case Study

Objective Data: Physical Examination

Source: Jean-Philippe Menard/Shutterstock.com.

A focused assessment of Amal Malcolm revealed the following information.

Mr. Malcolm is lying on the ED stretcher with his knees bent and drawn to his abdominal area. He appears restless and keeps moving from back to side in an effort to reduce his discomfort. Vital signs as follows: BP 156/70, apical pulse 108, respiratory rate 24, temperature 37.4°C, O_2 saturation 96% on room air. Awake, alert, and oriented ×3. Lungs clear to auscultation. Apical pulse regular. Abdomen nondistended with + bowel sounds in all four quadrants. No rebound tenderness. Positive costovertebral tenderness. Voiding small amounts of dark, smoky urine.

As you continue to read this chapter, consider which diagnostic studies would likely be performed for Mr. Malcolm.

See pp. 1151 and 1152 for more information on Mr. Malcolm.

Diagnostic Studies

Table 47-8 lists and describes diagnostic tests common to the urinary system. It is important to conduct appropriate diagnostic tests to locate, understand, and manage urinary problems. The accuracy of the results is influenced by (a) adherence to the proper procedures related to the study and (b) cooperation of the patient in restricting fluids, collecting urine specimens, lying quietly on the examination table, and following other instructions.

TABLE 47-8
DIAGNOSTIC STUDIES
Urinary System

Study	Description and Purpose	Nursing Responsibility
Urine Tests		
Urinalysis	This is a general examination of urine for routine and microscopic evaluation, to establish baseline information or provide data to establish a tentative diagnosis and determine whether further tests are to be ordered (see Table 47-9).	Usually the first urinated morning specimen is required, but it may not be appropriate for all diagnostic purposes. Ensure that the specimen is examined within 1 hr of urinating. Wash patient's perineal area if soiled with menses or fecal material.
Creatinine clearance	Creatinine is a waste product of protein breakdown (primarily body muscle mass). Clearance of creatinine by the kidney approximates the GFR. Normal creatinine clearance varies with age and is approximately 20% higher in men than in women. Normal finding is 1.42–2.25 mL/sec (85–135 mL/min).	Collect 24-hr urine specimen. Discard sample from first urination when test is started. Save urine from all subsequent urinations for 24 hr. Instruct patient to urinate at end of 24 hr and add that specimen to collection. Ensure that serum creatinine clearance is determined during 24-hr period.
Urine for culture and sensitivity (C&S) ("clean catch," "midstream")	Test is performed to confirm suspected urinary tract infection and identify causative organisms. Normally, the bladder is sterile, but the urethra contains bacteria and a few WBCs. If specimen is properly collected, stored, and handled, the following can be expected: <10 000 organisms/mL usually indicates no infection; 10 000–100 000/mL is usually not diagnostic, and test may have to be repeated; and >100 000/mL indicates infection.	Use sterile container for collection of urine. Touch only outside of container. For women, separate labia with one hand and clean meatus with other hand, using at least three sponges (saturated with cleansing solution) in a front-to-back motion. For men, retract foreskin (if present) and cleanse glans with at least three cleansing sponges (saturated with cleansing solution). After cleaning, instruct patient to start urinating and then continue voiding in sterile container. (The initial voided urine flushes out most contaminants in the urethra and the perineal area.) Catheterization may be needed if patient is unable to cooperate with this procedure.
Concentration test	Study is an evaluation of renal concentration ability. Concentration is measured from specific gravity readings. Normal finding is 1.020–1.035.	Instruct patient to fast after a given time in evening (in usual procedure). Collect three urine specimens at hourly intervals in morning.
Residual urine	Test is a determination of amount of urine left in bladder after urination. Finding may be abnormal in patients who have problems with bladder enervation, sphincter impairment, BPH, equine syndrome (nerve compression), or urethral strictures. Normal finding is ≤50 mL urine (increases with age).	If residual urine test is ordered, catheterize patient immediately after patient urinates, or use bladder ultrasonography equipment, including portable scanner. If a large amount of residual urine is obtained, health care provider may order catheter to be left in bladder.
Protein dipstick determination (Albustix, Combistix)	Test detects protein (primarily albumin) in urine. Normal finding is grade 0 to trace amounts.	Dip end of stick in urine, and read result by comparison with colour chart on label as directed. Grading is from 0 to 4+. Interpret with caution. A positive result may not indicate significant proteinuria; some medications may produce false-positive readings.

Study	Description and Purpose	Nursing Responsibility
Quantitative test for protein	A 12- or 24-hr collection yields a more accurate indication of the amount of protein in urine. Persistent proteinuria usually indicates glomerular renal disease. Normal finding is <0.15 g/24 hr (<150 mg/24 hr), and protein consists mainly of albumin.	Perform 12- or 24-hr urine collection.
Urine cytology	Test is used to identify changes in cellular structure indicative of malignancy, especially bladder cancer.	Obtain urine and send immediately to laboratory. The first morning specimen should not be used.
Blood Tests		
Bicarbonate (HCO_3^-)	Most patients in renal failure have metabolic acidosis and low serum HCO_3^- levels. Normal finding is 21–28 mmol/L.	Explain the test and watch for postpuncture bleeding.
BUN	Test is most commonly used to identify presence of renal problems. Concentration of urea in blood is regulated by rate at which kidney excretes urea. Normal finding is 3.6–7.1 mmol/L.	When interpreting BUN, the nurse should be aware that nonrenal factors (e.g., rapid cell destruction from infections, fever, GI bleeding, trauma, athletic activity and excessive muscle breakdown, corticosteroid therapy) may cause increase in BUN level. A low BUN level could result from overhydration or advanced liver disease.
Creatinine	Study is more reliable than BUN as a determinant of renal function. Creatinine is end product of muscle and protein metabolism and is liberated at a constant rate. Normal values: 53–106 mcmol/L for men, 44–97 mcmol/L for women. Normal finding is 44–133 mcmol/L.	Explain the test and watch for postpuncture bleeding.
Urea-to-creatinine ratio	Normal finding is 10 : 1.	—
Calcium (Ca^{2+})	Calcium is main mineral in bone and aids in muscle contraction, neurotransmission, and clotting. In renal disease, decreased reabsorption of Ca^{2+} leads to renal osteodystrophy. Normal calcium levels in adults range from 2.25–2.75 mmol/L.	Explain the test and watch for postpuncture bleeding.
Potassium (K^+)	Kidneys are responsible for excreting majority of body's potassium. In renal disease, K^+ determinations are critical because K^+ is one of the first electrolytes whose levels become abnormal. Highly elevated K^+ levels (>6 mmol/L) can lead to muscle weakness and cardiac dysrhythmias. Normal values are 3.5–5 mmol/L.	Explain the test and watch for postpuncture bleeding.
Phosphorus	Phosphorus balance is inversely related to Ca^{2+} balance. In renal disease, phosphorus levels are elevated because the kidney is the primary excretory organ. Normal values are 0.97–1.45 mmol/L.	Explain the test and watch for postpuncture bleeding.
Sodium (Na^+)	Sodium is the main extracellular electrolyte determining blood volume. Values usually stay within normal range until late stages of renal failure. Normal finding is 135–145 mmol/L.	Explain the test and watch for postpuncture bleeding.

Study	Description and Purpose	Nursing Responsibility
Uric acid	Study is used as a screening test primarily for disorders of purine metabolism but can indicate kidney disease as well. Values depend on renal function and rate of purine metabolism and dietary intake of food rich in purines. Normal findings are 160–430 mcmol/L for women and 340–501 mcmol/L for men.	Explain the test and watch for postpuncture bleeding.
Radiological Procedures		
Kidneys, ureters, bladder (KUB)	Study involves radiographic examination of abdomen and pelvis and delineates size, shape, and position of kidneys.	Perform bowel preparation (if ordered).
Intravenous pyelography (IVP)	Radiographic examination visualizes urinary tract after IV injection of contrast material.	Assess renal function. If BUN and creatinine levels are elevated, use of contrast dye in diagnostic procedure may not be safe. Evening before procedure, administer cathartic or enema to empty colon of feces and gas. Keep patient on NPO status 8 hr before procedure. Before procedure, assess patient for iodine sensitivity to avoid anaphylactic reaction. Inform patient that procedure involves lying on table and having serial radiographs taken. After procedure, encourage fluids (if permitted) to flush out contrast material.
Nephro-tomography	Radiograph is performed with rotating tubes. Test delineates segments of the kidney at different levels. Multiple exposures are obtained to visualize specific sections of the kidney after IV injection of contrast material.	Explain the procedure and prepare the patient as for IVP.
Retrograde pyelography	Radiograph of urinary tract is performed after injection of contrast material into kidneys. Cystoscope is inserted, and ureteral catheters are inserted through it into renal pelvis. Contrast material is injected through catheters.	Prepare patient as for IVP. Inform patient that pain may be experienced from distension of pelvis and discomfort from cystoscope. Inform patient that anaesthetic may be administered for procedure.
Renal arteriography (angiography)	Study helps visualize renal blood vessels. Contrast material is injected into renal artery via catheter inserted into femoral artery.	Prepare patient evening before procedure by administering cathartic or enema. Before injection of contrast material, test for iodine sensitivity. After procedure, check insertion site for bleeding, and measure peripheral pulses in involved leg every 30–60 min to detect occluded blood flow, if any.
Renal ultrasonography	Small external ultrasound probe is placed on patient's skin. Conductive gel is applied to the skin. Noninvasive procedure involves passing sound waves into body structures and recording images as the waves are reflected back. Computer interprets tissue density on the basis of sound waves and displays it in picture form. Study is most valuable in detection of renal or perirenal masses and in differential diagnosis of renal cysts, solid masses, and identification of obstructions. It can be used safely in patients with renal failure.	Explain procedure to patient.

Study	Description and Purpose	Nursing Responsibility
CT	Study provides excellent visualization of kidneys. Kidney size can be evaluated; tumours, abscesses, suprarenal masses (e.g., adrenal tumours, pheochromocytomas), and obstructions can be detected. Advantage of CT over ultrasonography is its ability to distinguish subtle differences in density. Use of IV-administered contrast media during CT accentuates density of renal tissue and helps differentiate masses.	Explain procedure to patient and ask patient about iodine sensitivity before injection of contrast material.
MRI	Computer-generated images rely on radiofrequency waves and alteration in magnetic field. Useful for visualization of kidneys. Not proven useful for detecting urinary calculi or calcified tumours.	Explain procedure to patient. Have patient remove all metal objects. Patients with a history of claustrophobia may need to be sedated.
Cystography	Purpose of study is to visualize bladder and evaluate vesico-ureteral reflux. Contrast material is instilled into bladder via cystoscope or catheter.	Explain procedure to patient. If procedure is performed via cystoscope, follow nursing care related to cystoscopy.
Renal Radionuclide Imaging		
Renal scan	Purpose of scan is to show blood flow, glomerular filtration, tubular function, and excretion. Radioactive isotopes are injected by IV route. Radiation detector probes are placed over kidney, and scintillation counter monitors radioactive material in kidney. Radioisotope distribution in kidney is scanned and mapped. Test is useful in showing location, size, and shape of kidney and, in general, assessing blood perfusion and kidney's ability to secrete urine. Abscesses, cysts, and tumours may appear as cold spots because of presence of nonfunctioning tissue.	Requires no dietary or activity restriction. Inform patient that no pain or discomfort should be felt during test.
Surgical Study		
Renal biopsy	Purpose is to obtain renal tissue for examination to determine type of renal disease or to monitor progress of renal disease. This technique is usually performed percutaneously (skin biopsy) through needle insertion into lower lobe of kidney. Can be guided by CT or ultrasonography.	Before procedure, ascertain coagulation status through patient's history, medication history, CBC, hematocrit, prothrombin time, and bleeding and clotting times. Type and crossmatch for blood. Ensure consent form is signed. After procedure, apply pressure dressing to biopsy site and check frequently for bleeding. Measure vital signs frequently. Observe urine for gross bleeding. Determine microscopic bleeding by use of dipstick. Assess patient for flank pain. Monitor hematocrit levels.
Endoscopy		
Cystoscopy	Study involves use of tubular lighted cystoscope to inspect bladder. Lithotomy position is used. Study may be performed while patient receives local or general anaesthesia, depending on needs and condition of patient.	Before procedure, force fluids or administer IV fluids if general anaesthesia is to be used. Ensure that consent form is signed. Explain procedure to patient. Administer preoperative medication. After procedure, explain that burning on urination, pink-tinged urine, and urinary frequency are expected effects after cystoscopy. Do not let patient walk alone immediately after procedure because orthostatic hypotension may occur. Offer warm sitz baths, heat, and mild analgesics to relieve discomfort.

Study	Description and Purpose	Nursing Responsibility
Urodynamics Testing		
Cystometrography	Purpose of study is to evaluate bladder tone, sensations of filling, and bladder (detrusor) stability. Study involves insertion of catheter and instillation of water or saline solution into bladder. Measurements of pressure exerted against bladder wall are recorded.	Explain procedure to patient and observe patient for manifestations of urinary infection after procedure.

BPH, benign prostatic hyperplasia; *BUN*, blood urea nitrogen; *CBC*, complete blood cell count; *CT*, computed tomographic (scan); *GFR*, glomerular filtration rate; *eGFR*, estimated glomerular filtration rate; *GI*, gastro-intestinal; *IV*, intravenous; *MRI*, magnetic resonance imaging; *NPO*, nothing by mouth; *WBC*, white blood cell.

For many radiological investigations, a bowel preparation must be used the evening before the study to clear the lower GI tract of feces and flatus. Because the kidneys lie in a retroperitoneal location, the contents of the colon may obstruct visualization of the urinary tract. If a bowel preparation is not properly performed, a test may be unsuccessful and must be rescheduled. Commonly used bowel preparations include enemas, castor oil, magnesium citrate, and bisacodyl (Dulcolax) tablets or suppositories. Some bowel preparations, such as magnesium citrate and Fleet enema, are contraindicated for use in patients with renal failure—magnesium cannot be excreted by patients with renal failure (see Chapter 49).

When a patient has repeated diagnostic studies on consecutive days, it is important to prevent dehydration. It is not uncommon for a patient to take nothing by mouth (NPO) after midnight, spend all morning in the radiology department, be too tired to eat, sleep all afternoon, and be on NPO status after midnight again because of studies scheduled for the next day. Severe dehydration, especially in a patient who is diabetic or debilitated, or in an older-adult patient, may lead to acute renal failure. The nurse is responsible for ensuring that a patient undergoing diagnostic studies is properly hydrated and given adequate nourishment between studies. The nurse should also check with the health care provider regarding the insulin dose for patients with diabetes who are NPO.

Case Study

Objective Data: Diagnostic Studies

Source: Jean-Philippe Menard/Shutterstock.com.

The health care provider orders the following initial diagnostic studies for Amal Malcolm:

- CBC, basic metabolic panel (electrolytes, BUN, creatinine)
- Urinalysis, culture if indicated
- Renal ultrasound

Although Mr. Malcolm's laboratory results are all within normal limits, his renal ultrasound identifies calculi in the left ureter. There is currently no hydronephrosis. The health care provider prescribes parenteral opioids for pain management and admits Mr. Malcolm to a medical unit for further observation.

See pp. 1151 and 1152 for more information on Mr. Malcolm.

Analysis of Urine

Urinalysis.

In evaluating disorders of the urinary tract, one of the first studies performed is a **urinalysis** (Table 47-9; see Table 47-8). This test is a general examination of urine for routine and microscopic findings and may establish baseline information, provide information about possible abnormalities, indicate what further studies need to be done, and supply information on the progression of a diagnosed disorder.

TABLE 47-9
URINALYSIS FINDINGS

Evaluation	Normal Finding	Abnormal Findings and Significance
Colour	Amber yellow	Dark, smoky colour suggests hematuria. Yellow-brown to olive green indicates excessive bilirubin. Cloudiness of freshly voided urine indicates infection. Colourless urine indicates excessive fluid intake, renal disease, or diabetes insipidus.
Smell	Aromatic	After urine has been standing, smell becomes more ammonia-like. In urinary tract infections, urine smells unpleasant.
Protein	<0.15 g/day	Persistent proteinuria is characteristic of acute and chronic renal disease, especially involving glomeruli. In absence of disease, positive reading may be caused by high-protein diet, strenuous exercise, dehydration, fever, or emotional stress. Vaginal secretions may contaminate urine specimen and produce positive reading.
Glucose	None	Glycosuria indicates diabetes mellitus or low renal threshold for glucose reabsorption (if blood glucose level is normal). Small amounts may be found after glucose loading (e.g., glucose tolerance test).
Ketones	None	Altered carbohydrate and fat metabolism indicates diabetes mellitus and starvation. Findings can also occur in dehydration, vomiting, and severe diarrhea.
Bilirubin	None	Bilirubinuria is as significant as jaundice in detection of liver disorders. Bilirubin may appear in urine before jaundice becomes visible or may be present in persons with hepatic disorders who do not have recognizable jaundice.*
Specific gravity	1.005–1.030 Maximum concentrating ability of kidney (1.025–1.030)	*Low:* dilute urine and possibly excessive diuresis. *High:* dehydration. *Fixed at about 1.010:* kidneys are unable to concentrate urine, which suggests that kidneys are progressing to end-stage renal disease.
Osmolality (random specimen)	50–1 200 mmol/kg	Measurement of osmolality is more accurate than measurement of specific gravity for determining diluting and concentrating ability of kidneys. Deviations from normal indicate tubular dysfunction. Findings indicate whether kidney has lost ability to concentrate or dilute urine. (Not part of routine urinalysis.)
pH	4.6–8.0 (average, 6.0)	A pH of >8.0 may be the result of standing of urine or urinary tract infection because bacteria decompose urea to form ammonia. A pH of <4.0 may indicate respiratory or metabolic acidosis.
RBC	0–4/hpf	Bleeding in urinary tract is caused by calculi, cystitis, neoplasm, glomerulonephritis, tuberculosis, kidney biopsy, or trauma.
WBC	0–5/hpf	Increased number of WBCs in urine (pyuria) indicates urinary tract infection or inflammation.
Casts	None; occasional hyaline casts	Casts are moulds of the renal tubules and may contain protein, WBCs, RBCs, or bacteria. Noncellular casts are hyaline in appearance, and a few may be found in normal urine. Casts indicate renal dysfunction or upper urinary tract infection.
Culture for organisms	No organisms in bladder; count of $<10^5$ CFU/L organisms/mL is result of normal urethral flora	Bacteria counts $>10^8$ CFU/L indicate urinary tract infection. Organisms most commonly found in urinary tract infections are *Escherichia coli, enterococci, Klebsiella* species, *Proteus* species, and *streptococci*.

*See Chapter 46 for further discussion.

CFU, colony-forming unit; *hpf,* high-powered field (or what can be seen in one view of the slide through the microscope); *RBC,* red blood cells; *WBC,* white blood cells.

For a routine urinalysis, a specimen may be collected at any time of the day. However, it is best to obtain the first specimen urinated in the morning. This concentrated specimen is more likely to contain abnormal constituents if they are present in the urine. The specimen should be examined within 1 hour of urination. If it is not, bacteria multiply rapidly, RBCs hemolyze, casts (moulds of renal tubules) disintegrate, and the urine becomes alkaline as a result of urea-splitting bacteria. If it is not possible to send the specimen to the laboratory immediately, it should be refrigerated. However, to obtain the best results, the nurse should coordinate specimen collection with routine laboratory hours.

Multiple reagent strips (also called *urine dipsticks*) are commonly used by laboratories and in outpatient settings to provide chemical analysis of urine, along with a microscopic interpretation. The results of a urinalysis usually include a description of the appearance, specific gravity (mass and density), pH, glucose, ketones, and protein in the urine and a microscopic examination of urine sediment for white blood cells (WBCs), RBCs, crystals, and casts (see Table 47-9).

Composite Urine Collections.

Composite urine specimens are collected over a period that may range from 2 to 24 hours. The purpose of a composite specimen is to examine or measure specific components, such as electrolytes, glucose, protein, 17-ketosteroids, catecholamines, creatinine, and minerals. These specimens may have to be refrigerated, or preservatives may have to be added to the container used for collecting urine.

For collection of a composite urine specimen, the patient is instructed to urinate and discard this first urine specimen. This time is noted as the start of the test. All urine from subsequent urinations is saved in a container for the designated period. Finally, at the end of the period, the patient is asked to urinate, and this urine sample is added to the container. Incomplete collections do not provide valid results. Reminding the patient to save all urine during the study period is critical.

Creatinine Clearance.

One of the most common composite indicators used to analyze urinary system disorders is creatinine clearance. **Creatinine** is a waste product produced by protein breakdown (primarily body muscle mass). Urinary excretion of creatinine is a measure of the amount of active muscle tissue in the body, not of body weight; therefore, people with larger muscle mass

have higher values. Because almost all creatinine in the blood is normally excreted by the kidneys, creatinine clearance is the most accurate indicator of renal function. The result of a creatinine clearance test closely approximates that of the GFR (National Kidney Foundation, 2016). A blood specimen for serum creatinine determination should be obtained during the period of urine collection.

Creatinine levels remain remarkably constant for each person because they are not significantly affected by protein ingestion, muscular exercise, water intake, or rate of urine production. Normal creatinine clearance values range from 1.42 to 2.25 mL/sec (85–135 mL/min). After age 40, the creatinine clearance rate decreases at a rate of about 1 mL/min/yr.

Urine Cytology.

Urine can be checked for abnormal cellular structures that occur with bladder cancer. Specimens may be obtained from voiding, catheterization, or bladder irrigation (bladder washing). The first morning's voided specimen should not be used because epithelial cells may change in appearance in urine held in the bladder overnight. As with urinalysis, the specimen should be fresh or brought to the laboratory within the hour. An alcohol-based fixative is then added to preserve the cellular structure. Urine cytological study is used for detection and monitoring the prognosis of bladder cancer.

Radiological Studies

Diagnostic urine studies are summarized in Table 47-8.

Kidney, Ureter, and Bladder Radiography.

The kidney, ureter, and bladder (KUB) radiograph is an abdominal view obtained without use of a contrast medium to show the renal outline, the psoas shadow, and the full bladder. Radiopaque stones and foreign bodies can be seen on this radiograph. The form, the size, and the position of the kidneys can also be seen. Abscesses, tumours, and cysts may distort anatomical relationships on the KUB image. Sometimes nephrotomography (sectional views that focus on a single plane of the kidney) is ordered at the same time as the KUB study to maximize visualization of the kidneys.

Intravenous Pyelography.

Intravenous pyelography (IVP), or excretory urography, enables visualization of the urinary tract. The presence, the position, the size, and the shape of the kidneys, the ureters, and the bladder can be evaluated. Cysts, tumours, lesions, and obstructions cause a distortion in the normal appearance of these structures.

The procedure consists of injecting an IV dose of contrast material, which circulates in the blood and is excreted by the kidneys into the urine. As with all contrast studies, possible iodine and shellfish allergies should be determined before the study. During injection, the patient may experience sensations of warmth, facial flushing, and a salty taste. After injection, radiographs are taken sequentially. The sequencing of images is planned so that contrast excretion can be followed from the cortex of the kidney to the bladder. The presence of bladder atony or outlet obstruction also can be detected by an image obtained after urination, which shows the residual volume of urine in the bladder.

Patients with significantly decreased renal function should not undergo IVP because the contrast material is not properly excreted by the kidneys. Contrast medium can also be nephrotoxic and can worsen renal function.

Retrograde Pyelography.

Retrograde pyelography is the radiographic visualization of the kidneys, the ureter, and the bladder after direct injection of contrast material into the kidney via a ureteral catheter introduced through a cystoscope. It may be performed if the urinary tract cannot be visualized using IVP or if the patient is allergic to IV contrast material or has decreased renal function. The risks associated with retrograde pyelography are similar to those related to cystoscopy, including the risk for infection and the use of anaesthetics.

Antegrade Pyelography.

Antegrade pyelography is performed to evaluate the upper urinary tract when the patient has an allergy to contrast media, when renal function is decreased, or when abnormalities prevent passage of a ureteral catheter. Contrast media may be injected percutaneously into the renal pelvis or via a nephrostomy tube that is already in place (this method is also called *nephrostography*) when tube function or ureteral integrity must be determined after trauma or surgery. Complications of antegrade pyelography include hematuria, infection, and hematoma.

Renal Ultrasonography.

Renal ultrasonography uses high-frequency sound waves to image the kidneys, the ureter, and the bladder. Because radiation exposure is avoided, a number of images can be obtained, and studies can be repeated over a brief period. Images can be obtained with the patient in both the prone and the supine positions. A bowel preparation is not required for renal ultrasonography.

Computed Tomography.

Computed tomographic (CT) scan of the abdomen and the pelvis may be performed to detect tumours and possible metastases. CT can differentiate these from cysts or abscesses. Contrast material may be used to help visualize urinary structures more clearly in the computer-generated images. The patient is instructed to lie very still during the procedure while the machine takes precise transaxial images. Sedation may be required if the patient is unable to cooperate.

Renal Arteriography.

The purpose of **renal arteriography** (angiography) is to visualize the renal blood vessels. In this radiological study, contrast material is injected into the renal artery via a catheter inserted into the femoral artery. The findings in arteriography can assist in diagnosing renal artery stenosis (Figure 47-9), additional or missing renal blood vessels, and renovascular hypertension and can assist in differentiating between a renal cyst and a renal tumour. Renal arteriography is also included in the workup of a potential renal transplant donor.

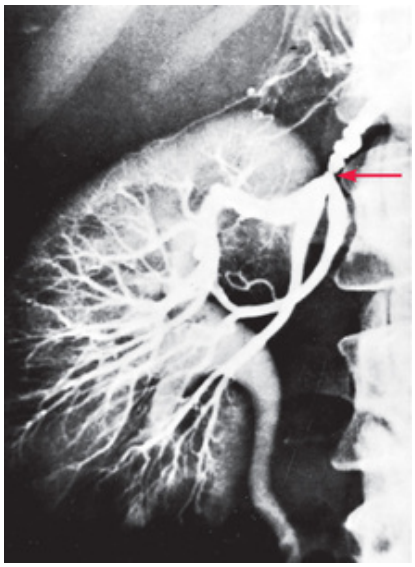

FIGURE 47-9 Renal arteriogram showing stenosis *(arrow)* of the right renal artery. Source: From Brundage, D. J. (1992). *Renal disorders*. St. Louis: Mosby.

The patient is given a local anaesthetic at the site of catheter insertion. Usually, a catheter is inserted into the femoral artery and passed up the aorta to the level of the renal arteries (Figure 47-10). Contrast media is then injected to outline the renal blood supply, and radiographic images are taken.

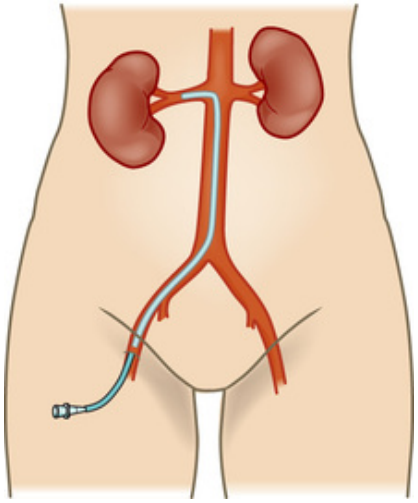

FIGURE 47-10 Diagram of catheter insertion for renal arteriography.

The patient may experience a transient warm feeling along the course of the blood vessel when the contrast material is injected. After the catheter is removed, a pressure dressing is placed over the femoral injection site. It is important to observe the site for bleeding. Usually, bed rest with the affected leg kept straight is prescribed. Peripheral pulses in the involved leg should be measured at least every 30 to 60 minutes to detect occlusion of blood flow caused by a thrombus, if any. Complications that may result from renal arteriography include thrombus, embolus, local inflammation, and hematoma. Patients with baseline renal insufficiency may experience a decrease in renal function secondary to the nephrotoxic contrast material.

Cystography.

The purpose of cystography is to outline and visualize the bladder and evaluate the UVJ for reflux. In addition to suspected vesico-ureteral reflux, indications for cystography include a neurogenic bladder and recurrent urinary tract infections. Cystography can also delineate abnormalities of the bladder, such as diverticula, calculi, and tumours. In this procedure, a contrast material is instilled via a cystoscope or catheter into the bladder.

Voiding cysto-urethrography (VCUG) is a voiding study of the bladder opening (bladder neck) and urethra. The bladder is filled with contrast material. During urination, images are obtained to visualize the bladder and the urethra. After urination, another image is obtained to assess for residual urine. VCUG can detect abnormalities of the lower urinary tract, urethral stenosis, bladder neck obstruction, and prostatic enlargement (Rosier, Kuo, de Gennaro, et al., 2013).

Urethrography.

Urethrography is similar to cystography. Contrast material is injected in a retrograde manner into the urethra to identify strictures, diverticula, or other urethral pathological conditions. When urethral trauma is suspected, urethrography is performed before catheterization.

Loopography.

Loopography is used to detect obstructions, anastomotic leaks, stones, reflux, and other uropathological features when a patient has a urinary pouch or ileal conduit. Because urinary diversions are created with sections of bowel, contrast absorption is a risk. The patient should be closely monitored for reactions to the contrast media.

Renal Radionuclide Imaging.

Renal scans involving the use of radionuclides are useful in evaluating the anatomical structures, perfusion, and function of the kidneys. The results reveal the difference between the two kidneys in regard to blood flow, tubular function, and excretion. A normal scan shows symmetrical functioning of both kidneys. Normally, the distribution of activity is recorded throughout the kidneys. A lesion (e.g., a tumour) is indicated by the absence of radioactivity in the involved area and the appearance of the resultant defect on the scan. This study is particularly useful in detecting renal vascular disease, acute renal failure, and upper urinary tract obstruction. It is also useful in monitoring the function of a transplanted kidney.

Renal Biopsy.

The purpose of **renal biopsy** is to obtain renal tissue for examination to establish a diagnosis or to monitor progress of renal disease. Biopsy material can be obtained through open biopsy or closed percutaneous needle biopsy. Open biopsy is rarely performed because it is a surgical procedure that necessitates general anaesthesia. Percutaneous needle biopsy, conducted through needle insertion into the lower lobe of the kidney, is more common.

Absolute contraindications to a percutaneous renal biopsy are bleeding disorders, the presence of a single kidney, and uncontrolled hypertension. Relative contraindications include suspected renal infection, hydronephrosis, and possible vascular lesions. Patients about to undergo biopsy should stop taking acetylsalicylic acid (ASA; Aspirin) or warfarin (Coumadin) before the procedure as advised by their physicians.

In this procedure, the patient lies prone with a pillow or sandbag to elevate the abdomen and the kidneys. The position of the kidney is marked on the body, under guidance with CT, IVP, or ultrasonography. Local anaesthetic is used, and a biopsy needle is inserted into the kidney just below the twelfth rib. The patient is instructed to hold his or her breath while the biopsy specimen is being taken.

After the procedure, a pressure dressing is applied, and the patient is kept prone for 30 to 60 minutes. Usually bed rest is prescribed for 24 hours. Vital signs should be measured every 5 to 10 minutes during the first hour and then, if no problems are noted, with decreasing frequency. The biopsy site should be inspected frequently for bleeding. Serial urine specimens should be assessed for gross and microscopic hematuria. A

dipstick can be used to test for bleeding, even when hematuria is not obvious. The physician may order all urine sent for laboratory analysis to detect possible hematuria. The patient should be assessed for flank pain, hypotension, decreasing hematocrit, and temperature elevation and should also be observed for chills, urinary frequency, and dysuria.

Complications of a renal biopsy include renal hemorrhage, hematoma, and infection. Even if no complications occur, the patient should be instructed to avoid lifting heavy objects for 5 to 7 days. The patient should be instructed not to take any anticoagulant drugs until permission is given by the physician who performed the biopsy.

Endoscopy

Cystoscopy.

Cystoscopy is a radiological bladder procedure in which contrast material is instilled into the bladder. The main purpose is to inspect the interior of the bladder and evaluate the vesico-ureteral reflux with a tubular lighted endoscope called a *cystoscope* (Figure 47-11).

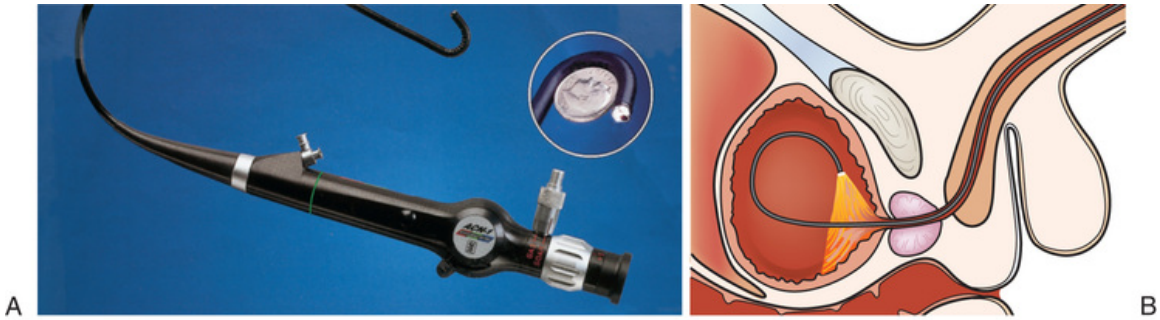

FIGURE 47-11 Cystoscopic examination of the bladder. **A,** Flexible cystonephroscope. **B,** Illustration of nephroscope inserted into male bladder. Source: Courtesy Circon Corp, Santa Barbara, California.

Cystoscopes can be used to insert ureteral catheters, remove calculi, obtain biopsy specimens of bladder lesions, and treat bleeding lesions. In most cases, bladder disorders can be determined by cystoscopic examination.

Cystoscopy is usually performed in a cystoscopy room in the radiology department, in a urology clinic, or in the operating room. Most of the pain associated with cystoscopy results from spasms and contractions of bladder and sphincter. Some of the bladder and sphincter spasms may be

alleviated if the patient uses relaxation and deep breathing. A local anaesthetic is instilled into the urethra before cystoscope insertion. During the examination, saline solution is instilled slowly to distend the bladder. This improves visualization but causes an urge to urinate.

After the procedure, the patient can expect to have some burning on urination, blood-tinged urine, and urinary frequency from the irritation of cystoscope insertion and manipulation. The nurse should observe for bright red bleeding, which is not normal. After the procedure, the nurse is responsible for keeping the patient well hydrated, administering mild analgesics, providing sitz baths, and applying heat to decrease the patient's discomfort. Complications that may result from cystoscopy include urinary retention, urinary tract hemorrhage, bladder infection, and perforation of the bladder.

Urodynamics Testing

Urodynamics testing is a set of studies designed to measure urinary tract function. Urodynamic tests entail study of the storage of urine within the bladder and the flow of urine through the urinary tract to the outside of the body. A combination of techniques may be used to provide a detailed assessment of urinary incontinence.

Urinary Flow Study.

The urinary flow study (uroflow) entails measurement of urine volume in a single voiding, expelled in a specified time and expressed in millilitres per second. As the patient voids, the stream pattern is depicted graphically on a printout.

The patient is asked to start the test with a reasonably full bladder, urinate into a special container, and try to empty the bladder completely. The container generates a graph in which flow rate is compared to time. This test is used to (a) assess the degree of outflow obstruction caused by such conditions as benign prostatic hyperplasia or stricture; (b) assess bladder or sphincter dysfunction effects on voiding such as occurs with neuropathological conditions; and (c) evaluate the effects of treatment for lower urinary tract problems. Residual urine volume should be measured immediately after a urinary flow study to help identify the degree of chronic urinary retention that is often associated with abnormal flow patterns.

A normal maximum flow rate is about 20 to 25 mL/sec for men and about 25 to 30 mL/sec for women. However, the volume voided and the

patient's age can affect the flow rate; thus variations are normal and common. Graphic displays can illustrate straining and intermittent flow patterns or other abnormal voiding disorders.

Cystometrography.

Cystometrography is an evaluation of the compliance (elastic property) and stability of the detrusor muscle of the bladder, as well as bladder tone, sensations of filling, and bladder (detrusor) instability. It is a measurement of intravesical pressure during the course of bladder filling. Usually, it is ordered if a patient has incontinence or neurogenic bladder. The procedure consists of insertion of a specially designed catheter while the patient is in a supine position. If abdominal pressure is also to be measured, a second tube is inserted into the rectum or the vagina. This tube is typically attached to a small, fluid-filled balloon to allow pressure recording. Saline or sterile water for irrigation, or contrast used for cystography, is infused into the bladder, and pressures are measured. During the infusion, the patient is asked about sensations of bladder filling, usually including the first urge to urinate, a strong urge to urinate, and perception of bladder fullness.

Sphincter Electromyography.

In electromyography (EMG), the electrical activity created when the nervous system stimulates motor units within a muscle is recorded. Through the placement of needles, percutaneous wires, or patches near the urethra, the pelvic floor muscle activity can be assessed. During filling cystometrography, sphincter EMG is used to identify voluntary pelvic floor muscle contractions and the response of these muscles to bladder filling, coughing, and other provocative manoeuvres.

Voiding Pressure Flow Study.

The voiding pressure flow study combines a urinary flow rate, cystometric pressures (intravesical, abdominal, and detrusor pressures), and a sphincter EMG for detailed evaluation of micturition. It is completed by assisting the patient to a specialized toilet and allowing him or her to urinate while the various pressure tubes and EMG apparatus remain in place.

Video-Urodynamics Testing.

Video-urodynamics testing is a combination of the filling cystometrography, sphincter EMG, or urinary flow study (or both of the latter tests) with anatomical imaging of the lower urinary tract, typically via fluoroscopy. This combination is used in selected cases to identify an obstructive lesion and characterize anatomical changes in the bladder and lower urinary tract.

Radionuclide Cystography.

Radionuclide cystography is used to detect and grade vesico-ureteral reflux. Similar to VCUG, a small dose of radioisotope tracer is instilled into the bladder via urethral catheter. The procedure is more sensitive than VCUG, and the radiation dose is one-thousandth that used in VCUG.

Whitaker Test.

Whitaker test is used to measure the pressure differential between the renal pelvis and the bladder. The presence of a ureteral obstruction can be assessed. Percutaneous access to the renal pelvis is achieved by placement of a catheter in the renal pelvis. A catheter is also placed in the bladder. Fluid is perfused through the percutaneous tube or needle at a rate of 10 mL/min. Pressure data are then collected. These pressure measurements are studied in combination with fluoroscopic imaging to identify the level of obstruction.

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Which of the following is affected by a renal stone in the pelvis of the kidney?
   a. The structural support of the kidney
   b. Regulation of the concentration of urine
   c. The entry and exit of blood vessels at the kidney
   d. Collection and drainage of urine from the kidney
2. A client with renal disease has oliguria and a creatinine clearance rate of 40 mL/min. Which of the following functions of the kidney is most directly implicated in these abnormal findings?
   a. Tubular secretion
   b. Glomerular filtration
   c. Capillary permeability
   d. Concentration of filtrate
3. Which of the following conditions might place a client at risk for urinary calculi?
   a. Adrenal insufficiency
   b. Serotonin deficiency
   c. Hyperaldosteronism
   d. Hyperparathyroidism
4. Which of the following are normal changes associated with aging of the urinary system that the nurse would assess in an older adult?
   a. Decreased levels of blood urea nitrogen
   b. Postvoiding residual urine
   c. Increased bladder capacity
   d. More easily palpable kidneys
5. Which of the following does the nurse undertake during physical assessment of the urinary system?
   a. Percussion of the flank area with a firm blow
   b. Palpation of an empty bladder as a small nodule
   c. Prone positioning of the client to palpate the kidneys

d. Auscultation to determine the level of urine in the bladder

6. Which of the following are normal findings, expected by the nurse on physical assessment of the urinary system? *(Select all that apply)*
   a. Nonpalpable left kidney
   b. Auscultation of renal artery bruit
   c. CVA tenderness elicited by a kidney punch
   d. No CVA tenderness elicited by a kidney punch
   e. Palpable bladder to the level of the symphysis pubis
7. Which of the following is an important nursing responsibility after IVP?
   a. Assessment of the client for flank pain
   b. Encouragement of extra oral fluid intake
   c. Observation of urine for remaining contrast material
   d. Encouragement of ambulation 2 to 3 hours after the study
8. Which of the following would the nurse expect to find on reading the urinalysis results of a dehydrated client?
   a. A pH of 8.4
   b. RBC measurement of 4 per high-powered field
   c. Colour and appearance: yellow, cloudy
   d. Specific gravity of 1.035

CHAPTER 48

Nursing Management

Renal and Urological Problems

Written by, Suzanne Teresa Parsell

Adapted by, Kathleen Rodger, Lynn Jansen

LEARNING OBJECTIVES

1. Describe the pathophysiology, clinical manifestations, collaborative care, and drug therapy of cystitis, urethritis, and pyelonephritis.
2. Explain the nursing management of urinary tract infections.
3. Describe the immunological mechanisms involved in glomerulo-nephritis.
4. Explain the clinical manifestations and the nursing and collaborative management of acute poststreptococcal glomerulo-nephritis, Goodpasture's syndrome, and chronic glomerulo-nephritis.
5. Describe the common causes, clinical manifestations, collaborative care, and nursing management of nephrotic syndrome.
6. Compare and contrast the etiology, clinical manifestations, collaborative care, and nursing management of various types of urinary calculi.
7. Explain the common causes and management of renal trauma, renal vascular problems, and hereditary renal problems.
8. Describe the mechanisms of renal involvement in metabolic and connective tissue disorders.
9. Describe the clinical manifestations and collaborative care of kidney and bladder cancers.
10. Describe the common causes and management of bladder dysfunctions.
11. Differentiate among ureteral, suprapubic, nephrostomy, and urethral catheters with regard to indications for use and nursing responsibilities.

12. Explain the nursing and collaborative management of the patient undergoing nephrectomy or urinary diversion surgery.

urinary incontinence (UI), p. 1186
urinary retention, p. 1186

Renal and urological disorders encompass a wide spectrum of clinical problems. The diverse causes of these disorders may involve infectious, immunological, obstructive, metabolic, collagen-related and vascular, traumatic, congenital, neoplastic, and neurological mechanisms. This chapter discusses specific disorders of the kidneys, ureters, bladder, and urethra. Acute kidney injury and chronic kidney disease are discussed in

Chapter 49. Female reproductive problems are discussed in Chapter 56. Male reproductive problems are discussed in Chapter 57.

Infectious and Inflammatory Disorders of the Urinary System

Urinary Tract Infection

Urinary tract infections (UTIs) are the most common bacterial infection in women. During their lifetime, more than half of women will have a UTI (Al-Badr & Al-Shaikh, 2013), and up to 50% of these will have another infection within a year (Zak, 2014). In the older-adult population, the prevalence of UTI varies from 30% to 50% in women and 25% to 40% in men. In some cases, patients who develop Gram-negative bacteremia die, and one-third of these cases are caused by bacterial infections originating in the urinary tract (National Institute of Diabetes and Digestive and Kidney Diseases [NIDDK], 2017).

Inflammation of the urinary tract may be attributable to a variety of disorders, but bacterial infection is by far the most common (Nicolle, 2013). In the majority of healthy persons, the bladder and its contents are free from bacteria. Nevertheless, a number of otherwise healthy individuals, including many young-adult women and older women and men, have some bacteria colonizing the bladder. This condition is called *asymptomatic bacteriuria* and does not warrant treatment. In contrast, an infection of the urinary system is diagnosed when bacterial invasion of the urinary tract occurs. Bacterial counts of 10^5 colony-forming units per millilitre (CFU/mL) or higher typically indicate a clinically significant UTI. However, counts as low as 10^2 to 10^3 CFU/mL in a person with signs and symptoms are indicative of UTI.

Escherichia coli (E. coli) (Table 48-1) is the most common pathogen leading to a UTI. Although fungal and parasitic infections may also cause UTIs, they are uncommon. UTIs from these causes are sometimes observed in immuno-suppressed patients, patients with diabetes mellitus, or patients who have undergone multiple courses of antibiotic therapy. They also may be seen in persons living in or having travelled to certain developing countries. Recurrent UTIs are one of the most common bacterial infections in women. Increased antibiotic resistance may be making treatment and prevention of UTIs difficult (Chisholm, 2015).

TABLE 48-1

COMMON MICRO-ORGANISMS CAUSING URINARY TRACT INFECTIONS

• *Escherichia coli**
• *Candida*
• *Enterobacter*
• *Enterococcus*
• *Klebsiella*
• *Proteus*
• *Pseudomonas*
• *Serratia*
• *Staphylococcus*

*Causes about 80% of infections in persons who do not have urinary tract structural abnormalities or calculi.

Classification

Several classification systems can be used for UTIs (Nicolle, 2013). For example, a UTI can be broadly classified as an upper or a lower UTI according to its location within the urinary system (Figure 48-1). Infection of the upper urinary tract (involving the renal parenchyma, renal pelvis, and ureters) typically causes fever, chills, and flank pain, whereas a UTI confined to the lower urinary tract does not usually have systemic manifestations. Specific terms are used to further delineate the location of a UTI or inflammation. For example, **pyelonephritis** implies inflammation (usually caused by infection) of the renal parenchyma and the collecting system. **Cystitis** indicates an inflammatory condition of the urinary bladder, characterized by pain, urgency and frequency of urination, and hematuria. **Urethritis** means inflammation of the urethra.

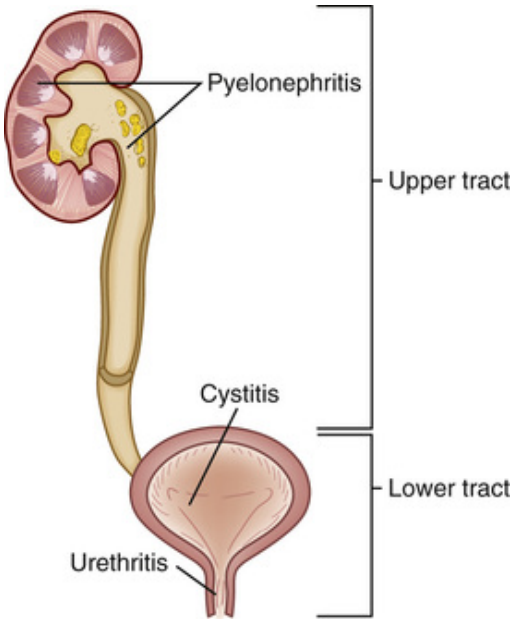

FIGURE 48-1 Sites of infectious processes in the urinary tract.

Classifying a UTI as complicated or uncomplicated is also useful. *Uncomplicated infections* are those that occur in an otherwise normal urinary tract (Nicolle, 2013). *Complicated infections* include those that occur concurrently with obstruction, stones, or catheters; those that occur in patients with existing diabetes or neurological diseases; and recurrent infections. Patients with a complicated infection are at risk for renal damage.

UTIs can also be classified according to their natural history. An *initial infection* (sometimes called a first or an isolated infection) refers to an uncomplicated UTI in a person who has never had an infection or who experiences one that is remote from any previous UTI (usually separated by a period of years). In contrast, a *recurrent UTI* is a reinfection in a person who experienced a previous infection that was successfully eradicated. A recurrent UTI that occurs because the original infection was not adequately eradicated is classified as unresolved bacteriuria or bacterial persistence. *Unresolved bacteriuria* occurs when bacteria are initially resistant to the antibiotic used to treat an infection, when the antibiotic agent fails to achieve adequate concentrations in the urine or the bloodstream to kill bacteria, or when the antibiotic is discontinued before the underlying bacteriuria is completely eradicated. *Bacterial persistence* also may occur when bacteria develop resistance to the antibiotic agent selected for treatment or when a foreign body in the urinary system serves as a harbour or anchor allowing bacteria to survive despite appropriate therapy.

Etiology and Pathophysiology

The urinary tract above the urethra is normally sterile. Several physiological and mechanical defence mechanisms assist in maintaining sterility and preventing UTIs. These defences include normal voiding with complete emptying of the bladder, normal antibacterial capability of the bladder mucosa and urine, uretero-vesical junction (UVJ) competence, and peristaltic activity that propels urine toward the bladder. An alteration in any of these defence mechanisms increases the risk of contracting a UTI. Table 48-2 lists predisposing factors to UTIs.

TABLE 48-2
PREDISPOSING FACTORS TO URINARY TRACT INFECTIONS

Factors Increasing Urinary Stasis
• Extrinsic obstruction (tumour, fibrosis compressing urinary tract) • Intrinsic obstruction (stone, tumour of urinary tract) • Urinary retention (including neurogenic bladder and low bladder-wall compliance)
Foreign Bodies
• In-dwelling catheter • Ureteral stent (proximity of urethral and anal orifices) • Urinary calculi
Anatomical Factors
• Congenital defects leading to obstruction or urinary stasis • Fistula (abnormal opening) exposing urinary stream to skin, vagina, or fecal stream • Shorter female urethra (proximity of urethral and anal orifices)
Factors Compromising Immune Response
• Diabetes mellitus • Human immunodeficiency virus infection
Functional Disorders
• Constipation • Voiding dysfunction with detrusor sphincter dyssynergia

The organisms that usually cause UTIs are introduced via the ascending route from the urethra. Other, less common routes are via the bloodstream or the lymphatic system. Most infections are caused by Gram-negative bacilli normally found in the gastro-intestinal (GI) tract, although Gram-positive organisms such as streptococci, enterococci, and *Staphylococcus saprophyticus* can also cause urinary infections. A common factor contributing to ascending infection is urological instrumentation (e.g., catheterization, cystoscopic examinations). Instrumentation allows bacteria that are normally present at the opening of the urethra to enter the urethra or the bladder. Sexual intercourse promotes “milking” of bacteria from the vagina and the perineum and may cause minor urethral trauma that predisposes women to UTIs.

Rarely do UTIs result from a hematogenous route, where bloodborne bacteria secondarily invade the kidneys, the ureters, or the bladder from elsewhere in the body. For a kidney infection to occur from hematogenous transmission, there must be prior injury to the urinary tract, such as obstruction of a ureter, damage caused by stones, or renal scars.

An important source of UTIs is health care–acquired, or health care–associated, infection. The cause of health care–associated infection is often *E. coli* and, less frequently, *Pseudomonas* organisms. Urological instrumentation, particularly with an in-dwelling urinary catheter, is the most common predisposing factor.

Clinical Manifestations

Bothersome lower urinary tract symptoms (LUTS) are seen in UTIs of the upper urinary tracts as well as those confined to the lower tract. These symptoms are related to either bladder storage or bladder emptying. These symptoms are defined in Table 48-3.

TABLE 48-3
LOWER URINARY TRACT SYMPTOMS

Emptying Symptoms
• Dysuria—difficulty voiding • Hesitancy—difficulty starting the urine stream, resulting in a delay between initiation of urination by relaxation of the urethral sphincter and the actual start of the urine stream • Intermittency—interruption of the urinary stream while voiding • Pain on urination • Postvoid dribbling—urine loss after completion of voiding • Urinary retention or incomplete emptying—inability to empty urine from the bladder, which can be caused by atonic bladder or obstruction of the urethra; can be acute or chronic • Weak urinary stream
Storage Symptoms
• Incontinence—involuntary or unwanted loss or leakage of urine • Nocturia—waking up two or more times at night because of the need or the urge to void • Nocturnal enuresis—complaint of loss of urine during sleep; called *bedwetting* in children • Urgency—a sudden, strong or intense desire to void immediately, usually accompanied by frequency • Urinary frequency—an abnormally frequent (usually eight times in a 24-hr period) desire to void, often of only small quantities (e.g., <200 mL)

These symptoms include dysuria, frequency of urination (>q2h), urgency, and suprapubic discomfort or pressure. The urine may contain grossly visible blood (hematuria) or sediment, giving it a cloudy appearance. Flank pain, chills, and the presence of a fever indicate an infection involving the upper urinary tract (pyelonephritis). It is important to remember that these symptoms, considered characteristic of a UTI, are often absent in older adults. Older adults tend to experience nonlocalized

abdominal discomfort rather than dysuria and suprapubic pain (Arinzon, Shabat, Peisakh, et al., 2012). In addition, they may have cognitive impairment, delirium, and falls. Older adults are also less likely to experience a fever with infection of the upper urinary tract. Patients older than age 80 may experience a slight decline in temperature. People with significant bacteriuria may have no symptoms or may have nonspecific symptoms such as fatigue or anorexia.

Multiple factors may produce bothersome LUTS like those that can accompany a UTI. For example, patients with bladder tumours or those receiving intravesical chemotherapy or pelvic radiation usually experience urinary frequency, urgency, and dysuria. Interstitial cystitis, discussed later in this chapter, is a chronic inflammatory condition of unknown etiology also producing bothersome urinary symptoms that sometimes cause it to be confused with a UTI.

Diagnostic Studies

Dipstick urinalysis should be obtained initially to identify the presence of nitrites (indicating bacteriuria), white blood cells (WBCs), and leukocyte esterase (an enzyme present in WBCs). These findings can be confirmed by microscopic urinalysis. Following confirmation of bacteriuria and pyuria, a urine culture may be obtained. A urine culture is indicated in complicated or health care–associated UTIs, persistent bacteria, or frequently recurring UTIs (more than two to three episodes per year). Urine also may be cultured when the infection is unresponsive to empirical therapy or the diagnosis is questionable. A voided midstream technique yielding a clean-catch urine sample is preferred for obtaining a urine culture in most circumstances. (See Chapter 47, Table 47-8, for a description of this technique.) However, a specimen obtained by catheterization or suprapubic needle aspiration provides more accurate results and may be necessary when an adequate clean-catch specimen cannot be readily obtained.

A urine culture is accompanied by *sensitivity testing* to determine the bacteria's susceptibility to a variety of antibiotic drugs. The results of this test allow the health care provider to select an antibiotic known to be capable of destroying the bacterial strain producing a UTI in a specific patient.

Imaging studies of the urinary tract are indicated in select cases. For example, an intravenous pyelogram (IVP) or abdominal computed

tomographic (CT) scan may be obtained when obstruction of the urinary system is suspected of causing a UTI.

Collaborative Care and Drug Therapy

Once a UTI has been diagnosed, appropriate antimicrobial therapy is initiated. An antibiotic may be selected based on the health care provider's best judgement (empirical therapy) or the results of sensitivity testing. The collaborative care and drug therapy of cystitis are summarized in Table 48-4. Uncomplicated cystitis can be treated by a short-term course of antibiotics, typically for 1 to 3 days. In contrast, complicated UTIs require longer-term treatment, lasting 7 to 14 days or even longer (Hooton, 2012).

TABLE 48-4
COLLABORATIVE CARE
Urinary Tract Infection

Diagnostic
• History and physical examination • Imaging studies of urinary tract (e.g., IVP, cystoscopy) (if indicated) • Urinalysis • Urine for culture and sensitivity (if indicated)
Collaborative Therapy
Uncomplicated UTI

• Adequate fluid intake
• Antibiotic: 1- to 3-day treatment regimen
  • Nitrofurantoin (MacroBid)
  • Trimethoprim–sulphamethoxazole (Septra)
• Counselling about risk for recurrence and reduction of risk factors

Recurrent, Uncomplicated UTI

• Repeated urinalysis and consideration of need for urine culture and sensitivity testing
• Antibiotic: 3- to 5-day treatment regimen
  • Nitrofurantoin (MacroBid)
  • Sensitivity-guided antibiotic (ampicillin, amoxicillin, first-generation cephalosporin, fluoroquinolone)
  • Trimethoprim–sulphamethoxazole (Septra)
• Consideration of 3- to 6-mo trial of suppressive antibiotics
• Adequate fluid intake
• Counselling about risk for recurrence and reduction of risk factors
• Imaging study of urinary tract in select cases

IVP, intravenous pyelogram; *UTI*, urinary tract infection.

Trimethoprim–sulphamethoxazole (TMP-SMX) or nitrofurantoin is often used empirically to treat uncomplicated or initial UTIs. TMP-SMX has the advantages of being relatively inexpensive and being taken only twice daily. Nitrofurantoin is normally given three to four times daily, but a long-acting preparation (MacroBid) is available that is taken twice daily. Ampicillin or amoxicillin is not frequently selected when empirically treating an uncomplicated UTI because these antibiotics must be

administered three to four times daily. In addition to these drugs, the fluoroquinolones (including ciprofloxacin [Cipro], levofloxacin, and norfloxacin) may be used to treat complicated UTIs (Nicolle, 2013). *Prophylactic*, or *suppressive*, *antibiotics* are sometimes administered to patients who experience repeated UTIs.

Drug Alert

Nitrofurantoin (MacroBid)

- Avoid sunlight. Use sunscreen, and wear protective clothing.
- Notify health care provider immediately if fever, chills, cough, chest pain, dyspnea, rash, or numbness or tingling of fingers or toes develops.

A low dose of TMP-SMX, nitrofurantoin, or another antibiotic, such as ciprofloxacin, may be administered on a daily basis in an attempt to prevent recurring UTIs, or a single dose may be taken before an event likely to provoke a UTI, such as intercourse. However, although suppressive therapy is often effective on a short-term basis, this strategy is limited because of the risk for antibiotic resistance, ultimately leading to breakthrough infections with increasingly virulent pathogens.

Nursing Management Urinary Tract Infection

Nursing Assessment

Subjective and objective data that should be obtained from a patient with a UTI are presented in Table 48-5.

TABLE 48-5

NURSING ASSESSMENT
Urinary Tract Infection

Subjective Data
Important Health Information
Past health history: Previous UTIs; urinary calculi, stasis, reflux, strictures, or retention; neurogenic bladder; pregnancy; prostatic hyperplasia; sexually transmitted infection; bladder cancer *Medications:* Use of antibiotics, anticholinergics, antispasmodics *Surgery or other treatments:* Recent urological instrumentation (catheterization, cystoscopy, surgery)
Symptoms
• Lassitude, malaise • Nausea, vomiting, and anorexia; chills • Suprapubic or low back pain, pressure in bladder area, costovertebral tenderness; bladder spasms, dysuria, burning on urination, sense of incomplete emptying • Urinary frequency, urgency, hesitancy; nocturia
Objective Data
General
Fever
Urinary
Hematuria; cloudy, foul-smelling urine; tender, enlarged kidney
Possible Findings
Leukocytosis; urinalysis positive for bacteria, pyuria, RBCs, and WBCs; positive urine culture; IVP, CT scan, ultrasound, voiding cysto-urethrogram and cystoscopy demonstrating abnormalities of urinary tract

CT, computed tomography; *IVP,* intravenous pyelogram; *RBCs,* red blood cells; *UTI,* urinary tract infection; *WBCs,* white blood cells.

Nursing Diagnoses

Nursing diagnoses for the patient with a UTI may include but are not limited to the following:

- *Impaired urinary elimination* related to *multiple causality* (effects of UTI)
- *Readiness for enhanced health management* as evidenced by *expressed desire to enhance management of risk factors*

Planning

The overall goals are (a) that the patient with a UTI will have relief from bothersome LUTS, (b) prevention of upper urinary tract involvement, and (c) prevention of recurrence.

Nursing Implementation

Health Promotion.

Health-promotion measures include recognizing individuals who are at risk for a UTI. Debilitated persons, older adults, patients with underlying diseases (e.g., cancer, human immunodeficiency virus [HIV], or diabetes mellitus) that compromise host immune responses, and patients treated with immuno-suppressive drugs or corticosteroids are at high risk for UTIs. Especially for these individuals, health-promotion activities can help decrease the frequency of infections and promote early detection of infection. Health-promotion activities include educating the patient about preventive measures, such as (a) emptying the bladder regularly and completely, (b) evacuating the bowel regularly, (c) wiping the perineal area from front to back after urination and defecation, and (d) drinking an adequate amount of liquid each day. The recommended daily liquid intake for the ambulatory adult is approximately 33 mL/kg of body weight per day. Thus, a 70-kg person would require 2 310 mL each day. The person will obtain approximately 20% of this fluid from food, leaving 1 848 mL, or nearly eight 236-mL glasses of fluid, to be obtained by drinking. Although suppressive antibiotics are not generally recommended, daily intake of cranberry juice (consumed as pure juice, 236 mL twice daily) or cranberry essence tablets may reduce the risk for certain UTIs (Wang, Fang, Chen, et al., 2012) (see the "Evidence-Informed Practice" box). In addition, it is important to advise the patient to seek early treatment once symptoms are identified.

The nurse can play a major role in the prevention of health care–associated infections. Avoidance of unnecessary catheterization and early removal of in-dwelling catheters are the most effective means for reducing health care–associated UTIs. All patients undergoing instrumentation of the urinary tract are at risk of developing a health care–associated UTI. Aseptic technique must always be followed during these procedures. Washing hands before and after contact with each patient and wearing gloves for care involving the urinary system are especially important. When a catheter has been inserted, special measures must be employed, as explained in the section on urethral catheterization later in this chapter.

Routine and thorough perineal hygiene is important for all hospitalized patients, especially when a bedpan is used. Answering the call light quickly or offering the bedpan or urinal at frequent intervals to a bedridden patient should reduce the number of incontinent episodes.

Evidence-Informed Practice

Research Highlight

Do Cranberry Products Prevent Urinary Tract Infections?

Clinical Question

Among adults and children (P), what is the effect of cranberry-containing products (I) vs. placebo vs. nonplacebo control (C) in preventing urinary tract infections (O)?

Best Available Evidence

Systematic review of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence

- Thirteen RCTs (n = 1 616) of patients at high risk for recurrent urinary tract infections (UTIs), including women, older adults, patients with neuropathic bladder, and pregnant women. Children were also studied.
- Cranberry products were juice, capsules, or tablets given for 6 mo in most cases.
- Cranberry-containing products had a positive effect in preventing symptomatic UTIs.
- These products showed greater effect in women (especially those with recurrent UTIs), children, cranberry juice drinkers, and those taking the products more than twice daily.

Conclusions

- Cranberry-containing products can prevent UTIs.
- Cranberry juice was more effective than cranberry capsules. This difference may be due to increased hydration from the juice.

Implications for Nursing Practice

- Inform patients who are at an increased risk for recurrent UTIs that cranberry products have a protective effect in reducing UTIs.
- Cranberry juice works by preventing the attachment of bacteria to the epithelial cells in the bladder wall.
- Emphasize the importance of adequate fluid intake, including drinking cranberry juice.

P, Patient population of interest; *I,* intervention or area of interest; *C,* comparison of interest or comparison group; *O,* outcomes of interest (see Chapter 1).

Reference for Evidence

Wang C, Fang C, Chen N, et al. Cranberry-containing products for prevention of urinary tract infections in susceptible populations: A systematic review and meta-analysis of randomized controlled trials. *Archives of Internal Medicine*. 2012;172(13):988–996.

Acute Intervention.

Acute intervention for a patient with a UTI includes ensuring adequate fluid intake if it is not contraindicated. It is sometimes difficult to get the patient to maintain an adequate fluid intake because the person may think it will worsen the discomfort and frequency associated with a UTI. The patient needs to be told that fluids will increase frequency of urination at first but will also dilute the urine, making the bladder less irritable. Fluids will help flush out bacteria before they have a chance to colonize in the bladder. Caffeine, alcohol, citrus juices, chocolate, and highly spiced foods or beverages should be avoided because they are potential bladder irritants.

Local application of heat to the suprapubic area or lower back may relieve the discomfort associated with a UTI. The patient can be advised to apply a heating pad (turned to its lowest setting) to these areas. A warm shower can also be effective in providing temporary relief. The patient should be instructed about the prescribed drug therapy, including adverse effects. The nurse should emphasize the importance of taking the full course of antibiotics. Often patients stop antibiotic therapy once symptoms disappear. This practice can lead to inadequate treatment and recurrence of infection or to bacterial resistance to antibiotics. Sometimes a second drug or a reduced dose of drug is ordered after the initial course to suppress bacterial growth in certain patients susceptible to recurrent UTIs. The patient should be advised to watch for any changes in the colour or the consistency of the urine and for a decrease in or cessation of symptoms as a sign of the effectiveness of therapy. The patient should be counselled that persistence of bothersome LUTS beyond the antibiotic treatment course or the onset of flank pain or fever should be reported promptly to a health care provider.

Ambulatory and Home Care.

The nurse's responsibility in ambulatory and home care settings is to work with the patient to promote understanding about the need for ongoing care (Table 48-6).

TABLE 48-6

PATIENT & CAREGIVER TEACHING GUIDE
Urinary Tract Infection

The following information should be included when teaching the patient and caregiver about UTI to prevent recurrence:
1. The patient must take all antibiotics as prescribed. Symptoms may improve after 1 to 2 days of therapy, but organisms may still be present. 2. The patient must be instructed about appropriate hygiene, including the following: a. Careful cleansing of perineal region b. Wiping from front to back after urinating c. Cleansing with soap and water after each bowel movement 3. The patient should be taught about the importance of emptying the bladder before and after intercourse, which may help flush out bacteria introduced during intercourse. The patient should wash the genital area with warm water before having sex. 4. The patient should be advised to urinate regularly, approximately q2–4 hr during the day. 5. The patient should be advised about how to maintain adequate fluid intake (33 mL [1 oz] per kilogram of body weight per day). 6. The patient should understand why harsh soaps, bubble baths, powders, and sprays should not be applied in the perineal area. 7. The patient should be advised to report symptoms or signs of recurrent UTI (e.g., cloudy urine, pain on urination, urgency, frequency).

UTI, urinary tract infection.

The patient must understand the need for follow-up care with urine culture to determine if the infection has been adequately treated. Recurrent symptoms caused by bacterial persistence or inadequate treatment typically occur within 1 to 2 weeks after completion of therapy. If the patient has been adherent, a relapse indicates the need for further evaluation.

Evaluation

Acute Pyelonephritis

Etiology and Pathophysiology

Pyelonephritis is an inflammation of the renal parenchyma (Figure 48-2) and collecting system (including the renal pelvis). The most common cause is bacterial infection, but fungi, protozoa, or viruses sometimes infect the kidney (Kumar, Ankur, Wolf, et al., 2015).

FIGURE 48-2 Acute pyelonephritis. Cortical surface shows greyish-white areas of inflammation and abscess formation. Source: Kumar, V., Abbas, A. K., & Aster, J. (2015). *Robbins and Cotran pathologic basis of disease* (9th ed., p. 931, Figure 20-27). Philadelphia: Saunders.

Urosepsis is a systemic infection arising from a urological source. Its prompt diagnosis and effective treatment are critical because, unless promptly eradicated, it leads to septic shock and death in 15% of cases. Septic shock is the outcome of unresolved bacteremia involving a Gram-negative organism. (Septic shock is discussed in Chapter 69.)

Pyelonephritis usually begins with colonization and infection of the lower urinary tract via the ascending urethral route. Bacteria normally found in the intestinal tract, such as *E. coli, Proteus, Klebsiella,* or *Enterobacter* species, frequently cause pyelonephritis. A pre-existing factor is often present, such as *vesico-ureteral reflux* (retrograde or backward movement of urine from lower to upper urinary tract) or dysfunction of lower urinary tract function such as obstruction from benign prostatic hyperplasia (BPH), a stricture, or a urinary stone.

Acute pyelonephritis commonly starts in the renal medulla and spreads to the adjacent cortex. Recurring episodes of pyelonephritis, especially in the presence of obstructive abnormalities, can lead to a scarred, poorly functioning kidney and a condition called *chronic pyelonephritis.*

Clinical Manifestations and Diagnostic Studies

The clinical manifestations of acute pyelonephritis vary from mild fatigue to the sudden onset of chills, fever, vomiting, malaise, flank pain, and the

bothersome LUTS characteristic of cystitis. *Costovertebral tenderness* is typically present on the affected side. The clinical manifestations usually subside within a few days, even without specific therapy, but bacteriuria and pyuria usually persist.

Urinalysis shows pyuria, bacteriuria, and varying degrees of hematuria. WBC casts may be found in the urine, indicating involvement of the renal parenchyma. A complete blood cell count (CBC) will show leukocytosis and a shift to the left with an increase in immature neutrophils (bands). Urine cultures must be obtained when pyelonephritis is suspected. In patients with more severe illness who are hospitalized, blood cultures are also obtained.

Imaging studies, such as an IVP or CT scan, requiring intravenous injection of contrast materials are usually not obtained in the early stages of pyelonephritis so as to prevent the possible spread of infection. Alternatively, ultrasonography of the urinary system may be obtained to identify anatomical abnormalities or the presence of an obstructing stone and reduce the need for catheterization. Imaging studies are also used to assess for complications of pyelonephritis such as impaired renal function, scarring, chronic pyelonephritis, or abscesses.

Urosepsis is characterized by bacteriuria and bacteremia (presence of bacteria in blood). If bacteremia is a possibility, close observation and monitoring of vital signs are essential. Prompt recognition and treatment of septic shock may prevent irreversible damage or death.

Collaborative Care and Drug Therapy

The diagnostic tests and the collaborative therapy of acute pyelonephritis are summarized in Table 48-7. Patients with severe infections or complicating factors, such as nausea and vomiting with dehydration, require hospital admission.

TABLE 48-7

COLLABORATIVE CARE
Acute Pyelonephritis

Diagnostic
• History and physical examination • Blood culture (if bacteremia is suspected) • CBC count with WBC differential • Palpation for flank pain • Ultrasound (initially), IVP, VCUG, radionuclide imaging, CT scan • Urinalysis • Urine for culture and sensitivity
Collaborative Therapy
Mild Symptoms

• Adequate fluid intake
• Follow-up urine culture and imaging studies
• Nonsteroidal anti-inflammatory drugs or antipyretic drugs
• Outpatient management or short hospitalization for IV antibiotics:
  • Empirically selected broad-spectrum antibiotics (ampicillin, vancomycin) combined with an aminoglycoside (e.g., tobramycin, gentamicin)
  • Switch to sensitivity-guided therapy (when results available) for 14–21 days
  • Trimethoprim–sulphamethoxazole (Septra)
  • Fluoroquinolones (e.g., ciprofloxacin [Cipro], norfloxacin)

Severe Symptoms

• Adequate fluid intake (initially parenteral; switched to oral fluids as nausea, vomiting, and dehydration subside)
• Hospitalization
• Nonsteroidal anti-inflammatory or antipyretic drugs to reverse fever and relieve discomfort
• Parenteral antibiotics:
  • Empirically selected broad-spectrum antibiotics (e.g., ampicillin, vancomycin) combined with an aminoglycoside (e.g., tobramycin, gentamicin)
  • Switch to sensitivity-guided antibiotic therapy when results of urine and blood cultures are available
  • Oral antibiotics when patient tolerates oral intake; administer for 7–21 days
• Urinary analgesics (e.g., to relieve bothersome lower urinary tract symptoms)
• Follow-up urine culture and imaging studies

CBC, complete blood count; *CT,* computed tomography; *IV,* intravenous; *IVP,* intravenous pyelogram; *VCUG,* voiding cysto-urethrogram; *WBC,* white blood cell.

Patients with mild symptoms may be treated on an outpatient basis with antibiotics for 14 to 21 days (see Table 48-7). Parenteral antibiotics are often given initially in the hospital to rapidly establish high serum and urinary drug levels. When initial treatment resolves acute symptoms and the patient is able to tolerate oral fluids and drugs, the person may be discharged on a regimen of oral antibiotics for an additional 14 to 21 days. Symptoms and signs typically improve or resolve within 48 to 72 hours after starting therapy (Grabe, Bartoletti, Bjerklund-Johansen, et al., 2014).

Relapses may be treated with a 6-week course of antibiotics. Reinfections may be treated as individual episodes of disease or managed with long-term antibiotic therapy. Antibiotic prophylaxis may also be used for recurrent infections. The effectiveness of therapy is evaluated in

accordance with the presence or absence of bacterial growth on a urine culture.

Nursing Management Acute Pyelonephritis

Nursing Assessment

Subjective and objective data that should be obtained from a patient with pyelonephritis are presented in Table 48-5.

Nursing Diagnoses

Nursing diagnoses for a patient with pyelonephritis include but are not limited to those for a patient with a UTI (see NCP 48-1).

Planning

The overall goals are that the patient with pyelonephritis will have (a) relief of pain, (b) normal body temperature, (c) no complications, (d) normal renal function, and (e) no recurrence of symptoms.

Nursing Implementation

Health Promotion.

Health promotion and maintenance measures are similar to those for cystitis (see "Nursing Management: Urinary Tract Infection," earlier in this chapter). In addition, it is important that patients receive early treatment for cystitis to prevent ascending infections. The need for regular medical care should be stressed to patients with structural abnormalities of the urinary tract because these patients are at high risk for infection.

Acute Intervention and Home Care.

Nursing interventions vary depending on the severity of symptoms. Interventions include teaching and working with the patient to promote understanding about the disease process with emphasis on (a) the need to continue drugs as prescribed, (b) the need for a follow-up urine culture to ensure proper management, and (c) identification of risk for recurrence or relapse (see Table 48-5 and NCP 48-1). In addition to antibiotic therapy, patients should be encouraged to drink at least eight glasses of fluid every day, even after the infection has been treated. Rest is often indicated to increase patient comfort. Patients with frequent relapses or reinfections

may be treated with long-term, low-dose antibiotics. Understanding the rationale for therapy is important to enhance patient application of knowledge for disease management.

Evaluation

Chronic Pyelonephritis

Chronic pyelonephritis is a term used to describe a kidney that has become shrunken and has lost function owing to scarring or fibrosis (Davis, Brady, & Creagh, 2014). It usually occurs as the outcome of recurring infections involving the upper urinary tract. However, it also may occur in the absence of an existing infection and a recent or remote history of UTIs. Alternative terms used to describe this condition include *interstitial nephritis, chronic atrophic pyelonephritis,* or *reflux nephropathy* (when scarring occurs in the presence of vesico-ureteral reflux).

Chronic pyelonephritis is diagnosed by radiological imaging and histological testing rather than assessment of clinical features. Imaging studies reveal a small, contracted kidney with a thinned parenchyma. The collecting system may be small or hydronephrotic. Pathological analysis reveals loss of functioning nephrons, infiltration of the parenchyma with inflammatory cells, and fibrosis.

The level of renal function in chronic pyelonephritis varies, depending on whether one or both kidneys are affected, the magnitude of scarring, and the presence of coexisting infection. Chronic pyelonephritis often progresses to end-stage renal disease when both kidneys are involved, even if the underlying infection is successfully eradicated. (Nursing and collaborative management of patients with chronic kidney disease are discussed in Chapter 49.)

Urethritis

Urethritis is an inflammation of the urethra. Causes of urethritis include a bacterial or viral infection, *Trichomonas* and monilial infection (especially in women), chlamydia, and gonorrhea (especially in men). In men, urethritis usually arises from sexual transmission; purulent discharge usually indicates a gonococcal urethritis, whereas a clear discharge typically signifies a nongonococcal urethritis. (Sexually transmitted infections are discussed in Chapter 55.) Urethritis also produces

bothersome LUTS, including dysuria and frequent urination, similar to those seen with cystitis.

Urethritis is difficult to diagnose in women, as urethral discharge may not be present. Cultures on split urine collections (taken at beginning of urine flow and then midstream) or any urethral discharge may confirm a diagnosis of urethral infection.

Treatment is based on identifying and treating the cause and providing symptomatic relief. Sulphamethoxazole with trimethoprim or nitrofurantoin are examples of drugs used for bacterial infections. Metronidazole (Flagyl) and clotrimazole may be used for treating *Trichomonas.* Drugs such as fluconazole (Diflucan) may be prescribed for monilial infections. In chlamydial infections, doxycycline may be used. Women with negative urine cultures and no pyuria do not usually respond to antibiotics. Hot sitz baths may temporarily relieve symptoms. Patients should be instructed to avoid the use of vaginal deodorant sprays, to properly cleanse the perineal area after bowel movements and urination, and to avoid intercourse until symptoms subside. Patients with sexually transmitted urethritis should be instructed to refer their sex partners for evaluation and testing if they had sexual contact in the 60 days preceding onset of symptoms or diagnosis.

Urethral Diverticula

Urethral diverticula are the result of obstruction and subsequent rupture of the periurethral glands into the urethral lumen with epithelialization (regrowth of tissue) over the opening of the resulting periurethral cavity (Urology Care Foundation, n.d.). Urethral diverticula are much more common in females than in males, with an incidence in women of 1% to 5%. Urethral diverticula occur mostly in the area of the periurethral glands. These glands are found along the entire length of the urethra, with the majority draining into the distal third of the urethra; Skene glands are the largest and most distal. A person may have more than one diverticulum, caused by urethral trauma from child-bearing, urethral instrumentation, dilation or infection with gonococcal organisms, or normal vaginal flora. Urethral diverticula present some of the more challenging diagnostic and reconstructive cases in urology.

Symptoms include dysuria, postvoid dribbling, frequent urination (>q2h), urgency, suprapubic discomfort or pressure, dyspareunia, a feeling of incomplete bladder emptying, and urinary incontinence. As well, the urine may contain gross hematuria or sediment, giving it a cloudy

appearance. However, one in four women have no symptoms. An anterior vaginal wall mass may be noted on physical examination, which, upon palpation, may be quite tender and express purulent discharge through the urethra. Radiographic studies such as voiding cysto-urethrography (VCUG) should be used to confirm the diagnosis. Additional studies include ultrasound and magnetic resonance imaging (MRI) to determine the size of the diverticulum in relation to the urethral lumen.

Surgical options include transurethral incision of the diverticular neck, marsupialization (creation of a permanent opening) of the diverticular sac into the vagina (often referred to as a *Spence procedure*), and surgical excision. Surgical excision of a urethral diverticulum should be performed with caution because the diverticular sac may be adherent to the adjacent urethral lumen, and careless excision of the sac may result in a large urethral defect requiring construction of a neourethra (new urethra). Other important considerations during surgery include identification and closure of the diverticular neck, complete removal of the mucosal lining of the diverticular sac to prevent recurrence, and a multiple-layered closure to prevent postoperative urethro-vaginal fistula formation. A complication of the surgery may be stress urinary incontinence.

Interstitial Cystitis

Interstitial cystitis (IC) is a chronic, painful inflammatory disease of the bladder believed to be associated with an autoimmune or allergic response. It is thought to affect as many 101 228 Canadians (3%). IC is most frequently diagnosed in midlife (Davis, Brady, & Creagh, 2014). The ratio of women to men with IC is 10 to 12 : 1 (NIDDK, 2011). Although the etiology of IC remains unknown, probable contributing factors include chronic inflammation with mast cell invasion of the bladder wall (possibly provoked by an infection or an autoimmune disorder), defects of the glycosaminoglycan layer that protects the bladder mucosa from the irritating effects of urine exposure, abnormal constituents in the urine, and neurological dysfunction (Gish, 2011).

The two primary clinical manifestations that characterize IC are pain and bothersome LUTS (e.g., frequency, urgency). The pain associated with IC is usually located in the suprapubic area but may involve the vagina, labia, or entire perineal region. It varies from moderate to severe in intensity and is exacerbated by bladder filling, postponing urination, physical exertion, pressure against the suprapubic area, dietary intake of certain foods, and emotional distress. The pain is transiently relieved by

urination. Bothersome LUTS are very similar to those of a UTI, and the condition is often misdiagnosed as a recurring or chronic UTI. The pain and voiding symptoms produced by IC remit and exacerbate over time. Some patients experience an onset of symptoms that disappear altogether after a period of weeks to months, whereas others have persistent symptoms over a period of months to years.

IC is a diagnosis of exclusion. The condition is suspected whenever a patient experiences symptoms of a UTI despite the absence of bacteriuria, pyuria, or a positive urine culture. A careful history and physical examination are necessary to exclude a variety of disorders that may produce somewhat similar symptoms, such as UTI or endometriosis. This evaluation must include at least one negative urine culture during a period of active symptoms. Cystoscopic examination may reveal a small bladder capacity and superficial ulcerations with bladder filling called *glomerulations,* but these findings are frequently absent and are not unique to IC. Criteria for diagnosing IC are presented in Table 48-8.

TABLE 48-8

CLINICAL CRITERIA FOR THE DIAGNOSIS OF INTERSTITIAL CYSTITIS

Inclusion Criteria
• Bothersome urinary urgency • Cystoscopic evidence of ulcerations or glomerulations (not specific to interstitial cystitis) • Pain with bladder filling or postponing urination • Small bladder capacity on urodynamic testing
Exclusion Criteria
• Active genital herpes • Bladder capacity >350 mL on urodynamic testing • Bladder tumour • Daytime voiding frequency (eight or more times per day) • History of chemotherapy, particularly if treated with cyclophosphamide (Procytox) • History of pelvic irradiation • Overactive bladder contractions on urodynamic testing • Tubercular cystitis

Collaborative Care and Drug Therapy

Because the etiology of IC is unknown, no single treatment has been identified that consistently reverses or relieves symptoms. Various therapies have been effective in alleviating or relieving uncomfortable symptoms in most patients (Gish, 2011; Quillin & Erickson, 2012). Dietary and lifestyle alterations are used to relieve pain and diminish voiding frequency and nocturia. Dietary alterations include elimination of foods

and beverages likely to exacerbate the symptoms. Eating a diet low in acidic foods and avoiding consumption of beverages such as coffee, tea, and carbonated and alcoholic drinks can be helpful in reducing IC symptoms. Patients may be advised that an over-the-counter dietary supplement called calcium glycerophosphate alkalinizes the urine and can provide relief from the irritating effects of certain foods. This agent may be particularly helpful when dining away from home where the patient has less control over the preparation of foods.

A number of tricyclic antidepressants, including amitriptyline (Elavil) and doxepin, are used to reduce the burning pain and urinary frequency. Pentosan (Elmiron) is a drug used to enhance the protective effects of the glycosaminoglycan layer of the bladder. It is thought to relieve pain associated with IC by reducing the irritating effects of urine on the bladder wall. Medications that may provide modest relief from IC symptoms include nifedipine, which is a calcium channel blocker. Although these drugs are effective over time (weeks to months), they do not provide the immediate relief that may be needed when a patient experiences an acute exacerbation of symptoms. For this relief, a short course of opioid analgesics may be given.

Several drugs may be instilled directly into the bladder through a small catheter. Dimethyl sulphoxide probably acts by desensitizing pain receptors in the bladder wall. Heparin and hyaluronic acid also may be instilled into the bladder to relieve IC symptoms. Like pentosan, they are thought to enhance the protective properties of the glycosaminoglycan layer of the bladder. These medications are often administered with lidocaine, which rapidly desensitizes the bladder wall, rendering the patient better able to tolerate instillation of additional heparin or hyaluronic acid and providing transient relief from pain. The bacille Calmette–Guérin (BCG) vaccine, an attenuated form of *Mycobacterium bovis* administered intravesically, is now in clinical trials. The mechanism of action of BCG is unclear, but it may alleviate a possible autoimmune disorder provoking the chronic inflammation characteristic of the disorder.

Distension of the bladder during endoscopic examination relieves IC-related pain and voiding frequency, probably by temporarily disrupting sensory nerve endings in the bladder wall. Several surgical procedures have been used in an attempt to relieve severe, debilitating pain. Urinary diversion, the surgical removal of the bladder and rerouting flow of urine to an ostomy on the abdomen, is an approach that can be used when other measures fail. Unfortunately, some patients have reported pain within the

urinary diversion, possibly indicating that components of the urine may contribute to IC in certain cases.

Nursing Management Interstitial Cystitis

Assessment focuses on characterization of the pain associated with IC. The patient is asked about specific dietary or lifestyle factors known to exacerbate or alleviate pain and about the intensity of the pain. Objective data collection includes a bladder log or voiding diary kept over a period of at least 3 days to determine diurnal voiding frequency and patterns of nocturia. A simultaneous pain record may be useful.

Reassurance that IC is a real condition experienced by others and that it can be effectively treated may relieve the anxiety, anger, guilt, and frustration related to experiences of chronic pain and voiding dysfunction in the absence of a clear-cut diagnosis and treatment strategy.

A UTI may occur during the course of IC management. A UTI is likely to produce an acute exacerbation of bothersome LUTS and urinary frequency as well as dysuria (not typically associated with IC) and odorous urine, possibly with hematuria.

Broad dietary restrictions are often necessary to control IC-related pain. Patients must be given instruction about the need to maintain good nutrition. Specifically, they may be advised to take a multivitamin containing no more than the recommended dietary allowance for essential vitamins and to avoid high-potency vitamins, because these formulations may irritate the bladder. Patients are also advised to obtain information, including recipes and menus for a well-balanced diet specifically designed to avoid bladder-irritating foods and beverages, from support organizations such as the Women's College Hospital in Toronto and the Interstitial Cystitis Association in the United States (see the Resources at the end of this chapter). Elimination of a variety of foods and beverages from the diet that are likely to irritate the bladder typically provides modest to profound relief from symptoms. Typical bladder irritants include caffeine, alcohol, citrus products, aged cheeses, nuts, foods containing vinegar, curries or hot peppers, and foods or beverages likely to lower urinary pH. In addition, the patient should be taught to self-manage the use of calcium glycerophosphate or pantoprazole (Pantoloc). The patient is advised to avoid clothing that creates suprapubic pressure, including pants with tight belts or restrictive waistlines.

Written educational materials concerning diet, coping with the need for frequent urination, and strategies for coping with the emotional burden of

IC are available from the Interstitial Cystitis Association. Providing such materials affords an excellent opportunity for the nurse to introduce the patient to the existence of this patient advocacy group.

Renal Tuberculosis

Renal tuberculosis (TB) is rarely a primary lesion. It is usually secondary to TB of the lung. In a small percentage of patients with pulmonary TB, the tubercle bacilli reach the kidneys via the bloodstream. Onset occurs 5 to 8 years after the primary infection. The patient is often asymptomatic when the kidney is initially infiltrated with bacilli. Sometimes, the patient complains of fatigue and develops a low-grade fever. As the lesions ulcerate, infection descends to the bladder, and the patient experiences frequent urination, burning on voiding, and epididymitis (in men). Symptoms of a UTI are the first sign in the majority of patients with renal TB. Renal lesions may calcify as they heal. Infrequently, renal colic, lumbar and iliac pain, and hematuria may be present. A diagnosis is based on localization of tubercle bacilli in the urine and on IVP findings.

Long-term complications of renal TB depend on the duration of the disease before treatment. The renal parenchyma become scarred, and ureteral strictures develop. The earlier treatment is initiated, the less likely renal failure is to develop. Reduced bladder volume may be irreversible in advanced disease. The patient may require long-term urological follow-up. (Nursing and collaborative management for the patient with TB are discussed in Chapter 30.)

Immunological Disorders of the Kidney

Glomerulo-Nephritis

Immunological processes involving the urinary tract predominantly affect the renal glomerulus. The disease process results in **glomerulo-nephritis,** an immune-related inflammation of the glomeruli characterized by proteinuria, hematuria, decreased urine production, and edema. The condition affects both kidneys equally. Although the glomerulus is the primary site of inflammation, tubular, interstitial, and vascular changes also occur. Glomerulo-nephritis is divided into a number of classifications, which may describe (a) the extent of damage (diffuse or focal), (b) the initial cause of the disorder (e.g., systemic lupus erythematosus, systemic sclerosis [scleroderma], streptococcal infection), or (c) the extent of changes (minimal or widespread).

Clinical Manifestations

Clinical manifestations of glomerulo-nephritis include varying degrees of hematuria (ranging from microscopic to gross) and urinary excretion of various formed elements, including red blood cells (RBCs), WBCs, and casts. Proteinuria and elevated serum urea (blood urea nitrogen [BUN]) and serum creatinine levels are other manifestations. In most cases, recovery from the acute illness is complete. However, if progressive involvement occurs, the result is destruction of renal tissue and marked renal insufficiency.

A patient's history provides important information related to glomerulo-nephritis. It is necessary to assess exposure to drugs, immunizations, microbial infections, and viral infections such as hepatitis. It is also important to evaluate the patient for more generalized conditions involving immune disorders, such as systemic lupus erythematosus and systemic sclerosis.

Acute Poststreptococcal Glomerulo-Nephritis

Acute poststreptococcal glomerulo-nephritis (APSGN) is most common in children and young adults, but all age groups can be affected. APSGN develops 5 to 21 days after an infection of the pharynx or the skin (e.g., streptococcal sore throat, impetigo) by certain nephrotoxic strains of group A β-hemolytic streptococci. The patient produces antibodies to the

streptococcal antigen. Although the specific mechanism is not known, the antigen–antibody complexes are deposited in the glomeruli and activate complement (Doig & Huether, 2014). Complement activation (discussed in Chapter 14) causes an inflammatory reaction to the injury. The response to the injury is also a decrease in the filtration of metabolic waste products from the blood and an increase in the permeability of the glomerulus to larger protein molecules.

Clinical Manifestations and Complications

The clinical manifestations of APSGN appear as a variety of signs and symptoms, which may include generalized body edema, hypertension, oliguria, hematuria with a smoky or rusty appearance, and proteinuria. Fluid retention occurs as a result of decreased glomerular filtration. The edema appears initially in low-pressure tissues, such as around the eyes (periorbital edema), but later progresses to involve the total body as ascites or peripheral edema in the legs. Smoky urine indicates bleeding in the upper urinary tract. The degree of proteinuria varies with the severity of the glomerulo-nephropathy. Hypertension primarily results from increased extracellular fluid volume. Patients with APSGN may have abdominal or flank pain. Some, however, will have no symptoms, and the problem is found on routine urinalysis.

More than 95% of patients with APSGN recover completely or improve rapidly with conservative management. Chronic glomerulo-nephritis develops in 5% to 15% of affected persons, and irreversible renal failure occurs in less than 1% of patients (Ralph & Carapetis, 2013).

Diagnostic Studies

The diagnosis of APSGN is based on a complete history and physical examination and laboratory studies (Table 48-9) to determine the presence or history of a group A β-hemolytic streptococcus in a throat or skin lesion. An immune response to the streptococcus is often demonstrated by assessment of antistreptolysin O titres. The finding of decreased complement components (especially C3 and CH50) indicates an immune-mediated response. A renal biopsy may be performed to confirm the presence of the disease.

TABLE 48-9

COLLABORATIVE CARE
Acute Glomerulo-Nephritis

Diagnostic
• History and physical examination • BUN, serum creatinine, and albumin • CBC • Complement levels and ASO titre • Renal biopsy (if indicated) • Urinalysis
Collaborative Therapy
• Adjustment of dietary protein intake to level of proteinuria and uremia • Antihypertensive therapy • Diuretics • Rest • Sodium and fluid restriction

ASO, antistreptolysin O; *BUN,* blood urea nitrogen; *CBC,* complete blood cell count.

Dipstick and urine sediment microscopy will reveal the presence of erythrocytes in significant numbers. Erythrocyte casts are highly suggestive of acute glomerulo-nephritis. Proteinuria may range from mild to severe. Screening blood tests include BUN and serum creatinine to assess the extent of renal impairment.

Nursing and Collaborative Management Acute Poststreptococcal Glomerulo-Nephritis

The management of APSGN focuses on symptomatic relief (see Table 48-9). Rest is recommended until the signs of glomerular inflammation (proteinuria, hematuria) and hypertension subside. Edema is treated by restricting sodium and fluid intake and by administering diuretics. Severe hypertension is treated with antihypertensive drugs. Dietary protein intake may be restricted if there is evidence of an increase in nitrogenous wastes (e.g., elevated BUN). The restriction varies with the degree of proteinuria. (Low-protein, low-sodium, fluid-restricted diets are discussed in Chapter 49.) Antibiotics should be given only if the streptococcal infection is still present. Corticosteroids and cytotoxic drugs have not been shown to be of value.

One of the most important ways to prevent the development of APSGN is to encourage early diagnosis and treatment of sore throats and skin lesions. If streptococci are found in the culture, treatment with appropriate antibiotic therapy (usually penicillin) is essential. The patient must be encouraged to take the full course of antibiotics to ensure that the bacteria

have been eradicated. Good personal hygiene is an important factor in preventing the spread of cutaneous streptococcal infections. (The Kidney Foundation of Canada website [see the Resources at the end of this chapter] provides information on the management of kidney disease and support groups.)

Goodpasture's Syndrome

Goodpasture's syndrome is an autoimmune disease characterized by the presence of antibodies circulating against the glomerular and alveolar basement membranes. Damage to the kidneys and lungs results when binding of the antibody causes an inflammatory reaction mediated by complement activation (see Chapter 14).

Goodpasture's syndrome is a rare disease that is seen mostly in young male smokers. The clinical manifestations include hemoptysis, pulmonary insufficiency, crackles, wheezes, renal involvement with hematuria and renal failure, weakness, pallor, and anemia. Pulmonary hemorrhage usually occurs and may precede glomerular abnormalities by weeks or months. Abnormal diagnostic findings include low hematocrit and hemoglobin levels, elevated BUN and serum creatinine levels, hematuria, and proteinuria. Circulating serum anti–glomerular basement membrane (anti-GBM) antibodies parallel the activity of the renal disease and are diagnostic of this syndrome.

Nursing and Collaborative Management Goodpasture's Syndrome

Until recently, the prognosis for patients with Goodpasture's syndrome was poor. However, with the development of immuno-suppressive therapy and advances in transplantation techniques, the outlook has improved. Management consists of corticosteroids, immuno-suppressive drugs (e.g., cyclophosphamide [Procytox], azathioprine [Imuran]), plasmapheresis (see Chapter 16), and dialysis.

Nursing management appropriate for a critically ill patient who is experiencing symptoms of acute kidney injury and respiratory distress is instituted. Death is often secondary to hemorrhage in the lungs and respiratory failure. (Nursing interventions for a patient in acute kidney injury are discussed in Chapter 49, and nursing interventions for a patient with respiratory failure are discussed in Chapter 70.)

Rapidly Progressive Glomerulo-Nephritis

Rapidly progressive glomerulo-nephritis (RPGN) is glomerular disease associated with rapid, progressive loss of renal function over days to weeks. Renal failure may occur within weeks to months, in contrast to chronic glomerulo-nephritis, in which it develops insidiously and progresses over many years. The manifestations of RPGN are hypertension, edema, proteinuria, hematuria, and RBC casts.

RPGN can occur in a variety of situations: (a) as a complication of inflammatory or infectious disease (e.g., APSGN), (b) as a complication of a multisystemic disease (e.g., systemic lupus erythematosus, Goodpasture's syndrome), (c) as an idiopathic disease, or (d) in association with the use of certain drugs (e.g., penicillamine).

Treatment is directed toward correction of fluid overload, hypertension, uremia, and inflammatory injury to the kidney. Treatment includes corticosteroids, cytotoxic agents, and plasmapheresis. Dialysis therapy and transplantation are used as maintenance therapy for the patient with RPGN. Following renal transplantation, RPGN may recur.

Chronic Glomerulo-Nephritis

Chronic glomerulo-nephritis is a syndrome that reflects the end stage of glomerular inflammatory disease. Most types of glomerulo-nephritis and nephrotic syndrome can eventually lead to chronic glomerulo-nephritis.

The syndrome is characterized by proteinuria, hematuria, and the slow development of uremic syndrome as a result of decreasing renal function. Chronic glomerulo-nephritis does not usually follow an acute course; it progresses insidiously toward renal failure over a few to as many as 30 years.

Chronic glomerulo-nephritis is often found coincidentally as an abnormality on a urinalysis or when elevated blood pressure is detected. It is common to find that the patient has no recollection or history of acute nephritis or any renal problems. A renal biopsy may be performed to determine the exact cause and nature of the glomerulo-nephritis. However, ultrasound and CT scanning are generally preferred as diagnostic measures.

Treatment is supportive and symptomatic. Hypertension and UTIs should be treated vigorously. Protein and phosphate restrictions may slow the rate of progression of kidney disease. (Management of chronic kidney disease is discussed in Chapter 49.)

Nephrotic Syndrome

Etiology and Clinical Manifestations

Nephrotic syndrome describes a clinical course that can be associated with a number of disease conditions. Some of the more common causes of nephrotic syndrome are listed in Table 48-10. In adults, about one-third of patients with nephrotic syndrome will have a systemic disease such as diabetes or systemic lupus erythematosus. The remainder will be categorized as having idiopathic nephrotic syndrome.

TABLE 48-10
CAUSES OF NEPHROTIC SYNDROME

Primary Glomerular Disease
• Primary nephrotic syndrome • Focal glomerulo-nephritis • Inherited nephrotic disease
Extrarenal Causes
Multisystem Disease
• Amyloidosis • Diabetes mellitus • Systemic lupus erythematosus
Infections
• Bacterial (streptococcal, syphilis) • Protozoal (malaria) • Viral (hepatitis, human immunodeficiency virus infection)
Neoplasms
• Hodgkin's disease • Leukemias • Solid tumours of lungs, colon, stomach, breast
Drugs
• Captopril • Heroin • Nonsteroidal anti-inflammatory drugs • Penicillamine
Allergens (e.g., bee sting, pollen)

The characteristic manifestations include peripheral edema, massive proteinuria, dyslipidemia, and hypoalbuminemia. Characteristic blood chemistries include decreased serum albumin, decreased total serum protein, and elevated serum cholesterol. The increased glomerular membrane permeability found in nephrotic syndrome is responsible for the massive excretion of protein in the urine. This excretion results in decreased serum protein and subsequent edema formation. Ascites and anasarca develop if there is severe hypoalbuminemia.

The diminished plasma oncotic pressure from the decreased serum proteins stimulates hepatic lipoprotein synthesis, which results in dyslipidemia. Initially, cholesterol and low-density lipoproteins are

elevated. Later, the triglyceride level also increases. Fat bodies (fatty casts) commonly appear in the urine.

Immune responses, both humoral and cellular, are altered in nephrotic syndrome. As a result, infection is an important cause of morbidity and mortality. Calcium and skeletal abnormalities may occur, including hypocalcemia, blunted calcemic response to parathyroid hormone, hyperparathyroidism, and osteomalacia.

With nephrotic proteinuria, loss of clotting factors can result in a relative hypercoagulable state. Hypercoagulability with thrombo-embolism is potentially the most serious complication of nephrotic syndrome. The renal vein is the most common site for thrombus formation. Pulmonary emboli occur in about 40% of nephrotic patients with thrombosis.

Collaborative Care

Treatment of nephrotic syndrome is symptomatic (Mayo Clinic Staff, 2012). The goals are to relieve edema and cure or control the primary disease. Management of the edema includes the cautious use of angiotensin-converting enzyme inhibitors, nonsteroidal anti-inflammatory drugs, and a low-sodium (2–3 g/day), low- to moderate-protein (0.5–0.6 g/kg of body weight per day) diet. Dietary salt restrictions are a key to managing edema. In some individuals, thiazide or loop diuretics may be needed. If urine protein loss exceeds 10 g/24 hr, additional dietary protein may be needed.

The treatment of dyslipidemia is often unsuccessful. However, treatment with lipid-lowering agents, such as colestipol (Colestid) and lovastatin, may result in moderate decreases in serum cholesterol levels. If thrombosis is detected, anticoagulant therapy may be necessary for up to 6 months.

Corticosteroids and cyclophosphamide (Procytox) may be used to treat severe cases of nephrotic syndrome. Management of diabetes and treatment of edema are the only measures used for nephrotic syndrome related to diabetes.

Nursing Management Nephrotic Syndrome

A major nursing intervention for patients with nephrotic syndrome is related to edema. It is important to assess the edema by weighing the patient daily, accurately recording intake and output, and measuring abdominal girth or extremity size. Comparing this information daily provides the nurse with a tool for assessing the effectiveness of treatment.

The edematous skin must be cleaned carefully. Trauma should be avoided, and the effectiveness of diuretic therapy must be monitored.

Patients with nephrotic syndrome have the potential to become malnourished or anorexic from the excessive loss of protein in the urine. Maintaining a low- to moderate-protein diet that is also low in sodium is not always easy. Serving small, frequent meals in a pleasant setting may encourage better dietary intake.

Because these patients are susceptible to infection, measures should be taken to avoid exposure to persons with known infections. People with nephrotic syndrome are often ashamed of an edematous appearance and need support in dealing with an altered body image.

Obstructive Uropathies

Urinary obstruction refers to any anatomical or functional condition that blocks or impedes the flow of urine (Figure 48-3). It may be congenital or acquired. Obstruction may be the result of (a) intrinsic causes such as anomalies, diverticula, tumours, or benign growth within the urinary tract; (b) extrinsic causes such as tumours, adhesions, retroperitoneal fibrosis, or prolapsed adjacent organs; or (c) functional causes as a result of neurological or psychogenic factors. Some common intrinsic obstructions are narrowing of the uretero-pelvic junction (UPJ), bladder neck contracture, BPH, urethral stricture, and urethral meatal stenosis. Common extrinsic causes include pelvic and abdominal tumours or a prolapsed uterus. Examples of functional causes are neurogenic bladder and vesico-sphincter dyssynergia (disturbance in muscle coordination) after spinal cord injury.

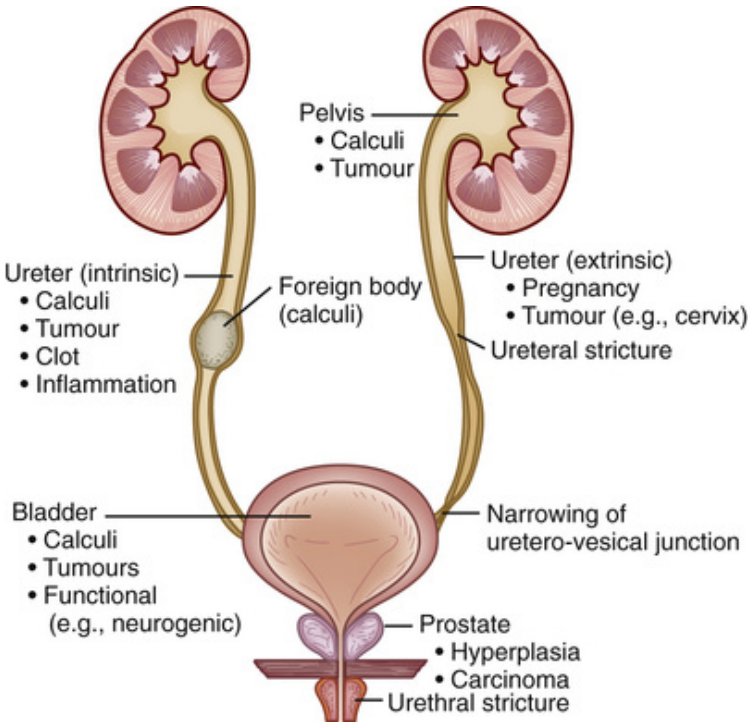

FIGURE 48-3 Common causes of urinary tract obstruction.

Damage from urinary tract obstruction affects the system above the level of the obstruction. The severity of these effects depends on location, duration of obstruction, amount of pressure or dilation, presence of

urinary stasis, and the presence of infection. Infection increases the risk of irreversible damage.

Although obstruction distal to the prostate in men or the bladder neck in women causes mucosal scarring and a slower stream, it rarely results in major obstructive uropathy because the urethral wall pressure is less than that of the bladder neck and bladder. Urethral obstruction may contribute to outlet resistance and cause lower or upper urinary tract damage when other obstructive or dysfunctional factors are also present. For example, there is an increased risk for compromised renal function in a patient with a spinal cord injury with vesico-sphincter dyssynergia.

When obstruction occurs at the level of the bladder neck or the prostate, significant bladder changes can occur. Detrusor muscle fibres hypertrophy (increase in size) to contract harder-to-push urine out a narrower pathway. Over a long period, the detrusor loses its ability to compensate for this resistance. Muscle bundles separate and become less compliant. This separation is called *trabeculation.* Trabeculation is caused by the deposition of collagen in the bladder wall that separates the smooth muscle fascicles. Trabeculation may hasten the decompensation of the detrusor. The areas between these muscle bundles are called *cellules.* Because these areas have no muscle support, the bladder mucosa can herniate between detrusor muscle bundles, forming sacs that drain poorly, called *diverticula*. The amount of residual urine in a noncompensating bladder can be very high.

Pressure increases during bladder filling or storage and can be transmitted to the ureter when *bladder outlet obstruction* is present. This pressure overcomes the normal peristaltic pressure and leads to *reflux* (a backflow of urine), which in turn causes ureteral dilation, kinking, and tortuosity; **hydroureter** (dilation of the renal pelvis); vesico-ureteral reflux (backflow or backward movement of urine from the lower to upper urinary tracts); and **hydronephrosis** (dilation or enlargement of the renal pelvis and the calyces; Figure 48-4) and consequent chronic pyelonephritis and renal atrophy. If only one kidney is obstructed, the other kidney may try to compensate by hypertrophy, but the ureter will not be dilated on this contralateral side.

FIGURE 48-4 Hydronephrosis of the kidney with marked dilation of the pelvis and the calyces and thinning of the renal parenchyma.

Source: Kumar, V., Abbas, A. K.., & Aster, J. (2015). *Robbins and Cotran pathologic basis of disease* (9th ed., p. 950, Figure 20-48). Philadelphia: Saunders.

Partial obstruction may occur in the ureter or at the UPJ. If the pressure remains low or moderate, the kidney may continue to dilate with no noticeable loss of function. There is an increased risk of pyelonephritis because of urinary stasis and reflux. If only one kidney is involved and the other kidney is functioning, the patient may be free of symptoms. If both kidneys or only one functioning kidney is involved (e.g., if the patient has only one kidney), alterations in renal function (e.g., increased BUN or serum creatinine levels) are found. If the obstruction progresses, oliguria or anuria develops. Often, episodes of oliguria are followed by polyuria if the obstruction is a stone that becomes dislodged. Treatment calls for location and relief of the blockage. This can include insertion of a tube (e.g., urethral or ureteral), surgical correction of the disease process, or diversion of the urinary stream above the level of blockage.

Urinary Tract Calculi

One in 10 Canadians will have a kidney stone at some point in life (Canadian Urological Association, 2014). Many of these people require hospitalization. In Canada, the incidence of kidney stones is highest in the East and decreases to the West. Except for struvite (magnesium–

ammonium phosphate) stones associated with UTI, stone disorders are more common in men than in women (Canadian Urological Association, 2014).

The majority of patients with stones are between 20 and 55 years of age. The incidence is also higher in persons with a family history of stone formation. Recurrence of stones can affect up to 50% of patients (Canadian Urological Association, 2014). There is seasonal variation, with stone formation occurring more often in the summer months in Canada, thus supporting the role of dehydration in this process. Stone formation in the kidney seems to increase in incidence as countries become more industrialized whereas the incidence of bladder stones decreases.

Etiology and Pathophysiology

Many factors affect the incidence and the type of stone formation, including metabolic, dietary, genetic, climatic, lifestyle, and occupational influences (Table 48-11). Various theories have been proposed to explain the formation of stones in the urinary tract; however, no single theory can account for stone formation in all cases. Crystals, when in a supersaturated concentration, can precipitate and unite to form a stone. Keeping urine dilute and free flowing reduces the risk for recurrent stone formation in many individuals. It is known that a *mucoprotein* (the matrix for the stone) is formed in the kidney that forms stones. Urinary pH, solute load, and inhibitors in the urine affect the formation of stones. The lower the pH is, the less soluble uric acid and cystine are. The higher the pH, the less soluble calcium and phosphate.

TABLE 48-11

RISK FACTORS FOR THE DEVELOPMENT OF URINARY TRACT CALCULI

Metabolic
• Abnormalities that result in increased urine levels of calcium, oxaluric acid, uric acid, or citric acid
Climate
• Warm climates that cause increased fluid loss, low urine volume, and increased solute concentration in urine
Diet
• Excessive amounts of tea or fruit juices that elevate urinary oxalate level • Large intake of calcium* and oxalate • Large intake of dietary proteins that increase uric acid excretion • Low fluid intake that increases urinary concentration
Genetic
• Family history of stone formation, cystinuria, gout, or renal acidosis
Lifestyle
• Sedentary occupation, immobility

*Recent research suggests that a high dietary calcium intake, which was previously thought to contribute to kidney stones, may actually lower the risk by reducing the urinary excretion of oxalate, a common factor in many stones (National Kidney Foundation, 2015a).

Source: National Institute of Diabetes and Digestive and Kidney Diseases. (2013). *Eating, diet & nutrition for kidney stones.* Retrieved from *http://kidney.niddk.nih.gov/KUDiseases/pubs/kidneystonediet/index.aspx#calcium*.

Other important factors in the development of stones include obstruction with urinary stasis and urinary infection with urea-splitting bacteria (e.g., *Proteus*, *Klebsiella*, *Pseudomonas*, and some species of staphylococci). These bacteria cause the urine to become alkaline and contribute to the formation of struvite (magnesium–ammonium phosphate) stones (Flannigan, Choy, Chew, et al., 2014).

Infected stones, when they are entrapped in the kidney, may assume a staghorn configuration as they enlarge (Figure 48-5). Infected stones are frequent in patients with an external urinary diversion, long-term indwelling catheter, neurogenic bladder, or urinary retention. Genetic factors may also contribute to urine stone formation. Cystinuria is an autosomal recessive disorder. In this disorder, there is a marked increased excretion of cystine.

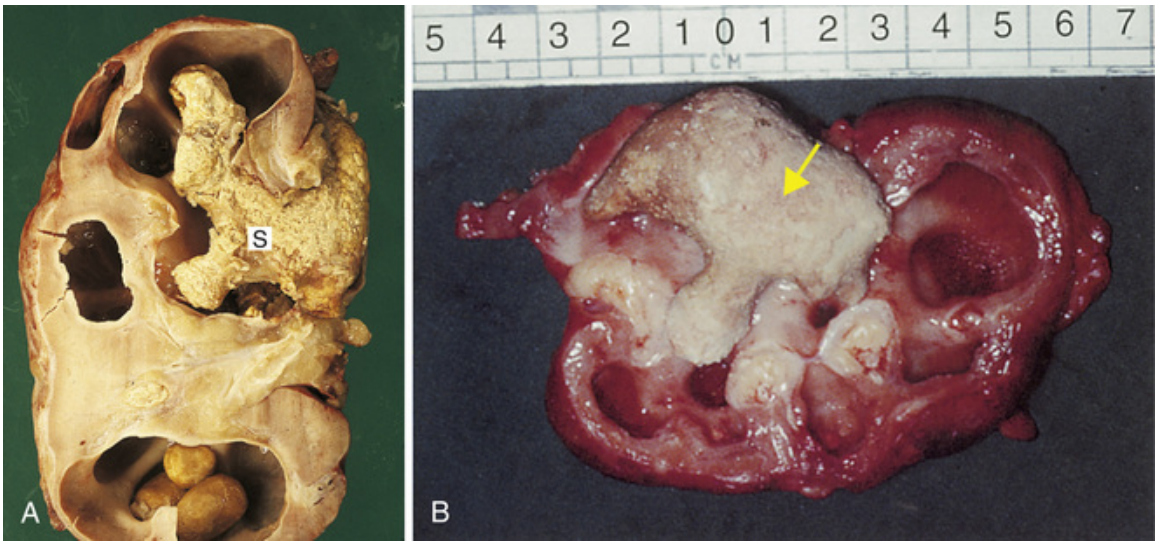

FIGURE 48-5 **A,** Renal staghorn calculus. A large calculus fills the renal pelvis, shaped to its contours and resembling the horn of a stag *(S).* **B,** Embedded staghorn calculus *(yellow arrow)* in a hydronephrotic, infected, nonfunctioning kidney. (2008). *Urology: An illustrated colour text.* London: Churchill Livingstone.

Types

A **calculus** is an abnormal stone formed in body tissues by an accumulation of mineral salts. The term *calculus* refers to the stone, and *lithiasis* refers to stone formation (**nephrolithiasis** thus indicates the formation of stones in the urinary tract). The five major categories of stones are (a) calcium phosphate, (b) calcium oxalate, (c) uric acid, (d) cystine, and (e) struvite (magnesium–ammonium phosphate) (Table 48-12). Stone composition may be mixed, although calcium stones are the most common. Calculi can be found in various locations in the urinary tract.

TABLE 48-12
TYPES OF URINARY TRACT CALCULI

Urinary Stone	Incidence (%)	Characteristics	Predisposing Factors	Therapeutic Measures
Calcium oxalate*	35–40	Small, often possible to get trapped in ureter; more frequent in men than in women	Idiopathic hypercalciuria; hyperoxaluria; family history; independent of urinary pH	Increase hydration. Reduce dietary oxalate.† Give thiazide diuretics. Give cellulose phosphate to chelate calcium and prevent GI absorption. Give potassium citrate to maintain alkaline urine. Give cholestyramine to bind oxalate. Give calcium lactate to precipitate oxalate in GI tract.
Calcium phosphate	8–10	Mixed stones (typically); occur with struvite or oxalate stones	Alkaline urine, primary hyperparathyroidism	Treat underlying causes and other stones.
Struvite ($MgNH_4PO_4$)	10–15	Three to four times more common in women than men; always in association with urinary tract infections; large staghorn type (usually)‡	Urinary tract infections (usually *Proteus* organisms)	Administer antimicrobial agents, acetohydroxamic acid (Lithostat). Use surgical intervention to remove stone. Take measures to acidify urine.
Uric acid	5–8	Predominant in men, high incidence in Jewish men	Gout; acidic urine; inherited condition	Reduce urinary concentration of uric acid. Alkalinize urine with potassium citrate. Administer allopurinol. Reduce dietary purines.†
Cystine	1–2	Genetic autosomal recessive defect, defective absorption of cystine in GI tract and kidney, excess concentrations causing stone formation	Acidic urine	Increase hydration. Give penicillamine and tiopronin to prevent cystine crystallization. Give potassium citrate to maintain alkaline urine.

*Calcium stones can exist as calcium oxalate, calcium phosphate, or a mixture of both. Calcium stones account for the majority of all stones.

†See Table 48-13.

‡See Figures 48-5 and 48-6.

GI, gastro-intestinal.

Clinical Manifestations

Urinary stones cause clinical manifestations when they obstruct urinary flow. Common sites of complete obstruction are at the UPJ (the point where the ureter crosses the iliac vessels) and the UVJ. Symptoms include abdominal or flank pain (usually severe), hematuria, and renal colic. The pain may be associated with nausea and vomiting. The type of pain is

determined by the location of the stone. If the stone is nonobstructing, pain may be absent. If the obstruction is in a calyx or at the UPJ, the patient may experience dull costovertebral flank pain or even colic. Pain resulting from the passage of a calculus down the ureter is intense and colicky. The patient may be in mild shock with cool, moist skin. As a stone nears the UVJ, pain will be felt in the lateral flank and sometimes down into the testicles, the labia, or the groin. Other clinical manifestations include the presence of urinary infection accompanied by fever, vomiting, nausea, and chills.

Diagnostic Studies

Diagnostic studies useful in the evaluation and management of renal lithiasis include urinalysis, urine culture, IVP, retrograde pyelogram, ultrasound, and cystoscopy. A plain film of the abdomen and renal ultrasound will identify larger, radiopaque stones. An IVP or retrograde pyelogram is used to localize the degree and the site of obstruction or to confirm the presence of a radiolucent stone, such as a uric acid or cystine calculus (see Figure 48-5, *B*). Ultrasonography can be used to identify a radiopaque or radiolucent calculus in the renal pelvis, the calyx, or the proximal ureter. It is less useful when attempting to locate stones trapped in the midureter. A CT scan may be used to differentiate a nonopaque stone from a tumour.

Retrieval and analysis of the stones are important in the diagnosis of the underlying problem contributing to stone formation. The patient's BUN and serum creatinine levels are also measured to assess renal function. A careful history, including previous stone formation, prescribed and over-the-counter medications and dietary supplements, and family history of urinary calculi, is useful. Measurement of urine pH can aid in the diagnosis of struvite stones and renal tubular acidosis (tendency to alkaline pH) and uric acid stones (tendency to acidic pH).

Collaborative Care

Evaluation and management of patients with renal lithiasis consist of two concurrent approaches. The first approach is directed toward management of the acute attack. This involves treating the symptoms of pain, infection, or obstruction as indicated for the individual patient. Opioids are typically required at frequent intervals for relief of renal colic pain. Many stones pass spontaneously. However, stones larger than 4 mm are unlikely to pass through the ureter.

The second approach is directed toward evaluation of the cause of the stone formation and the prevention of further development of stones. Information to be obtained from the patient includes family history of stone formation, geographic residence, nutritional assessment including the intake of vitamins A and D, activity pattern (active or sedentary), history of periods of prolonged illness with immobilization or dehydration, and any history of disease or surgery involving the GI or genito-urinary tract.

Therapy for people who are active stone formers requires a concerted management approach, with primary emphasis on teaching and on developing a therapeutic regimen that the patient can manage. Adequate hydration, dietary sodium restrictions, dietary changes (Table 48-13), and the use of medications keep urinary stone formation to a minimum. The medications prescribed depend on the specific problem underlying stone formation. These drugs prevent stone formation in various ways, including altering urine pH, preventing excessive urinary excretion of a substance, or correcting a primary disease (e.g., hyperparathyroidism).

TABLE 48-13
NUTRITIONAL THERAPY
Urinary Tract Calculi

Depending on the type of calculi, the diet should be modified to decrease foods that are high in the substance that is the cause of the calculi. Listed below are foods that are moderate or high in purine, calcium, or oxalate content.
Purine
• *High:* Sardines, herring, mussels, liver, kidney, goose, venison, meat soups, sweetbreads • *Moderate:* Chicken, salmon, crab, veal, mutton, bacon, pork, beef, ham
Calcium
• Milk, cheese, ice cream, yogourt, sauces containing milk; all beans (except green beans), lentils; fish with fine bones (e.g., sardines, kippers, herring, salmon); dried fruits, nuts; chocolate, cocoa, Ovaltine
Oxalate
• Spinach, rhubarb, asparagus, cabbage, tomatoes, beets, nuts, celery, parsley, runner beans; chocolate, cocoa, instant coffee, Ovaltine, tea; Worcestershire sauce

Treatment of struvite stones calls for control of infection, which may be difficult if the stone remains in place. In addition to antibiotics, acetohydroxamic acid (Lithostat) may be used in the treatment of kidney infections that result in the continual formation of struvite stones. Acetohydroxamic acid (Lithostat), an inhibitor of the chemical action caused by the persistent bacteria, can be used effectively to retard struvite stone formation (Flannigan, Choy, Chew, et al., 2014). This medication is available in Canada through the Special Access Drug Program at Health Canada. If the infection cannot be controlled, the stone may have to be removed surgically.

Indications for endo-urological, lithotripsy, or open surgical stone removal include the following:

- Stones too large for spontaneous passage
- Stones associated with bacteriuria or symptomatic infection
- Stones causing impaired renal function
- Stones causing persistent pain, nausea, or ileus
- Inability of patient to be treated medically
- Patient with one kidney

Endo-Urological Procedures.

To remove a small stone located in the bladder, a cystoscopy is done. For large stones (Figure 48-6), a *cystolitholapaxy* is done. In this procedure, large stones are broken up with an instrument called a *lithotrite* (stone crusher). The bladder is then irrigated and the crushed stones washed out. A *cystoscopic lithotripsy* uses an ultrasonic lithotrite to pulverize stones. Complications associated with these cystoscopic procedures include hemorrhage, retained stone fragments, and infection.

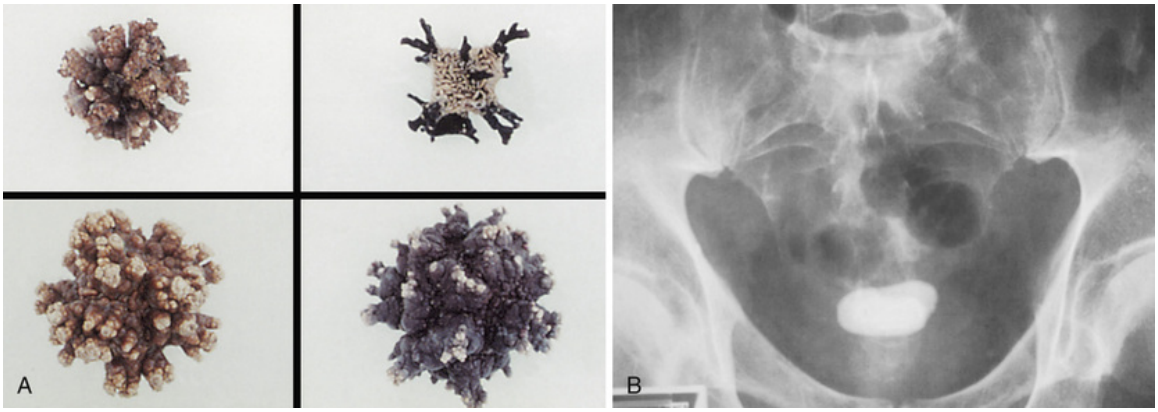

FIGURE 48-6 **A,** Calcium oxalate stones. **B,** Plain abdominal radiograph shows a large bladder calculus. Source: Bullock, N., Doble, A., Turner, W., et al. (2008). *Urology: An illustrated colour text.* London: Churchill Livingstone.

Flexible *ureteroscopes,* inserted via a cystoscope, can be used to remove stones from the renal pelvis and the upper urinary tract. Ultrasonic, laser,

or electrohydraulic lithotripsy can be used in conjunction with the ureteroscope to pulverize and break the stone into fragments.

In *percutaneous nephrolithotomy,* a nephroscope is inserted through a sinus tract from the skin into the kidney pelvis. Stones can be fragmented using ultrasound, electrohydraulic, or laser lithotripsy. The stone fragments are removed and the pelvis irrigated. A percutaneous nephrostomy tube is usually left in place to ensure that the ureter is not obstructed. Complications include bleeding, injury to adjacent structures, and infection.

Lithotripsy.

Lithotripsy involves the use of sound waves to break renal stones into small particles that can be eliminated from the urinary tract. Lithotripsy techniques include percutaneous ultrasonic lithotripsy, electrohydraulic lithotripsy, laser lithotripsy, and extracorporeal shock-wave lithotripsy (Ordon, Andonian, Blew, et al., 2015).

Extracorporeal shock-wave lithotripsy and laser lithotripsy are the most common. In *percutaneous ultrasonic lithotripsy,* an ultrasonic probe is placed in the renal pelvis via a percutaneous nephroscope (inserted through a small incision in the flank) and is positioned against the stone. The patient is given general or spinal anaesthesia for this procedure. The probe produces ultrasonic waves, which break the stone into sandlike particles. Percutaneous lithotripsy is not often used as a primary approach to a renal or upper ureteral stone unless the stone is large and other lithotripsy procedures have failed.

The *electrohydraulic lithotripsy* probe is also placed directly on a stone, but it breaks the stone into small fragments that are removed by forceps or suction. A continuous saline irrigation flushes out the stone particles, and all outflow drainage is strained so that the particles can be analyzed. Forceps or basket extraction can also be used to remove the calculi. Complications are rare but include hemorrhage, sepsis, and abscess formation. Postoperatively, the patient usually complains of moderate to severe colicky pain. The first few voids are bright red; as the bleeding subsides, the urine becomes dark red or turns a smoky colour. Antibiotics are usually given for 2 weeks to reduce the risk for infection.

Laser lithotripsy probes are used to fragment lower ureteral and large bladder stones. A holmium laser medium is preferred; it fragments stones but does not injure the surrounding tissue.

In *extracorporeal shock-wave lithotripsy,* a noninvasive procedure, the patient is anaesthetized (spinal or general) and placed in a water bath.

Anaesthesia is necessary to keep the patient very still during the procedure. Some of the newer-generation lithotripters do not require submersion and use other means of initiating shock waves.

Fluoroscopy or ultrasound is used to focus the lithotripter on the affected kidney, and a high-voltage spark generator produces high-energy acoustic shock waves that shatter the stone without damaging the surrounding tissues. The stone is broken into fine sand, which is excreted into the patient's urine within a few days after the procedure.

Hematuria is common after lithotripsy procedures. A self-retaining ureteral stent is often placed after the procedure to promote passage of sand from the fragmented stone and to prevent obstruction caused by its buildup in the ureter. The stent is removed 1 to 2 weeks after lithotripsy. A primary advantage of these techniques compared with open surgery is the decrease in the length of hospitalization and the patient's earlier return to normal activities. Additional treatment may be necessary, especially if a stone is large and in the midureter or the distal ureter.

Surgical Therapy.

A small group of select patients need open surgical procedures, such as patients with morbid obesity or those with complex abnormalities in the calyces or at the UPJ. The type of open surgery performed depends on the location of the stone. A *nephrolithotomy* is an incision into the kidney to remove a stone. A *pyelolithotomy* is an incision into the renal pelvis to remove a stone. If the stone is located in the ureter, a *uretero-lithotomy* is performed. A *cystotomy* may be indicated for bladder calculi. For open surgery on the kidney or ureter, a flank incision directly below the diaphragm and across the side is usually the preferred surgical approach. The most common complication following these surgical procedures is hemorrhage.

Nutritional Therapy.

Patients with an obstructing stone should be advised to drink adequate fluids to avoid dehydration. Forcing fluids is avoided because this strategy has not proved effective in assisting patients to spontaneously “pass” (excrete) the stone via the urine. In addition, forcing fluids may exacerbate the colic associated with this episode.

After an episode of urolithiasis, however, a high fluid intake (≈3 000 mL/day) is recommended to produce a urine output of at least 2 L/day. High urine output prevents supersaturation of minerals (i.e., dilutes the concentration) and promotes excretion of minerals within the urine, thus

preventing stone formation. Increasing the fluid intake is especially important for patients who are active in sports, live in a dry climate, perform physical exercise, have a family history of stone formation, or work in an occupation that requires outdoor labour or a great deal of physical activity that can lead to dehydration. Water is the preferred fluid, and consumption of colas, coffee, and tea should be limited because high intake of these beverages tends to increase rather than diminish the risk for recurring urinary calculi (Ferraro, Taylor, Gambaro, et al., 2013).

Dietary intervention may be important in the management of urolithiasis. In the past, calcium intake was routinely restricted for patients with kidney stones. However, more recent research suggests that a high dietary calcium intake, which was previously thought to contribute to kidney stones, may actually lower the risk by reducing the urinary excretion of oxalate, a common factor in many stones (Canadian Urological Association, 2014). Initial nutritional management should include limiting oxalate-rich foods and thereby reducing oxalate excretion. Foods high in calcium, oxalate, and purines are presented in Table 48-13.

Nursing Management Renal Calculi

Nursing Assessment

Subjective and objective data that should be obtained from a patient with urinary tract lithiasis are presented in Table 48-14.

TABLE 48-14

NURSING ASSESSMENT
Urinary Tract Calculi

Subjective Data
Important Health Information
Current health history: Dietary intake of purines, calcium, oxalates, phosphates; fluid intake *Past health history:* Recent or chronic UTI; bed rest or sedentary lifestyle; immobilization; previous urinary tract stones, obstruction, or kidney disease with urinary stasis; gout; prostatic hyperplasia; hyperparathyroidism; family history of renal calculi *Medications:* Prior use of medication for prevention of stones or treatment of UTI; allopurinol, analgesics *Surgery or other treatments:* External urinary diversion, long-term in-dwelling urinary catheter
Symptoms
• Acute, severe, colicky pain in flank, back, abdomen, groin, or genitalia; burning on urination, dysuria, anxiety • Decreased urinary output, urinary urgency, urinary frequency, feeling of bladder fullness • Nausea, vomiting; chills
Objective Data
General
Guarding, fever
Integumentary
Warm, flushed skin or pallor with cool, moist skin (mild shock)
Gastro-Intestinal
Abdominal distension, absence of bowel sounds
Urinary
Oliguria, hematuria, tenderness on palpation of renal areas, passage of stone or stones
Possible Findings
↑ Serum urea (BUN) and serum creatinine levels; RBCs, WBCs, pyuria, crystals, casts, minerals, bacteria on urinalysis; ↑ uric acid, calcium, phosphorus, oxalate, or cystine values on 24-hr urine sample; calculi or anatomical changes on IVP or KUB radiographic study; direct visualization of obstruction on cysto-ureteroscopy

BUN, blood urea nitrogen; *IVP*, intravenous pyelogram; *KUB*, kidneys, ureters, bladder; *RBCs*, red blood cells; *UTI*, urinary tract infection; *WBCs*, white blood cells.

Nursing Diagnoses

Nursing diagnoses for the patient with urinary tract lithiasis include but are not limited to the following:

- *Impaired urinary elimination* related to *multiple causality* (trauma or obstruction)
- *Acute pain* related to *physical injury agent, biological injury agent* (effects of stones)
- *Deficient knowledge* related to *insufficient information* (unfamiliarity with information resources, lack of experience with urinary stones)

Additional information on nursing diagnoses for the patient with urinary tract lithiasis is presented in NCP 48-2, available on the Evolve website.

Planning

The overall goals are that the patient with urinary tract calculi will have (a) relief of pain, (b) no urinary tract obstruction, and (c) an understanding of measures to prevent further recurrence of stones.

Nursing Implementation

A program to prevent stone recurrence always includes adequate fluid intake to produce a urine output of approximately 2 L/day. The nurse should consult with the health care provider concerning recommendations for fluid intake in a given patient. A modestly active, ambulatory patient would be required to drink about 2 000 to 2 200 mL/day with the residual 20% to 30% of fluids gained through consumption of foods. The volume of necessary fluids will be higher in the highly active patient who works outdoors or who regularly engages in demanding athletic activities. In contrast, fluid intake will be less for the very sedentary or immobile person. Preventive measures for the person who is on bed rest or is relatively immobile for a prolonged time include maintaining an adequate fluid intake, turning the patient every 2 hours, and helping the patient to sit or stand, if possible, to maximize urinary flow.

Additional preventive measures focus on reducing metabolic or secondary risk factors. For example, dietary restriction of purines may be helpful to patients at risk for developing uric acid stones. Reduced intake of oxalates may be indicated in patients with recurring calcium oxalate calculi. Patients are taught about dosage, scheduling, and potential adverse effects of medications used to reduce the risk for stone formation. Select patients may be taught to self-monitor urinary pH or be asked to measure urinary output.

Pain management and patient comfort are primary nursing responsibilities when managing an obstructing stone and renal colic (see NCP 48-2). It is important to ensure that the patient retrieves any spontaneously passed stones. All urine voided by the patient should be strained through gauze or a special urine strainer in an effort to detect the stone. The high fluid intake necessary for stone prevention is suspended, but consumption should be adequate to meet daily needs and prevent dehydration. Ambulation is generally encouraged to promote the

movement of the stone from the upper to the lower urinary tract, but the patient should not walk unattended when experiencing acute colic, particularly if opioid analgesics are being used.

Evaluation

Strictures

A **stricture** is an abnormal temporary or permanent narrowing of the lumen of a hollow organ, in this context, of the ureter or the urethra.

Ureteral Strictures

Ureteral strictures can affect the entire length of the ureter, from the UPJ to the UVJ. These strictures are usually an unintended result of surgical intervention, usually secondary to adhesions or scar formation. Depending on its severity, ureteral obstruction can threaten the function of the kidney. Clinical manifestations of a ureteral stricture include mild to moderate colic; this pain may be of moderate to severe intensity if the patient consumes a large volume of fluids (alcohol, in particular) over a brief period. Infection is unusual unless a calculus or foreign object such as a stent or nephrostomy tube is present.

The discomfort and obstruction of a ureteral stricture may be temporarily bypassed by placing a stent under endoscopic control or by diverting urinary flow via a nephrostomy tube inserted into the renal pelvis of the affected kidney. Definitive correction requires dilation with a balloon or catheter. If the stricture is severe or recurs after initial balloon or catheter dilation, it may be incised under endoscopic control *(endo-ureterotomy).* In select cases, an open surgical approach may be required to excise the stenotic area and reanastomose the ureter to the contralateral ureter *(uretero-ureterostomy)* or to the renal pelvis. Alternatively, distal ureteral strictures may be managed by a *uretero-neocystostomy* (reimplantation of the ureter into the bladder wall).

Urethral Stricture

A *urethral stricture* is the result of fibrosis or inflammation of the urethral lumen (Urology Care Foundation, n.d.). Causes of urethral strictures include trauma, urethritis (particularly following gonococcal infection), and a congenital defect in the canalization of the urethra; causes can also be iatrogenic (following surgical intervention). Once the process of

inflammation and fibrosis begins, the lumen of the urethra narrows, and its compliance (ability to close or open in response to bladder filling or micturition) is compromised. Meatal stenosis, a narrowing of the urethral opening, is also common.

Clinical manifestations associated with a urethral stricture include a diminished force of the urinary stream, spraying, or a split urine stream. The patient may report feelings of incomplete bladder emptying with urinary frequency and nocturia. Moderate to severe obstruction of the bladder outlet may lead to acute urinary retention. The patient may report a history of urethritis, difficulty with placement of a urinary catheter, or trauma involving the penis or the perineum. However, many patients are unable to recall any such events, thus leading to a diagnosis of an idiopathic stricture. A history of a UTI is not uncommon, particularly if the stricture involves the distal urethra.

Initial management of a stricture may be based on dilation. A metal instrument (urethral sound) or a series of progressively enlarging stents can be placed into the urethra (filiforms and followers) to expand its lumen in a stepwise fashion. Although this procedure may be initially successful, recurring stenosis is frequent. Recurrences may be managed by teaching the patient to repeatedly dilate the urethra by self-catheterization every few days. Alternatively, an endoscopic or open surgical procedure may provide a more durable solution to an obstructive urethral stricture. Shorter strictures may be managed by resection of the fibrotic area with primary reanastomosis. Longer strictures may require autotransplantation of a substitute segment such as a skin flap.

Renal Trauma

A rise in the incidence of traumatic renal injuries is related to an increase in the mechanization and speed of transportation and to the increase in violent crimes and injuries (da Costa, Amend, Stenzl, et al., 2016). Blunt trauma is the most common cause. Injury to the kidney should be considered in cases of multiple injuries, sports injuries, traffic accidents, and falls. It is especially likely when the patient injures the abdomen, the flank, or the back. Penetrating injuries may result from violent encounters (e.g., gunshot or stabbing incidents) or may be of iatrogenic origin.

Clinical findings include a history of trauma to the area of the kidneys. Gross or microscopic hematuria may be present. Diagnostic studies include urinalysis, IVP with cystography, ultrasound, CT scan, or MRI evaluation. Renal arteriography may also be used. Both the injured kidney and the uninvolved kidney should be evaluated to provide information for further management.

The severity of renal trauma depends on the extent of the injury. Treatments range from bed rest, fluids, and analgesia to surgical exploration and repair or nephrectomy.

Nursing interventions vary with the type and the extent of associated injuries. Specific interventions related to renal trauma include ensuring increased fluid intake, providing comfort measures, monitoring for shock (e.g., penetrating injury), monitoring intake and output, observing for hematuria, determining the presence of myoglobinuria, assessing the cardiovascular status, and monitoring the use of potentially nephrotoxic antibiotics.

Renal Vascular Problems

Vascular problems involving the kidney include (a) nephrosclerosis, (b) renal artery stenosis, and (c) renal vein thrombosis.

Nephrosclerosis

Nephrosclerosis is sclerosis of the small arteries and arterioles of the kidney, resulting in renal tissue destruction. The decreased blood flow results in patchy necrosis of the renal parenchyma. Ischemic necrosis and destruction of glomeruli with subsequent fibrosis also occur.

Benign nephrosclerosis usually occurs in adults 30 to 50 years of age. It is caused by vascular changes resulting from hypertension and from the process of atherosclerosis. Atherosclerotic vascular changes account for most of the loss of renal function associated with aging. There is a direct relation between the degree of nephrosclerosis and the severity of hypertension. The patient with benign nephrosclerosis may have normal renal function in the early stages. The only detectable abnormality may be hypertension.

Accelerated nephrosclerosis, or *malignant nephrosclerosis,* is associated with malignant hypertension, a complication of hypertension characterized by a sharp increase in blood pressure with a diastolic pressure greater than 130 mm Hg (Linas, 2011). The patient is usually a young adult, with a male-to-female predominance of 2 : 1. Renal insufficiency progresses rapidly.

Treatment for benign nephrosclerosis is the same as that for essential hypertension (see Chapter 35). Malignant nephrosclerosis is treated with aggressive antihypertensive therapy (see Chapter 35). The availability and use of antihypertensives have improved the prognosis for patients with benign and malignant nephrosclerosis. Renal dysfunction and renal failure (in some persons) constitute two of the major complications of hypertension. The prognosis for patients with malignant hypertension is poor, with the major cause of death related to renal failure.

Diabetic patients who have renal complications such as diabetic nephropathy often suffer progressive impairment of renal function (see Chapter 52).

Renal Artery Stenosis

Renal artery stenosis, a partial occlusion of one or both renal arteries and their major branches, is a major cause of abrupt-onset hypertension. It can be caused by atherosclerotic narrowing or fibromuscular hyperplasia. Renal artery stenosis accounts for 1% to 2% of all cases of hypertension.

When hypertension develops rather abruptly, renal artery stenosis should be considered as a possible cause, especially in patients younger than 30 or older than 50 years and in patients with no familial history of hypertension. This contrasts with the age distribution for essential hypertension, which peaks between 30 and 50 years of age. A renal arteriogram is the best diagnostic tool for identifying renal artery stenosis.

The goals of therapy are control of blood pressure and restoration of perfusion to the kidney. Percutaneous transluminal renal angioplasty is the procedure of choice, especially in older patients who are poor surgical risks. Surgical revascularization of the kidney is indicated when blood flow is decreased enough to cause renal ischemia or when evidence indicates that renovascular hypertension is present and might be resolved by surgical intervention. The surgical procedure usually involves anastomoses between the kidney and another major artery, usually the splenic artery or the aorta. In select cases of unilateral renal involvement with high renin production, unilateral nephrectomy may be indicated.

Renal Vein Thrombosis

Renal vein thrombosis, an embolus occurring in the renal vein, may occur unilaterally or bilaterally. Trauma, extrinsic compression (e.g., tumour, aortic aneurysm), renal cell carcinoma, pregnancy, contraceptive use, and nephrotic syndrome are associated with renal vein thrombosis.

Symptoms include flank pain, hematuria, or fever or nephrotic syndrome. Anticoagulation is important in treatment because there is a high incidence of pulmonary emboli. Corticosteroids may be used for patients with nephrosis. Surgical thrombectomy may be performed instead of or along with anticoagulation (Barbour, Greenwald, Djurdjev, et al., 2012).

Hereditary Renal Diseases

Hereditary renal diseases involve developmental abnormalities of the renal parenchyma. These abnormalities are either isolated or part of more complex malformation syndromes. The majority of inherited structural abnormalities are cystic. However, cysts may also develop as a result of obstructive uropathies, metabolic derangements, or neurological diseases. Cysts may be evaluated to rule out any tumour content.

Polycystic Kidney Disease

Polycystic kidney disease (PKD) is one of the most common genetic diseases in Canada. It may first become apparent in either childhood or adulthood. It involves both kidneys and occurs in both men and women. The cortex and the medulla are filled with thin-walled cysts that are several millimetres to several centimetres in diameter (Figure 48-7). The cysts enlarge and destroy surrounding tissue by compression. They are filled with fluid and may contain blood or pus.

FIGURE 48-7 Comparison of polycystic kidney with normal kidney.

Source: Brundage, D. J. (1992). *Renal disorders.* St. Louis: Mosby.

There are two forms of hereditary polycystic renal disease. The adult form of PKD is an autosomal dominant disorder. It is latent for many years

and is usually evidenced between the ages 30 and 40. However, PKD has also been found in newborns. The childhood form of PKD is a rare autosomal recessive disorder that is often rapidly progressive (see the "Genetics in Clinical Practice" box).

Genetics in Clinical Practice

Polycystic Kidney Disease

	Adult	Child
Genetic basis	• Autosomal dominant	• Autosomal recessive
Incidence	• 1 in 500 to 1 000	• 1 in 6 000 to 40 000
Gene location	• Chromosomes 4 and 16	• Chromosome 6
Genetic testing	• DNA testing available	• DNA testing available
Age of onset	• Usually between the ages of 30 and 40 yr, but can begin earlier	• Infancy or childhood
Clinical implications	• Multisystem involvement • Systemic hypertension occurs in 60%–80% of patients • Families at risk should be screened	• 30%–50% of affected newborns die shortly after birth

Clinical Manifestations

In the patient with PKD (Figure 48-8), symptoms appear when the cysts begin to enlarge. A common early symptom of adult PKD is abdominal or flank pain, which is steady and dull or abrupt in onset as well as episodic and colicky. This pain is often caused by bleeding into the cysts. On physical examination, palpable bilateral enlarged kidneys are often found. Other clinical manifestations include hematuria (from rupture of cysts), UTI, and hypertension.

FIGURE 48-8 Man with an 11-kg polycystic kidney. Source: Lemmi, F. O., & Lemmi, C. A. E. (2000). *Physical assessment findings* (CD-ROM). Philadelphia: Saunders.

Diagnosis is based on clinical manifestations, family history, IVP, ultrasound, or CT scan. Usually, the disease progresses to end-stage renal failure, although some individuals have relatively mild disease and die from unrelated problems. Loss of kidney function to the point of end-stage renal disease occurs by age 60 in 50% of patients (Mayo Clinic Staff, 2014).

Collaborative Care

There is no specific treatment for PKD. A major aim of treatment is to prevent infections of the urinary tract or to treat them with appropriate antibiotics if they occur. Nephrectomy may be necessary if pain, bleeding, or infection becomes a chronic, serious problem.

When the patient begins to experience progressive renal failure, the interventions are determined by the remaining renal function. Nursing measures are those used for management of end-stage renal disease (see Chapter 49). They include diet modification; fluid restriction; medications (e.g., antihypertensives); assisting the patient to accept the chronic disease process; and assisting the patient and family to deal with physical, socioeconomic, and emotional reactions to the disease.

Patients with adult PKD often have children by the time the disease is diagnosed. Each child of a parent with PKD has a 50% chance of having the disease. Patients will need appropriate counselling regarding plans for

having more children. In addition, genetic counselling resources should be provided for the children.

Medullary Cystic Disease

Medullary cystic disease is a hereditary disorder that occurs in two forms. The *autosomal recessive form* is associated with renal failure before age 20; the *autosomal dominant form* is associated with renal failure after age 20. Most cysts are located in the medulla. The kidneys are asymmetrical, are significantly scarred, and have defects in their concentration ability. Polyuria, progressive renal failure, severe anemia, metabolic acidosis, and poor sodium conservation are common. Hypertension in patients with this disease can be a terminal event. Genetic counselling may be helpful in family planning. Treatment measures are those related to end-stage renal disease (see Chapter 49).

Alport Syndrome

Alport syndrome is also known as *chronic hereditary nephritis.* Two forms of the disease exist: (a) classic Alport syndrome, which is inherited as a sex-linked disorder with hematuria, sensorineural deafness, and deformities of the anterior surface of the lens, and (b) nonclassic Alport syndrome, which is inherited as an autosomal trait that causes hematuria but not deafness or lens deformities (National Kidney Foundation, 2015b). The disease affects males earlier and more severely than females and is often diagnosed in the first decade of life. The basic defect is altered synthesis of the GBM, and patients most commonly have hematuria and progressive uremia. Treatment is supportive, although the disease will not recur after kidney transplantation. Corticosteroids and cytotoxic drugs are not effective.

Renal Involvement in Metabolic and Connective Tissue Diseases

Various metabolic and connective tissue disease processes may have an effect on renal function. The pathophysiological effects on the renal parenchyma are not always specific to each process. The clinical course of renal involvement is that of chronic progressive nephropathy, which can result in uremia and death. Management includes treatment of the primary disorder along with symptomatic relief of renal involvement. If renal involvement progresses to end-stage renal disease, management includes dialysis or transplantation (see Chapter 49). Nursing interventions include teaching the patient about the primary disease process, the renal involvement, and the resulting need to comply with dietary and fluid restrictions and drug regimens.

Diabetic nephropathy is the primary cause of end-stage renal failure in Canada (Canadian Diabetes Association Clinical Practice Guidelines Expert Committee, 2013). Diabetes mellitus may affect the kidneys in several ways. Microangiopathic changes in diabetes consist of diffuse glomerulo-sclerosis, involving thickening of the GBM, and nodular glomerulo-sclerosis (Kimmelstiel–Wilson syndrome), which is characterized by nodular lesions. Nodular glomerulo-sclerosis is reasonably specific for type 1 diabetes mellitus. Patients with diabetes who are prone to glomerulo-nephropathy (i.e., the presence of trace proteinuria or retinopathy) require careful monitoring of glucose levels and insulin requirements. (Diabetes mellitus is discussed in Chapter 52.)

Gout is a syndrome of acute attacks of arthritis caused by hyperuricemia (see Chapter 67). Monosodium urate crystals deposited in joints are responsible for the syndrome. Renal disease may develop as a result of damage caused by deposition of uric acid crystals in the renal interstitium and the tubules.

Amyloidosis is a group of disorders evidenced by impaired organ function from the infiltration of tissues with a hyaline substance (amyloid). The hyaline consists largely of protein. Kidney involvement is common in amyloidosis. Proteinuria is often the first clinical manifestation.

Systemic lupus erythematosus is a connective tissue disorder characterized by the involvement of several tissues and organs, particularly the joints, the skin, and the kidneys. (Systemic lupus erythematosus is discussed in Chapter 67.) Clinical manifestations of lupus nephritis are similar to those

of other forms of glomerulo-nephritis. Renal failure frequently occurs in systemic lupus erythematosus and has a poor prognosis.

Systemic sclerosis (scleroderma) is a disease of unknown etiology characterized by widespread alterations of connective tissue and vascular lesions in many organs (see Chapter 67). In the kidney, vascular lesions are associated with fibrosis. An immune complex mechanism has been postulated as a possible etiological factor. The severity of renal involvement varies. Patients who develop severe renal lesions have a poor prognosis.

Urinary Tract Tumours

Kidney Cancer

The incidence of kidney cancer in Canada is rising. In 2012, it was estimated that 5 600 new cases would be diagnosed across the country that year and that 1 700 people would die from it. Kidney cancers arise from the cortex or the pelvis (and the calyces). Tumours arising from both areas may be benign or malignant. However, malignant tumours are more frequent. Adenocarcinoma (renal cell carcinoma) is the most common type. Adenocarcinoma occurs twice as often in men as in women and is typically discovered when the person is 50 to 70 years old. Cigarette smoking is the most significant risk factor for the development of adenocarcinoma (Canadian Cancer Society, 2016). Other risk factors are obesity, the use of phenacetin-containing analgesics, and exposure to asbestos, cadmium, and gasoline (Nogueras, Thomas, & Porter, 2015).

There are no characteristic early symptoms. Generalized symptoms of weight loss, weakness, and anemia are the earliest manifestations. The classic manifestations of gross hematuria, flank pain, and a palpable mass are those of advanced disease. The most common sites of metastases include the lungs, liver, and long bones. Local extension of kidney cancer into the renal vein and the vena cava is common (Figure 48-9). Renal cystic disease and renal-associated carcinomas may develop in patients with end-stage renal disease who are receiving maintenance renal dialysis (see Chapter 49).

FIGURE 48-9 Adenocarcinoma. Cross-section shows yellowish cancer in one pole of the kidney. The tumour also involves the dilated thrombosed renal vein. Source: Kumar, V., Abbas, A. K., & Aster, J. (2015). *Robbins and Cotran pathologic basis of disease* (9th ed., p. 954, Figure 20-51). Philadelphia: Saunders.

Several studies are used to diagnose kidney cancer. IVP with nephrotomography is the primary examination by which most masses are detected and evaluated. Ultrasounds have improved the ability to differentiate between a tumour and a cyst. Angiography, percutaneous needle aspiration, CT, and MRI are also used in the diagnosis of renal tumours. Small renal tumours are found earlier because of the increased use of CT scans and MRI. Radionuclide isotope scanning is used to detect metastases.

Robson's system of staging renal carcinoma is presented in Table 48-15. The treatment of choice is a radical nephrectomy, which is the removal of the kidney, the adrenal gland, the surrounding fascia, part of the ureter, and the draining lymph nodes. Radiation therapy is used palliatively in inoperable cases and when there are metastases to bone or lungs.

TABLE 48-15

ROBSON'S SYSTEM OF STAGING RENAL CARCINOMA

Stage	Description
I	Limitation to renal capsule
II	Spreading to perirenal fat but confined within fascia; includes metastasis to adrenal gland
III	Regional lymph node involvement, tumour thrombus in renal vein or vena cava, involvement of renal vein or vena cava
IV	Presence of distant metastases

Chemotherapy using 5-fluorouracil (5-FU) and gemcitabine is used to treat metastatic disease. However, renal cell carcinoma is refractory to most chemotherapy drugs. Biological therapy, including interferon-alfa (IFN-α) and interleukin-2 (IL-2), is most promising in the treatment of metastatic disease (North, Basappa, Bjarnason, et al., 2013). Adverse effects of IL-2 include capillary leakage syndrome, fever, chills, fatigue, and hypotension.

The 5-year survival rate of patients with early-stage kidney cancer is 60% to 70% after undergoing radical nephrectomy. The 5-year survival rate for patients with metastatic disease is only 3% to 10%. However, patients with metastatic disease often remain stable for a prolonged period (North, Basappa, Bjarnason, et al., 2013).

Bladder Cancer

It was estimated that 8 900 Canadians would be diagnosed with bladder cancer in 2017 and that 2 400 Canadians would die from this disease (Canadian Cancer Society's Advisory Committee on Cancer Statistics, 2017). Bladder cancer is the sixth most common type of cancer diagnosed in Canadians. The most frequent malignant tumour of the urinary tract is transitional cell carcinoma of the bladder. Most bladder tumours are papillomatous growths within the bladder (Figure 48-10). Cancer of the bladder is most common between the ages of 60 and 70 years and is at least three times more common in men than in women. Risk factors for bladder cancer include cigarette smoking, exposure to dyes used in the rubber and cable industries, and chronic use of phenacetin-containing analgesics (Canadian Cancer Society, 2016). Women treated with radiation for cervical cancer and patients receiving cyclophosphamide (Procytox) also have increased risk, but the reason is unknown.

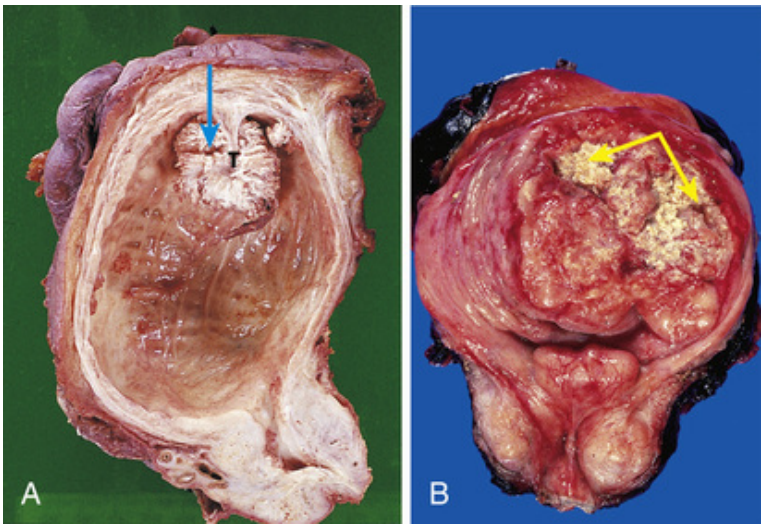

FIGURE 48-10 **A,** A papillary transitional cell carcinoma is seen arising from the dome of the bladder as a cauliflower-like lesion. **B,** Opened bladder shows a bladder cancer at an advanced stage. The yellow areas represent ulcerations and necrosis. Source: *A,* Stevens, A., & Lowe, J. (2000). *Pathology: Illustrated review in color* (2nd ed.). London: Mosby; *B,* Kumar, V., Abbas, A. K., & Aster, J. (2015). *Robbins and Cotran pathologic basis of disease* (9th ed., p. 967, Figure 21-12). Philadelphia: Saunders.

Individuals with chronic, recurrent stones (often bladder) and chronic lower urinary infections have an increased risk for squamous cell cancer of the bladder. Patients who have in-dwelling catheters for long periods can develop these chronic conditions.

Clinical Manifestations and Diagnostic Studies

Gross, painless hematuria (chronic or intermittent) is the most common clinical finding. Bladder irritability with dysuria, urinary frequency, and urinary urgency may also occur. When cancer is suspected, urine specimens for cytology can be obtained to determine the presence of neoplastic or atypical cells. Exfoliated cells from the epithelial surface of the bladder can readily be detected in voided specimens. Other recent urine tests assess for specific factors associated with bladder cancer, such as bladder tumour antigens. Bladder cancers can be detected using IVP, ultrasound, CT, or MRI. However, the presence of cancer is confirmed by cystoscopy and biopsy.

The depth of invasion of the bladder wall and surrounding tissue determines the clinical staging of carcinoma of the bladder. The Jewett–Strong–Marshall classification system broadly classifies bladder cancer as superficial (carcinoma in situ, O, A), invasive (B_1, B_2, C), or metastatic (D_1–

D_4) disease. Pathological grading systems are also used to classify the malignant potential of tumour cells, indicating a scale from well-differentiated to anaplastic categories. Low-stage, low-grade bladder cancers are the most responsive to treatment and are more easily cured.

Nursing and Collaborative Management Bladder Cancer

Collaborative care of the patient with bladder cancer is outlined in Table 48-16.

TABLE 48-16

COLLABORATIVE CARE
Bladder Cancer

Diagnostic
• History and physical examination • CT scan • Cystoscopy with biopsy • Cytology studies • Intravenous pyelogram • Ultrasound • Urinalysis
Collaborative Therapy

• Surgical treatment
  • Laser photocoagulation
  • Open loop resection or fulguration
  • Radical cystectomy
  • Segmental cystectomy
  • Transurethral resection with fulguration
• Radiation
• Intravesical immunotherapy
  • Bacille Calmette–Guérin
  • Interferon alfa
• Intravesical chemotherapy
  • Doxorubicin
  • Mitomycin
  • Thiotepa
• Systemic chemotherapy

CT, computed tomography.

Surgical Therapy

Surgical therapies include a variety of procedures. *Transurethral resection with fulguration* (electrocautery) is used for the diagnosis and treatment of superficial lesions with a low recurrence rate. This procedure is also used to control bleeding in the patient who is a poor operative risk or who has

advanced tumours. With this technique, the tumour mass is excised by means of a blade inserted through the cystoscope. The remaining portions of the tumour are cauterized.

A second technique, *laser photocoagulation,* is also used to treat superficial bladder cancers. This procedure can be repeated a number of times to manage recurrences. The advantages of laser include bloodless destruction of the lesion, minimal risk for perforation, and lack of need for a urinary catheter. The primary disadvantage is that, owing to destruction of the tumour, pathological evaluation for grading and staging cannot be completed.

A third technique used is *open loop resection* (snaring of polyp types of lesion) *with fulguration.* It is used for the control of bleeding, for large superficial tumours, and for multiple lesions. Treatment of large lesions entails a segmental resection of the bladder *(segmental cystectomy).*

Postoperative instructions for any of these procedures includes drinking a large volume of fluid each day for the first week following the procedure and avoiding intake of alcoholic beverages. Patients are taught to self-monitor their urine. It is anticipated to be pink during the first several days after the procedure, but it should not be bright red or contain blood clots. Approximately 7 to 10 days following tumour resection or ablation, the patient may observe dark-red or rust-coloured flecks in the urine. These are anticipated and represent scabs from the healing tumour resection sites. Opioid analgesics may be required for a brief period after the procedure, along with stool softeners. Patients can be encouraged to take a 15- to 20-minute sitz bath two or three times a day to promote muscle relaxation and to reduce the risk for urinary retention. The nurse should also help the patient and family cope with fears about cancer, surgery, and sexuality and should emphasize the importance of regular follow-up care. Frequent routine cystoscopies are required.

When the tumour is invasive or when it involves the trigone (the area where the ureters insert into the bladder) and the patient is free from metastasis beyond the pelvic area, a partial or radical cystectomy with urinary diversion is the treatment of choice (see the section on urinary diversion later in the chapter). A *partial cystectomy* includes resection of that portion of the bladder wall containing the tumour, along with a margin of normal tissue. A *radical cystectomy* involves removal of the bladder, the prostate, and the seminal vesicles in men and the bladder, the uterus, the cervix, the urethra, and the ovaries in women (Kassouf, Traboulsi, Kulkarni, et al., 2015).

Radiation Therapy and Chemotherapy

Radiation therapy is used with cystectomy or as the primary therapy when the cancer is inoperable or when surgery is refused. Increasingly, radiation therapy is being combined with systemic chemotherapy. Sometimes, combination systemic chemotherapy is used for bladder cancer, usually preoperatively or before radiation therapy, or is used to treat distant metastases. Chemotherapy drugs used in treating invasive bladder cancer include cisplatin, vinblastine, and methotrexate.

Intravesical Therapy

Chemotherapy with local instillation of chemotherapeutic or immune-stimulating agents can be delivered directly into the bladder by a urethral catheter. Protocols vary, but intravesical therapy is usually initiated at weekly intervals for 6 to 12 weeks. The chemotherapeutic drugs are instilled directly into the patient's bladder and retained for about 2 hours. The patient's position may be changed every 15 minutes for maximum contact in all areas of the bladder, especially if the tumour occurred on the bladder dome. The use of maintenance therapy after the initial induction regimen may be beneficial.

BCG, a weakened strain of *Mycobacterium bovis,* is the treatment of choice for carcinoma in situ. BCG stimulates the immune system rather than acting directly on cancer cells in the bladder. When BCG alone fails, IFN-α may be used in addition to BCG. Other treatments that can be used when BCG fails include thiotepa, an alkylating agent.

Most patients have irritation upon voiding and hemorrhagic cystitis following intravesical therapy. Thiotepa, when absorbed into circulation from the bladder wall, can significantly reduce WBC and platelet counts in some individuals. BCG may cause flulike symptoms, hematuria, or systemic infection. Other adverse effects usually associated with chemotherapy, such as nausea, vomiting, and hair loss, are not experienced with intravesical chemotherapy.

Nursing responsibilities include encouraging the patient to increase the daily fluid intake and to quit smoking, assessing the patient for secondary UTI, and stressing the need for routine urological follow-up. The patient may have fears or concerns about sexual activity or bladder function that will have to be addressed.

Urinary Incontinence and Retention

Urinary incontinence (UI) is an uncontrolled loss of urine that is of sufficient magnitude to be a problem. Approximately 3.3 million Canadians experience incontinence, including 10% of children 6 years of age and up, 25% of women middle-aged and older, and 15% of men aged 60 years and older (Canadian Continence Foundation, 2016). Among younger adults, more women than men are affected by UI. Although UI has traditionally been viewed as a social or hygienic problem, it is now known to affect quality of life as well as contribute to morbidity in older adults. (UI is not a natural consequence of aging.)

Causes of UI may be transient (e.g., caused by confusion or depression, infection, medications, restricted mobility, or stool impaction). Acquired disorders are described in Table 48-17. Patients may have more than one type of incontinence and may not disclose UI symptoms because of associated stigma.

TABLE 48-17
ACQUIRED DISORDERS CAUSING URINARY INCONTINENCE

Type and Description	Causes	Treatment
Stress Incontinence*		
Sudden increase in intra-abdominal pressure causes involuntary passage of urine. It can occur during coughing, heavy lifting, straining, or laughing.	*Females:* Condition is found most commonly in women with relaxed pelvic musculature (frequently from obstetrical complications or multiple pregnancies). Structures of the female urethra atrophy when estrogen decreases.	Perineal muscle exercises (e.g., Kegel exercises), weight loss if patient is obese, insertion of vaginal pessary, estrogen (vaginal creams, tablets, or vaginal ring)
	Males: Prostate surgery for benign prostatic hyperplasia or prostatic carcinoma.	Condom catheters or penile clamp, surgery Urethral inserts, patches, or bladder neck support devices to correct underlying problem
Urge Incontinence*		
Condition occurs randomly when involuntary urination is preceded by warning a few seconds to a few minutes in advance. Leakage is periodic but frequent. Nocturnal frequency and incontinence are common. Condition may appear with varying severity during psychological stress.	Condition is caused by uncontrolled contraction or overactivity of detrusor muscle. Bladder escapes central inhibition and contracts reflexively. Conditions include central nervous system disorders (e.g., cerebro-vascular disease, Alzheimer's disease, brain tumour, Parkinson's disease), bladder disorders (e.g., carcinoma in situ, radiation effects, interstitial cystitis), interference with spinal inhibitory pathways (e.g., malignant growth in spinal cord, spondylosis), and bladder outlet obstruction, as well as conditions of unknown etiology.	Treatment of underlying cause, instruction to have patient urinate more frequently or on time schedule, anticholinergic drugs (e.g., imipramine) at bedtime, calcium channel blockers, condom catheters, vaginal estrogen
Overflow Incontinence		
Pressure of urine in overfull bladder overcomes sphincter control. Urination may also occur frequently in small amounts during the night. Bladder remains distended and is usually palpable.	Disorder is caused by outlet obstruction (prostatic hyperplasia, bladder neck obstruction, urethral stricture) or by underactive detrusor muscle caused by myogenic or neurogenic factors (e.g., herniated disk, diabetic neuropathy). It may also occur after anaesthesia and surgery (especially procedures such as hemorrhoidectomy, herniorrhaphy, cystoscopy). Neurogenic bladder (flaccid type) is another cause.	Urinary catheterization to decompress bladder, implementation of Credé or Valsalva manoeuvre, α-adrenergic blocker (e.g., prazosin) to decrease outlet resistance, bethanechol (Duvoid) to enhance bladder contractions, intermittent catheterization, surgery to correct underlying problem
Reflex Incontinence		
No warning or stress precedes periodic involuntary urination. Urination is frequent, is moderate in volume, and occurs equally during the day and night.	Spinal cord lesion above S2 interferes with central nervous system inhibition. Disorder results in detrusor hyper-reflexia and interferes with pathways coordinating detrusor contraction and sphincter relaxation.	Treatment of underlying cause, bladder decompression to prevent ureteral reflux and hydronephrosis, intermittent self-catheterization, α-adrenergic blocker (e.g., prazosin) to relax internal sphincter, diazepam or baclofen to relax external sphincter, prophylactic antibiotics, surgical sphincterotomy
Incontinence After Trauma or Surgery		

Type and Description	Causes	Treatment
Vesico-vaginal or urethro-vaginal fistula may occur in women. Alteration in continence control in men involves proximal urethral sphincter (bladder neck and prostatic urethra) and distal urethral sphincter (external striated muscle).	Fistulas may occur during pregnancy, after delivery of baby, as a result of hysterectomy or invasive cancer of cervix, or after radiation therapy. Incontinence is found as postoperative complication after transurethral, perineal, or retropubic prostatectomy.	Surgery to correct fistula, urinary diversion surgery to bypass urethra and bladder, external condom catheter, penile clamp, placement of artificial implantable sphincter
Functional Incontinence		
Loss of urine resulting from problems of patient mobility or environmental factors.	Older adults often have problems that affect balance and mobility.	Modifications of environment or care plan that facilitate regular, easy access to toilet and promote patient safety (e.g., better lighting, ambulatory assistance equipment, clothing alterations, timed voiding, different toileting equipment)

*Patients can have a combination of stress and urge incontinence that is referred to as *mixed incontinence*.

Urinary retention is the inability to empty the bladder despite micturition or the accumulation of urine in the bladder because of the inability to urinate. It may be associated with dribbling urinary leakage called *overflow UI. Acute urinary retention* is the total inability to pass urine via micturition; it is a medical emergency. *Chronic urinary retention* is defined as incomplete bladder emptying despite urination. Postvoid residual volumes in patients with chronic urinary retention vary widely; values of 150 to 200 mL or higher generally necessitate further evaluation. Smaller volumes may justify evaluation when they produce LUTS or occur in a context of recurring UTIs. Urinary retention is caused by two different dysfunctions of the urinary system: bladder outlet obstruction and deficient detrusor contraction strength. Obstruction leads to urinary retention when the blockage prevents bladder evacuation of its contents despite a detrusor contraction. A common cause of obstruction in men is an enlarged prostate. Urinary retention also results when the detrusor muscle no longer has the strength to contract with enough force or for long enough to completely empty the bladder.

Common causes of deficient detrusor muscle contraction strength are neurological diseases affecting sacral segments 2, 3, and 4; longstanding diabetes mellitus; overdistension; chronic alcoholism; and drugs (e.g., anticholinergic drugs).

Nursing Management Urinary Incontinence

Nurses' relational care approaches through listening to patients' questions and valuing patients' knowledge about UI are required to address socioemotional well-being and promote application of UI management techniques. The majority of UI symptoms can be managed conservatively with the following interventions: hydration; reduction in consumption of caffeine and alcohol (bladder irritants); smoking cessation (smoking increases the risk of stress incontinence); and constipation management, which includes adequate fluid intake, increase in dietary fibre, light exercise, and judicious use of stool softeners. (The management of constipation is discussed in Chapter 45.) As well, continence strategies can assist in preventing falls and fall-related injuries in older adults (Registered Nurses' Association of Ontario [RNAO], 2011).

Habit training or prompted toileting is useful for patients with urge, mixed, and functional UI. Habit training uses the results of a voiding diary or bladder log to determine patterns of daytime voiding frequency. A goal is then established for voiding frequency, usually ranging from 2 to 3 hours. Voiding is scheduled rigidly during waking hours according to the baseline urinary frequency identified on the bladder log. At night, the person is advised to urinate as normal if awakened from sleep with the desire to void. Habit training may be combined with pelvic muscle training, focusing on techniques such as urge suppression. Prompted toileting is indicated for patients with altered cognitive function and functional UI (usually coexisting with urge UI). Specifically, caregivers are taught to remind the patient to toilet on a regular basis (usually q2–3h), and the patient is assisted to the toilet and given praise for successful toileting. A trial of prompted toileting, in conjunction with a urological evaluation, is used to predict the ultimate success of such a program.

In the hospital, nursing management includes maximizing toilet access and promoting privacy when offering the urinal or bedpan or assisting the patient to the bathroom every 2 to 3 hours or at scheduled times.

When attempting to manage UI, many women use feminine hygiene pads, and many men and women use household products such as rags, paper towels, or folded toilet tissue. None of these products is adequately designed to wick urine away from the skin, prevent soiling of clothing, and reduce or eliminate odour. The nurse should share information on products specifically designed to contain urine. For example, patients with mild to moderate UI often benefit from incontinence pads containing a material specifically designed to absorb many times its weight in water. Patients with higher volume urine loss or those with double urinary and

fecal incontinence may benefit from disposable or reusable incontinence briefs or pad–pant systems.

Diagnostic Studies

The basic evaluation for UI and urinary retention includes a focused history, physical assessment, and a bladder log or voiding record whenever possible. Information should be obtained regarding the onset of UI, factors that provoke urinary leakage, and associated conditions. The nurse should pay special attention to factors known to produce transient UI, particularly when a relatively sudden onset of urine loss is reported. The physical examination begins with an assessment of general health and functional issues associated with urinary function, including mobility, dexterity, and cognitive function. A pelvic examination includes careful inspection of the perineal skin for signs of erosion or rashes related to UI. Local innervation and pelvic muscle strength should also be evaluated. Whenever possible, the patient is asked to keep a bladder log or voiding diary documenting the timing of urinations, episodes of urinary leakage, and frequency of nocturia for a period of 1 to 7 days. This record can be kept by nursing staff if the person is in an inpatient facility.

The urinalysis is used to identify possible factors contributing to transient UI or urinary retention (e.g., urinary infection, diabetes mellitus). A postvoid residual urine must be measured in the patient undergoing evaluation for urinary retention and UI. The postvoid residual volume is obtained by asking the patient to urinate, followed by catheterization within a relatively brief period (preferably 5–10 min). Alternatively, a bladder scan device can be used to estimate the residual volume. Although less accurate than the catheterized residual measurement, this technique avoids catheterization with its associated discomfort and risk for UTI. Urodynamic testing is indicated in select cases of UI and urinary retention (Bettez, Tu, Carlson, et al., 2012). Imaging studies of the upper urinary tract (e.g., ultrasound, IVP) are obtained when retention or UI is associated with UTIs or when there is evidence of upper urinary tract involvement.

Collaborative Care: Urinary Incontinence

An estimated 80% of incontinence can be cured or significantly improved. Transient, reversible factors are corrected initially, followed by management of established UI (see Table 48-17). In general, less invasive treatments are attempted before more invasive methods (e.g., surgery) are used. Nevertheless, the choice of initial treatment is highly individualized

and based on patient preference, the type and severity of UI, and associated anatomical defects.

Several therapies may be employed to improve urinary continence. These interventions are outlined in Table 48-18. Pelvic muscle training (Kegel exercises) is used to manage stress, urge, or mixed UI (Table 48-19). Biofeedback is used to assist the patient to identify, isolate, contract, and relax the pelvic muscles (see the "Complementary & Alternative Therapies" box). Strength training is used to improve the efficiency of the sphincter. Neuro-muscular education is used to teach patients how and when to contract the pelvic floor muscles to maximize continence. Bladder training or habit training involves rigidly scheduled toileting intervals designed to enhance bladder capacity and reduce the frequency and volume of urine loss. *Prompted toileting* is a behavioural technique used in patients with functional UI. In this case, patients with impaired cognitive function are regularly reminded to urinate, assisted to the toilet, and offered praise for successful toileting.

TABLE 48-18
INTERVENTIONS FOR URINARY INCONTINENCE

Intervention	Description
Lifestyle Modifications	
	Self-management strategies to reduce or eliminate risk factors, including the following: • Smoking cessation • Weight reduction • Good bowel regimen • Reduction of bladder irritants such as caffeine • Fluid modifications for those with urge incontinence
Scheduling Voiding Regimens	
• Timed voiding	Toileting on a fixed schedule (typically q2–3h during waking hours)
• Habit retraining	Scheduled toileting with adjustments of voiding intervals (longer or shorter) based on the individual's voiding pattern
• Prompted voiding	Scheduled toileting that requires prompts to void from a caregiver (typically q3h); used in conjunction with operant conditioning techniques for rewarding individuals for maintaining continence and appropriate toileting
• Bladder retraining and urge-suppression strategies	Scheduled toileting with progressive voiding intervals; includes teaching of urge-control strategies using relaxation and distraction techniques, self-monitoring, use of reinforcement techniques, and other strategies such as conscious contraction of pelvic floor muscles
Pelvic Floor Muscle Rehabilitation	
• Pelvic floor muscle (Kegel) exercises or training	See Table 48-19
• Vaginal weight training	Active retention of increasing vaginal weights at least twice a day; typically used in combination with pelvic floor muscle exercises
• Biofeedback	See “Complementary & Alternative Therapies” box
• Electrical stimulation	Application of low-voltage electric current to sacral and pudendal afferent fibres through vaginal, anal, or surface electrodes; used to inhibit bladder overactivity and improve awareness, contractility, and efficiency of pelvic muscle contraction
Anti-Incontinence Devices	
• Intravaginal support devices (pessaries and bladder neck support prostheses)	Devices to support bladder neck, relieve minor pelvic organ prolapse, and change pressure transmission to the urethra
• Transvaginal sling device	Prevents involuntary release of urine through urethral support
• Intraurethral occlusive device (urethral plug)	Single-use device that is worn in the urethra to provide mechanical obstruction to prevent urine leakage; removed for voiding
• Penile compression device	Mechanical fixed compression applied to the penis to prevent any flow or leakage via the urethra; must be released hourly to void
Containment Devices	
• External collection devices	External catheter (condom) systems (i.e., penile sheaths) direct urine into a drainage bag; most commonly used by men
• Absorbent products	Variety of reusable and disposable pads and pant systems

TABLE 48-19

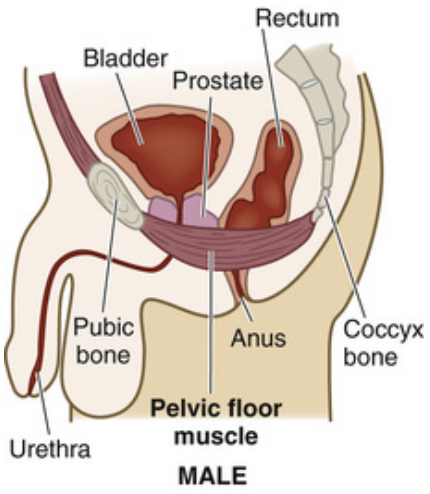
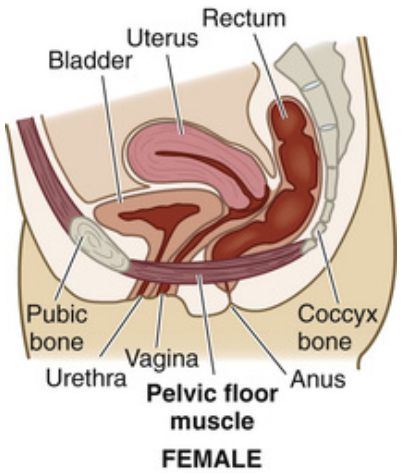
Pelvic Floor Muscle (or Kegel) Exercises

What Is the Pelvic Floor Muscle?

Your pelvic floor muscle provides support for your bladder and rectum and, in women, the vagina and the uterus. If it weakens or is damaged, it cannot support these organs and their position can change. This causes problems with the normal bladder and rectal function. If you have a weak pelvic floor muscle, you might want to do special exercises to make the muscle stronger, prevent unwanted urine leakage, and lessen urinary urgency.





Finding the Pelvic Floor Muscle

Without tensing the muscles of your leg, buttocks, or abdomen, imagine that you are trying to control the passing of gas or pinching off a stool. Or imagine you are in an elevator full of people and you feel the urge to pass gas. What do you do? You tighten or pull in the ring of muscle around your rectum—your pelvic floor muscle. You should feel a lifting sensation in the area around the vagina or a pulling in of your rectum.

How to Do the Exercises

There are two different kinds of exercises—short squeezes and long squeezes.

1. To do the *short squeezes,* tighten your pelvic floor muscle quickly, squeeze hard for 2 sec, and then relax the muscle. Also, when you have strong urinary urges, try to tighten your pelvic floor muscle quickly and hard several times in a row until the urge passes.
2. To do the *long squeezes,* tighten the muscle for 5–10 sec before you relax. Do both of these exercises 40–50 times each day.

When to Do These Exercises

You can do these exercises anytime and anywhere. You can do these exercises in any position, but sitting or lying down may be the easiest.

How Long Does It Take Before You Notice a Change?

After 4–6 wk of doing these exercises, you should start to see less urine leakage and urinary urgency.

Complementary & Alternative Therapies

Biofeedback for Urinary Incontinence in Women

Clinical Uses

Kegel exercises help to strengthen the pelvic floor muscles. Biofeedback helps to isolate muscle groups in the pelvis.

Effects

Sensors for biofeedback are placed in the vagina or on the skin outside of the vagina. These sensors measure electrical signals produced when muscles contract. Biofeedback training develops an awareness of and control of the pelvic floor muscles.

Nursing Implications

- If done correctly, pelvic floor muscle exercise is effective treatment for mild to moderate UI and other conditions related to pelvic floor muscle weakness. Unfortunately, many women do not do these exercises correctly. Biofeedback is a tool to make sure that these exercises are done correctly. Most supplementary insurance plans cover the cost of biofeedback.

Electrical stimulation of the pelvic floor muscles relies on very-low-voltage and low-frequency pulses to stimulate muscle contraction and diminish overactive bladder contractions. It can be used as monotherapy for the treatment of urge or mixed UI or in conjunction with pelvic muscle training in the management of stress UI. Minimally invasive electrical stimulation uses a transvaginal or transrectal probe, or a device can be surgically implanted near the pelvic nerve roots.

Drug Therapy.

Drug therapy varies according to the UI type (Table 48-20). Drugs have a very limited role in the management of stress UI. α-Adrenergic agonists can be used to increase urethral resistance at the level of the sphincter mechanism. Unfortunately, they exert a limited beneficial effect, and they are associated with adverse effects including exacerbation of hypertension and tachycardia. Drugs play a more central role in the management of urge or reflex UI. Antimuscarinic (also called anticholinergic or antispasmodic) drugs relax the bladder muscle and inhibit overactive detrusor contractions. Two preparations, long-acting tolterodine (Detrol LA) and oxybutynin in a releasing capsule (Ditropan XL), are preferred

because of their efficacy and the modest incidence of their adverse effects compared with older antimuscarinic agents.

TABLE 48-20
DRUG THERAPY
Voiding Dysfunction*

Drug Class and Mechanism of Action	Drug
Muscarinic Receptor Antagonists and Anticholinergics	
Reduce overactive bladder contractions in urge urinary incontinence and overactive bladder	• Oxybutynin (Ditropan XL, Oxytrol transdermal system) • Tolterodine (Detrol, Detrol LA) • Dicyclomine (Bentylol)
α-Adrenergic Antagonists	
Reduce urethral sphincter resistance to urinary outflow	• Doxazosin (Cardura) • Terazosin • Tamsulosin (Flomax CR)
5α-Reductase Inhibitors	
Androgen suppression that results in epithelial atrophy and a decrease in total prostate size	• Finasteride (Proscar)
Tricyclic Antidepressants	
Reduce sensory urgency and burning pain of interstitial cystitis Reduce overactive bladder contractions	• Imipramine • Amitriptyline (Elavil)
Calcium Channel Blockers	
Reduce smooth muscle contraction strength May reduce burning pain of interstitial cystitis	• Nifedipine (Adalat) • Diltiazem • Verapamil (Isoptin)
Hormone Therapy	
Local application reduces urethral irritation and increases host defences against UTI	• Estrogen cream (Premarin, Estrace) • Estrogen vaginal ring (Estring) • Estrogen vaginal tablets (Vagifem)

*The type of drug therapy depends on the type of incontinence.

UTI, urinary tract infection.

Drug Alert

Tolterodine (Detrol)

- Overdosage can result in severe anticholinergic effects.
- These effects include GI cramping, diaphoresis, blurred vision, and urinary urgency.

Surgical Therapy.

Surgical techniques also vary according to the type of UI (Bettez, Tu, Carlson, et al., 2012). The Marshall–Marchetti–Krantz procedure involves suspending the urethra and the bladder neck by suturing the anterior vaginal wall on each side to the periosteum of the pubic bones and the lower rectum through an abdominal incision. The Pereyra procedure and subsequent modifications involve suspending the tissues adjacent to the bladder neck to the abdominal fascia, mainly through a transvaginal approach. Placement of a suburethral sling, using autologous fascia, cadaveric fascia, or a synthetic material, can also correct stress UI in women. An artificial urethral sphincter can be used in women or men with intrinsic sphincter deficiency and severe stress UI. Bolsters can also be implanted in men with stress UI to increase urethral resistance. This procedure is technically similar to the suburethral sling surgery often performed in women. A tension-free synthetic vaginal tape also can be used to treat stress UI. This transvaginal slinglike material is placed under the midurethra through incisions in the abdominal and vaginal wall (Kociszewski, Rautenberg, Kuszka, et al., 2012). Alternatively, one of several bulking agents can be injected underneath the mucosa of the urethra to correct stress UI in women or men (Bettez, Tu, Carlson et al., 2012).

Bulking agents include glutaraldehyde cross-linked bovine collagen (GAX collagen), small silicone beads (Durasphere), or polytetrafluoroethylene (Teflon). Because of the risk of migration of Teflon particles, GAX collagen or Durasphere injections are most commonly used today.

Collaborative Care: Urinary Retention

Scheduled toileting and double voiding may be effective in chronic urinary retention with moderate postvoid residual volumes. However, for acute or chronic urinary retention, intermittent catheterization may be required. It allows the patient to remain free of an in-dwelling catheter with its associated risk of UTI and urethral irritation. However, an in-dwelling catheter is used when urethral obstruction renders intermittent catheterization uncomfortable or unfeasible, or when a patient is unwilling or unable to perform intermittent catheterization.

Drug Therapy.

Several drugs may be administered to promote bladder evacuation. For patients with obstruction at the level of the bladder neck, an α-adrenergic

blocker may be prescribed. These drugs relax the smooth muscle of the bladder neck, the prostatic urethra, and possibly the dually innervated rhabdo-sphincter, diminishing urethral resistance. Examples of α-adrenergic blocking agents are listed in Table 48-20. They are indicated for use in patients with BPH, bladder neck dyssynergia, or detrusor sphincter dyssynergia. Finasteride (Proscar) is a 5α-reductase enzyme inhibitor that reduces prostate size by inhibiting the conversion of testosterone to dihydrotestosterone. Finasteride is also useful for the hematuria that occasionally complicates symptomatic BPH in older men. Bethanechol chloride (Duvoid) is sometimes prescribed to promote contractility in the weakened detrusor muscle (Bettez, Tu, Carlson, et al., 2012).

Surgical Therapy.

Surgical interventions are often useful when managing urinary retention caused by obstruction. Transurethral or open surgical techniques are used in select patients to treat benign or malignant prostatic enlargement, bladder neck contracture, urethral strictures, or dyssynergia of the bladder neck. Pelvic reconstruction using an abdominal or transvaginal approach can be used to correct bladder outlet obstruction in women with severe pelvic organ prolapse.

Unfortunately, surgery plays little role in the management of urinary retention caused by deficient detrusor contraction strength. Attempts to create a bladder stimulator (implanted device capable of stimulating micturition) have proved largely unsuccessful because of the difficulty in achieving a coordinated detrusor contraction associated with pelvic muscle and striated sphincter relaxation.

Nursing Management Urinary Retention

Acute urinary retention is a medical emergency that requires prompt recognition and bladder drainage. The nurse should insert a catheter (as prescribed) unless otherwise directed. A catheter with a retention balloon is used in anticipation of the need for an in-dwelling catheter.

Patients with acute urinary retention (as well as patients predisposed to these episodes) should be taught strategies to minimize risk, including avoiding intake of large volumes of fluid over a brief period. Instead, patients should be advised to drink small volumes throughout the day. Patients are advised to warm up before attempting urination when chilled and to avoid large volumes of alcohol intake because it leads to polyuria and a diminished awareness of the need to urinate until the bladder is

distended. Patients who are unable to urinate are advised to drink a cup of coffee or brewed tea containing caffeine to create or maximize urinary urgency and to take a warm shower and attempt to urinate while in the bathtub or shower, with reassurance that they can easily bathe immediately following bladder evacuation. If these strategies do not lead to successful urination, patients are advised to seek immediate care.

Patients with chronic urinary retention may be managed by behavioural methods, in-dwelling or intermittent catheterization (Table 48-21), surgery, or drugs (Bettez, Tu, Carlson, et al., 2012). Scheduled toileting and double voiding are the primary behavioural interventions used for chronic retention. Scheduled toileting is used to reduce rather than expand bladder capacity. In this case, patients are asked to void every 3 to 4 hours regardless of the desire to urinate. This intervention is particularly useful in patients with chronic overdistension, diabetes mellitus, or chronic alcohol use characterized by a large bladder capacity and diminished or delayed sensations of bladder filling and urgency. Double voiding is an attempt to maximize bladder evacuation. The patient is asked to urinate, sit on the toilet for 3 to 4 minutes, and urinate again before exiting the bathroom.

TABLE 48-21
INDICATIONS FOR URINARY CATHETERIZATION

In-Dwelling Catheter
• Accurate measurement of urinary output in critically ill patient • Bladder decompression preoperatively and operatively for lower abdominal or pelvic surgery • Facilitation of surgical repair of urethra and surrounding structures • Measurement of residual urine after urination (referred to as postvoid residual [PVR]) if portable ultrasound not available • Relief of urinary retention caused by lower urinary tract obstruction, paralysis, or inability to void • Splinting of ureters or urethra to facilitate healing after surgery or other trauma in area • Terminal illness or severe impairment that makes positioning or clothing changes uncomfortable or that is associated with intractable pain • Urine contamination of stage 3 or 4 pressure injuries that has impeded healing, despite appropriate personal care for the incontinence
Straight (In-and-Out) Catheter
• Collection of sterile urine sample in select situations • Instillation of medications into bladder • Study of anatomical structures of urinary system • Urodynamic testing

Instrumentation

Reasons for short-term urinary catheterization are listed in Table 48-21. Two reasons that are not valid indications for catheterization are (1) routine acquisition of a urine specimen for laboratory analysis and (2) convenience of the nursing staff or the patient's family. The risks for health care–associated infection are too high to allow catheterization of a patient for the convenience of health care providers or family members. Catheterization to obtain sterile urine specimens may occasionally be indicated when patients have a history of complicated urinary infection. These specimens have to be as free of contaminants as possible. A catheter should be the final means of providing the patient with a dry environment for prevention of skin breakdown and protection of dressings or skin lesions.

Urinary catheterization is used when indicated in the management of hospitalized patients. However, it is not without serious risks. The urinary tract is the most common site of health care–associated infections. Urinary catheterization is a major cause of UTIs. Strict aseptic technique is mandatory when a urinary catheter is inserted. After insertion, maintenance and protection of the closed drainage system are major nursing responsibilities. Irrigation of the catheter should not be routinely performed.

While a patient has a catheter in place, nursing actions should include maintaining patency of the catheter, managing fluid intake, providing for the comfort and safety of the patient, and preventing infection. Attention should be given to the psychological implications of urinary drainage. Patient concerns can include embarrassment related to exposure of the body, an altered body image, and fear concerning the care of the catheter, which results in increased dependency.

Catheters vary in construction materials, tip shape (Figure 48-11), and size of the lumen. Catheters are sized according to the French scale. Each French unit equals 0.33 mm of diameter. The diameter measured is the internal diameter of the catheter. The size used varies with the size of the individual and the purpose for catheterization. In women, urethral catheter sizes 12 to 14F are the most common; in men, sizes 14 to 16F are used. The primary problem resulting from too large a catheter is tissue erosion secondary to excessive pressure on the meatus or the urethra. Four routes are used for urinary tract catheterization: urethral, ureteral, suprapubic, and via a nephrostomy tube.

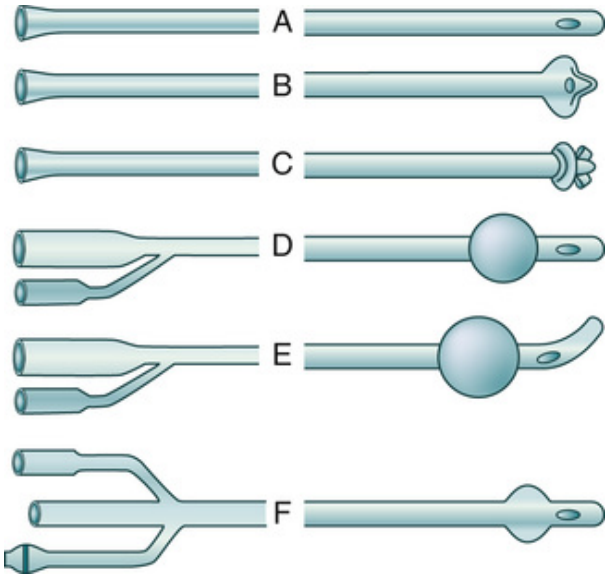

FIGURE 48-11 Different types of commonly used catheters. **A,** Simple urethral catheter. **B,** Mushroom or Pezzar (can be used for suprapubic catheterization). **C,** Winged-tip or Malecot catheter. **D,** In-dwelling with inflated balloon. **E,** In-dwelling with coudé tip or Tiemann tip. **F,** Three-way in-dwelling (the third lumen is used for irrigation of the bladder).

Urethral Catheterization

The most common route of catheterization is through the external meatus into the urethra, past the internal sphincter, and into the bladder. Principles that should be considered in the management of patients with a urethral catheter include the following:

- Catheterized patients, particularly those who are ambulatory, should receive appropriate instruction regarding catheter care.
- A sterile, closed drainage system should always be used in short-term catheterization. The distal urinary catheter and the proximal drainage tube should not be disconnected except for necessary catheter irrigation. The catheter should be taped to the leg. Unobstructed downhill flow must be maintained. The collecting bag

should be emptied regularly and kept below the level of the bladder. A poorly functioning catheter should be replaced. A leg bag should not be used for patients in a hospital setting on a short-term basis because the risk for bacterial infection is great when the catheter is disconnected and the drainage bags are exchanged.

- Perineal care (one to two times per day and when necessary) should include cleaning of the meatus–catheter junction with soap and water. Following this, an antimicrobial ointment may be applied. Lotion or powder should not be used near the catheter. The catheter should be properly secured to the leg to prevent movement and urethral traction.
- Sterile technique must be used whenever the collecting system is opened. Catheter irrigation is performed only when obstruction or blood clots are suspected or, in the case of long-term catheterization, to reduce sediment buildup. If frequent irrigations are necessary in short-term catheterization for catheter patency, a triple-lumen catheter may be preferable, permitting continuous irrigations within a closed system. Small volumes of urine for culture can be aspirated from the distal catheter by means of a sterile syringe and a 21-gauge needle after the drainage tubing is clamped. The puncture site must first be prepared with a tincture of iodine or alcohol solution. Many drainage systems are now equipped with a sampling port. Silicone or plastic catheters do not self-seal. Urine for chemical analysis (e.g., electrolytes) can be obtained from the drainage bag.

- When a patient is catheterized for less than 2 weeks, routine catheter change is not necessary. For long-term use of an in-dwelling catheter, regular replacement is necessary. With long-term use of a catheter, a leg bag may be used. If the collection bag is reused, it should be washed with soap and water and rinsed thoroughly. When not reused immediately, it should be filled with 0.5 cup of vinegar and drained. The vinegar is effective against *Pseudomonas* and other organisms and eliminates odours.

Ureteral Catheters

The ureteral catheter is placed through the ureters into the renal pelvis. The catheter is inserted either (a) by being threaded up the urethra and bladder to the ureters under cystoscopic observation or (b) by surgical insertion through the abdominal wall into the ureters. The ureteral catheter is used after surgery to splint the ureters and to prevent them from being obstructed by edema. The urine volume from the ureteral catheter should be recorded separately from other urinary catheters. The patient is usually kept on bed rest while a ureteral catheter is in place until specific orders indicate that ambulation is permissible. The self-retaining ureteral catheter is often inserted after a lithotripsy procedure or when ureteral obstruction from adjacent tumours or fibrosis threatens renal function. The double-J ureteral catheter is often used and allows the patient to ambulate. One end coils up in the kidney pelvis, and the other coils in the bladder.

The placement of the ureteral catheter should be checked frequently, and tension on the catheter should be prevented. The catheter drains urine from the renal pelvis, which has a capacity of 3 to 5 mL. If the volume of urine in the renal pelvis increases, the additional pressure will cause tissue damage to the pelvis. Therefore, the ureteral catheter should not be clamped. If the physician orders irrigation of the ureteral catheter, strict aseptic technique is required. If output is decreased, the physician should be notified immediately. Drainage should be checked often (at least q1–2h). It is normal for some urine to drain around the ureteral catheter into the bladder. Accurate recording of urine output from both the ureters and

the urethral catheter is essential. Sometimes, a ureteral catheter may be used as a stent and is not expected to drain. It is important to check with the physician as to the type of catheter and what to expect.

Suprapubic Catheters

Suprapubic catheterization is the simplest and oldest method of urinary diversion. The two methods of insertion of a suprapubic catheter into the bladder are (a) through a small incision in the abdominal wall and (b) by the use of a trocar. A suprapubic catheter is placed while the patient is under general anaesthesia for another surgical procedure or at the bedside with a local anaesthetic. The catheter may be sutured into place. The nursing responsibility includes taping the catheter to prevent dislodgement. The care of the tube and catheter is similar to that of the urethral catheter. A pectin-based skin barrier (e.g., Stomahesive) is effective around the insertion site in protecting the skin from breakdown.

The suprapubic catheter is used in temporary situations such as bladder, prostate, and urethral surgery. The suprapubic catheter is also used long-term in select patients (e.g., male patient with tetraplegia [quadriplegia] who tends to form penoscrotal fistulas).

A suprapubic catheter is prone to poor drainage because of mechanical obstruction of the catheter tip by the bladder wall, sediment, and clots. Nursing interventions to ensure patency of the tube include (a) preventing tube kinking by coiling the excess tubing and maintaining gravity drainage, (b) having the patient turn from side to side, and (c) milking the tube. If these measures are not effective, the catheter is irrigated with sterile technique after a physician's order has been obtained.

If the patient experiences bladder spasms that are difficult to control, urinary leakage may result. Oxybutynin (Ditropan XL) or other oral antispasmodics or belladonna and opium (B&O) suppositories may be prescribed to decrease bladder spasms.

Nephrostomy Tubes

The nephrostomy tube (catheter) is inserted on a temporary basis to preserve renal function when a complete obstruction of the ureter is present. It is inserted directly into the pelvis of the kidney and attached to connecting tubing for closed drainage. The principle is the same as with the ureteral catheter; that is, the catheter should never be kinked, lain or leaned on, or clamped. If the patient complains of excessive pain in the area or if there is excessive drainage around the tube, the catheter should

be checked for patency. If irrigation is ordered, strict aseptic technique is required. No more than 5 mL of sterile saline solution is gently instilled at one time to prevent overdistension of the kidney pelvis and renal damage. Infection and secondary stone formation are complications associated with the insertion of a nephrostomy tube.

Intermittent Catheterization

An alternative approach to a long-term in-dwelling catheter is *intermittent catheterization* (Newman & Willson, 2011). It is being used with increasing frequency in conditions characterized by neurogenic bladder (e.g., spinal cord injuries, chronic neurological diseases) or bladder outlet obstruction in men and can be self-managed. This type of catheterization may also be used in the oliguric and anuric phases of acute kidney injury to reduce the possibility of infection from an in-dwelling catheter. Intermittent catheterization is also used postoperatively, often after a surgical procedure for female incontinence or radioactive seed implantation into the prostate for cancer. The main goal of intermittent catheterization is to prevent urinary retention, stasis, and compromised blood supply to the bladder caused by prolonged pressure.

The technique consists of inserting a urethral catheter into the bladder every 3 to 5 hours. Some patients do intermittent catheterization only once or twice a day to measure residual urine and to ensure an empty bladder. Patients should be instructed to wash and rinse the catheter and their hands with soap and water before and after catheterization. Lubricant is necessary for men and may make catheterization more comfortable for women. The catheter may be inserted by the patient or the care provider. Once the bladder is emptied, the catheter is removed. The catheter can be dried and placed in a carrying pouch or purse or folded in a paper towel until it is next needed. The same catheter can be used for weeks at a time. In general, patients should change the catheter every 2 to 4 weeks.

In the hospital, sterile technique is used. For home care, a clean technique that includes good handwashing with soap and water is used. There has been no significant increase in infection with the use of an appropriate clean technique as compared with sterile technique. Several patients living in the community have permanent in-dwelling catheters, which can pose risks for infection, as well as limit the patient's ability to lead an active life. Community patients who are candidates for clean intermittent self-catheterization need personal instruction and support to become comfortable with the procedure. Patients need to demonstrate the

desire, motivation, and manual dexterity required to manage the procedure, and commit to assimilating it into regular activities of daily living. They may feel anxious about performing such an intimate and possibly uncomfortable procedure. The nurse may need to balance the risks versus benefits of implementing the self-catheterization procedure for the patient. Instructing the patient to learn the proper clean procedure, in a logical step-by-step fashion, is recommended to support patients so that they can achieve independence (Woodward, Steggal, and Tinhunu, 2013). The patient is taught to observe for signs of UTI so that treatment can be instituted early. If indicated, some patients are placed on a regimen of prophylactic antibiotics.

Surgery of the Urinary Tract

Renal and Ureteral Surgery

The most common indications for nephrectomy are a renal tumour, polycystic kidneys that are bleeding or severely infected, massive traumatic injury to the kidney, and the elective removal of a kidney from a donor. Surgery involving the ureters and the kidneys is most commonly performed to remove calculi that become obstructive, correct congenital anomalies, and divert urine when necessary.

Preoperative Management

The basic needs of the patient undergoing renal and ureteral surgery are similar to those of any patient who experiences surgery (see Chapters 20 through 22). In addition, it is especially important preoperatively to ensure adequate fluid intake and a normal electrolyte balance. The patient should be told that there will probably be a flank incision on the affected side and that surgery will require a hyperextended, side-lying position. This position frequently causes the patient to experience muscle aches after surgery. If a nephrectomy is planned, the patient must be assured that one working kidney is sufficient to maintain normal renal function.

Postoperative Management

Specific postoperative needs of a patient are related to urine output, respiratory status, and abdominal distension.

Urine Output.

In the immediate postoperative period, urine output should be determined at least every 1 to 2 hours. Drainage from various catheters should be recorded separately. The catheter or tube should not be clamped or irrigated without a specific order. The total urine output should be at least 0.5 mL/kg/hr. Peak flow rates can be measured with a urometer. It is also important to assess for urine drainage on the dressing and to estimate the amount. Daily weighing of the patient is important. The same scale should be used and properly balanced, and the patient should wear similar clothing and dressings each time.

It is important to observe and monitor the colour and the consistency of urine. Urine with increased amounts of mucus, blood, or sediment may

occlude the drainage tubing or catheter.

Respiratory Status.

Renal surgery is often performed through a flank incision just below the diaphragm and often involves removal of the twelfth rib. Postoperatively, it is important to ensure adequate ventilation. The patient is often reluctant to turn, cough, and deep breathe because of the incisional pain. Adequate pain medication should be given to ensure the patient's comfort and ability to perform coughing and deep-breathing exercises. Frequently, additional respiratory devices such as an incentive spirometer are used every 2 hours while the patient is awake. In addition, early and frequent ambulation assists in maintaining adequate respiratory function.

Abdominal Distension.

Abdominal distension is present to some degree in most patients who have had surgery on their kidneys or ureters. It is most commonly the result of paralytic ileus caused by manipulation and compression of the bowel during surgery. Oral intake is restricted until bowel sounds are present (usually 24–48 hr after surgery). Intravenous fluids are given until the patient can take oral fluids. Progression to a regular diet follows.

Laparoscopic Nephrectomy

Laparoscopic nephrectomy can be performed in select situations to remove a diseased kidney. It can also be used to obtain a kidney from a living donor to be transplanted into a person with end-stage renal disease. In contrast to the open incision of about 18 cm required in a conventional nephrectomy, a laparoscopic nephrectomy is performed using five puncture sites. One incision is to view the kidney and another is to dissect it. The laparoscope contains a miniature camera so that the surgeons can watch what they are doing on a video monitor. Once dissected, the kidney is manoeuvred into a nylon impermeable sack, and its contents can then be safely removed from the patient. Compared with conventional nephrectomy, the laparoscopic approach is less painful and requires no sutures or staples, involves a shorter hospital stay, and has a much faster recovery. NCP 48-3, regarding care of patients with an ileal conduit, identifies key nursing diagnoses that apply to caring for patients with a nephrectomy pertaining to (a) management of anxiety related to lack of knowledge regarding a major surgical procedure, (b) knowledge deficits

about preoperative, operative, and postoperative procedures, (c) risks for infection related to the surgical procedure, and (d) deficient fluid volume.

Urinary Diversion

Urinary diversion may be performed with and without cystectomy. Urinary diversion procedures are performed to treat cancer of the bladder, neurogenic bladder, congenital anomalies, strictures, trauma to the bladder, and chronic infections with deterioration of renal function. Numerous urinary diversion techniques and bladder substitutes are possible, including an incontinent urinary diversion, continent urinary diversion catheterized by patient, or an orthotopic bladder so that the patient voids urethrally. Types of these surgical procedures are presented in Table 48-22 and Figure 48-12.

TABLE 48-22

TYPES OF URINARY DIVERSION SURGERY REQUIRING COLLECTION DEVICES

Description	Advantages	Disadvantages	Special Considerations
Ileal			
Conduit ureters are implanted into part of ileum or colon that has been resected from intestinal tract. Abdominal stoma is created.	Relatively good urine flow with few physiological alterations	External appliance necessary to continually collect urine	Surgical procedure is more complex. Postoperative complications may be increased. Reabsorption of urea by ileum occurs. Meticulous attention is necessary to care for stoma and collecting device.
Cutaneous Ureterostomy			
Ureters are excised from bladder and brought through abdominal wall, and stoma is created. Ureteral stomas may be created from both ureters, or ureters may be brought together and one stoma created.	No need for major surgery as required with ileal conduit	External appliance necessary because of continuous urine drainage; possibility of stricture or stenosis of small stoma	Periodic catheterizations may be required to dilate stomas to maintain patency.
Nephrostomy			
Catheter is inserted into pelvis of kidney. Procedure may be done to one or both kidneys and may be temporary or permanent. It is most frequently done in advanced disease as palliative procedure.	No need for major surgery	High risk for renal infection; predisposition to calculus formation from catheter	Nephrostomy tube may have to be changed every month. Catheter must never be clamped.

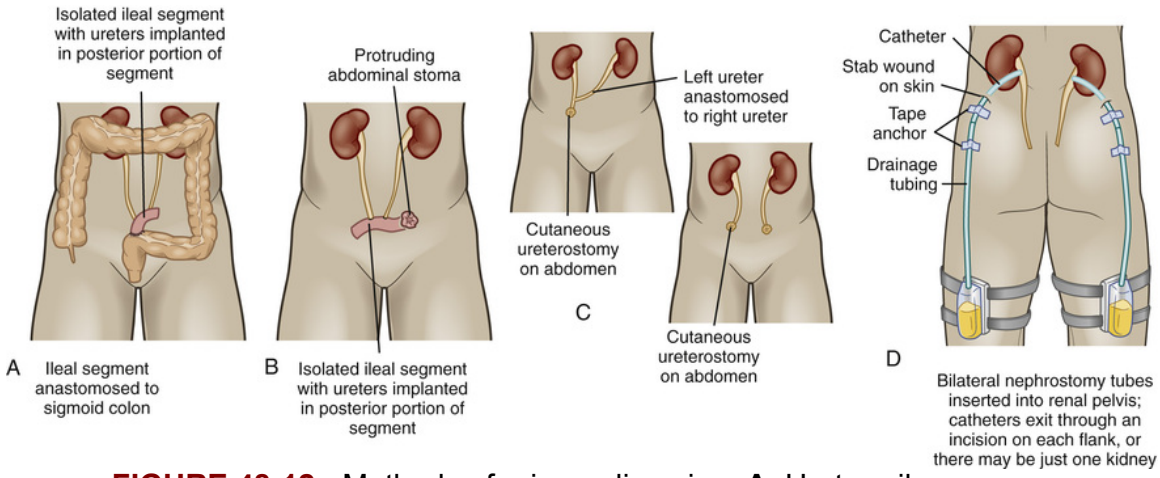

FIGURE 48-12 Methods of urinary diversion. **A,** Uretero-ileo-sigmoidostomy. **B,** Ileal loop (or ileal conduit). **C,** Ureterostomy (transcutaneous ureterostomy and bilateral cutaneous ureterostomies). **D,** Nephrostomy.

Incontinent Urinary Diversion

Incontinent urinary diversion is diversion to the skin, requiring an appliance. The simplest form is the cutaneous ureterostomy, but scarring and strictures of the ureter have led to the use of ileal or colonic conduits. The most commonly performed incontinent urinary diversion procedure is the **ileal conduit** (ileal loop). In this procedure, a 15- to 20-cm segment of the ileum is converted into a conduit for urinary drainage. The colon (colon conduit) can be used instead of the ileum. The ureters are anastomosed into one end of the conduit, and the other end of the bowel is brought out through the abdominal wall to form a stoma (Figure 48-13). Although the segment of bowel remains supported by the mesentery, it is completely isolated from the intestinal tract. The bowel is anastomosed and continues to function normally. Because there is no valve and no voluntary control over the stoma, drops of urine flow from the stoma every few seconds, requiring the use of a permanent external collecting device. The visible stoma and the need for external collection devices are obvious disadvantages of this procedure. The lifelong care and dealing with the stoma and collection devices may be psychologically difficult. These problems have stimulated the increasing use of continent diversions and orthotopic bladder substitutes.

FIGURE 48-13 Ideal urinary stoma. It is symmetrical, has no skin breakdown, and protrudes about 1.5 cm. The mucosa is a healthy red, and the configuration is flat when the patient is upright and supine. Source: Courtesy Lynda Brubacher, Virginia Mason Hospital, Seattle, WA.

Continent Urinary Diversions

A *continent urinary diversion* is an intra-abdominal urinary reservoir that is catheterizable or has an outlet controlled by the anal sphincter. Continent diversions are internal pouches created similarly to the ileal conduit. Reservoirs have been constructed from the ileum, ileocecal segment, or colon. Large segments of bowel are altered to prevent peristaltic action. A continence mechanism is formed between this large, low-pressure reservoir and the stoma by intussuscepting a portion of bowel. In this way, a patient does not leak involuntarily. The patient with a continent reservoir needs to self-catheterize every 4 to 6 hours but does not need to wear external attachments. Examples of continent diversions are the Kock (Figure 48-14), Mainz, Indiana, and Florida pouches. A main difference among these diversions is the segment of bowel used. For example, the Indiana pouch uses the right colon as a reservoir and has become a popular form of continent urinary diversion.

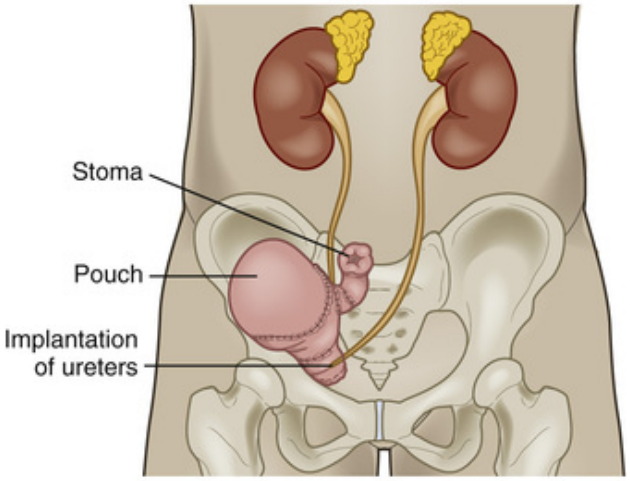

FIGURE 48-14 Creation of a Kock pouch with implantation of ureters into one intussuscepted portion of the pouch and creation of a stoma with the other intussuscepted portion.

Orthotopic Bladder Substitution

Orthotopic bladder substitutes can be derived from various segments of the intestines. An isolated segment of the distal ileum is often preferred. Various procedures include the hemi-Kock pouch, Studer pouch, and the ileal W-neobladder. In these procedures, the bowel is surgically reshaped to become a neobladder. The ureters and urethra are sutured into the neobladder. Orthotopic bladder reconstruction has become a more viable option for both men and women if cancer does not involve the bladder neck or urethra (Park & Ahn, 2011). The advantage of orthotopic bladder substitution is that it allows for natural micturition. Incontinence is a possible problem with this technique, and intermittent catheterization may be required.

Nursing Management Urinary Diversion

Preoperative Management

Patients awaiting cystectomy and urinary diversion must be given a great deal of information. The nurse must assess ability and readiness to learn before initiating a teaching program. If a patient is not ready to learn, the teaching plan should be adjusted. The patient's anxiety and fear may be decreased by the information. However, the anxiety and fear may also interfere with learning. The patient's family and caregivers should be involved in the teaching process. A discussion of the social aspects of

living with a stoma (including clothing, changes in body image and sexuality, exercise, and odour) provides the patient with facts that may allay some fears. Patients who will have a continent diversion must be taught to catheterize and irrigate the pouch and be able to adhere to a strict catheterization schedule. Patients with an orthotopic neobladder may have problems with incontinence. Concerns about the effect on sexual activities should be discussed. The enterostomal therapy nurse should be involved in the preoperative phase of the patient's care. A visit from an ostomate or enterostomal therapy nurse can be helpful. Additional interventions are presented in NCP 48-3, available on the Evolve website.

Postoperative Management

Nursing interventions during the postoperative period (see NCP 48-3 for care after an ileal conduit) should be planned to prevent surgical complications such as postoperative atelectasis and shock (see Chapter 22). The incidence of thrombo-phlebitis increases after pelvic surgery. With removal of part of the bowel, the incidence of paralytic ileus and small bowel obstruction increases, the patient is kept on nothing-by-mouth status, and a nasogastric tube is necessary for 3 to 5 days.

Specific attention should be given to preventing injury to the stoma and maintaining urine output. Mucus is present in the urine because it is secreted by the intestines as a result of the irritating effect of the urine. Patients should be told that this is a normal occurrence. A high fluid intake is encouraged to “flush” the ileal conduit or continent diversion.

When an ileal conduit is created, the skin around the stoma requires meticulous care. Alkaline encrustations with dermatitis may occur when alkaline urine comes in contact with exposed skin (Figure 48-15). Other common peristomal skin problems include yeast infections, product allergies, and shearing-effect excoriations. Changing appliances (pouches) is described in Table 48-23. A properly fitting appliance is essential to prevent skin problems. The appliance should be about 0.2 cm larger than the stoma. It is normal for the stoma to shrink within the first few weeks after surgery. The urine is kept acidic to prevent alkaline encrustations.

TABLE 48-23

PATIENT & CAREGIVER TEACHING GUIDE
Changing Ileal Conduit Appliances

Temporary Appliance
1. Cut hole in pouch to fit over stoma (pouch 3.2 mm [⅛ inch] larger than stoma). 2. Remove old pouch. 3. Clean area gently, and remove old adhesive. 4. Wash area with warm water. 5. Place wick (rolled-up 4 × 4–inch) over stoma to keep area dry during rest of procedure. 6. Dry skin around stoma. 7. Apply a prescribed skin protectant around stoma to area where pouch will be placed. 8. Apply pouch by first smoothing its edges toward side and lower portion of body. 9. Remove wick and complete application of bag. 10. For a patient who is usually in bed: Apply bag so that it lies toward side of body. 11. For a patient who is ambulatory: Apply bag so that it lies vertically. 12. Connect drainage tubing to pouch. 13. Keep drainage pouch on same side of bed as stoma.
Permanent Appliance*
1. Keep appliance in place for 2–14 days. 2. Change appliance when fluid intake has been restricted for several hours. 3. Sit or stand in front of mirror. 4. Moisten edge of faceplate with adhesive solvent and gently remove. 5. Clean skin with adhesive solvent. 6. Wash skin with warm water. (Patient may shower.) 7. Dry skin and inspect. 8. Place wick (rolled-up 4 × 4–inch) over stoma to keep skin free of urine. 9. Apply skin cement to faceplate and skin. 10. Place appliance over stoma. 11. Wash removed appliance with soap and lukewarm water; soak in distilled vinegar; rinse with lukewarm water and air dry.

*Many disposable appliances with self-adhesive backing are used as permanent appliances.

Acceptance of the surgery and of alterations in body image is needed to ensure the patient's best adjustment. Concerns of the patient include fear that the stoma will be offensive to others and will interfere with sexual, personal, professional, and recreational activities. The patient should know that few activities, if any, will be restricted as a result of the urinary diversion.

Discharge planning after an ileal conduit includes teaching the patient symptoms of obstruction or infection and care of the ostomy. The patient with an ileal conduit is fitted for a permanent appliance 7 to 10 days after surgery and may need to be refitted at a later time, depending on the degree of stoma shrinkage. Appliances are made of a variety of products, including natural and synthetic rubbers, plastics, and metals. Most appliances have a faceplate that adheres to the skin, a collecting pouch, and an opening to drain the pouch. The faceplate may be secured to the skin with glues, adhesives, or adhering synthetic wafers. Some appliances

do not require adhesives, but their design relies on pressure to keep the pouch in place. If improperly fitted or applied, the faceplate may cause skin problems (Figure 48-16). A bag may be used for night drainage. The patient needs information on where to purchase supplies, emergency telephone numbers, location of ostomy support groups, and follow-up visits with an enterostomal therapist. Physician follow-up is imperative to monitor and correct homeostatic abnormalities and to prevent complications and renal function deterioration.

Case Study

Urinary Tract Infection

Source: Syda Productions/Shutterstock.com.

Patient Profile

Maria Guinto, a 28-year-old woman with diabetes, was seen in the nurse practitioner's office for a history of painful, frequent urination.

Subjective Data

- Has had history of painful, frequent urination with passage of small volumes of urine for 3 days
- Has had intermittent fever, chills, and back pain during these 3 days
- Was frightened when she saw blood in her urine
- Is anxious because her father died of kidney cancer
- Has a history of recurrent UTIs

Objective Data

Physical Examination

- Complains of bilateral flank pain and abdominal tenderness to palpation
- Temperature is 38°C

Diagnostic Study

- Urinalysis: pyuria and hematuria

Discussion Questions

1. What are the most common organisms that cause UTIs?
2. What factors predispose a patient to a UTI?

3. What is the difference between upper and lower UTIs?
4. ***Priority decision:*** What are the priority nursing interventions that will help Ms. Guinto cope with her symptoms?
5. What can the nurse do to help Ms. Guinto prevent another UTI?
6. Why might she be having recurrent bouts of UTIs? What other diagnostic tests may be indicated?
7. ***Priority decision:*** Based on the data presented, write one or more appropriate nursing diagnoses. Are there any collaborative problems?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Organisms that cause pyelonephritis most commonly reach the kidneys through which means?
   a. The bloodstream
   b. The lymphatic system
   c. A descending infection
   d. An ascending infection
2. What should the nurse teach the female client who has frequent urinary tract infections (UTIs)?
   a. Urinate after sexual intercourse.
   b. Take tub baths with bubble bath.
   c. Take prophylactic sulphonamides for the rest of her life.
   d. Restrict fluid intake to prevent the need for frequent voiding.
3. Which of the following immunological mechanisms are involved in glomerulo-nephritis?
   a. Tubular blocking by precipitates of bacteria and antibody reactions
   b. Deposition of immune complexes and complement along the glomerular basement membrane (GBM)
   c. Thickening of the GBM from autoimmune microangiopathic changes
   d. Destruction of glomeruli by proteolytic enzymes contained in the GBM
4. What is one of the most important roles of the nurse in relation to acute poststreptococcal glomerulo-nephritis (APSGN)?
   a. To promote early diagnosis and treatment of sore throats and skin lesions
   b. To encourage clients to request antibiotic therapy for all upper respiratory infections
   c. To teach clients with APSGN that long-term prophylactic antibiotic therapy is necessary to prevent recurrence
   d. To monitor clients for respiratory symptoms that indicate that the disease is affecting the alveolar basement membrane
5. Why does edema occur in nephrotic syndrome?

a. Decreased aldosterone secretion from adrenal insufficiency
b. Increased hydrostatic pressure caused by sodium retention
c. Increased fluid retention caused by decreased glomerular filtration
d. Decreased colloidal osmotic pressure caused by loss of serum albumin

6. A client is admitted to the hospital with severe renal colic caused by renal lithiasis. What is the nurse's first priority in management of the client?
a. To administer opioids as prescribed
b. To obtain supplies for straining all urine
c. To encourage fluid intake of 3 to 4 L/day
d. To keep the client on nothing-by-mouth status in preparation for surgery

7. In which of the following conditions should the nurse recommend genetic counselling for the client's children?
a. Nephrotic syndrome
b. Chronic pyelonephritis
c. Malignant nephrosclerosis
d. Adult-onset polycystic renal disease

8. The nurse instructs a client with diabetes to maintain careful control of his blood glucose levels related to which disease-related complication?
a. Uric acid calculi and nephrolithiasis
b. Renal sugar-crystal calculi and cysts
c. Lipid deposits in the glomeruli and the nephrons
d. Thickening of the GBM and glomerulo-sclerosis

9. Which of the following conditions would the nurse identify as a risk factor for kidney and bladder cancers? *(Select all that apply)*
a. acetylsalicylic acid (ASA: Aspirin) use
b. Tobacco use
c. Chronic alcohol abuse
d. Use of artificial sweeteners
e. Chronic use of phenacetin-containing analgesics

10. Which nursing interventions are most important in order to increase bladder control in a client with urinary incontinence? *(Select all that apply)*

a. Restricting fluids to diminish the risk for urinary leakage

b. Counselling the client to maintain a regular voiding schedule

c. Clamping and releasing a catheter to increase bladder tone

d. Teaching the client biofeedback mechanisms to suppress the urge to void

11. A client with a uretero-lithotomy returns from surgery with a nephrostomy tube in place. What is the priority nursing action related to caring for this client?

a. Encouraging the client to drink fruit juices and milk

b. Forcing fluids of at least 2 to 3 L/day after nausea has subsided

c. Notifying the physician if nephrostomy tube drainage is more than 30 mL/hr

d. Irrigating the nephrostomy tube with 10 mL of normal saline solution as needed

12. A client has had a cystectomy and ileal conduit diversion performed. Four days postoperatively, mucous shreds are seen in the drainage bag. Which action should the nurse undertake?

a. Notify the physician.

b. Notify the charge nurse.

c. Irrigate the drainage tube.

d. Chart it as a normal observation.

1. d; 2. a; 3. b; 4. a; 5. d; 6. a; 7. d; 8. d; 9. b, e; 10. a, b; 11. b; 12. d.

CHAPTER 49

Nursing Management

Acute Kidney Injury and Chronic Kidney Disease

Written by, Hazel A. Dennison

Adapted by, Debbie Rickeard

LEARNING OBJECTIVES

1. Differentiate between acute kidney injury and chronic kidney disease.
2. Identify criteria used in the classification of acute kidney injury using the acronym RIFLE (risk, injury, failure, loss, end-stage kidney disease).
3. Describe the clinical course of acute kidney injury.
4. Explain the collaborative care and nursing management of a patient with acute kidney injury.
5. Define chronic kidney disease and delineate the five stages of chronic kidney disease based on the glomerular filtration rate.
6. Select risk factors that contribute to the development of chronic kidney disease.
7. Summarize the significance of cardiovascular disease in individuals with chronic kidney disease.
8. Explain the collaborative care and related nursing management of the patient with chronic kidney disease.
9. Differentiate among renal replacement therapies for individuals with chronic kidney disease.
10. Discuss the role of the nurse in the management of individuals who receive a renal transplant.

KEY TERMS

acute kidney injury (AKI), p. 1202
acute renal failure (ARF), p. 1202
acute tubular necrosis (ATN), p. 1203
arteriovenous fistula (AVF), p. 1221
arteriovenous graft (AVG), p. 1221
azotemia, p. 1202
automated peritoneal dialysis (APD), p. 1219
chronic kidney disease (CKD), p. 1208
chronic kidney disease–mineral and bone disorder (CKD–MBD), p. 1211
continuous ambulatory peritoneal dialysis (CAPD), p. 1219
continuous renal replacement therapy (CRRT), p. 1224
dialysis, p. 1217
end-stage renal disease (ESRD), p. 1208
hemodialysis (HD), p. 1217
oliguria, p. 1203
paired organ donation, p. 1227
peritoneal dialysis (PD), p. 1217
renal osteodystrophy, p. 1211
renal replacement therapy (RRT), p. 1201
uremia, p. 1208

Kidney disease may cause the partial or complete impairment of kidney function. It results in an inability to excrete metabolic waste products and water, as well as functional disturbances of all body systems. This impairment may be acute or chronic in nature (Table 49-1). Acute kidney injury (AKI) has a rapid onset. Chronic kidney disease (CKD) usually develops slowly over months to years. If CKD progresses to stage 5 (worst functioning), **renal replacement therapy (RRT)** (dialysis or transplantation) is necessary for long-term survival. Early CKD care focuses on prevention and delaying progression of disease and educating patients about the treatment options for RRTs so an informed decision can

be made when the time comes. As with other chronic illnesses in Canada, CKD is much more common in the older-adult population. Between 2003 and 2013, the number of Canadians aged 45 to 64 with CKD increased by 46%, while Canadians 65 and older saw a 66% increase. During the same time period, the number of Canadians aged 45 and older with diabetes also increased by more than 60% (Canadian Institute for Health Information [CIHI], 2014).

TABLE 49-1

COMPARISON OF ACUTE KIDNEY INJURY AND CHRONIC KIDNEY DISEASE

	Acute Kidney Injury	Chronic Kidney Disease
Onset	Sudden	Gradual, often over many years
Most common cause	Acute tubular necrosis	Diabetic nephropathy
Diagnostic criteria	Acute reduction in urine output, elevation in serum creatinine, or both	GFR <60 mL/min/1.73 m^2 for >3 mo, kidney damage >3 mo, or both
Reversibility	Potentially	Progressive and irreversible
Mortality	High (~60%)	19%–24% (patients on dialysis)
Primary cause of death	Infection	Cardiovascular disease

GFR, glomerular filtration rate.

Source: Kellum, J., Bellomo, R., & Ronco, C. (2008). Definition and classification of acute kidney injury. *Nephron Clinical Practice, 109*(4), 182–187. doi:10.1159/000142926; and U.S. Renal Data System. (2008). USRDS 2008 annual data report: Atlas of end-stage renal disease. Bethesda, MD: National Institute of Diabetes and Digestive and Kidney Diseases.

In 2012, 41 252 Canadians were being treated for kidney failure, with 23 814 on dialysis and 17 438 with a functioning kidney transplant (CIHI, 2014).

Acute Kidney Injury

Acute kidney injury (AKI), previously known as **acute renal failure (ARF),** is a more inclusive term encompassing a broader subset of patients with varying degrees of kidney injury (Moreland & Phiri, 2015). AKI is characterized by an abrupt decline in kidney function, leading to a rise in serum creatinine or a reduction in urine output, or both (Moreland & Phiri, 2015). The severity of dysfunction can range from a small increase in serum creatinine or reduction in urine output to the development of **azotemia** (an accumulation of nitrogen waste products [urea nitrogen, creatinine] in the blood).

Although AKI is potentially reversible, despite advances in its treatment, the mortality rate is high (Libório, Leite, Neves, et al., 2015). Usually, AKI affects people with other life-threatening conditions. Most commonly, AKI follows severe, prolonged hypotension or hypovolemia or exposure to a nephrotoxic agent.

The ARF associated with AKI usually develops over hours or days, with progressive elevations of blood urea nitrogen (BUN), creatinine, and potassium, with or without oliguria. Severe AKI develops in over 60% of intensive care unit (ICU) patients, with mortality rates of 70% to 80%.

One of the most commonly used classification systems for AKI uses serum creatinine, glomerular filtration rate (GFR), and urine output to identify **r**isk, **i**njury, **f**ailure, **l**oss, and **e**nd-stage kidney disease (the RIFLE Criteria) (Figure 49-1) (Williams, 2014). The criteria for evaluating AKI have been found to correlate with outcome and are a good predictor of mortality in hospitalized patients (Liborio et al., 2015).

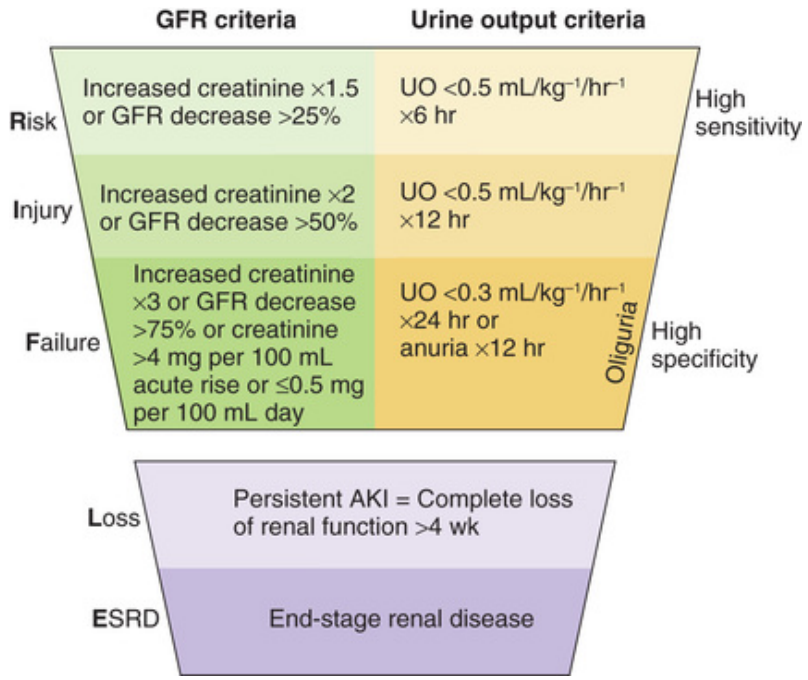

FIGURE 49-1 RIFLE (risk, injury, failure, loss, end-stage kidney disease) Criteria. *AKI,* acute kidney injury; *ESRD,* end-stage renal disease; *GFR,* glomerular filtration rate; *UO,* urine output. Williams, L. (2014). Take aim at acute kidney injury with RIFLE criteria. *Nursing*, *44*(7), 50–55 6p. doi:10.1097/01.NURSE.0000445730.84886.88

Etiology and Pathophysiology

AKI is a complex disorder, with many etiological factors and varied clinical manifestations that range from minimal elevation in serum creatinine to anuric renal failure (Ellis, 2013; Williams, 2014). The causes leading to AKI with renal failure are divided into prerenal, intrarenal (or intrinsic), and postrenal categories (Table 49-2).

TABLE 49-2
COMMON CAUSES OF ACUTE KIDNEY INJURY

Prerenal	Intrarenal
• Anaphylaxis • Antihypertensive drugs • Bilateral renal vein thrombosis • Burns • Cardiac dysrhythmias • Cardiogenic shock • Decreased cardiac output • Decreased peripheral vascular resistance • Decreased renovascular blood flow • Dehydration • Embolism • Excessive diuresis • GI losses (diarrhea, vomiting) • Heart failure • Hemorrhage • Hepatorenal syndrome • Hypoalbuminemia • Hypovolemia • Myocardial infarction • Neurological injury • Pericardial tamponade • Pulmonary edema • Renal artery thrombosis • Septic shock • Valvular heart disease	• Acute glomerulo-nephritis • Allergies (antibiotics [sulphonamides, rifampin], nonsteroidal anti-inflammatory drugs, ACE inhibitors) • Chemical exposure (ethylene glycol, lead, arsenic, carbon tetrachloride) • Drugs (aminoglycosides [gentamicin, amikacin], amphotericin B) • Hemolytic blood transfusion reaction • Infections (bacterial [acute pyelonephritis], viral [CMV], fungal [candidiasis]) • Interstitial nephritis • Malignant hypertension • Nephrotoxic injury • Prolonged prerenal ischemia • Radiocontrast agents • Severe crush injury • Systemic lupus erythematosus • Thrombotic disorders • Toxemia of pregnancy **Postrenal** • Benign prostatic hyperplasia • Calculi formation • Cancer (bladder, prostate, cervical, colorectal) • Neuro-muscular disorders • Spinal cord disease • Strictures • Trauma (back, pelvis, perineum)

ACE, angiotensin-converting enzyme; *CMV*, cytomegalovirus; *GI*, gastro-intestinal.

Prerenal causes of AKI are factors external to the kidneys. These factors reduce systemic circulation, causing a reduction in renal blood flow and lead to decreased glomerular perfusion and filtration. Although renal tubular and glomerular function is preserved, glomerular filtration is reduced as a result of decreased perfusion. Hypovolemia, decreased cardiac output, decreased peripheral vascular resistance, and vascular obstruction can all decrease the effective circulating volume of the blood. With a decrease in circulating blood volume, autoregulatory mechanisms that increase angiotensin II, aldosterone, norepinephrine, and antidiuretic hormone attempt to preserve blood flow to essential organs. Prerenal azotemia results in a reduction in the excretion of sodium (<20 mmol/L), increased salt and water retention, and decreased urine output.

Prerenal AKI can also be caused by vasoactive medications such as angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), epinephrine, and large doses of dopamine that cause intrarenal vasoconstriction leading to hypoperfusion of the glomeruli

(Ellis, 2013). AKI associated with prerenal causes is usually reversible. If the course of prerenal failure is prolonged, intrarenal damage may ensue, usually resulting in acute tubular necrosis.

Intrarenal causes include conditions that cause direct damage to the renal tissue (parenchyma), resulting in impaired nephron function. Intrarenal causes of AKI are usually owing to prolonged ischemia or the presence of nephrotoxins, hemoglobin released from hemolyzed red blood cells (RBCs), or myoglobin released from necrotic muscle cells. Nephrotoxins can cause obstruction of intrarenal structures by crystallization or by actually damaging the epithelial cells of the tubules. Hemoglobin and myoglobin block the tubules and cause renal vasoconstriction. Primary renal diseases such as acute glomerulo-nephritis and systemic lupus erythematosus may also cause AKI.

Acute tubular necrosis (ATN) is the most common intrarenal cause of AKI and is primarily the result of ischemia, nephrotoxins, or sepsis (Figure 49-2). Severe renal ischemia causes a disruption in the basement membrane and patchy destruction of the tubular epithelium. Nephrotoxic agents cause necrosis of tubular epithelial cells, which slough off and plug the tubules. ATN is potentially reversible if the basement membrane is not destroyed and the tubular epithelium regenerates.

FIGURE 49-2 Acute tubular necrosis. In acute tubular necrosis, the kidneys are swollen and pale. Source: Stevens, A., & Lowe, J. (2000). *Pathology: Illustrated review in color* (2nd ed.). London: Mosby.

Possible pathological processes involved in ATN include the following:

1. Hypovolemia and decreased renal blood flow stimulate renin release, which activates the renin–angiotensin–aldosterone system (see Chapter 47, Figure 47-6) and results in constriction of the peripheral arteries and the renal afferent arterioles. With decreased renal blood flow, there is decreased glomerular capillary pressure and GFR as well as tubular dysfunction and, ultimately, oliguria.
2. Ischemia alters glomerular epithelial cells and decreases glomerular capillary permeability. This reduces the GFR, which significantly reduces blood flow and leads to tubular dysfunction.
3. When tubules are damaged, interstitial edema occurs, and necrotic epithelial cells accumulate in the tubules. The debris lowers the GFR by obstructing the tubules and increasing intratubular pressure.
4. Glomerular filtrate leaks back into plasma through holes in the damaged tubular membranes, which decreases intratubular fluid flow.

Postrenal causes of AKI involve mechanical obstruction of urinary outflow. As the flow of urine is obstructed, urine refluxes into the renal pelvis, impairing kidney function. The most common causes are benign prostatic hyperplasia, prostate cancer, calculi, trauma, and extrarenal tumours. Postrenal AKI is almost always treatable if identified before permanent kidney damage occurs.

Clinical Manifestations

Prerenal or postrenal AKI that has not caused intrarenal damage usually resolves quickly with correction of the cause. However, if parenchymal damage has occurred from either cause, or from intrarenal causes, ATN results or the course of AKI is prolonged. Clinically, ATN progresses through three phases: initiation, maintenance, and recovery (Lang, 2014). In some situations, the patient does not recover from AKI, and CKD results.

Initiation Phase.

The initiation phase of ATN is characterized by an increase in serum creatinine and BUN and a decrease in urine output (Murphy & Byrne, 2010).

Maintenance Phase.

The maintenance phase of ATN may last from days to weeks. During this phase, patients may be anuric, oliguric, or nonoliguric. In the case of patients who are nonoliguric, a dilute urine (low specific gravity) is made, but uremic toxins are not removed. The oliguric phase usually lasts 10 to 14 days, but it can last for months in some cases. The longer the oliguric phase lasts, the poorer the prognosis for recovery of complete renal function.

The manifestations of the oliguric phase are changes in urinary output, fluid and electrolyte abnormalities, and uremia. (For a definition of *uremia*, see the discussion of the clinical manifestations of CKD, later in this chapter.) The nurse must be alert for the signs and symptoms of these changes.

Urinary Changes.

The most common initial manifestation of ATN is **oliguria,** in which urine output generally decreases to less than 400 mL/24 hr. If ATN is caused by ischemia, oliguria will occur within 24 hours. If ATN is caused by nephrotoxic drugs, the onset may be delayed for as long as a week. The duration of the oliguric phase is generally 10 to 14 days, but it can last months in some cases.

Oliguria associated with ATN is characterized by urine with a normal specific gravity (1.010) and a high sodium concentration (>40 mmol/L), and urine osmolality at about 300 mmol/kg, indicating that the injured tubules cannot respond to autoregulatory mechanisms. The urine sediment may show RBCs and white blood cells (WBCs), casts, and proteinuria. The casts are formed from mucoprotein impressions of the necrotic renal tubular epithelial cells, which detach or slough into the tubules.

Fluid Volume Excess.

When urinary output decreases, fluid retention occurs. The severity of the symptoms depends on the extent of the fluid overload. The neck veins may become distended with a bounding pulse. Edema and hypertension may develop. Fluid overload can eventually lead to heart failure, pulmonary edema, and pericardial and pleural effusions.

Metabolic Acidosis.

In renal failure, the kidneys cannot synthesize ammonia, which is needed for hydrogen ion excretion or to excrete acid products of metabolism. The

serum bicarbonate level decreases because bicarbonate is used up in buffering hydrogen ions. In addition, defective reabsorption and regeneration of bicarbonate occurs. The patient may develop Kussmaul's respirations (rapid, deep respirations) to increase the excretion of carbon dioxide. Lethargy and stupor will occur if treatment is not started.

Sodium Balance.

Damaged tubules cannot conserve sodium. Consequently, the urinary excretion of sodium may increase, resulting in normal or below-normal levels of serum sodium. Excessive intake of sodium should be avoided because it can lead to volume expansion, hypertension, and heart failure. Uncontrolled hyponatremia or water excess can lead to cerebral edema.

Potassium Excess.

Hyperkalemia is a common, life-threatening complication seen in patients with oliguria. Serum potassium levels increase because the normal ability of the kidneys to regulate and excrete potassium is impaired. Hyperkalemia associated with AKI may be precipitated by a number of causes. Massive tissue trauma may result in the release of additional potassium into the extracellular fluid by the damaged cells. Bleeding and blood transfusions may cause cellular destruction, releasing more potassium into the extracellular fluid. Acidosis worsens hyperkalemia as hydrogen ions enter the cells and potassium is driven out of the cells into the extracellular fluid.

Most often, patients with hyperkalemia are asymptomatic. Some patients may complain of weakness with severe hyperkalemia. Severe hyperkalemia requires immediate treatment. Before clinical signs of hyperkalemia are apparent, the electrocardiogram (ECG) will show tall, peaked T waves; widening of the QRS complex; and ST depression. Progressive changes in the ECG that are related to increasing potassium levels are depicted in Chapter 19, Figure 19-14. Because cardiac muscle is very intolerant of acute increases in potassium, treatment is essential when hyperkalemia develops.

Hematological Disorders.

Several hematological disorders are seen in connection with AKI. Anemia occurs because renal failure results in impaired erythropoietin production. Uremia decreases platelet adhesiveness and can lead to bleeding from multiple sources (e.g., intestines, brain). WBCs are also altered, causing immunodeficiency. This leaves the patient susceptible to numerous

systemic and local infections. Infection (sepsis) in combination with AKI is associated with double the mortality rate, and half of the survivors suffer permanent kidney damage or chronic kidney disease (Emlet, Shaw, & Kellum, 2015).

Calcium Deficit and Phosphate Excess.

Activated vitamin D must be present for calcium absorption from the gastro-intestinal (GI) tract to occur. Only functioning kidneys can activate vitamin D. Thus, in the presence of kidney failure, GI absorption of calcium decreases, and a low serum calcium level results. When hypocalcemia occurs, the parathyroid gland secretes parathyroid hormone (PTH), which stimulates bone demineralization and causes calcium to be released from the bones. Phosphate is released as well, leading to hyperphosphatemia, which is worsened by the decreased excretion of phosphate by the kidneys. Normally, plasma calcium is found ionized or free (physiologically active form) or bound to protein. In the acidotic state associated with renal failure, more calcium is in the ionized form. Although it is unusual for hypocalcemia to be symptomatic in renal failure, an ionized calcium level that does decrease significantly can lead to tetany.

Waste Product Accumulation.

The kidneys are the primary excretory organs for urea, an end product of protein metabolism, and creatinine, an end product of endogenous muscle metabolism. The BUN and creatinine levels are elevated in kidney failure. An elevated BUN level must be interpreted with caution because dehydration, corticosteroids, catabolism resulting from infections, fever, severe injury, and GI bleeding can also elevate BUN. The best serum indicator of renal failure is creatinine because it is not significantly altered by other factors. Measuring creatinine clearance by using radioactive tracer (inulin) is the most accurate method for assessing renal function, but it is expensive and impractical. Clinically, the recommended method to evaluate kidney function is with an estimated glomerular filtration rate (eGFR) (Baron, Cheng, Bazari, et al., 2015).

Neurological Disorders.

Neurological changes can occur as nitrogenous waste products accumulate in the brain and other nervous tissue. The symptoms can be as mild as fatigue and difficulty concentrating or can escalate to seizures, stupor, and coma.

Eventually, all body systems become involved in the acute uremic syndrome. The extrarenal manifestations are generally similar to those found in the patient with chronic uremia (see the discussion of CKD later in this chapter).

Recovery Phase.

The recovery phase of AKI is marked by a return of BUN, creatinine, and GFR toward normal ranges (Baron et al., 2015). During this phase, patients may experience a diuretic phase that can result in fluid and electrolyte abnormalities. The diuretic phase begins with a gradual increase in daily urine output to 1 to 3 L/day, but it may reach 3 to 5 L or more per day. Although urine output increases, the nephrons are still not fully functional. The high urine volume is caused by osmotic diuresis from the high urea concentration in the glomerular filtrate and the inability of the tubules to concentrate the urine. In this phase, the kidneys have recovered their ability to excrete wastes but not to concentrate the urine. Hypovolemia and hypotension can occur from massive fluid losses. Because of the large losses of fluid and electrolytes, the patient must be monitored for hyponatremia, hypokalemia, and dehydration. The diuretic phase may last 1 to 3 weeks. Near the end of this phase, the patient's acid–base, electrolyte, and waste product (BUN, creatinine) values begin to normalize. Although the major improvements occur in the first 1 to 2 weeks of this phase, renal function may take up to 12 months to stabilize.

The outcome of AKI is influenced by the patient's overall health, the severity of renal failure, and the number and type of complications. Some individuals do not recover and progress to CKD. The older-adult patient is less likely to recover full kidney function than the younger patient. Among the individuals who recover, the majority achieve clinically normal kidney function with no complications (e.g., hypertension).

Diagnostic Studies.

Urinalysis is an important diagnostic test. Urine sediment containing abundant cells, casts, or proteins suggests intrarenal disorders. The urine osmolality, sodium content, and specific gravity help to differentiate the types of AKI. Urine sediment may be normal in both prerenal and postrenal AKI. Hematuria, pyuria, and crystals may be seen with postrenal AKI.

To establish a diagnosis of AKI, other testing may be required. A renal ultrasound is often the first test done and provides information about

anatomy and function. Ultrasound does not require the use of nephrotoxic contrast agents. A renal scan can assess renal blood flow and the integrity of the collecting system. A computed tomographic (CT) scan can identify lesions and masses as well as obstruction, but exposure to radiation is higher and it may involve contrast that can be nephrotoxic. Magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) are not recommended—gadolinium, a contrast medium used with MRI and MRA, has been associated with the development of *nephrogenic systemic fibrosis* in patients with compromised renal function.

Collaborative Care

Because AKI is potentially reversible, the primary goals of treatment are to eliminate the cause, manage the signs and symptoms, and prevent complications while the kidneys recover (Table 49-3). The first step is to determine whether there is sufficient intravascular volume and cardiac output to ensure adequate perfusion of the kidneys. Diuretic therapy is often administered along with volume expanders to prevent fluid overload. Diuretic therapy usually includes loop diuretics (e.g., furosemide [Lasix]) or an osmotic diuretic (e.g., mannitol). If AKI is already established, forcing fluids and diuretics will not be effective and may, in fact, be harmful. Medical management without RRT may be all that is necessary until renal function improves. The general trend is to initiate early and frequent RRT to minimize symptoms and prevent complications.

TABLE 49-3

COLLABORATIVE CARE
Acute Kidney Injury

Diagnostic	Collaborative Therapy

• History and physical examination
• Identification of precipitating cause
• Serum creatinine and BUN levels
• Serum electrolytes
• Urinalysis
• Renal ultrasound
• Renal scan (as indicated)
• CT scan (as indicated and without contrast if possible)
• Retrograde pyelogram (as indicated)
	• Treatment of precipitating cause
	• Fluid restriction (allowance = 600 mL + previous 24-hr fluid loss)
	• Nutritional therapy
	  • Adequate protein intake (0.6–2 g/kg/day), depending on degree of catabolism
	  • Potassium restriction
	  • Phosphate restriction
	  • Sodium restriction
	• Measures to lower potassium (if elevated)*
	• Calcium supplements or phosphate-binding agents
	• Parenteral nutrition (if indicated)†
	• Enteral nutrition (if indicated)†
	• Initiation of renal replacement therapy (if necessary)

*See Table 49-4.

†Renal formulations of these two forms of nutrition are available.

BUN, blood urea nitrogen; *CT,* computed tomographic.

Fluid intake must be closely monitored during the oliguric phase. The general rule for calculating the permitted fluid intake is to add all losses for the previous 24 hours (e.g., urine, diarrhea, emesis, blood) plus 600 mL for insensible losses (e.g., respiration, diaphoresis). For example, if a patient excreted 300 mL of urine on Tuesday with no other losses, the fluid intake on Wednesday would be restricted to 900 mL.

Hyperkalemia is one of the most serious complications of AKI because it can cause life-threatening cardiac dysrhythmias. The various therapies used to treat elevated potassium levels are listed in Table 49-4. Both insulin and salbutamol temporarily shift potassium into the cells, but it eventually shifts back out. Calcium gluconate raises the threshold at which dysrhythmias will occur, serving to temporarily stabilize the myocardium. Only cation exchange resins, such as sodium polystyrene sulphonate (Kayexalate) or calcium resonium, and dialysis actually remove potassium from the body. Sodium polystyrene sulphonate should not be given, or mixed with sorbitol, to patients who do not have normal bowel function because of associated bowel necrosis (Batterink, Lin, Au-Yeung, et al., 2015).

TABLE 49-4
TREATMENT OF HYPERKALEMIA

Stabilize Myocardium
• If the ECG shows hyperkalemia-related abnormalities, *calcium gluconate IV* is given. Calcium raises the threshold potential, thus counteracting the toxic effect of potassium on the myocardium, which can induce life-threatening dysrhythmias.
Shift Potassium Into Cells
• *Regular IV insulin administration* causes potassium to move into cells. Glucose is given concurrently to prevent hypoglycemia. When effects of insulin diminish, potassium shifts back out of cells. • *Salbutamol* will also temporarily shift potassium back into cells. • *Sodium bicarbonate* can correct acidosis and causes shift of potassium into cells.
Enhance Potassium Removal
• *Cation exchange resins* such as *sodium polystyrene sulphonate (Kayexalate)* are administered by mouth or retention enema. When resin is in the bowel, potassium is exchanged for sodium. Therapy removes 1 mmol of potassium/g of drug. *Calcium resonium* is another such resin. • Loop diuretics such as *furosemide* can increase potassium excretion in the urine if the patient has any urine output. • *Dialysis,* particularly *hemodialysis,* can bring potassium levels to normal within 30 min to 2 hr.
Long-Term Treatment
• *Restrict intake of dietary potassium* to 40 mmol/day and avoid potassium-containing salt substitutes. • Limit or discontinue medications that can precipitate or exacerbate hyperkalemia such as ACE inhibitors, ARBs, and potassium-sparing diuretics.

ACE, angiotensin-converting enzyme; *ARBs,* angiotensin receptor blockers; *ECG,* electrocardiogram; *IV,* intravenous.

The most common indications for RRT in AKI include (1) volume overload resulting in compromised cardiac or pulmonary status, or both; (2) elevated potassium levels; (3) metabolic acidosis (serum bicarbonate level <15 mmol/L); (4) BUN level greater than 43 mmol/L; (5) significant change in mental status; and (6) pericarditis, pericardial effusion, or cardiac tamponade. Although laboratory values provide rough parameters, the best guide to treatment is good clinical assessment.

If RRT is required, many options are available, but there is no consensus regarding the best approach. Even though peritoneal dialysis (PD) is considered a viable option for RRT, it is rarely used. Intermittent hemodialysis (HD) (e.g., at intervals of 4 hr, either daily or every other day, or three to four times per week) and continuous renal replacement therapy (CRRT) have both been used effectively. CRRT is provided continuously over approximately 24 hours and has much slower blood flow rates than intermittent HD.

HD is the method of choice when rapid changes are required in a short time. It is technically more complicated because specialized staff and equipment are required. It also requires anticoagulation to prevent the patient's blood from clotting when it contacts the foreign material in the dialysis circuit. Rapid fluid shifts during HD may cause hypotension.

RRT, PD, HD, and CRRT are discussed later in this chapter.

Nutritional Therapy.

The challenge of nutritional management in AKI is to provide adequate calories to prevent catabolism despite the restrictions required to prevent electrolyte and fluid disorders and azotemia. Adequate energy should be provided from carbohydrate and fat sources to prevent ketosis from endogenous fat breakdown and gluconeogenesis from muscle-protein breakdown. The daily caloric intake for patients with AKI should be about 25 to 35 kcal/kg, based on estimated metabolic stress and protein energy requirements (Fiaccadori, Maggiore, Cabassi, et al., 2013). Protein dosage varies from 1.5 to 2.5 g/kg/day, depending on the stage of AKI and whether or not RRT is required (Fiaccadori et al., 2013).

Potassium and sodium are regulated in accordance with plasma levels. Sodium is restricted as needed to prevent edema, hypertension, and heart failure. Hyperphosphatemia, hypocalcemia, and hypermagnesemia are common and must be monitored and regulated (Fiaccadori et al., 2013). Dietary fat intake is increased so that the patient receives at least 30% to 40% of total calories from fat. Fat-emulsion intravenous (IV) infusions can also be given as a nutritional supplement and provide a good source of nonprotein calories (see Chapter 42). If a patient cannot maintain adequate oral intake, enteral nutrition is the preferred route for nutritional support (see Chapter 42). When the GI tract is not functional, parenteral nutrition (PN) is necessary for the provision of adequate nutrition. The patient treated with PN may need daily HD or CRRT to remove the excess fluid. Concentrated PN formulas are available to minimize fluid volume (Baron et al., 2015).

Nursing Management Acute Kidney Injury

Nursing Assessment

An assessment of the patient with AKI includes the specific areas presented in Table 49-5. It is important to monitor the vital signs and intake and output. The urine should be examined for colour, specific gravity, glucose, protein, blood, and sediment. The patient's general appearance should be assessed, including skin colour, peripheral edema, neck vein distension, and bruises.

TABLE 49-5

MANIFESTATIONS OF ACUTE KIDNEY INJURY

Body System	Clinical Manifestations
Urinary	Casts ↓ Osmolality Proteinuria ↓ Specific gravity Urinary output ↑ Urinary sodium
Cardiovascular	Dysrhythmias Heart failure Hypertension (after development of fluid overload) Hypotension (early) Pericardial effusion Pericarditis Volume overload
Respiratory	Kussmaul's respirations Pleural effusions Pulmonary edema
Gastro-intestinal	Anorexia Bleeding Constipation Diarrhea Nausea and vomiting Stomatitis
Hematological	Anemia (development within 48 hr) Defect in platelet functioning Leukocytosis ↑ Susceptibility to infection
Neurological	Asterixis Lethargy Memory impairment Seizures
Metabolic	↑ BUN ↑ Creatinine ↑ Phosphate ↑ Potassium ↓ Bicarbonate ↓ Calcium ↓ pH ↓ Sodium

BUN, blood urea nitrogen.

If the patient is receiving RRT, the access site should be observed for signs of inflammation. Evaluate the patient's mental status and level of consciousness. Examine the oral mucosa for dryness and inflammation. Auscultate the lung fields for crackles and wheezes or diminished breath sounds. Monitor the heart for the presence of a third heart sound (S_3 or gallop), murmurs, or a pericardial friction rub. Assess ECG readings for the presence of dysrhythmias. Review laboratory values and diagnostic test results. All of the previous data are essential for developing a collaborative plan of care.

Nursing Diagnoses

Nursing diagnoses and potential complications for the patient with AKI include, but are not limited to, the following:

- *Risk for infection* as evidenced by *alteration in skin integrity* (invasive lines)
- *Excess fluid volume* related to *excessive fluid intake* (kidney injury and fluid retention)
- *Fatigue* related to *malnutrition, physical deconditioning* (anemia, metabolic acidosis, uremic toxins)
- *Anxiety* related to *threat to current status, threat of death* (disease processes, therapeutic interventions, uncertainty of prognosis)
- Potential complication: dysrhythmias related to electrolyte imbalances

Planning

The overall goals for the patient with AKI are to (1) completely recover without any loss of kidney function, (2) maintain normal fluid and electrolyte balance, (3) have decreased anxiety, and (4) understand and adhere to the treatment plan and follow-up care.

Nursing Implementation

Health Promotion.

Prevention of AKI is essential because of the high mortality rate associated with it and is primarily directed toward identifying and monitoring high-risk populations, controlling nephrotoxic drugs and industrial chemicals, and preventing prolonged episodes of hypotension and hypovolemia. In the hospital, the factors that increase the risk of developing AKI are advanced age, massive trauma, major surgical procedures, extensive burns, cardiac failure, sepsis, obstetrical complications, and baseline renal insufficiency caused by hypertension or diabetes mellitus. Careful monitoring of intake and output and of fluid and electrolyte balance is essential. Extrarenal losses of fluid should be assessed and recorded from

vomiting, diarrhea, hemorrhage, and increased insensible losses. Prompt replacement of significant fluid losses will help prevent ischemic tubular damage associated with trauma, burns, and extensive surgery. Intake and output records and the patient's weight provide valuable indicators of fluid volume status. Aggressive diuretic therapy for the patient with fluid overload resulting from any cause can lead to decreased renal blood flow.

For patients with any level of renal insufficiency—and particularly patients with diabetes or older-adult patients with renal insufficiency—who are undergoing diagnostic studies requiring IV contrast media, special attention must be given to prevent a nephrotoxic injury secondary to the dye. Adequate hydration before and after the test is critical. The use of acetylcysteine may be helpful in providing added protection to the kidneys (Quintavalle, Donnarumma, Fiore, et al., 2013). Patients with urinary tract infections need prompt treatment and careful follow-up care. Chemotherapeutic drugs that cause hyperuricemia also can put a patient at risk for renal injury.

Individuals taking drugs that are potentially nephrotoxic (see Chapter 47, Table 47-3) must have renal function monitored. Nephrotoxic drugs should be used sparingly in high-risk patients. When these drugs must be used, they should be given in the smallest effective doses for the shortest possible periods. The patient should be cautioned about the abuse of over-the-counter analgesics (especially nonsteroidal anti-inflammatory drugs [NSAIDs]) because some of these may worsen renal function in the patient with borderline renal insufficiency by decreasing glomerular pressure or causing interstitial nephritis. ACE inhibitors can also decrease perfusion pressure and cause hyperkalemia, and their use may be contraindicated in renal insufficiency. Industrial and agricultural chemicals and products (e.g., organic solvents, insecticides, cleaning agents) must be monitored regularly to assess their safety for employees and the general population.

Acute Intervention.

The patient with AKI is most often critically ill and often has a high burden of comorbid illness (e.g., diabetes, cardiovascular disease) that also affects renal function. The nurse needs to focus on the patient holistically because there are many physical and emotional needs. Usually, the changes caused by AKI arise suddenly. Both the patient and the family need assistance in understanding that the functioning of the whole body can be disrupted by renal failure.

The nurse has an important role in managing fluid and electrolyte balance during the oliguric and diuretic phases. Observing and recording accurate intake and output are essential. It is important to measure weights daily, with the same scale and at the same time each day, to allow for the evaluation and detection of excessive gains or losses of body fluid (1 kg is equivalent to 1 000 mL of fluid). The nurse needs to be knowledgeable about the common signs and symptoms of hypervolemia (in the oliguric phase) or hypovolemia (in the diuretic phase), potassium and sodium disturbances, and other electrolyte imbalances that may occur in AKI (see Chapter 19).

Because infection is the leading cause of death in AKI, meticulous aseptic technique is critical. The patient must be protected from other individuals with infectious diseases. The nurse should be alert for local manifestations of infection (e.g., swelling, redness, pain) as well as systemic manifestations (e.g., malaise, leukocytosis) but should realize that an elevated temperature may not be present. Patients with renal failure have a blunted febrile response to an infection (e.g., pneumonia). If antibiotics are used to treat an infection, the type, frequency, and dosage must be carefully considered because the kidneys are the primary route of excretion for many antibiotics. Dosages and dosing intervals need to be considered in relation to the patient's level of kidney function if the drug is primarily eliminated by the kidneys. Nephrotoxic drugs (see Chapter 47, Table 47-3) should be avoided.

Skin care and measures to prevent pressure injuries should be performed because the patient usually develops edema as well as decreased muscle tone. Mouth care is important to prevent stomatitis, which develops when ammonia (produced by bacterial breakdown of urea) in saliva irritates the mucous membranes.

Informatics in Practice

Computer Monitoring of Antibiotic Safety

- Many patients receiving antibiotic therapy are at risk for kidney failure.
- The computer should be set to send an alert about elevated creatinine levels and, if possible, send a text message.

- With earlier notification of the health care provider, medications can be stopped or doses adjusted and the patient's kidney function preserved.

Ambulatory and Home Care.

Recovery from AKI is highly variable and depends on the underlying illness, the general condition and the age of the patient, the length of the oliguric phase, and the severity of nephron damage. Good nutrition, rest, and activity are necessary. Dietary restrictions should be regulated in accordance with kidney function. Follow-up care and regular evaluation of renal function are necessary. Teach the patient the signs and symptoms of recurrent kidney disease. Emphasize measures to prevent the recurrence of AKI.

The long-term convalescence of 3 to 12 months may cause psychosocial and financial hardships for the family. Make referrals for counselling as appropriate. If the kidneys do not recover, the patient will need to transition to life on chronic dialysis or possible future transplantation.

Evaluation

The following are expected outcomes for the patient with AKI:

- Regain and maintain normal fluid and electrolyte balance.
- Comply with treatment regimen.
- Experience no infectious complications.
- Have complete recovery.

Age-Related Considerations

Acute Kidney Injury

Older adults are more susceptible than younger adults to AKI because the number of functioning nephrons decreases with age. Impaired function of other organ systems (e.g., cardiovascular disease, impaired pancreas function) can increase the risk of developing AKI. The aging kidney is less able to compensate for changes in fluid volume, solute load, and cardiac output. Common causes of AKI in the older adult include dehydration, hypotension, diuretic therapy, aminoglycoside therapy, obstructive disorders (e.g., prostatic hyperplasia), surgery, infection, and radiocontrast agents.

Chronic Kidney Disease

Chronic kidney disease (CKD) involves the progressive, irreversible loss of kidney function. The Kidney Disease Outcomes Quality Initiative (KDOQI) defines CKD as either kidney damage or GFR <60 mL/min/1.73 m^2 for 3 months or longer. CKD is classified as one of five stages, depending on the level of severity based on GFR (Table 49-6). CKD involves progressive, irreversible destruction of the nephrons in both kidneys. Not all people with CKD will progress to stage 5, in which RRT would be necessary; however, all those affected will require ongoing monitoring.

TABLE 49-6
STAGES* AND DESCRIPTIONS OF CHRONIC KIDNEY DISEASE†

	Description	GFR (mL/min/1.73 m^2)	Action‡
Stage 1	Kidney damage with normal or ↑ GFR	≥90	Diagnosis and treatment of comorbid conditions CVD risk reduction
Stage 2	Kidney damage with mild ↓ GFR	60–89	Estimation of progression
Stage 3	Moderate ↓ GFR	30–59	Evaluation and treatment of complications
Stage 4	Severe ↓ GFR	15–29	Preparation for renal replacement therapy
Stage 5	Kidney failure	<15 (or dialysis)	Renal replacement therapy (if uremia present and patient desires treatment)

*Stages 1 to 5 identify patients who have chronic kidney disease.

†Chronic kidney disease is defined as either kidney damage or GFR <60 mL/min/1.73 m^2 for 3 mo. Kidney damage is defined as pathological abnormalities or markers of damage, including abnormalities in blood or urine tests or imaging studies.

‡Includes actions from preceding stages.

CVD, cardiovascular disease; *GFR*, glomerular filtration rate.

Source: Reprinted from National Kidney Foundation. KDOQI Clinical Practice Guidelines for Chronic Kidney Disease: Evaluation, Classification and Stratification. *Am J Kidney Dis* 39:S1-S000, 2002 (suppl 1), with permission from Elsevier.

Identifying the stage of CKD allows for early intervention to reduce cardiovascular risk, delay progression, and prevent the need for RRT (Grams, Chow, Segev, et al., 2013). RRTs include PD, HD, and renal transplantation. Stage 5 CKD, often referred to as **end-stage renal disease (ESRD)**, is advanced kidney disease with GFR less than 15 mL/min/1.73 m^2, when most patients with CKD require some form of RRT. At this point, RRT (dialysis or transplantation) is usually required. In 2012, there were 5 431 new patients on dialysis in Canada. Of these, over half (53%) were older than 65 years (CIHI, 2014). Although there are many causes of CKD, the leading causes of CKD in Canada are diabetes mellitus (38%) and renal vascular disease (15%) (CIHI, 2014).

The kidneys have remarkable functional reserve. Up to 80% of the GFR (reflected in creatinine clearance measurements) may be lost with few overt changes in the functioning of the body. A person is born with about 2 million nephrons and can survive without RRT until almost 90% of the nephrons are lost. In the majority of cases, the individual passes through the early stages of CKD without recognizing the disease state because the

remaining nephrons hypertrophy to compensate. The prognosis and the course of CKD are highly variable, depending on the etiology, the individual's condition and age, and the adequacy of medical follow-up. Some individuals live normal, active lives with compensated renal failure, whereas others may rapidly progress to ESRD.

Since 1973, many deaths have been prevented through the use of RRTs. Dialysis modalities remain the most common RRT for people with stage 5 CKD because of (1) a lack of donated organs, (2) medical conditions that preclude transplantation, or (3) personal reasons, in which an individual may decline transplantation as a treatment option. With the advances made in medical science, an increasing number of individuals are receiving RRTs, including older adults and those with complex medical problems. All people with advanced CKD, regardless of age, should be offered RRT unless it is medically contraindicated.

Determinants of Health

Chronic Kidney Disease

Culture; Biology and Genetic Endowment

- Chronic kidney disease (CKD) has a disproportionate impact on certain ethnic groups in Canada, related to the higher incidence of diabetes and hypertension within these populations. These groups include Canadians who are of Indigenous, Asian, South Asian, Pacific Island, African/Caribbean, and Latin American origin.*
- The rate of CKD is six times higher among Indigenous people with diabetes than among other ethnic groups with diabetes.
- The specific causes of cultural and ethnic differences in occurrence of CKD are not clear. However, it appears that genetic factors contribute to differences in diabetic nephropathy among ethnic groups.

Clinical Manifestations

As renal function progressively deteriorates, excretory, regulatory, and endocrine function are lost, and these effects are manifested in every body system, no matter what the underlying cause of CKD. These excretory, regulatory, and endocrine functional impairments are manifested in retained substances, including urea, creatinine, phenols, hormones, electrolytes, water, and many other substances. **Uremia** is a constellation of signs and symptoms resulting from the buildup of waste products and excess fluid associated with kidney failure. These signs and symptoms may include, but are not limited to, elevated serum creatinine and BUN, abnormal electrolytes, acidosis, anemia, fluid volume excess, nausea, loss of appetite, fatigue, decreased cognition, pruritus, and neuropathy (Figure 49-3). It is important to recognize that the manifestations of uremia vary among patients, according to the cause of the kidney disease, comorbid conditions, age, and degree of adherence to the prescribed medical regimen. Many patients are very tolerant of the changes that occur because the changes develop gradually. Uremia often occurs when the GFR is 10 mL/min/1.73 m^2 or lower.

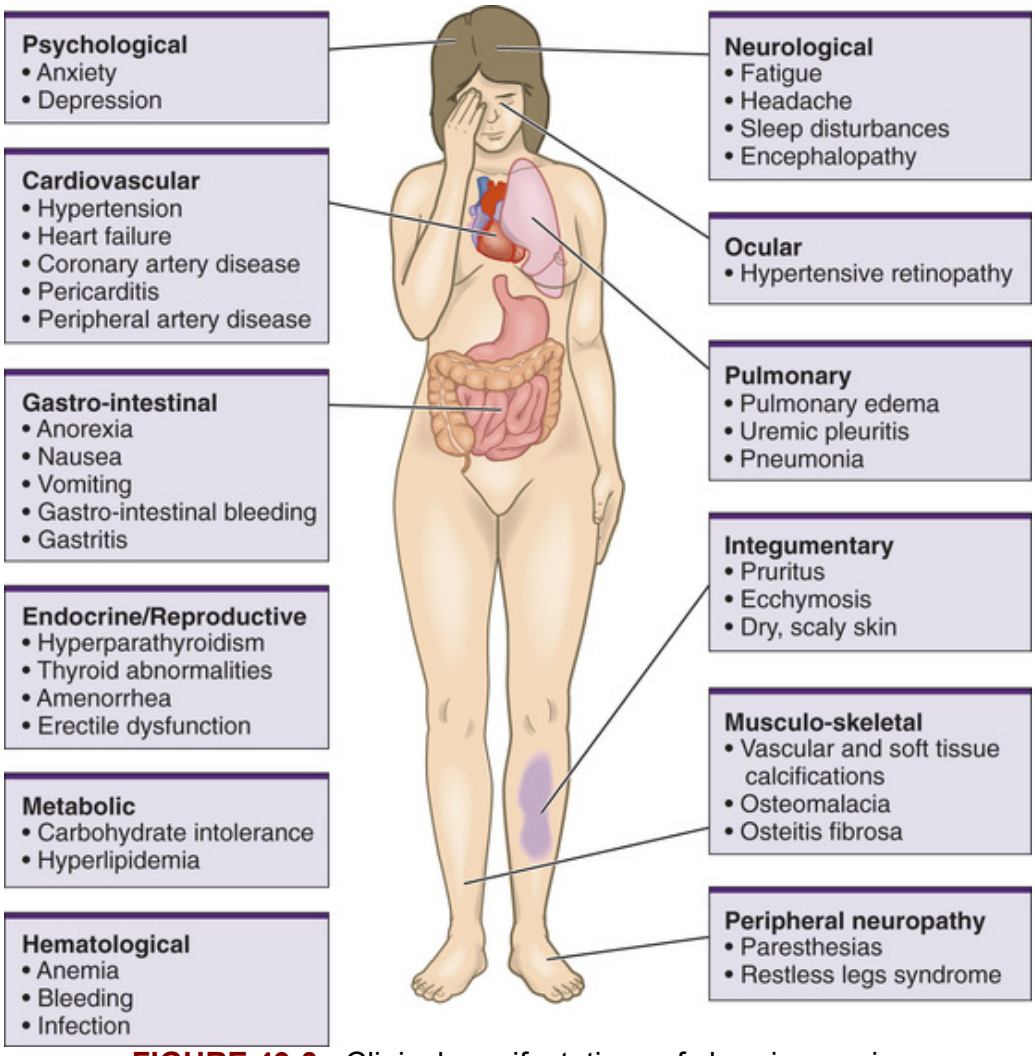

FIGURE 49-3 Clinical manifestations of chronic uremia.

Urinary System.

In the early stage of CKD, polyuria results from the inability of the kidneys to concentrate urine. This happens most often at night, and the patient must arise several times to urinate (nocturia). Because of the decrease in renal concentrating ability, the specific gravity of urine gradually becomes fixed at around 1.010 (the osmolar concentration of plasma). As CKD worsens, oliguria develops, and eventually anuria (urine output 40 mL/24 hr) develops. If the patient is still producing urine, proteinuria, casts, pyuria, and hematuria could be present, depending on the cause of the kidney disease.

Metabolic Disturbances

Waste Product Accumulation.

As GFR declines, the serum creatinine and BUN levels increase. Accumulation of nitrogenous waste products in advanced stages of CKD is often manifested by symptoms of nausea, vomiting, lethargy, fatigue, impaired thought processes, and headaches as a result of the multisystemic involvement of CKD.

Serum creatinine continues to be the most common biochemical parameter to estimate the GFR, but it alone is not an accurate measure of GFR (Baron et al., 2015) (Serum creatinine tends to be an ineffective marker of early as well as advanced kidney disease. The eGFR is a better measure of overall kidney function than creatinine or BUN. The eGFR may be calculated by the laboratory using mathematical formulas. If this method is not available, GFR calculators and tables can be used (see link to the MDRD [modification of diet in renal disease] calculator in Table 49-8). The serum creatinine level in an older-adult patient with ESRD will be lower than it is in a younger person with the same degree of renal dysfunction. Decreased muscle mass and decreased muscle activity from aging account for this finding because creatinine is an end product of muscle metabolism.

Altered Carbohydrate Metabolism.

Defective carbohydrate metabolism is caused by impaired glucose use resulting from cellular insensitivity to the normal action of insulin. The exact nature of this insulin resistance is unclear, but it may be related to circulating insulin antagonists, alterations in hormone receptors, or abnormalities of transport mechanisms. Moderate hyperglycemia, hyperinsulinemia, and abnormal glucose tolerance tests may be seen. Insulin and glucose metabolism may improve (but not to normal values) after the initiation of dialysis.

Patients with diabetes who become uremic may require less insulin than before the onset of CKD. This is because insulin, which is dependent on the kidneys for excretion, remains in circulation longer. The insulin regimen must be individualized and glucose levels monitored carefully.

Elevated Triglycerides.

Hyperinsulinemia stimulates hepatic production of triglycerides. Almost all patients with uremia develop dyslipidemia, with elevated very-low-density lipoproteins, normal or decreased low-density lipoproteins, and lowered high-density lipoproteins. The altered lipid metabolism is related

to decreased levels of the enzyme lipoprotein lipase, which is important in the breakdown of lipoproteins.

Electrolyte and Acid–Base Imbalances

Potassium.

Hyperkalemia is a serious electrolyte disorder associated with kidney disease. Fatal dysrhythmias can occur when the serum potassium level reaches 7 to 8 mmol/L. Hyperkalemia results from the decreased excretion by the kidneys, the breakdown of cellular protein, bleeding, and metabolic acidosis. The most common causes of hyperkalemia in CKD are associated with diet, dietary supplements, drugs, and IV infusions.

Sodium.

Sodium may be normal or low in renal failure. Because of impaired sodium excretion, sodium is retained along with water. If large quantities of body water are retained, dilutional hyponatremia occurs. Sodium retention can contribute to edema, hypertension, and heart failure. Sodium intake must be individually determined but is generally restricted to 2 g/24 hr.

Calcium and Phosphate.

Calcium and phosphate alterations are in the Musculo-Skeletal System section, later in this chapter.

Magnesium.

Magnesium is excreted primarily by the kidneys. It is sometimes used as a phosphate-binding agent in patients with CKD. Hypermagnesemia is generally not a problem unless the patient is ingesting magnesium (e.g., milk of magnesia, magnesium citrate, antacids containing magnesium). Clinical manifestations of hypermagnesemia can include absence of reflexes, decreased mental status, cardiac dysrhythmias, hypotension, and respiratory failure.

Metabolic Acidosis.

Metabolic acidosis results from the impaired ability of the kidneys to excrete the acid load (primarily ammonia) and from defective reabsorption and regeneration of bicarbonate. The average adult produces 80 to 90 mmol/day of acid. In renal failure, plasma bicarbonate, which is an indirect measure of acidosis, usually falls to a new steady state at around

16 to 20 mmol/L. It generally does not progress below this level because hydrogen ion production is usually balanced by buffering from demineralization of the bone (the phosphate buffering system). Although Kussmaul's respiration is uncommon in CKD, this breathing pattern reduces the severity of acidosis by increasing carbon dioxide excretion.

Hematological System

Anemia.

Anemia is very common in CKD. A normocytic, normochromic anemia is associated with CKD and is a result of decreased production of the hormone erythropoietin by the kidneys, resulting in decreased erythropoiesis by the bone marrow (Wittwer, 2013). Erythropoietin stimulates precursor cells in the bone marrow to produce RBCs. Other factors contributing to anemia are nutritional deficiencies, decreased RBC lifespan, increased hemolysis of RBCs, frequent blood samplings, and bleeding from the GI tract. For patients receiving maintenance HD, blood loss in the dialyzer may also contribute to the anemic state. Elevated levels of PTH (produced to compensate for low serum calcium levels) can inhibit erythropoiesis, shorten survival of RBCs, and cause bone marrow fibrosis, which can result in decreased numbers of hematopoietic cells.

Sufficient iron stores are needed for erythropoiesis. Many patients with renal failure are iron deficient and require iron replacement. Folic acid, which is water soluble and essential for RBC maturation, is removed with dialysis and needs to be replaced in the diet with supplementation (1 mg/day).

Bleeding Tendencies.

The most common cause of bleeding in uremia is a qualitative defect in platelet function. This dysfunction is caused by impaired platelet aggregation and impaired release of platelet factor III. In addition, alterations in the coagulation system with increased concentrations of both factor VIII and fibrinogen are found in the serum of these patients. The altered platelet function, hemorrhagic tendencies, and GI bleeding can usually be corrected with regular HD or PD.

Infection.

Patients with advanced CKD have an increased susceptibility to infection. Infectious complications are caused by changes in leukocyte function and altered immune response and function. Both cellular and humoral

immune responses are suppressed. Other factors contributing to the increased risk for infection include malnutrition, hyperglycemia, and external trauma (e.g., catheters, needle insertions into vascular access sites).

Cardiovascular System.

Morbidity and mortality from cardiovascular disease are high in patients with CKD, and the presence of CKD worsens the outcomes of cardiovascular disease (Sarafidis & Bakris, 2015). Many patients will die from cardiovascular disease before CKD stage 5 requiring dialysis develops (Sarafidis & Bakris, 2015). Management of cardiovascular risk factors in patients with CKD should be a focus of care (Sarafidis & Bakris, 2015).

The most common cardiovascular abnormality is hypertension, which usually exists before ESRD sets in and is worsened by sodium retention and increased extracellular fluid volume. In some individuals, increased renin production contributes to the problem (see Chapter 47, Figure 47-6). Hypertension accelerates atherosclerotic vascular disease, produces intrarenal arterial spasm, and eventually leads to left ventricular hypertrophy and heart failure (Sarafidis & Bakris, 2015). Hypertension also causes retinopathy, encephalopathy, and nephropathy.

The vascular changes from longstanding hypertension and the accelerated atherosclerosis from elevated triglyceride levels are responsible for many cardiovascular complications (e.g., myocardial infarction, stroke). Diabetes mellitus is a major risk factor for the development of vascular problems.

Heart failure from left ventricular hypertrophy can lead to pulmonary edema. Peripheral edema is often present. Cardiac dysrhythmias may result from hyperkalemia, hypocalcemia, and decreased coronary artery perfusion.

Uremic pericarditis can develop and occasionally progresses to pericardial effusion and cardiac tamponade. Pericarditis is manifested by a friction rub, chest pain, and low-grade fever.

Respiratory System.

Respiratory changes include dyspnea from fluid overload, pulmonary edema, uremic pleuritis (pleurisy), pleural effusion, a predisposition to respiratory infections, and in very advanced CKD, Kussmaul's respiration. “Uremic lung,” or uremic pneumonitis, is typically found in CKD and

shows up as interstitial edema on chest radiograph. This condition usually responds to vigorous fluid removal during dialysis treatments.

Gastro-Intestinal System.

Every part of the GI system is affected with CKD, as a result of inflammation of the mucosa caused by excessive urea. Stomatitis with exudates and ulcerations, a metallic taste in the mouth, and *uremic fetor* (a urinous odour of the breath) are commonly found. As CKD progresses, anorexia, nausea, and vomiting caused by irritation of the GI tract by waste products may be present. Patients are also at risk for weight loss and malnutrition. Diabetic gastroparesis (delayed gastric emptying) can compound these problems for patients with diabetes. GI bleeding is also a risk because of irritation of the mucosa by waste products, coupled with the platelet defect. Constipation may be caused by the ingestion of iron salts or calcium-containing phosphate binders, or both. Constipation can be made worse by the limited fluid intake and inactivity.

Neurological System.

Neurological changes are expected as renal failure progresses. They are attributed to increased nitrogenous waste products, electrolyte imbalances, metabolic acidosis, and axonal atrophy and demyelination of nerve fibres (Walton, 2015). High levels of uremic toxins have been implicated in axonal damage.

The central nervous system (CNS) becomes depressed, resulting in lethargy, apathy, decreased ability to concentrate, fatigue, irritability, and altered mental ability. Although uncommon, seizures and coma may result from a rapidly increasing BUN and hypertensive encephalopathy.

Peripheral neuropathy is initially manifested by a slowing of nerve conduction to the extremities. The patient complains of restless legs syndrome and may describe it as “bugs crawling inside the leg.” Paresthesias occur most often in the feet and legs and may be described by the patient as a burning sensation. Eventually, motor involvement may lead to bilateral foot drop, muscular weakness and atrophy, and loss of deep tendon reflexes. Muscle twitching, jerking, asterixis (hand-flapping tremor), and nocturnal leg cramps also occur. In patients with diabetes, uremic neuropathy is compounded by the neuropathy associated with diabetes mellitus.

The treatment for neurological problems is dialysis or transplantation. Dialysis should improve the general CNS symptoms and may slow or halt

the progression of neuropathies. However, motor neuropathy may not be reversible.

Musculo-Skeletal System.

Chronic kidney disease–mineral and bone disorder (CKD–MBD) is a term used to describe the systemic components of this clinical syndrome that include characteristic bone abnormalities, changes in mineral balance (calcium, phosphorus, PTH, and vitamin D), and vascular and other soft tissue calcification (Felsenfeld, Levine, & Rodriguez, 2015). These manifestations develop owing to progressive deterioration in kidney function (Figure 49-4). As kidney function declines, phosphorus elimination decreases and less vitamin D is converted to its active form, resulting in decreased serum levels (Felsenfeld et al., 2015). To absorb calcium from the GI tract, activated vitamin D is necessary. Thus, decreased active vitamin D levels result in less calcium absorption from the intestine and, therefore, decreased serum calcium levels (Alshayeb, Josephson, & Sprague, 2013). When hypocalcemia occurs, the parathyroid gland secretes PTH, which stimulates bone demineralization with the release of calcium from the bones. Phosphate is released as well, leading to elevated serum phosphate levels. Hyperphosphatemia has been shown to directly decrease serum calcium levels and further reduce the ability of the kidneys to activate vitamin D (Felsenfeld et al., 2015).

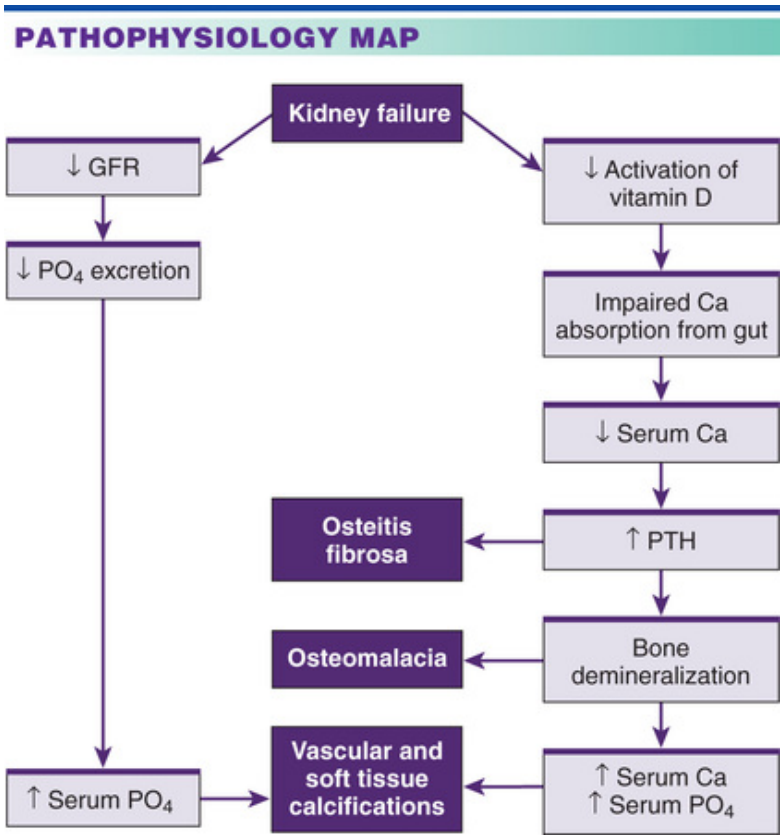

FIGURE 49-4 Mechanisms of chronic kidney disease–mineral and bone disorder (CKD–MBD). *Ca*, calcium; *GFR*, glomerular filtration rate; *PO_4*, phosphate; *PTH*, parathyroid hormone.

Hyperphosphatemia, decreased vitamin D level, and hypocalcemia lead to overstimulation of the parathyroid glands, resulting in excess secretion of PTH (Felsenfeld et al., 2015). PTH that remains elevated for long periods of time leads to hypertrophy of the parathyroid gland and bone disease (Felsenfeld et al., 2015).

CKD–MBD is a common complication of CKD and results in both skeletal (renal osteodystrophy) and extraskeletal complications (vascular and soft tissue complications). **Renal osteodystrophy** includes a number of skeletal disorders: (1) *osteitis fibrosa,* in which there is an increased number of osteoclasts and osteoblasts, high bone turnover, and fibrosis of the marrow; (2) *osteomalacia,* with low bone turnover and abnormal mineralized bone; (3) *adynamic bone disorder,* in which there is low bone turnover with normal mineralization; and (4) *mixed osteodystrophy,* with high bone turnover and abnormal mineralization (Miller, 2014).

Extraskeletal complications include vascular and soft tissue calcification (Felsenfeld et al., 2015). The excess phosphate binds with calcium, leading to the formation of insoluble calcifications that are deposited in the

vascular walls and soft tissue. Common sites are blood vessels, GI tract, lungs, muscles, skin, subcutaneous tissues, myocardium, and eyes (Zyga & Kolovos, 2013). Cardiovascular calcification is an important contributor to cardiovascular disease in people with CKD and CKD–MBD (Hain & Haras, 2015), and vascular calcification is the likely cause of high cardiovascular morbidity and mortality in patients with CKD (Zyga & Kolovos, 2013).

Integumentary System.

Pruritus is highly prevalent in patients with CKD. It most commonly results from a combination of the dry skin, calcium–phosphate deposition in the skin, and sensory neuropathy. The itching may be so intense that it can lead to bleeding or infection secondary to scratching. Uremic frost is a rare condition in which urea crystallizes on the skin and is usually seen only when BUN levels are extremely high.

Reproductive System.

Both men and women can experience infertility and a decreased libido in CKD. Women usually have decreased levels of estrogen, progesterone, and luteinizing hormone, causing anovulation and menstrual changes (usually amenorrhea). Menses and ovulation may return after dialysis is started. Men experience loss of testicular consistency, decreased testosterone levels, and low sperm counts. Sexual dysfunction in both sexes may also be caused by anemia, which causes fatigue and decreased libido. In addition, peripheral neuropathy can cause impotence in men and anorgasmy in women. Additional factors that may cause changes in sexual function are psychological problems (e.g., anxiety, depression), physical stress, and adverse effects of drugs.

Sexual function may improve with maintenance dialysis and may become normal with successful transplantation. Pregnant patients undergoing dialysis have been able to carry a fetus to term, but there is significant risk to mother and infant. Pregnancy in patients undergoing transplantation is more common, but here, too, there is a risk to both mother and fetus.

Psychological Changes.

Personality and behavioural changes, emotional lability, withdrawal, and depression are commonly observed. Fatigue and lethargy contribute to the feeling of illness. The changes in body image caused by edema, integumentary disturbances, and access devices (e.g., fistulas, catheters)

lead to further anxiety and depression. Decreased ability to concentrate and slowed mental activity can give the appearance of dullness and disinterest in the environment. There are also significant changes in lifestyle, occupation, family responsibilities, and financial status that must be dealt with by the patient. Long-term survival depends on drugs, dietary restrictions, dialysis, and possibly transplantation. The patient will also grieve the loss of renal function. This can be a prolonged process for some individuals.

Diagnostic Studies

Adverse outcomes of CKD can often be prevented or delayed through early detection and treatment. Early stages of CKD can be detected through routine laboratory measurements (Table 49-7). Proteinuria is one of the most important risk factors for the progression of CKD leading to dialysis and is the earliest marker of kidney damage (Sarafidis & Bakris, 2015). Patients at high risk for kidney disease, such as those with diabetes, hypertension, vascular disease, autoimmune disease, GFR less than 60 mL/min/1.73 m^2, and edema should be screened for proteinuria (Sarafidis & Bakris, 2015). The preferred method for screening for proteinuria is the measurement of the urine protein-to-creatinine ratio or the albumin-to-creatinine ratio (Sarafidis & Bakris, 2015). A dipstick evaluation for protein in the urine may be done but is not as accurate. Patients with diabetes need to have examination of their urine for microalbuminuria if none is detected on routine urinalysis. The presence of proteinuria in two or three consecutive urine samples is needed to determine persistent proteinuria (Sarafidis & Bakris, 2015). A person with persistent proteinuria (1+ protein on standard dipstick testing, two or more times, over a 3-month period) should have further assessment of risk factors and a diagnostic workup with blood and urine tests. A urine test for albumin-to-creatinine ratio provides an accurate estimate of the protein and albumin excretion rate. A ratio greater than 300 mg albumin/1 g creatinine signals CKD (Bakker, 2013).

TABLE 49-7

COLLABORATIVE CARE
Management of Chronic Kidney Disease

Diagnostic
• BUN, serum creatinine, and eGFR • CT scan • History and physical examination • Identification of reversible renal disease • Protein-to-creatinine ratio in first, morning-voided specimen • Renal biopsy • Renal scan • Renal ultrasound • Serum calcium, phosphorous, albumin, and parathyroid hormone levels • Serum electrolytes • Serum hemoglobin level and iron indices • Urinalysis and urine culture
Collaborative Therapy
• Adjustment of drug dosages according to degree of renal function • Antihypertensive therapy • Calcium supplementation, phosphate binders, or both • Correction of extracellular fluid volume overload or deficit • Erythropoietin therapy • Measures to lower potassium* • Nutritional therapy† • Renal replacement therapy (dialysis, kidney transplantation)

*See Table 49-4.

†See Tables 49-9 and 49-10.

BUN, blood urea nitrogen; *CT*, computed tomographic (scan); *eGFR*, estimated glomerular filtration rate.

A urinalysis can detect RBCs, WBCs, protein, casts, and glucose. Imaging of the kidneys to exclude obstruction and note the size of the kidneys is usually done by ultrasound. Other diagnostic studies (see Table 49-7) help establish the diagnosis and cause of CKD.

Serum creatinine alone poorly reflects kidney function, and a rise in blood creatinine is observed only after significant loss of functioning nephrons (National Institute of Diabetes and Digestive and Kidney Diseases, 2013). GFR is the preferred measure used to determine kidney function. Several GFR calculators are available. The two equations used most frequently to estimate GFR are the Cockcroft–Gault formula and the Modification of Diet in Renal Disease (MDRD) Study equation (Table 49-8). The National Kidney Foundation KDOQI guidelines recommend the MDRD Study equation to estimate GFR (McAlister, Exekowitz, Grisolia, et al., 2015).

TABLE 49-8
SERUM CREATININE IS A POOR INDICATOR OF KIDNEY FUNCTION

Calculation of GFR is considered the best index to estimate kidney function, as indicated by the following example.		
	Type of Patient	
Estimation of GFR	**76-Year-Old White Woman (Weight 56 kg)**	**28-Year-Old White Man (Weight 74 kg)**
SCr	155 mmol/L	155 mmol/L
GFR—estimated by the Cockcroft-Gault formula*	28.4 mL/min	65.7 mL/min
GFR—estimated by MDRD equation†	30 mL/min/1.73 m^2	49 mL/min/1.73 m^2

*Cockcroft-Gault GFR = [(140 − age) × (weight in kg) × 1.2]/(SCr (mmol/L). For women, multiply the result by 0.85 (Flamant et al., 2012).

†GFR as estimated by MDRD and Cockcroft-Gault equation calculator can be accessed at http://www.mdcalc.com/mdrd-gfr-equation/.

GFR, glomerular filtration rate; *MDRD*, modification of diet in renal disease; *SCr*, serum creatinine.

Collaborative Management: Chronic Kidney Disease

The focus in CKD is on prevention and early identification to deter the progression of kidney disease. When a patient is diagnosed as having CKD, every effort is made to detect and treat potentially reversible causes (e.g., cardiac failure, dehydration, infections, nephrotoxins, urinary tract obstruction, renal artery stenosis). A renal biopsy may be necessary to provide a definitive diagnosis. The goals of CKD care are to preserve existing renal function, delay progression of renal disease, treat clinical manifestations, prevent complications, educate patients and families regarding kidney disease and options for care, and prepare patients for RRT (Chenoweth, Hines, Hall, et al., 2015). The care of the patient with CKD must be tailored to the stage of CKD. Early CKD care can lead to effective planning and appropriate timing of dialysis start and creation of the dialysis access. In the early stages of CKD, pharmacological and nutritional therapy and supportive care are essential components of the CKD care plan.

Drug Therapy

Hyperkalemia.

There are multiple strategies for managing hyperkalemia (see Table 49-4). Every effort is made to control it with the restriction of high-potassium

foods and drugs. Acute hyperkalemia may require urgent intervention. The level of potassium that should be treated has not been firmly established; however, based on a systematic review (Kovesdy, 2015), it is suggested that nonpharmacological steps be instituted for management of potassium levels above 5.5 mmol/L and pharmacological intervention at potassium levels of 6.0 mmol/L or greater. An ECG should be considered to assess for cardiac dysrhythmias that may require treatment. Common ECG changes associated with hyperkalemia include peaked T waves and widened QRS complexes. Patients with ECG changes consistent with severe hyperkalemia should be treated with IV calcium-based salts such as calcium gluconate or calcium chloride (Chih-Hung, Chien-Hua, We-Tien, et al., 2016). Acute hyperkalemia may require treatment with IV glucose and insulin and/or β_2-adrenergic agonists such as salbutamol to shift potassium into the cells. Rebound after potassium-shifting therapy occurs within 2 hours if steps have not been taken to reduce potassium either through urine excretion or HD (Chih-Hung et al., 2016). A cation exchange resin, such as sodium polystyrene sulphonate (Kayexalate), is commonly used to lower potassium levels and can be administered on an outpatient basis. Cation exchange resins take hours to days to reduce potassium.

Because sodium polystyrene sulphonate exchanges sodium ions for potassium ions, the patient should be observed for sodium and water retention. If life-threatening dysrhythmias are present, dialysis may be required.

Hypertension.

The progression of CKD can be delayed by controlling hypertension (Ritchie, Rainone, Green, et al., 2013). Treatment of hypertension consists of lifestyle modifications (e.g., exercise, weight reduction, avoidance of alcohol, stress management), dietary sodium and fluid restriction, and the administration of antihypertensive drugs (Judd & Calhoun, 2015). The Canadian Hypertension Education Program (CHEP, 2015) recommends a target blood pressure for patients with nondiabetic CKD of less than 140/90 mm Hg; for those with diabetes mellitus, it should be less than 130/80 mm Hg.

For patients with nondiabetic CKD and proteinuria, ACE inhibitors (e.g., ramipril [Altace], enalapril [Vasotec]) or ARBs (e.g., irbesartan [Avapro], losartan [Cozaar]) are recommended as initial therapy (CHEP, 2015). ACE inhibitors and ARBs decrease proteinuria and delay the progression of renal failure. For additional therapy, the use of thiazide

diuretics (e.g., hydrochlorothiazide) or loop diuretics (e.g., furosemide [Lasix]) for volume overload is suggested (CHEP, 2015).

For patients with renovascular disease, CHEP suggests cautious use of ACE inhibitors and ARBs as patients with bilateral disease or a solitary kidney are at increased risk for AKI (CHEP, 2015).

For patients with diabetes, CHEP (2015) suggests use of ACE inhibitors or ARBs as initial therapy. Other antihypertensive drugs commonly used include dihydropyridine calcium channel blockers (nifedipine [Adalat], amlodipine [Norvasc] and thiazide or thiazide-like diuretics).

ACE inhibitors and ARBs must be used cautiously in CKD because they can further decrease the GFR and increase serum potassium levels. Most people require a number of antihypertensives to achieve target blood pressure, and regimens must be individualized based on other existing comorbidities.

Blood pressure (BP) should periodically be measured in supine, sitting, and standing positions to effectively monitor the effect of antihypertensive drugs. The patient should be taught how to monitor the BP at home and taught what BP readings require immediate intervention. BP control is essential to slow atherosclerotic changes that could further impair renal function.

Chronic Kidney Disease–Mineral and Bone Disorder.

Interventions for CKD–MBD include limiting dietary phosphorus, administering phosphate binders, and supplementing vitamin D. Phosphate intake is generally restricted to less than 1 000 mg/day, but usually dietary control is not adequate. Calcium-based phosphate binders such as calcium carbonate and calcium acetate are used to bind the phosphate, which is then excreted in the stool. Giving a calcium-based binder when the phosphate levels are still high (1.98 mmol/L) may cause the formation of calcium–phosphate deposits. Sevelamer (Renagel) is a phosphate binder that contains neither calcium nor aluminum.

Because dementia (aluminum toxicity) and bone disease (osteomalacia) are associated with excessive absorption of aluminum, aluminum preparations should be avoided if possible and used with caution in patients with renal failure. Magnesium-containing antacids (Maalox, Mylanta) are used in moderation because magnesium is dependent on the kidneys for excretion. Phosphate binders should be administered with each meal to be effective because most phosphate is absorbed within 1 hour after eating. Hypercalcemia may occur with calcium supplementation and is associated with increased cardiac calcifications

and mortality in patients with ESRD. Calcium binders are generally limited to a maximum of 1 500 mg/day with the total daily calcium intake including diet not exceeding 2 g. Constipation is a frequent adverse effect of phosphate binders and may necessitate the use of stool softeners.

Hypocalcemia is often a problem because of the inability of the GI tract to absorb calcium in the absence of vitamin D. If hypocalcemia persists even when serum phosphate levels are controlled and supplemental calcium is given, the active form of vitamin D should be given. It is commercially available in oral preparations such as calcitriol (Rocaltrol). It is important to lower the phosphate level before administering calcium or vitamin D because these drugs may contribute to soft tissue calcification if both calcium and phosphate levels are elevated. Calcimimetics such as cinacalcet (Sensipar) may be prescribed to lower PTH and may also cause hypocalcemia (Felsenfeld et al., 2015).

If renal osteodystrophy remains severe despite medical management, a subtotal parathyroidectomy may be performed to decrease the synthesis and secretion of PTH. In some situations, a total parathyroidectomy is performed, and some parathyroid tissue is transplanted into the forearm. The transplanted cells produce PTH as needed. If production of PTH becomes excessive, some of the cells can be removed from the forearm under local anaesthesia.

The most common methods for evaluating the status of the bone disease are skeletal radiographs, bone scans, bone biopsy, and bone densitometry. PTH and alkaline phosphatase levels should also be measured. Alkaline phosphatase is elevated when there is demineralization of the bone but can also be increased by liver disease.

Anemia.

The most important cause of anemia in CKD is a decreased production of erythropoietin. With the use of recombinant DNA technology, erythropoiesis-stimulating agents (ESAs) are available for the treatment of anemia. ESAs can be administered intravenously or subcutaneously. They have been very effective in treating anemia. A significant increase in hemoglobin is usually not seen for 2 to 3 weeks. The patient who is receiving erythropoietin has improved exercise tolerance and an enhanced quality of life.

Significant morbidity and mortality have been associated with trying to normalize hemoglobin levels (Sarafidis & Bakris, 2015). The Canadian Society of Nephrology (CSN) *Guidelines for the Management of Chronic Kidney Disease* recommend a target hemoglobin of 110 g/L, with an

acceptable range between 100 and 120 g/L (Sarafidis & Bakris, 2015; Hung & Tarng, 2014). A common adverse effect of ESAs is the development or acceleration of hypertension. The underlying mechanism is related to the hemodynamic changes (e.g., increased whole blood viscosity) that occur as the anemia is corrected. Patients with significantly elevated BP should not receive ESAs.

Another adverse effect of ESA therapy is the development of functional iron deficiency resulting from the increased demand for iron to support erythropoiesis. The CSN *Guidelines for the Management of Chronic Kidney Disease* recommend a target ferritin level greater than 100 ng/mL and a transferring saturation level greater than 20% (Sarafidis & Bakris, 2015; Hung & Tarng, 2014). Most patients receive iron supplements. The GI adverse effects of oral iron, including gastric irritation and constipation, may lead to nonadherence to therapy. Orally administered iron should not be taken at the same time as phosphate binders because calcium binds the iron, preventing absorption. The patient should be advised that iron may make the stool a dark colour.

Most patients on HD receive IV iron. Supplemental folic acid is usually given because it is needed for RBC formation and is removed by dialysis.

Blood transfusions should be avoided in treating anemia unless the patient experiences an acute blood loss or has symptomatic anemia (e.g., dyspnea, excess fatigue, tachycardia, palpitations, chest pain). Undesirable effects of transfusions are the suppression of erythropoiesis as a result of a decrease in the hypoxic stimulus, the possible transmission of hepatitis B or C or human immunodeficiency virus (HIV), the possibility of developing antibodies that may affect transplantation, and the possibility of iron overload because each unit of blood contains about 250 mg of iron.

Dyslipidemia.

There is a high prevalence of dyslipidemia for patients with CKD (Levin, Hemmelgarn, Culleton, et al., 2008). Currently, good evidence-informed research is lacking to guide the management of dyslipidemia in CKD. The National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF KDOQI) recommends the use of statins in patients with stages 1 to 3 CKD, per guidelines for the general population (Kim, Langworthy, & Hennessey, 2014).

Complications of Drug Therapy.

Because the kidneys play a large role in the absorption, distribution, metabolism, and elimination of drugs, people with CKD are at risk for

medication-related problems that can lead to increased morbidity and mortality (Liles, 2014). Many drugs are partially or totally excreted by the kidneys. Delayed and decreased elimination lead to an accumulation of drugs in the body and potential for drug toxicity. Dialysis may remove or lower drug levels. Drug doses and frequency of administration must be adjusted based on the level of kidney function and whether or not the patient is receiving dialysis. Drugs of particular concern include digoxin, oral glycemic agents (e.g., metformin, glyburide), antibiotics, and opioid medication (e.g., hydromorphone [Dilaudid], morphine).

Patients should be advised to avoid NSAIDs. These drugs block the synthesis of the renal prostaglandins that promote vasodilation. This can worsen renal hypoperfusion and cause interstitial nephritis. Many NSAIDs are available over the counter, so it is essential that the patient be cautioned. Acetaminophen can be substituted.

Nutritional Therapy

Protein Restriction.

The diet is designed to be as normal as possible to maintain good nutrition (Table 49-9). All patients with CKD should be seen by a dietitian. Protein energy wasting in CKD is a strong predictor of mortality (Ikizler, Cano, Franch, et al., 2013). Protein is moderately restricted because BUN is an end product of protein metabolism. For the patient who is not undergoing dialysis, one guide is to restrict protein intake to 0.6 to 0.75 g/kg of ideal body weight (IBW)/day when the creatinine clearance is less than 25 mL/min (Goldstein-Fuchs & Kalantar-Zadeh, 2015). This moderate restriction may slow progression of CKD for these patients. For patients with more severe renal insufficiency, low-protein diets should be used with caution because these patients are at risk of developing malnutrition.

TABLE 49-9

NUTRITIONAL THERAPY
Daily Requirements for the Patient With Chronic Kidney Disease

	CKD Stages 3–4 Management	Hemodialysis	Peritoneal Dialysis
Fluid allowance	Urine output + 600 mL	Urine output + 600 mL	Often no restriction
Protein*	0.6–0.75 g/kg body weight	1.2–1.3 g/kg IBW	≥1.2–1.3 g/kg IBW
Calories	30–35 kcal/kg EDW	30–35 kcal/kg EDW†	30–35 kcal/kg IBW†
Fat	Determined by caloric requirement	Determined by caloric requirement	Determined by caloric requirement
Carbohydrate	Unlimited intake of sugars, starches; bread and cereal products limited owing to protein restriction	Same as for conservative management	Dependent on individual patient needs
Iron	Variable	Variable	Variable
Potassium	2–3 g	2–3 g	3–4 g, no restrictions
Sodium	2–3 g	2–3 g	2–4 g
Phosphorus	800–1 000 mg	1 000 mg	1 000 mg
Calcium	Variable	1 000–1 500 mg	1 000–1 500 mg
Folic acid	1-mg supplement	1-mg supplement	1-mg supplement

*At least 50% of protein intake should be of high biological value (e.g., coming from eggs, milk, meat).

†Includes dialysate calories.

CKD, chronic kidney disease; *EDW,* estimated dry weight; *IBW,* ideal body weight.

Once the patient starts dialysis, protein intake can be increased to 1.2 to 1.3 g/kg of IBW/day. Dietary protein guidelines for PD differ from those for HD because excessive amounts of protein are lost in the dialysate. The protein intake must be high enough to compensate for the losses so that the nitrogen balance is maintained. The recommended protein intake is at least 1.2 g/kg of IBW/day and can be increased depending on the individual needs of the patient. At least 50% of protein intake should have high biological value, containing all of the essential amino acids (e.g., eggs, milk, meat, poultry).

Sufficient calories from carbohydrates and fat are needed to minimize catabolism of body protein and to maintain body weight. Therefore, 100 g of carbohydrates and an appropriate amount of fat are prescribed to maintain an intake of 30 to 35 kcal/kg body weight/day. See Table 49-9 for specific guidelines.

For patients with malnutrition or inadequate caloric intake, commercially prepared products that are high in calories and low in protein, sodium, and potassium are available.

Because the diet for CKD is deficient in vitamins, and water-soluble vitamins are lost through dialysis, multivitamins are prescribed.

Sodium and Fluid Restriction.

Fluid intake for patients with CKD depends on the daily urine output and overall fluid balance. For patients not yet on dialysis, fluids are generally not restricted and diuretics and a low-sodium diet help to manage fluid retention. For patients receiving HD, fluids are generally restricted as urine output begins to decline. Generally, 600 mL (from insensible loss) plus an amount equal to the previous day's urine output is allowed for a patient receiving dialysis. Foods that are liquid at room temperature (e.g., gelatin, ice cream) should be counted as fluid intake. The fluid allotment should be spaced throughout the day so that the patient does not become thirsty. For the patient receiving long-term HD, fluid intake is adjusted so that weight gains are no more than 1 to 3 kg between dialyses.

To achieve the optimal fluid balance, sodium must also be restricted. Sodium-restricted diet allowances may vary from 2 to 4 g, depending on the degree of edema and hypertension. Sodium and salt should not be equated because the sodium content in 1 g of sodium chloride is equivalent to 400 mg of sodium. The patient should be instructed to avoid high-sodium foods such as cured meats, pickled foods, canned soups and stews, frankfurters, cold cuts, soy sauce, and salad dressings. Most salt substitutes should not be used because they contain potassium chloride.

Potassium Restriction.

The potassium restriction depends on the ability of the kidneys to excrete this electrolyte. Dietary allowances for potassium range from about 2 to 4 g. Some patients on PD do not need potassium restrictions. Some foods with high potassium content that should be avoided are oranges, bananas, melons, tomatoes, prunes, raisins, deep green and yellow vegetables, beans, and legumes (Table 49-10).

TABLE 49-10

NUTRITIONAL THERAPY
High-Potassium Foods

Fruits and Fruit Juices	Vegetables	Cereal
• Apple juice	• Beans, white and pinto*	• All-Bran*
• Avocados*	• Broccoli	• Raisin Bran*
• Bananas*	• Carrots	**Meat and Poultry**
• Grapefruit juice	• Lima beans, cooked*	• Beef,* pork, cooked
• Honeydew melons*	• Mushrooms, fresh*	• Chicken
• Orange juice*	• Potato, baked*	• Turkey
• Oranges	• Squash, baked*	**Miscellaneous**
• Prune juice*	• Spinach, cooked*	• Chocolate
• Prunes*	**Dairy**	• Molasses
• Raisins*	• Milk*	• Sunflower seeds*
• Tomato juice*	• Yogourt*	
• Tomatoes		

*>10 mmol of potassium per serving.

Phosphate Restriction.

CKD alters the homeostasis of calcium, phosphorus, and vitamin D (Felsenfeld et al., 2015). As CKD progresses, phosphorus excretion diminishes, resulting in hyperphosphatemia. Phosphate should be limited to approximately 1 000 mg/day. Foods that are high in phosphate include dairy products (e.g., milk, ice cream, cheese, yogourt) and foods containing dairy products (pudding). Most foods that are high in phosphate are also high in calcium. Restricting phosphate will restrict calcium intake.

Nursing Management Chronic Kidney Disease

Nursing Assessment

The nurse should obtain a complete history of any existing renal disease or family history of renal disease because some renal disorders have a hereditary basis (e.g., polycystic kidney disease, Alport's syndrome). Information on long-term health problems such as hypertension, diabetes, recurrent urinary tract infections, and systemic lupus erythematosus should be obtained because these conditions can lead to CKD. Because the kidneys play a large role in the absorption, distribution, metabolism, and elimination of drugs and because many drugs are potentially nephrotoxic, both current and past use of prescription and over-the-counter drugs must be reviewed.

The nurse should assess the patient's dietary habits and discuss any problems. The height and weight should be measured, and any recent weight changes must be evaluated.

Clinical manifestations of CKD are apparent in multiple body systems (see Figure 49-3). Fatigue, lethargy, and pruritus are often the early symptoms of CKD. Hypertension and changes in urine characteristics are often the first signs.

CKD is a lifelong and life-limiting illness. The chronicity of renal disease and the long-term nature of treatment modalities affect every area of a person's life, including family relationships, social and work activities, and self-image and emotional state. Support systems should be assessed. The choice of treatment modality may be related to support systems available to the patient.

It is important to respect a patient's choice not to receive treatment. Many times, patients will initiate the conversation about palliative care themselves. The discussion needs to focus on moving from the curative approach to promotion of comfort care and consideration for end-of-life care. The nurse should listen to the patient and caregiver, allowing them to do most of the talking, and pay special attention to their hopes and fears (Schell & Holley, 2013) (Table 49-11). (Palliative and end of-life care is discussed in Chapter 13.)

TABLE 49-11

SUMMARY OF RECOMMENDATIONS FOR DECISION SUPPORT FOR ADULTS LIVING WITH CHRONIC KIDNEY DISEASE

Practice Recommendations	
Patient Decision-Making Needs	
1.0	Nurses know the common decisions faced by an adult with CKD. *Nursing Actions:* • Nurses identify the decision the patient is facing at a particular point in time.
2.0	Nurses screen the patient for decisional conflict at initial contact and as the patient's situation and condition changes. *Nursing Actions:* • Nurses screen for decisional conflict.
3.0	Nurses determine the source of the patient's decisional conflict. *Nursing Actions:* • Nurses assess the patient's knowledge and expectations about the options. • Nurses assess and discuss the availability of resources. • Nurses objectively measure the patient's confidence and ability for making decisions and self-managing their CKD. • Nurses assist the patient to clarify his or her values. • Nurses clarify the patient's preferred role in decision making and who else the patient wants to involve in the decision-making process.
Decision Support Interventions	
4.0	Nurses understand the difference between providing patient education and providing decision support. *Nursing Actions:* • Nurses describe patient education. • Nurses describe the additional elements involved with decision support.
5.0	Nurses use patient decision aids and other tools to provide decision support. *Nursing Actions:* • Nurses remain neutral when supporting the patient in the decision-making process. • Nurses use validated tools to provide decision support. • Nurses help the patient to build confidence in participation in decision making. • Nurses meet the patient's knowledge needs. • Nurses help the patient clarify his or her values. • Nurses help the patient mobilize resources. • Nurses help the patient to communicate with others during the decision-making process. • Nurses obtain commitment from the patient for the next decision-making step(s).

CKD, chronic kidney disease.

Nursing Diagnoses

Nursing diagnoses for the patient with CKD in stage 4 may include, but are not limited to, the following:

- *Excess fluid volume* related to *excessive fluid intake* (impaired kidney function)

- *Risk for electrolyte imbalance* as evidenced by *excessive fluid volume* (impaired kidney function)
- *Imbalanced nutrition: less than body requirements* related to *insufficient dietary intake* (restricted intake of nutrients, nausea, vomiting, anorexia, stomatitis)

Additional information on nursing diagnoses for the patient with CKD is presented in Nursing Care Plan (NCP) 49-1, available on the Evolve website.

Planning

The majority of CKD care occurs in the ambulatory care setting. The overall goals are that a patient with CKD will (1) demonstrate knowledge and ability to comply with the therapeutic regimen, (2) participate in decision making for the plan of care and future treatment modality, (3) demonstrate effective coping strategies, and (4) continue with activities of daily living within physiological limitations.

Nursing Implementation

Health Promotion.

Identify individuals at risk for CKD. These include people with a history (or a family history) of renal disease, hypertension, diabetes mellitus, and repeated urinary tract infection. These individuals should have regular checkups, including assessments of serum creatinine and BUN and urinalysis. People with diabetes should have their urine checked for microalbuminuria if routine urinalysis is negative for protein. They should be advised that any changes in urine appearance (colour, odour), frequency, or volume must be reported to the health care provider. If a patient must be prescribed a potentially nephrotoxic drug, it is important to monitor renal function with serum creatinine and BUN.

Individuals who have been identified as being at risk need to take measures to prevent or delay the progression of CKD and reduce the risk for cardiovascular disease. These measures include glycemic control for patients with diabetes (see Chapter 52), optimizing BP control, and lifestyle modifications, including smoking cessation.

Care Considerations for Chronic Kidney Disease in Stages 4 to 5.

The specific nursing management of the patient with CKD in stages 4 to 5 is detailed in NCP 49-1, available on the Evolve website. It is important to teach the patient and the family because diet, drugs, and follow-up medical care are the responsibilities of the patient (Table 49-12). The patient should check weight daily, learn to take daily BPs, and be able to identify signs and symptoms of fluid overload, hyperkalemia, and other electrolyte imbalances. The patient and the family must understand the importance of strict dietary adherence. A registered dietitian should meet with the patient and the family on a regular basis for diet planning. A diet history and consideration of cultural variations will facilitate diet planning and adherence.

TABLE 49-12

PATIENT & CAREGIVER TEACHING GUIDE
Chronic Kidney Disease in Stages 4 and 5

When teaching the patient and caregiver about management of chronic kidney disease, the nurse should:

1. Explain dietary (protein, sodium, potassium, phosphate) and fluid restrictions incorporating the patient's own cultural dietary patterns.
2. Encourage discussion of difficulties in modifying diet and fluid intake.
3. Explain signs and symptoms of electrolyte imbalance, especially high potassium.
4. Teach alternative ways of reducing thirst, such as sucking on ice cubes, lemon, or hard candy.
5. Explain the rationale for prescribed drugs and common adverse effects.
   Examples
   - Phosphate binders should be taken with meals.
   - Iron supplements should be taken between meals.
6. Explain the importance of reporting any of the following:
   - Weight gain >2 kg
   - Increasing blood pressure
   - Shortness of breath
   - Edema
   - Increasing fatigue or weakness
   - Confusion or lethargy
7. Encourage patient and caregiver(s) to share concerns about lifestyle changes, living with a chronic illness, and decisions about type of dialysis or transplantation.

The patient needs a complete understanding of prescribed drugs, the dosages, and the common adverse effects. It may be helpful to make a list of the drugs and the times of administration that can be posted in the home. The patient must be instructed to avoid certain over-the-counter drugs such as NSAIDs and natural and herbal preparations. ACE inhibitors may have to be discontinued if they are contributing to hyperkalemia or decreased GFR.

Motivation on the part of the patient to assume the primary role in the management of the disease is essential. The period of predialysis care provides an opportunity to evaluate each patient's ability to manage the disease. This knowledge will be helpful when determining the treatment modality.

Ambulatory and Home Care.

The length of time that a patient with CKD can be managed without RRT is highly variable and depends on the progression of renal failure and the presence of other comorbid conditions. When RRT is required, HD, PD, and transplantation are the available treatment options.

Extensive and ongoing teaching and discussion about RRTs should occur early (CKD in stage 3) in order for the patient to make an informed decision about future therapies, including RRT and advanced directives.

The patient and the family need a clear explanation of what is involved in dialysis and transplantation. The patient should be informed that, if dialysis is chosen, the option of transplantation still remains, if the patient is medically suitable. It should be emphasized that, if a transplanted organ fails, the patient can return to dialysis. The patient should also be counselled that retransplantation may also be an option.

Evaluation

The expected outcomes for the patient with CKD are presented in NCP 49-1, available on the Evolve website.

Dialysis

Dialysis is the movement of fluid and molecules across a semipermeable membrane from one compartment to another. Clinically, dialysis is a technique in which substances move from the blood through a semipermeable membrane (dialyzer) and into a dialysis solution (dialysate). It is used to correct fluid and electrolyte imbalances and to remove waste products in renal failure. It can also be used to treat drug overdoses. The two methods of dialysis available are PD and HD (Table 49-13). **Peritoneal dialysis (PD)** is a method of removing waste products and excess fluid from the blood using a natural semipermeable membrane, the peritoneum. Dialysis fluid is infused into the peritoneal cavity, and excess fluid and waste products pass across the membrane into the fluid, which is then drained and discarded. In **hemodialysis (HD),** waste products and excess fluid are removed from the blood using a machine to pump the blood through an artificial semipermeable membrane (usually made of cellulose-based or synthetic materials).

TABLE 49-13
COMPARISON OF PERITONEAL DIALYSIS AND HEMODIALYSIS

Peritoneal Dialysis	Hemodialysis
Advantages	*Advantages*
• Fewer dietary restrictions • Home dialysis possible • Less cardiovascular stress • Less complicated than hemodialysis • Portable system with CAPD • Preferable for the diabetic patient • Relatively short training time • Usable in the patient with vascular access problems	• Effective potassium removal • Home dialysis possible • Less protein loss than with peritoneal dialysis • Lowering of serum triglycerides • Rapid fluid removal • Rapid removal of urea and creatinine • Temporary access can be placed at bedside
Disadvantages	*Disadvantages*
• Catheter can migrate • Contraindication in the patient with multiple abdominal surgeries, trauma, unrepaired hernia • Protein loss into dialysate • Risk for aggravated dyslipidemia • Risk for bacterial or chemical peritonitis • Risk for exit-site and tunnel infections • Risk for hyperglycemia • Risk for self-image problems with catheter placement • Surgery for catheter placement	• Added blood loss that contributes to anemia • Dietary and fluid restrictions • Extensive equipment necessary • Heparinization may be necessary • Hypotension during dialysis • Longer training time for home hemodialysis vs. peritoneal • Self-image problems with permanent access • Specially trained personnel necessary (if in-centre option chosen) • Surgery for permanent access placement • Vascular access problems

CAPD, continuous ambulatory peritoneal dialysis.

When CKD progresses to the point that the patient's symptoms, fluid volume status, or both can no longer be managed without dialysis, dialysis therapy is initiated. Generally, dialysis is initiated when the GFR (or creatinine clearance) is less than 15 mL/min/1.73 m^2. This criterion can vary widely in different clinical situations. Certain uremic complications, including encephalopathy, neuropathies, uncontrolled hyperkalemia, pericarditis, and accelerated hypertension, indicate a need for immediate dialysis.

General Principles of Dialysis

Solutes and water move across the semipermeable membrane from the blood to the dialysate or from the dialysate to the blood, in accordance with concentration gradients. The principles of diffusion, osmosis, and ultrafiltration are involved in dialysis (Figure 49-5). *Diffusion* is the movement of solutes from an area of greater concentration to an area of lesser concentration. In renal failure, urea, creatinine, uric acid, and electrolytes (potassium, phosphate) move from the blood to the dialysate with the net effect of lowering their concentration in the blood. RBCs, WBCs, and plasma proteins are too large to diffuse through the pores of the membrane. Bacteria and viruses that may be present in the dialysate are too large to migrate through the pores into the blood.

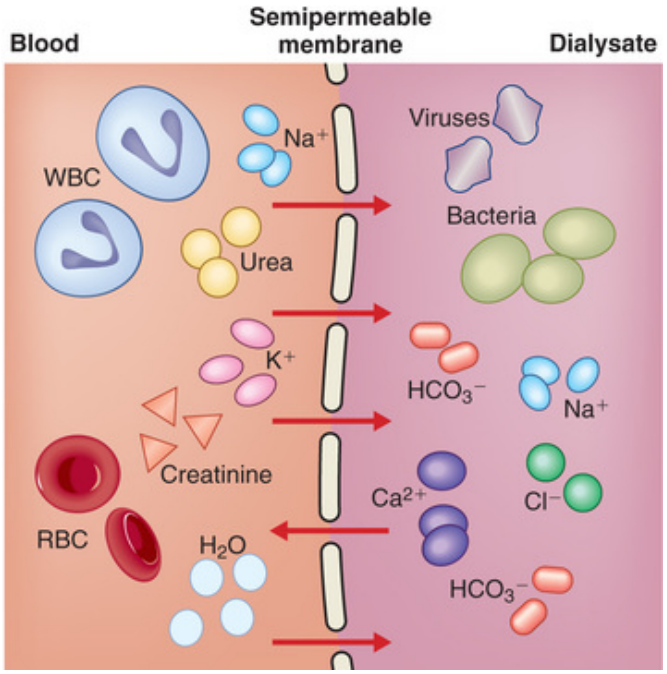

FIGURE 49-5 Osmosis and diffusion across a semipermeable membrane. *Ca,* calcium; *Cl,* chlorine; *HCO_3,* bicarbonate; *H_2O,* water; *K,* potassium; *Na,* sodium; *RBC,* red blood cell; *WBC,* white blood cell.

Osmosis is the movement of fluid from an area of lesser to an area of greater concentration of solutes. Glucose is added to the dialysate and creates an osmotic gradient across the membrane, pulling excess fluid from the blood.

Ultrafiltration (water and fluid removal) results when there is an osmotic gradient or pressure gradient across the membrane. In PD, excess fluid is removed by increasing the osmolality of the dialysate (osmotic gradient) with the addition of glucose. In HD, the gradient is created by increasing pressure in the blood compartment (positive pressure) or decreasing pressure in the dialysate compartment (negative pressure). Extracellular fluid moves into the dialysate because of the pressure gradient. The excess fluid is removed by creating a pressure differential between the blood and the dialysate solution, with a combination of positive pressure in the blood compartment and negative pressure in the dialysate compartment.

Peritoneal Dialysis

Although PD was first used in 1923, it did not come into widespread use for chronic treatment until the 1970s with the development of soft, pliable peritoneal solution bags and the introduction of the concept of continuous

PD. In Canada, 19% of patients were receiving peritoneal dialysis compared with 79% who were receiving HD in 2012 (CIHI, 2014).

Catheter Placement

Peritoneal access is obtained by inserting a catheter through the anterior abdominal wall (Figure 49-6). Most catheter exit sites are in the abdomen; however, some catheters are inserted using a presternal technique, where the catheter exits on the chest (Crabtree, 2015). The catheters vary in length and have one or two Dacron cuffs on the subcutaneous and peritoneal portions of the catheter that act as anchors and prevent the migration of microorganisms down the shaft from the skin. Within a few weeks of insertion, fibrous tissue grows into the Dacron cuff, holding the catheter in place and preventing bacterial penetration into the peritoneal cavity. The tip of the catheter rests in the peritoneal cavity and has many perforations spaced along the distal end of the tubing to allow fluid to flow in and out of the catheter. There are numerous types of PD catheters.

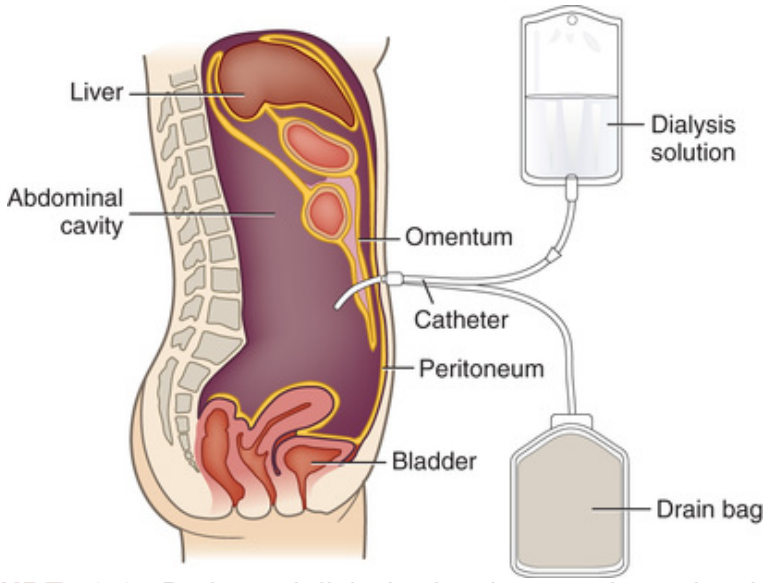

FIGURE 49-6 Peritoneal dialysis showing a peritoneal catheter inserted into the peritoneal cavity.

The technique for catheter placement varies. Although it is possible to place a permanent catheter in the peritoneal cavity at the bedside with a trocar, it is usually done via surgery so that its placement can be directly visualized, minimizing potential complications. Preparation of the patient

for catheter insertion includes emptying the bladder and the bowel, weighing the patient, and obtaining a signed consent form.

In the nonsurgical (bedside) approach, an area approximately 2 cm below the umbilicus is numbed with a local anaesthetic, and a small stab wound is made. A stylet is inserted, and the abdomen is distended with dialysis solution. The catheter is then placed into the peritoneal cavity. When the patient feels pressure in the rectal area and has the urge to defecate, the catheter is in place.

In the surgical approach, a midline umbilical incision is made, and a small puncture is made to one side and below this incision. The distal end of the catheter is placed in the peritoneum, and it is tunnelled under the skin to the puncture site. The tunnel helps prevent peritonitis. After the catheter is inserted, the skin is cleaned with an antiseptic solution, and a sterile dressing is applied. Complications of catheter insertion include perforation of the bladder, the bowel, or a blood vessel and the introduction of bacteria.

The catheter is connected to a sterile tubing system and secured to the abdomen with tape. The catheter is irrigated immediately with heparinized dialysate (usually 500 mL) to clear blood and fibrin from it. Prophylactic antibiotics may also be given. Catheter placement is usually done with same-day surgery, and the patient is discharged home with a sterile dressing covering the PD catheter. The patient needs instructions on keeping the dressing dry, avoiding accidentally pulling the catheter, and receiving follow-up care.

Before starting PD, it is preferable to allow a waiting period of 7 to 14 days for proper sealing of the catheter and for tissue to grow into the cuffs. Postoperative exit-site care should be restricted to trained staff (Young, Chan, Blagg, et al., 2012). About 2 to 4 weeks after catheter implantation, the exit site should be clean, dry, and free of redness and tenderness (Figure 49-7). Once the catheter incision site is healed, routine care should be done daily or every other day. This care includes the use of antibacterial soap or mild, medical-grade disinfectants as well as examination of the catheter site for signs of infection. Each centre will have a policy about exit-site care, and patients are taught how to examine and care for their PD catheter and exit site by the PD nursing staff.

FIGURE 49-7 Peritoneal catheter exit site. Source: Mediscan/Alamy Stock Photo.

Dialysis Solutions and Cycles

PD is accomplished by putting dialysis solution into the peritoneal space. The three phases of the PD cycle are *inflow* (fill), *dwell* (equilibration), and *drain.* The three phases are called an *exchange.* The dialysis prescription is tailored to the patient's needs. During inflow, a prescribed amount of solution, usually 2 L, is infused through an established catheter over about 10 minutes. After the solution has been infused, the inflow clamp is closed before air enters the tubing.

During the dwell phase, or equilibration phase, diffusion and osmosis occur between the patient's blood and the peritoneal cavity. The dwell time can last from 20 to 30 minutes to 8 or more hours, depending on the goals of PD.

Drain time takes 15 to 30 minutes. The cycle starts again with the infusion of another 2 L of solution. For manual PD, a period of about 30 to 50 minutes is required to complete an exchange.

Dialysis solutions vary, and the choice of exchange volume is primarily determined by the size of the peritoneal cavity. A larger person may tolerate a 3-L volume without any difficulty, whereas an average-size person usually tolerates a 2-L exchange.

Ultrafiltration (fluid removal) during PD depends on osmotic forces, with glucose being the most effective agent available. Dextrose remains the most commonly used osmotic agent available in PD solutions. It is relatively safe but has been associated with high rates of peritoneal glucose absorption leading to hypertriglyceridemia, hyperglycemia, and long-term peritoneal membrane dysfunction. The amount of dextrose in the solution varies among 0.5%, 1.5%, 2.5%, and 4.25%, depending on the fluid volume

goal. Alternate osmotic agents include icodextrin and amino acid solutions.

Peritoneal Dialysis Systems

Two types of PD currently being used are automated peritoneal dialysis (APD) and continuous ambulatory peritoneal dialysis (CAPD).

Automated Peritoneal Dialysis.

Automated peritoneal dialysis (APD), also called *continuous cycling peritoneal dialysis,* is a popular form of PD that is done while the patient sleeps. An automated device called a *cycler* is used to perform the dialysis exchanges (Figure 49-8). The automated cycler times and controls the fill, dwell, and drain phases. The machine cycles four or more exchanges per night, with 1 to 2 hours per exchange. Alarms and monitors are built into the system to make it safe for the patient to dialyze while sleeping. The patient disconnects from the machine in the morning and usually leaves fluid in the abdomen during the day. One to two daytime manual exchanges may also be prescribed to ensure adequate dialysis.

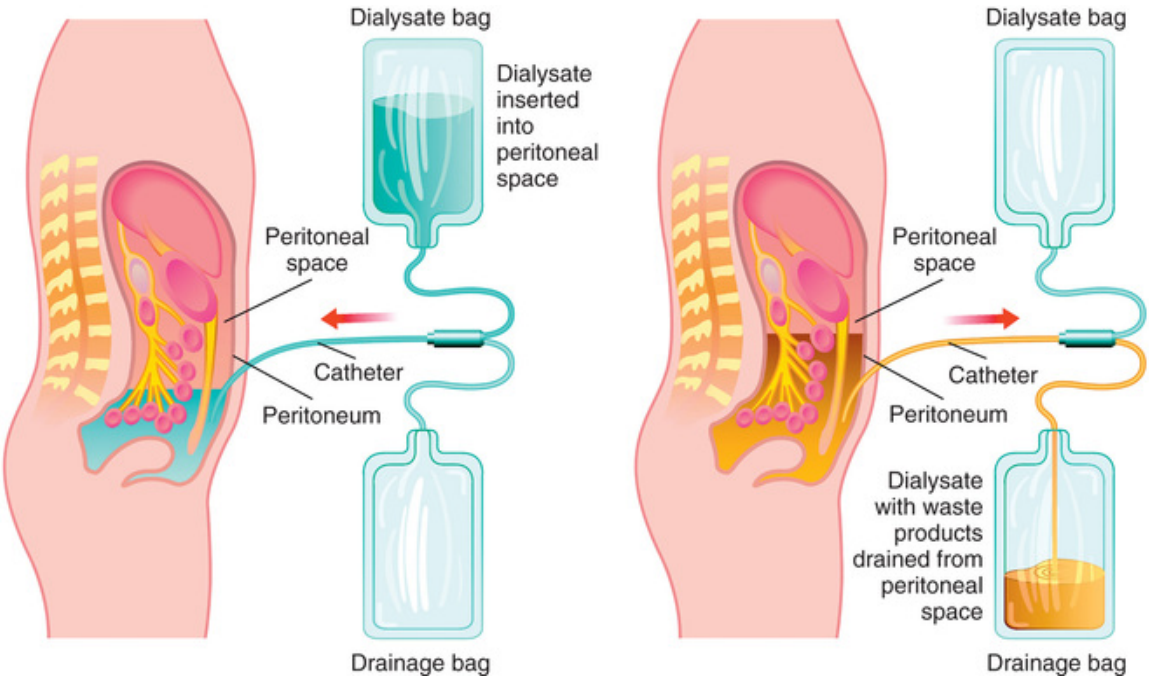

FIGURE 49-8 Automated peritoneal dialysis cycler, which can be used while the patient is sleeping at night or for hospitalized patients who require frequent exchanges. Source: © Can Stock Photo/rob3000.

Continuous Ambulatory Peritoneal Dialysis.

Continuous ambulatory peritoneal dialysis (CAPD) is a type of PD that is done during the day and consists of a minimum of four exchanges of dialysis fluid per day. CAPD exchanges are carried out manually by exchanging 1.5 to 3 L of peritoneal dialysate at least four times daily, with dwell times averaging 4 hours. For example, one schedule starts the exchanges at 0700 hours, 1200 hours, 1700 hours, and 2200 hours.

Dialysis fluid is instilled into the peritoneal cavity and remains (dwells) there for a specified period, allowing for the removal of waste products and excess fluid; it is then drained and fresh fluid is instilled. It is continuous in that dialysis fluid is always in the peritoneal cavity so dialysis is continuously going on. After the equilibration period, the dialysate (effluent) is drained from the peritoneal cavity, and a new 2-L bag of dialysate solution is infused. It is critical in PD to maintain aseptic technique to avoid peritonitis. Several tubing connections and devices are commercially available to help maintain an aseptic system.

Potential contraindications for PD include the following:

1. History of multiple abdominal surgical procedures or severe abdominal pathological condition (e.g., severe pancreatitis, diverticulitis).
2. Recurrent abdominal wall or inguinal hernias.
3. Excessive obesity with large abdominal wall and fat deposits.
4. Pre-existing vertebral disease (e.g., chronic back problems).
5. Severe obstructive pulmonary disease.

Complications of Peritoneal Dialysis

Exit-Site Infection.

Infection of the peritoneal catheter exit site is most commonly caused by *Staphylococcus aureus* or *Staphylococcus epidermidis* (from skin flora). Superficial exit-site infections caused by these organisms are generally resolved with antibiotic therapy. Clinical manifestations of an exit-site infection include redness at the site, tenderness, and drainage. If not treated immediately, subcutaneous tunnel infections usually result in abscess formation and may cause peritonitis, necessitating catheter removal.

Peritonitis.

Peritonitis results from contamination or from progression of an exit-site or tunnel infection. Most frequently, peritonitis occurs because of improper technique in making or breaking connections for exchanges. Less commonly, peritonitis results from bacteria in the intestine crossing over into the peritoneal cavity. Peritonitis is usually caused by *S. aureus* or *S. epidermidis.*

The primary clinical manifestation of peritonitis is a cloudy peritoneal effluent that has a WBC count of over 0.1×10^9/L (particularly neutrophils) or demonstration of bacteria in the peritoneal effluent by Gram stain or culture. GI manifestations may also be present, including diffuse abdominal pain, diarrhea, vomiting, abdominal distension, and hyperactive bowel sounds. Fever may or may not be present. Cultures, Gram stain, and a cell count with WBC differential of the peritoneal effluent are used to confirm the diagnosis of peritonitis. Antibiotics can be given by mouth or by IV or intraperitoneal route. The patient is usually treated on an outpatient basis. Repeated infections may necessitate the removal of the peritoneal catheter and termination of PD. The formation of adhesions in the peritoneum can result from repeated infections and interferes with the peritoneal membrane's ability to act as a dialyzing surface.

Abdominal Pain.

Although not severe, pain is a common complication, caused by the low pH of the dialysate solution, peritonitis, intraperitoneal irritation (which usually subsides in 1 to 2 weeks), and placement of the catheter. Pain can also occur when the tip of the catheter touches the bladder, the bowel, or the peritoneum. A change in the position of the catheter should correct this problem. Accidental infusion of air or infusing the dialysate too rapidly may cause referred pain in the shoulder. If the infusion rate is decreased, the pain usually subsides.

Outflow Problems.

It is expected that at least 80% of the volume instilled in the peritoneal cavity is returned when draining the cavity after an exchange. Causes of poor outflow include constipation, a kink in the catheter or transfer set, omentum wrapped around the catheter, and migration of the catheter out of the pelvic region. Laxatives and stool softeners can be used to relieve constipation and promote regular bowel movements. Outflow problems related to omental entrapment or migration may necessitate radiological intervention, surgical manipulation of the catheter, or both.

Hernias.

Because of increased intra-abdominal pressure secondary to the dialysate infusion, umbilical or inguinal hernias or diastasis recti can develop in predisposed individuals such as multiparous women and older men. However, in most situations after hernia repair, PD can be resumed after several days, using small dialysate volumes and keeping the patient supine.

Lower Back Problems.

Increased intra-abdominal pressure can cause or aggravate lower back pain. The lumbosacral curvature is increased by intraperitoneal infusion of dialysate. Orthopedic binders and a regular exercise program for strengthening the back muscles have been beneficial for some patients.

Bleeding.

Effluent drained after the first few exchanges may be pink or slightly bloody because of the trauma of catheter insertion. Bloody effluent over several days or the new appearance of blood in the effluent can indicate active intraperitoneal bleeding. If this occurs, BP and hemoglobin should be checked. Blood may also be present in the effluent of women who are menstruating or ovulating; this occurrence necessitates no intervention.

Pulmonary Complications.

Atelectasis, pneumonia, and bronchitis may occur from repeated upward displacement of the diaphragm, resulting in decreased lung expansion. The longer the dwell time, the greater the likelihood of pulmonary problems. Frequent repositioning and deep-breathing exercises can help. When the patient is lying in bed, elevation of the head of the bed may prevent these problems.

Protein Loss.

The peritoneal membrane is permeable to plasma proteins, amino acids, and polypeptides. These substances are lost in the dialysate fluid. The amount of loss may be as much as 5 to 15 g/day. This loss may increase to up to 40 g/day during episodes of peritonitis as the membrane becomes more permeable. Positive nitrogen balance can be maintained with adequate protein intake.

Carbohydrate and Lipid Abnormalities.

Dialysate glucose is absorbed via the peritoneum in quantities that may be as high as 100 to 150 g/day. Continuous absorption of glucose results in increased insulin secretion and increased plasma insulin levels. The hyperinsulinemia stimulates hepatic production of triglycerides.

Effectiveness of and Adaptation to Chronic Peritoneal Dialysis

Learning the self-management skills required to do PD involves a relatively short training program. PD provides independence and flexibility with treatment, and travelling is easier. A major advantage of PD is its simplicity and that it is a home-based treatment that allows the patient to be in control.

Clinically, the patient receiving PD does as well as the patient receiving HD and sometimes better. There are fewer dietary restrictions, and greater mobility is possible than with conventional HD. The major disadvantage is the possibility of developing peritonitis.

PD is especially indicated for the individual who has vascular access problems or responds poorly to the hemodynamic stresses of HD (e.g., the older-adult patient with diabetes and cardiovascular disease). The diabetic patient with ESRD does better with PD than with HD. The advantages of PD for the diabetic patient include better BP control, less hemodynamic instability because fluid shifts are gradual, and prevention of retinal hemorrhage because heparin is not required as it is in HD.

Hemodialysis

HD is a method of removing waste products and excess fluid from the blood using a machine to pump the blood through an artificial semipermeable membrane (dialyzer).

Vascular Access Sites for Hemodialysis

Obtaining vascular access is one of the greatest challenges associated with HD. To carry out HD, a very rapid blood flow is required, and access to a large blood vessel is essential. The types of vascular access in current use include arteriovenous fistulas (AVFs) and grafts (AVGs), and tunnelled and nontunnelled central venous catheters (CVCs). AVFs are superior to synthetic AVGs and CVCs and are associated with better long-term survival, lower infection and complication rates, and lower health care

expenditure (Gowda, Pavan, & Babu, 2014; Kuhan, Antoniou, Nikam, et al., 2013).

Arteriovenous Fistulas and Grafts.

A native **arteriovenous fistula (AVF)** is the preferred HD access, created by surgically connecting a vein and an artery, usually in the forearm (Gowda et al., 2014; Kuhan et al., 2013) (Figures 49-9, *A* and 49-10). The preferred sites for creating an AVF are the wrist (radiocephalic) and the elbow (brachiocephalic) (Gowda et al., 2014). The fistula provides for arterial blood flow through the vein. The increased pressure of the arterial blood flow through the vein causes the vein to dilate and become tough, making it amenable to repeated venipuncture. The vein is accessed using two large-gauge needles.

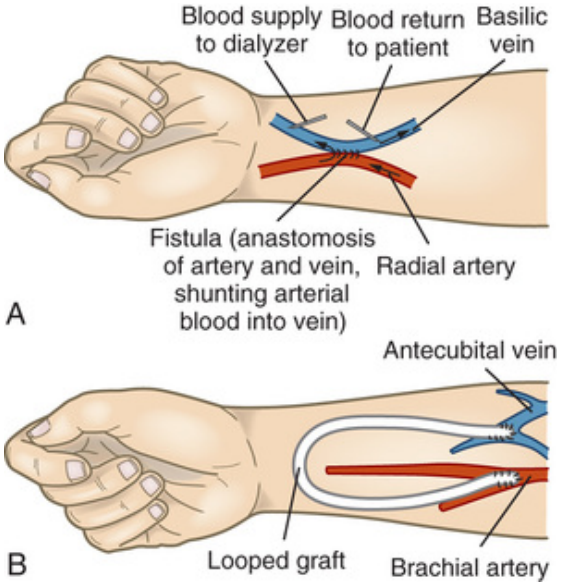

FIGURE 49-9 Vascular access for hemodialysis. **A,** Arteriovenous fistula. **B,** Arteriovenous graft.

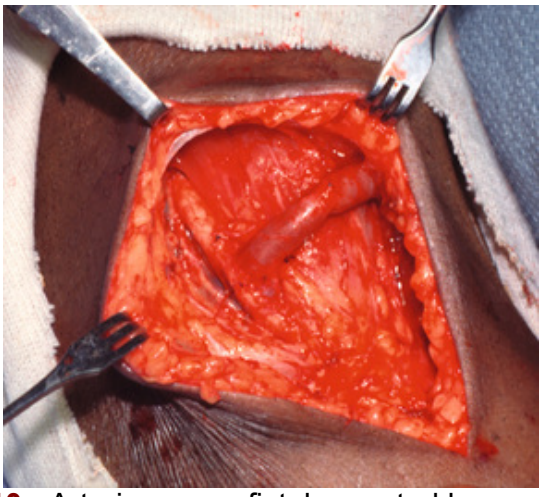

FIGURE 49-10 Arteriovenous fistula created by anastomosing an artery and a vein. Source: Courtesy Dr. Stephen Van Voorst, MD.

AVFs have the best overall patency rates and the least number of complications (e.g., thrombosis, infection) of all vascular accesses. The CSN *Clinical Practice Guidelines for Vascular Access* suggest that the AVF should be created at least 3 to 4 months before starting dialysis (Canadian Society of Nephrology, 2012) The AVF requires 4 to 6 weeks, and preferably 3 months, to mature (dilate and toughen) sufficiently for use. AVFs are more difficult to create in people with severe peripheral vascular disease, diabetes, prolonged IV drug use, or previous multiple IV procedures in the forearm. For these individuals, a synthetic graft may be required.

An **arteriovenous graft (AVG)** is an HD access created with a synthetic graft that is attached to an artery and a vein. It is used for people who do not have suitable vessels for an AVF. The preferred site for a synthetic graft is a forearm, using a curved loop radiocephalic graft. The graft is a surgically created anastomosis between an artery (usually radial) and a vein (usually cephalic) (see Figure 49-9, *B*). An interval of 3 to 6 weeks is usually necessary to allow the graft to heal, but some centres may use it earlier (Canadian Society of Nephrology, 2012). The graft, like the fistula, is under the skin and is accessed using two large-gauge needles. The graft material is self-healing, meaning it should close over any puncture site after the needle is removed. Infections in other parts of the body can result in infection and damage to the graft and have a tendency to be thrombogenic (Gowda et al., 2014).

Normally, a *thrill* can be felt by palpating the area of anastomosis, and a bruit can be heard with a stethoscope. The bruit and the thrill are created by the turbulence of arterial blood rushing into the vein. BPs, IV insertion,

and venipuncture should not be performed on an extremity with an AVF or AVG. This is to prevent thrombosis and infection in the vascular access. Protection of the vascular access site is of paramount importance.

An AVF is much less likely to clot and become infected than a graft. Thrombosis in AVGs is common but can often be corrected using interventional radiology techniques or a surgical procedure. AVFs and AVGs can cause the development of distal ischemia (steal syndrome) because too much of the arterial blood is being shunted or "stolen" from the distal extremity. This is usually seen soon after surgery and may require surgical correction. Aneurysms can also develop at the fistula site and can rupture if left untreated. AVG infections are not uncommon, and immediate treatment is essential to salvage the graft and prevent bacteremia. Severe AVG infections may necessitate graft removal.

Central Venous Catheters.

In some situations when immediate vascular access is required, a temporary CVC is placed by percutaneous cannulation of the internal jugular or the femoral vein. Internal jugular vein cannulation is associated with a low incidence of thrombosis, which is the primary reason this method is preferred over subclavian cannulation. In addition to vessel thrombosis and stenosis, subclavian vein cannulation has been associated with pneumothorax and brachial plexus; therefore, this site should be used as a last resort. A flexible Teflon, silicone rubber, or polyurethane catheter can be inserted at the bedside into the internal jugular vein and provides access to circulation without surgery (Figure 49-11, *A*). The catheters usually have a double external lumen with an internal septum separating the two internal segments (see Figure 49-11, *B*). One lumen is used for blood removal and the other for blood return. Femoral catheters should be sutured into place and can be left in place as long as there are no complications (Jin, Wang, Wu, et al., 2015).

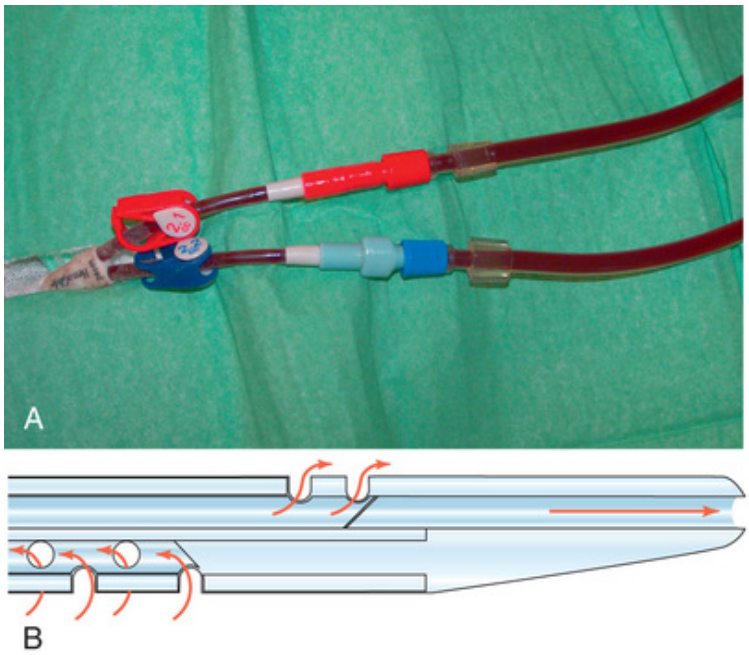

FIGURE 49-11 Temporary double-lumen vascular access catheter for acute hemodialysis. **A,** Soft, flexible dual-lumen tube is attached to a Y hub. **B,** Blood is withdrawn continuously through the red lumen (upstream) and returned through the blue lumen (downstream), thus reducing recirculation. Source: *A,* © Can Stock Photo/Terrapanthera.

Disadvantages of femoral vessel cannulation include the following: (1) the location encourages catheter kinking and (2) the groin is not a clean site. Potential complications of femoral catheterization are femoral vein thrombosis with pulmonary emboli (especially if the treatment is prolonged), infections, immobility, and inadvertent blood vessel punctures with hematoma formation. Temporary catheters are generally stiff and inflexible. They can cause trauma to the vessel, so bedrest is recommended. Temporary catheters in the internal jugular vein should be sutured in place and should be replaced as soon as possible by a tunnelled catheter that can be left in place for several weeks. Proper catheter position should be confirmed using radiography before use (Jin et al., 2015). Temporary catheters are generally left in place only for short periods or until a tunnelled catheter can be inserted.

Tunnelled catheters, which are soft and flexible, may be an option for patients who have exhausted all other vascular access sites. These catheters can be used as temporary access while awaiting fistula placement and development or as long-term access when other forms of access have failed. This type of catheter exits on the upper chest wall and is tunnelled

subcutaneously to the internal jugular vein (Figure 49-12). The catheter tip rests in the right atrium. It has one or two subcutaneous Dacron cuffs that prevent infection from tracking along the catheter and anchor the catheter, eliminating the need for sutures.

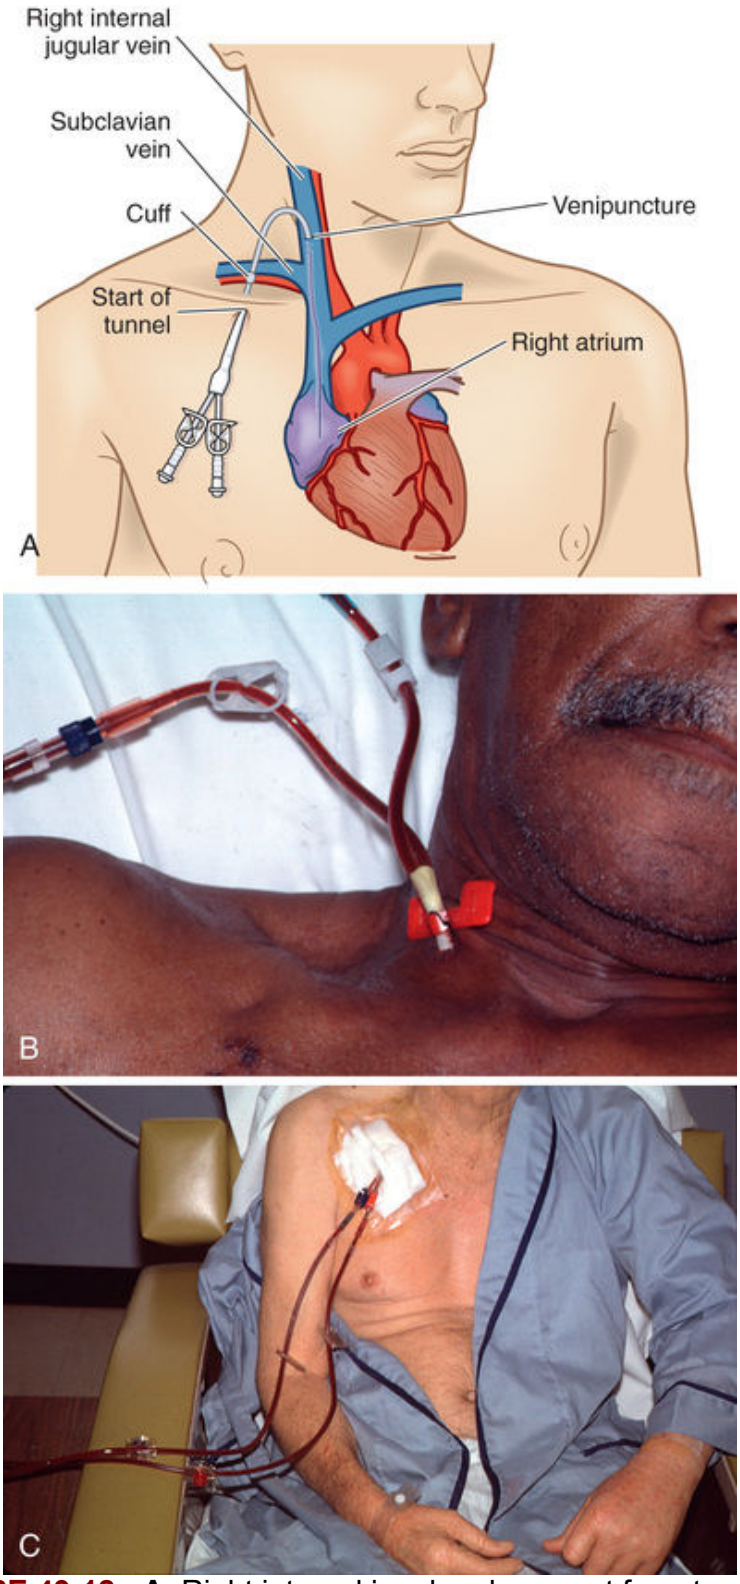

FIGURE 49-12 **A,** Right internal jugular placement for a tunnelled, cuffed semipermanent catheter. **B,** Temporary hemodialysis catheter in place. **C,** Long-term cuffed hemodialysis catheter. Source: *B* and *C,* Courtesy Dr. Stephen Van Voorst, MD.

For CVCs, no drugs should be administered or blood withdrawn via the catheter by nondialysis staff. This is to minimize the risk for infection, catheter loss, and accidental injection of heparin. Trained dialysis staff will instill heparin into the lumens of the catheter at the end of each treatment to ensure patency and withdraw it before the next treatment.

Dialyzers

The dialyzer is a long plastic cartridge that contains thousands of parallel hollow tubes or fibres (Figure 49-13). The fibres are the semipermeable membrane, made of cellulose-based or other synthetic materials. The blood is pumped into the top of the cartridge and is dispersed into all of the fibres. Dialysis fluid (dialysate) is pumped into the bottom of the cartridge and bathes the outside of the fibres. Ultrafiltration, diffusion, and osmosis occur across the pores of this semipermeable membrane. When the dialyzed blood reaches the end of the semipermeable fibres, it converges into a single tube that returns it to the patient. Available dialyzers differ in regard to surface area, membrane composition and thickness, clearance of waste products, and removal of fluid.

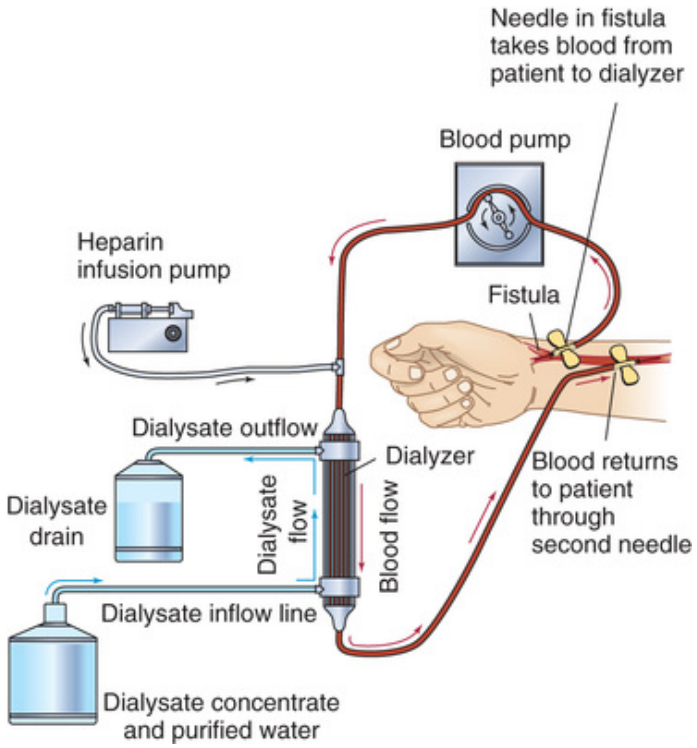

FIGURE 49-13 Components of a hemodialysis system. Blood is removed via a needle inserted in a fistula or via catheter lumen. It is propelled to the dialyzer by a blood pump. Heparin is infused to prevent clotting. Dialysate is pumped in and flows in the opposite direction to that of the blood. The dialyzed blood is returned to the patient through a second needle or catheter lumen. Old dialysate and ultrafiltrate are drained and discarded.

Procedure

To initiate chronic dialysis in a patient with an AVG or AVF, two needles are placed in the fistula or graft. One needle is used to draw blood from the patient and circulate it through the extracorporeal circuit and dialyzer, and the other needle is used to return the blood. If the patient has a catheter, the two blood lines are attached to the two catheter lumens, and blood is circulated through the dialysis blood circuit similar to that of the AVF and is sent to the dialyzer with the assistance of a blood pump. Heparin is added to the blood as it flows into the dialyzer because any time blood contacts a foreign substance it has a tendency to clot. When the blood enters the extracorporeal circuit, it is propelled through the top of the dialyzer by a blood pump at a flow rate of 200 to 500 mL/min, while the dialysate circulates in the opposite direction at a rate of 300 to 900

mL/min. Blood is returned from the dialyzer to the patient through the second needle or the blue (venous) catheter lumen.

In addition to the dialyzer, there is a dialysate delivery and monitoring system (Figure 49-14). This system pumps the dialysate through the dialyzer in the direction opposite to that of the blood flow.

FIGURE 49-14 Patient receiving in-centre hemodialysis. Source: © Can Stock Photo/PicsFive.

Before beginning treatment, the nurse must complete an assessment of the patient that includes fluid status (weight, BP, peripheral edema, lung and heart sounds), condition of vascular access, temperature, and general skin condition. The difference between the last postdialysis weight and the present predialysis weight represents the amount of fluid weight gained since the last treatment. This information is used to determine the ultrafiltration or the amount of fluid to be removed. Each kilogram represents approximately 1 L of fluid. Ideally, no more than 1 to 1.5 kg should be gained between treatments to prevent the hypotension associated with the removal of larger volumes of fluid. Many patients gain 2 to 3 kg between treatments, and this volume usually can be removed if

their BP is not labile. While the patient is on dialysis, vital signs should be taken at least every 30 to 60 minutes because rapid changes may occur in the BP.

Most maintenance dialysis units use reclining chairs that allow for elevation of the feet if hypotension develops. Most people sleep, read, talk, or watch television during dialysis. Treatments usually last 3 to 5 hours and are done a minimum of three times per week to achieve adequate clearance and maintain fluid balance.

Settings for Hemodialysis.

HD units and treatments are performed in a variety of settings. Acutely ill patients may require dialysis in the ICU setting. Most large teaching hospitals in Canada have dialysis units that accommodate patients who are in hospital as well as a chronic outpatient population. Many satellite and outpatient clinics provide chronic HD treatments. The patient may choose to do self-care with backup support from trained personnel if needed. Self-care patients generally put in their dialysis needles, set up the machine, and monitor the course of their treatment. Patients receiving HD are able to travel if dialysis treatments can be arranged at another dialysis unit.

Dialysis done at home is an optimal option for patients requiring RRT. Treatments are more cost effective and have many benefits for the patient (Czajkowski, Pienkos, Schiller, et al., 2013). HD can also be done at home. Today, in Canada, almost 20% of patients receiving HD use it at home (Johnson, 2014; Young et al., 2012). One of the main advantages of home HD is that it allows greater freedom in choosing dialysis times. Some modifications for a special electrical outlet, plumbing, and water treatment are necessary to accommodate the HD machine in the home setting.

Complications of Hemodialysis

Hypotension.

Hypotension that occurs during HD primarily results from rapid removal of vascular volume (hypovolemia), decreased cardiac output, and decreased systemic intravascular resistance. The drop in BP during dialysis may precipitate lightheadedness, nausea, vomiting, seizures, vision changes, and chest pain from cardiac ischemia. The usual treatment for hypotension includes decreasing the volume of fluid being removed and infusion of 0.9% saline solution (100–300 mL). If a patient experiences recurrent hypotensive episodes, a reassessment may have to be done of

dry weight and BP drugs. BP drugs should be held before dialysis if there are frequent episodes of hypotension during dialysis.

Muscle Cramps.

Painful muscle cramps are a common problem with HD. They result from rapid removal of sodium and water or from neuro-muscular hypersensitivity. Treatment includes reducing the ultrafiltration rate and infusing hypertonic saline or a normal saline bolus. The nurse should also educate the patient about restricting salt and fluid in the diet to reduce weight gains between dialysis treatments.

Loss of Blood.

Blood loss may result from blood not being completely rinsed from the dialyzer, accidental separation of blood tubing, dialysis membrane rupture, or bleeding after the removal of needles at the end of dialysis. If a patient has received too much heparin or has clotting problems, there can be significant postdialysis bleeding. It is essential to rinse back all blood, to closely monitor heparinization to prevent excess anticoagulation, and to hold firm but nonocclusive pressure on access sites until the risk of bleeding has passed.

Hepatitis.

A common cause of hepatitis B and C in dialysis patients includes transmission of health care–associated infection within hemodialysis units. As blood is screened for hepatitis B and C, blood transfusions are an unlikely source for the hepatitis infection. Dialysis patients may contract the bloodborne pathogen of hepatitis B and C as the general population does, through IV drug use or unprotected sex. (See Chapter 17 for infection control precautions and Chapter 46 for more detailed discussion on hepatitis.)

Sepsis.

Sepsis is most often related to infections of vascular access sites. Bacteria can also be introduced during the dialysis treatment as a result of poor technique or interruption of blood tubing or dialyzer membranes. Bacterial endocarditis can occur because of the frequent and prolonged access to the vascular system. Aseptic technique is essential to prevent this problem. Nurses must monitor patients for signs and symptoms of sepsis, such as fever, hypotension, and an elevated WBC count. (See Chapter 69 for nursing management of septic shock.)

Disequilibrium Syndrome.

Disequilibrium syndrome is a rare complication of modern HD and develops as a result of very rapid changes in the composition of the extracellular fluid. Urea, sodium, and other solutes are removed more rapidly from the blood than from the cerebro-spinal fluid and the brain. This rapid removal creates a high osmotic gradient in the brain, resulting in the shift of fluid into the brain, causing cerebral edema. Manifestations include nausea, vomiting, confusion, restlessness, headaches, twitching and jerking, and seizures. The rapid changes in osmolality may cause muscle cramps and worsen hypotension. Treatment consists of slowing or stopping dialysis and infusing hypertonic saline solution, albumin, or mannitol to draw fluid from the brain cells back into the systemic circulation. It is more commonly observed in the initial treatment of the patient when the BUN level is high. First dialysis treatment sessions are purposely short, with limited total solute removal, to prevent this rare syndrome.

Effectiveness of and Adaptation to Hemodialysis

HD is still an imperfect technique to treat stage 5 CKD. It cannot fully replace the metabolic and hormonal functions of the kidneys. It can ease many of the symptoms of CKD and, if started early, can prevent certain complications. It does not alter the accelerated atherosclerosis.

The 5-year survival rate for patients receiving maintenance HD is 41.4% (CIHI, 2014). Age and primary diagnosis are associated with survival of dialysis patients—the 5-year survival rate is 26% for those age 75 and older, whereas patients with renal vascular disease and diabetes have a 5-year survival rate of 37% and 41% respectively (CIHI, 2014).

Individual adaptation to maintenance HD varies considerably. Initially, many patients feel positive about the dialysis because it makes them feel better and keeps them alive, but there is often great ambivalence about whether it is worthwhile. Dependence on a machine is a reality, and some have dreams about being tied to the machine. In response to their illness, patients undergoing dialysis may demonstrate nonadherence to medical therapy, depression, and suicidal tendencies. The primary nursing goals are to help patients regain or maintain positive self-esteem and control of their lives and continue to be productive in society.

Continuous Renal Replacement Therapy

Continuous renal replacement therapy (CRRT) is an alternative or adjunctive method for treating AKI. It provides a means by which uremic

toxins and fluids are removed from a patient who is hemodynamically unstable, while acid–base status and electrolytes are adjusted slowly and continuously. Patients selected for this treatment are usually those who do not respond to dietary interventions or pharmacological agents.

Various types of CRRT are available, such as continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF) (Claure-Del Grando, Macedo, & Mehta, 2012) (Table 49-14). Various hybrid modalities that combine aspects of conventional HD and CRRT can be used and are determined based on the needs of the patient. Some common hybrid modalities include slow low-efficiency dialysis (SLED) and slow continuous ultrafiltration (SCUF) (Claure-Del Grando et al., 2012).

TABLE 49-14

TYPES OF CONTINUOUS RENAL REPLACEMENT THERAPIES

Therapies	Abbreviation	Purpose
Continuous venovenous hemofiltration*	CVVH	Solute loss via convection; hemodilution using replacement fluid
Continuous venovenous hemodialysis*	CVVHD	Solute loss via convection and diffusion
Continuous venovenous hemodiafiltration	CVVHDF	—
Slow continuous ultrafiltration	SCUF	Fluid removal via ultrafiltration
Slow low-efficiency dialysis	SLED	—

*Most commonly used therapies.

Vascular access for CRRT is achieved through the use of a double-lumen catheter (as used in HD, noted in Figure 49-13, *A*) placed in the femoral or the jugular vein. The subclavian vein should be used only if no other access site is available, owing to the increased complication rates of pneumothorax, hemorrhage, and stenosis (Claure-Del Grando et al., 2012). Under the influence of hydrostatic pressure and osmotic pressure, water and nonprotein solutes pass out of the filter into the extracapillary space and drain through the ultrafiltrate port into a collection device (Foley bag) (Figure 49-15). The remaining fluid continues through the filter and returns to the patient via the return port of the double-lumen catheter. While the ultrafiltrate drains out of the hemofilter, fluid and electrolyte replacements can be infused into the infusion port located after the filter, as the blood returns to the patient. This fluid is designed to replace volume and solutes such as sodium, chloride, bicarbonate, and glucose. It will also further dilute intravascular fluid, decreasing the concentration of unwanted solutes such as BUN, creatinine, and potassium. The infusion

rate of replacement fluid is determined by the degree of the fluid and electrolyte imbalance. Replacement fluid may also be infused into the infusion port before the hemofilter. This method allows for greater clearance of urea and can decrease filter clotting.

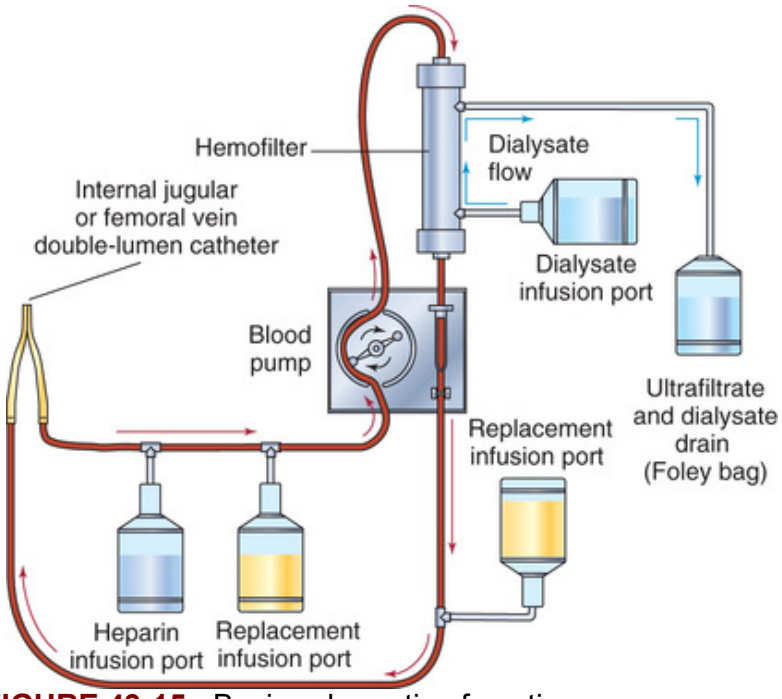

FIGURE 49-15 Basic schematic of continuous venovenous therapies. Blood pump is required to pump blood through the circuit. Replacement ports are used for continuous venovenous hemofiltration (CVVH) and continuous venovenous hemodialysis (CVVHD) only; replacements can be given prefilter or postfilter. Dialysate port is used for CVVHD only. Regardless of modality, ultrafiltrate is drained via the ultrafiltration drain port.

Anticoagulation (e.g., heparin) is needed to prevent blood clotting during CRRT. Heparin dosage is based on the patient's activated clotting time (ACT), partial prothrombin time (PPT), or prothrombin time (PT).

Several features of CRRT differ from those of HD:

1. It is continuous rather than intermittent. Large volumes of fluid can be removed over days (24 hr to >2 wk) versus hours (3 to 4 hr).
2. Solute removal can occur by convection (no dialysate required) in addition to osmosis and diffusion.
3. It causes less hemodynamic instability (e.g., hypotension).

4. It does not require constant monitoring by a specialized HD nurse but does require a trained ICU nurse.
5. It does not require complicated HD equipment, but a blood pump is needed for venovenous therapies.

The type of CRRT is customized to the needs of the patient. Some types involve the use of replacement fluids. Large volumes of fluid may be removed hourly (200–800 mL), and then a portion of this fluid is replaced. The type of fluid replacement is dependent on the stability of the patient's condition and the patient's individualized needs. Ultrafiltration and convective losses occur, and solute concentrations in the blood are diluted with the replacement fluid.

CRRT can be continued as long as 30 to 40 days, but the hemofilter should be changed every 24 to 48 hours because of loss of filtration efficiency and the potential for clotting.

The nurse responsible for the care of the patient with AKI who is receiving CRRT may be a critical care nurse or a nephrology nurse specialist, working in collaboration with other health care providers. Specific nursing interventions include obtaining weights and monitoring and documenting laboratory values daily to ensure adequate fluid and electrolyte balance. Hourly intake–output measurements and monitoring of vital signs and hemodynamic status are essential. Although reductions in central venous pressure and pulmonary artery pressure are expected, there should be little change in mean arterial pressure or cardiac output. Patency of the CRRT system is assessed and maintained, and the patient's vascular access site is cared for to prevent infection. Treatment is discontinued and the vascular access is removed once the patient's AKI is resolved or there is a decision to withdraw treatment owing to patient deterioration.

Kidney Transplantation

Major progress has been made in organ transplantation since the first kidney transplantation was performed in 1954 in Boston between identical twins. The advances made in organ procurement and preservation, surgical techniques, tissue typing and matching, understanding the immune system, immuno-suppressant therapy, and preventing and treating rejection have dramatically increased the success of organ transplantation.

The disparity between the supply and the demand for organs is significant. In Canada, over 23 000 patients received dialysis in 2012, a level that has remained virtually unchanged since 2003. Over 17 438 patients were living with a kidney transplant in 2012, almost triple the number in 1993 (CIHI, 2014). According to CIHI data, 10 641 adult patients received renal transplants between 2000 and 2009. Transplantation from a deceased donor usually requires a prolonged waiting period, with median waiting times between 2010 and 2012 of 3.9 years (CIHI, 2014). By province, the longest median wait time was in British Columbia (5.0 years), while the shortest median wait time was in Saskatchewan, at just 2.2 years (CIHI, 2014).

Kidney transplantation is extremely successful, with 1-year graft survival rates of about 93% for deceased donor transplants and greater than 97.5% for living donor transplants (CIHI, 2014). An advantage of kidney transplantation when compared with dialysis is that when normal kidney function is restored, many of the pathophysiological changes associated with renal failure are reversed. It also eliminates the dependence on dialysis and the accompanying dietary and lifestyle restrictions. Transplantation is also less expensive than dialysis after the first year.

Ethical Issues

Transplantation health care in Canada is governed by laws and statutes. It is complex and involves many people, professionals, services, functions, and levels of government. Voluntary consent must be given by the donor (Gill, Klarenbach, Barnieh, et al., 2014); in some provinces, one can provide advance written consent on a driver's licence or in a will (although permission from the donor's legal next of kin is still required after brain death is determined). In the absence of formal written consent at death, family or significant others can donate organs of the deceased if they had prior knowledge of the donor's intent. Kidneys may be obtained from deceased or living donors. It is illegal to buy or sell organs in Canada. (See the "Ethical Dilemmas" box in this chapter and in Chapter 16.)

Ethical Dilemmas

Allocation of Resources

Situation

A transplantation nurse coordinator is considering her feelings about two patients who are being evaluated for placement on the waiting list for a deceased donor kidney transplantation. One patient is a 40-year-old school teacher. She is married and has two children. The other patient is a 22-year-old unemployed man who is actively using cocaine. He misses three to four dialysis treatments per month and does not take his phosphate binders or antihypertensive drugs consistently.

Important Points for Consideration

- Psychological, physiological, and adherence factors are included in the assessment process for eligibility for organ transplantation.
- In kidney transplantation, the organ is transplanted into the patient who has received the most points based on a scoring system, regardless of the health care provider's opinion of the patient's worth. If a patient is denied transplantation candidacy on this basis, he or she must be given a chance to change or improve the problem or condition in a specified period.
- The national organ procurement system is designed to be unbiased about the patient in all respects. Once a patient is placed on the list for transplantation, that patient is deemed of no greater or lesser worth than any other patient.
- Because organ donation is voluntary in Canada, any concerns that the system of procurement and transplantation is not fair may negatively affect the pool of available organs.

Clinical Decision-Making Questions

1. What guidance is provided by the Canadian Nurses Association (CNA) *Code of Ethics for Registered Nurses* (2017) to help nurses address kidney transplantation issues?
2. What might be the nurse's feelings about which of the patients should receive the next available organ?

Recipient Selection

Appropriate recipient selection is important for a successful outcome. Candidacy is determined by a variety of medical and psychosocial factors

that vary among transplantation centres. A careful evaluation is completed in an attempt to identify and minimize potential complications after transplantation. Certain patients, particularly those with cardiovascular disease and diabetes mellitus, are considered high risk. With careful evaluation and monitoring, high-risk patients can achieve the same success rates as other patients. Some patients who are approaching ESRD can receive a transplant before dialysis is required if they have a living donor. This approach is most advantageous for patients with diabetes, who have a much higher mortality rate on dialysis than people who do not have diabetes.

Contraindications to transplantation include disseminated malignancies, refractory or untreated cardiac disease, chronic respiratory failure, extensive vascular disease, chronic infection, and unresolved psychosocial disorders (e.g., alcoholism, drug addiction) and nonadherence to medical regimens. The presence of hepatitis B or C is not a contraindication to transplantation.

Surgical procedures may be required before transplantation based on the results of the recipient evaluation. Coronary artery bypass graft surgery may be indicated for advanced coronary artery disease. Cholecystectomy may be necessary for patients with a history of gallstones, biliary obstruction, or cholecystitis. On rare occasions, bilateral nephrectomies may be done for patients with refractory hypertension, recurrent urinary tract infections, or grossly enlarged kidneys resulting from polycystic kidney disease.

Histocompatibility Studies

Histocompatibility testing is discussed in Chapter 16.

Donor Sources

Kidneys for transplantation may be obtained from compatible blood–type deceased donors, blood relatives, emotionally related living donors (e.g., spouses, friends), and altruistic living donors who are unknown to the recipient. Expanding the living donor pool is one of the best possibilities for decreasing the size of the deceased donor waiting list and reducing waiting times.

Living Donors.

Living donors must undergo an extensive multidisciplinary evaluation to be certain they are in good health and have no history of disease that

would place them at risk of developing kidney failure or operative complications. Psychosocial and financial evaluations are done as well. Crossmatches are done at the time of the evaluation and about a week before the transplantation to ensure that no antibodies to the donor are present or that the antibody titre is below the allowed level. Advantages of a living donor transplantation include better patient and graft survival rates regardless of histocompatibility match, immediate organ availability, immediate function because of minimal "cold time" (kidney out of the body and not getting blood supply), and the opportunity to have the recipient in the best possible medical condition because the surgery is elective.

The potential donor will see a nephrologist for a complete history and physical and laboratory and diagnostic studies. Laboratory studies include a 24-hour urine study for creatinine clearance and total protein, complete blood count, and chemistry and electrolyte profiles. Hepatitis B and C, HIV, and cytomegalovirus (CMV) testing are done to assess for the presence of any transmissible diseases. An ECG and chest radiography are also obtained. A renal ultrasound and a renal arteriogram or three-dimensional CT are performed to ensure that the blood vessels supplying each kidney are adequate and that there are no anomalies and to determine which kidney will be removed.

A transplantation psychologist or social worker will determine whether the individual is emotionally stable and able to deal with the issues related to organ donation. All donors must be informed about the risks and benefits of donation, the potential short- and long-term complications, and what can be expected during the hospitalization and recovery phases. Although the cost of the evaluation and surgery are covered by the recipient's insurance, there is no compensation available for lost wages during the posthospitalization recovery period. This period can last 6 weeks or longer.

Incompatibility between a potential transplant recipient and a prospective donor is a major barrier to living donor transplantations. **Paired organ donation** is another option that allows a living donor to donate a kidney to a different compatible recipient, with the intent that another donor will donate to the first donor's designated recipient (Paramesh, 2013). In 2009, the Canadian Blood Services launched a pilot project for a living donor paired exchange (LDPE) registry that is now available to every province (The Organ Registry Team [ORT] [Ottawa] & The Organ and Tissue Donation and Transplantation [OTDT] Team [Ottawa and Edmonton], 2015). The registry is designed to facilitate

transplants between recipients and living donors who have an incompatible match with other recipient donor pairs in the same situation (ORT & OTDT, 2015). The recipient–donor pairs in the LDPE registry are entered in a complex computer algorithm that identifies opportunities for transplants between them (ORT & OTDT, 2015).

Deceased Donors.

Deceased (cadaver) kidney donors are relatively healthy individuals who have suffered an irreversible brain injury with a declaration of brain death. The most common causes of injury are cerebral trauma from motor vehicle accidents or gunshot wounds, intracerebral or subarachnoid hemorrhage, and anoxic brain damage caused by cardiac arrest. The donor must have effective cardiovascular function and be supported on a ventilator to preserve the organs. The age range of most suitable kidney donors is from 2 to 70 years. The age of the donor is less important than the quality of kidney function. The donor must be free of active IV drug use; severe hypertension; longstanding diabetes mellitus; malignancies; sepsis; and communicable diseases, including HIV, hepatitis B and C, syphilis, and tuberculosis. Permission from the donor's legal next of kin is required after brain death is determined, even if the donor carried a signed donor card.

The kidneys are removed and preserved. They can be preserved for up to 72 hours, but most transplantation surgeons prefer to transplant kidneys before the cold time reaches 24 hours. Experience has shown that prolonged cold time increases the likelihood that the kidney will not function immediately and the transplant recipient will require dialysis until the ATN from the extended cold time resolves.

In Canada, patients who receive a kidney from deceased donors are selected from provincial waiting lists that use an objective computerized point system. ABO group, human lymphocyte antigen (HLA) typing, age, antibody level, and length of time waiting are entered into the computer matching program as each candidate is listed. When a donor becomes available, the donor's HLA data, ABO type, and other key information is compared with the data of all patients awaiting transplantation locally. Donors and recipients must have the same blood type. The kidney is offered to the recipient with the most points. If there are no patients in the local area who are suitable, the organ is then offered in the region, and then to the nation. When a kidney arrives at the recipient's transplantation centre, a final crossmatch is done. The final crossmatch must be negative for the deceased donor transplantation to proceed. (Crossmatching is discussed in Chapter 16.)

Surgical Procedure

Living Donor.

The donor nephrectomy is performed by a urologist or transplantation surgeon. The donor's surgery begins 1 to 2 hours before the recipient's surgery is started. The recipient is surgically prepared for the kidney transplantation in a nearby operating room.

Laparoscopic donor nephrectomy is the most common approach to removing a kidney from a living donor. (Laparoscopic nephrectomy is discussed in Chapter 48.) The laparoscopic approach significantly decreases the hospital stay, pain, operative blood loss, debilitation, and length of time off work.

For a conventional nephrectomy, the donor is placed in the lateral decubitus position on the operating table so that the flank is presented laterally. An incision is made at the level of the eleventh rib. The rib may have to be removed to provide adequate visualization of the kidney.

Kidney Transplant Recipient.

The transplanted kidney is usually placed extraperitoneally in the iliac fossa. The right iliac fossa is preferred to facilitate anastomoses and minimize the occurrence of ileus.

Before any incisions are made, a urinary catheter is placed into the bladder. An antibiotic solution is instilled to distend the bladder and decrease the risk for infection. A crescent-shaped incision is made, extending from the iliac crest to the symphysis pubis (Figure 49-16). The peritoneum is left intact. The iliac and the hypogastric vessels are dissected free.

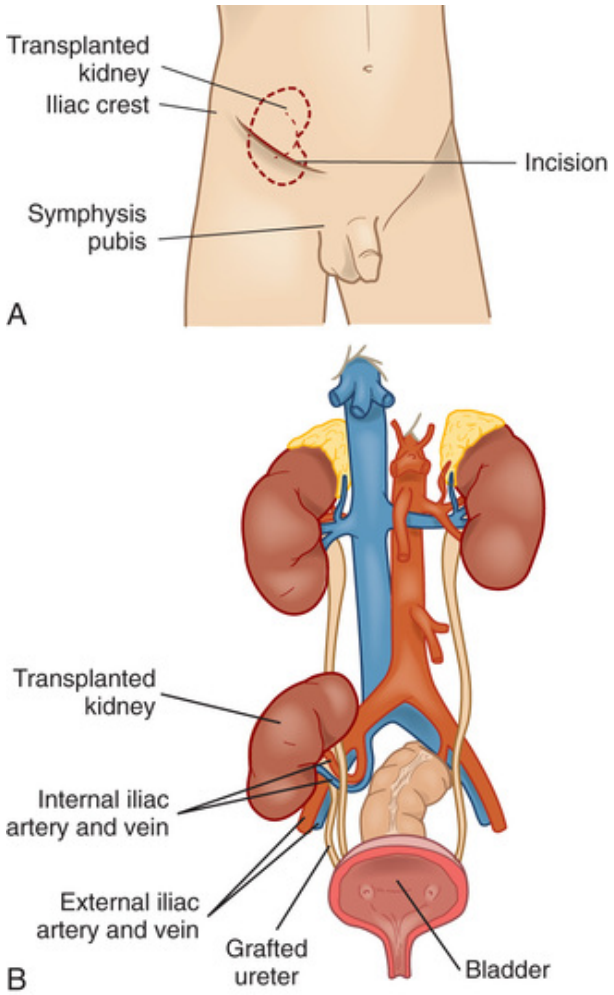

FIGURE 49-16 **A,** Surgical incision for a renal transplantation. **B,** Surgical placement of a transplanted kidney.

Rapid revascularization is critical to prevent ischemic injury to the kidney. The donor artery is anastomosed to the recipient's internal iliac (hypogastric) or external iliac artery. The donor vein is anastomosed to the recipient's external iliac vein. Kidney transplants with living donors can be technically more difficult because the blood vessel lengths can be shorter than in cadaveric transplants.

When the anastomoses are complete, the clamps are released, and blood flow to the kidney is re-established. The kidney should become firm and pink. Urine may begin to flow from the ureter immediately. Mannitol or furosemide (Lasix) may be administered to promote diuresis.

The donor ureter in most cases is then tunnelled through the bladder submucosa before entering the bladder cavity and being sutured in place. This approach is called a *ureteroneocystostomy.* This approach allows the bladder wall to compress the ureter as it contracts for micturition, thereby

preventing reflux of urine up the ureter into the transplanted kidney. The transplantation surgery takes approximately 3 to 4 hours.

Nursing Management Kidney Transplant Recipient

The successful recovery and rehabilitation of the recipient are made possible with careful nursing assessment, diagnosis, intervention, and evaluation of all body systems. With a length of hospital stay averaging 4 to 5 days, discharge planning and teaching needs must be identified and addressed early in the hospital course.

Preoperative Care

Nursing care of the patient in the preoperative phase includes emotional and physical preparation for surgery. Because the patient and the family may have been waiting years for the kidney transplantation, a review of the operative procedure and what can be expected in the immediate postoperative recovery period is necessary. It is important to stress that there is a chance the kidney may not function immediately and that dialysis may be required for days to weeks. The need for immunosuppressive drugs and measures to prevent infection must be reviewed.

To ensure the patient is in optimal physical condition for surgery, an ECG, chest radiograph, and laboratory studies are ordered. Dialysis may be required before surgery for any significant abnormality such as fluid overload or hyperkalemia. A patient on PD must empty the peritoneal cavity of all dialysate solution before going to surgery. Because dialysis may be required after transplantation, the patency of the vascular access must be maintained. The vascular access extremity should be labelled "dialysis access, no procedures" to prevent use of the affected extremity for BP measurement, blood drawing, or IV infusions.

Postoperative Care

Living Donor.

The usual postoperative care for the donor is similar to that following conventional or laparoscopic nephrectomy (see Chapter 48). Close monitoring of renal function, to assess for impairment, and of the hemoglobin, to assess for bleeding, is essential. The creatinine should be less than 124 mcmol/L, and the hemoglobin should be stable. The pain experienced by a donor who had a conventional nephrectomy is greater

than that of the donor who had a laparoscopic procedure. Generally, all donors have more pain than the recipients. Conventional donors are ready to be discharged from the hospital in 4 to 7 days and can usually return to work in 6 to 8 weeks. Laparoscopic donors are able to be discharged from the hospital in 2 to 4 days and can return to work in 4 to 6 weeks. The donor is seen by the surgeon 1 to 2 weeks after discharge.

Nurses caring for the living donor need to acknowledge the precious gift that this person has given. The donor has taken physical, emotional, and financial risks to assist the recipient. It is vital that this individual not be forgotten after surgery. The donor will need even greater support if the donated organ either does not work immediately or, for some reason, fails.

Kidney Transplant Recipient.

The first priority during this period is maintenance of fluid and electrolyte balance. In some centres, kidney transplant recipients spend the first 12 to 24 hours in the ICU because of the close monitoring required. Very large volumes of urine may be produced soon after the blood supply to the transplanted kidney is re-established. This diuresis is owing to (1) the new kidney's ability to filter BUN, which acts as an osmotic diuretic; (2) the abundance of fluids administered during the operation; and (3) initial renal tubular dysfunction, which inhibits the kidney from concentrating urine normally. Urine output during this phase may be as high as 1 L/hr and gradually decreases as the BUN and creatinine levels become more normal. Urine output is replaced, millilitre for millilitre, hourly for the first 12 to 24 hours. Central venous pressure readings are essential for monitoring postoperative fluid status. Dehydration must be prevented to prevent subsequent renal hypoperfusion and renal tubular damage. Electrolyte monitoring is critical to assess for the hyponatremia and hypokalemia often associated with rapid diuresis. Treatment with potassium supplements or 0.9% normal saline solution infusion may be indicated. IV sodium bicarbonate may also be required if the patient becomes acidotic.

ATN is becoming more common because of prolonged cold times and the use of marginal deceased donors (those who are medically suboptimal) —the ischemic damage from extended cold times causes ATN. While ATN is present, dialysis may be required to maintain fluid and electrolyte balance. If high-output ATN is present, the ability to excrete fluid is intact but not the ability to regulate metabolic wastes or electrolytes. If oliguric or anuric ATN is present, there is risk for fluid overload in the immediate

postoperative period, and the patient must be assessed closely for the need for dialysis. The period of ATN can last anywhere from days to weeks, with gradually improving kidney function. Most patients experiencing ATN will be discharged from the hospital on dialysis. This is extremely discouraging for the patient, who will need reassurance that renal function usually improves. Dialysis will be discontinued when urine output increases and kidney function begins to normalize.

A sudden decrease in urine output in the early postoperative period is a cause for concern. It may be owing to dehydration, rejection, a urine leak, or obstruction. A common cause of early obstruction is a blood clot in the urinary catheter. Catheter patency must be maintained because the catheter remains in the bladder for 3 to 5 days to allow the bladder anastomosis to heal. If blood clots are suspected, gentle catheter irrigation with an order from the health care provider can re-establish patency.

Postoperative teaching should include the prevention and treatment of rejection, infection, and complications of surgery and the purpose and adverse effects of immuno-suppression (Trevitt, Dunsmore, Murphy, et al., 2012). Frequent blood tests and clinic visits help detect rejection early. Patient education to ensure a smooth transition from hospital to home is an integral part of the nursing care.

Immuno-suppressive Therapy

The goal of immuno-suppression is to adequately suppress the immune response to prevent rejection of the transplanted kidney while maintaining sufficient immunity to prevent overwhelming infection. Immuno-suppressive therapy is discussed in Chapter 16 and in Table 16-16.

Complications of Transplantation

Rejection.

Rejection is one of the major problems following kidney transplantation. Rejection can be hyperacute or acute or chronic. (These types of rejection are discussed in Chapter 16.) Prevention and early diagnosis of rejection is essential for long-term graft function.

Infection.

Infection remains a significant cause of morbidity and mortality after transplantation (Hoffart, 2014; Trevitt et al., 2012). The transplant recipient is at risk for infection because of suppression of the body's normal defence

mechanisms by surgery, immuno-suppressive drugs, and the effects of ESRD. Underlying systemic illness such as diabetes mellitus or systemic lupus erythematosus, malnutrition, and advanced age can further compound the negative effects on the immune response. At times, the signs and symptoms of infection can be subtle. Nurses caring for transplant recipients must be astute in their observation and assessment because prompt diagnosis and treatment of infections will improve patient outcomes.

The most common infections observed in the first month after transplantation are similar to those acquired by any postoperative patient, such as pneumonia, wound infections, IV line and drain infections, and urinary tract infections. Fungal and viral infections are not uncommon because of the patient's immuno-suppressed state. Fungal infections can include *Candida, Cryptococcus, Aspergillus,* and *Pneumocystis jiroveci.* Fungal infections are difficult to treat, require prolonged treatment periods, and often involve the administration of nephrotoxic drugs. Transplant recipients usually receive prophylactic antifungal drugs to prevent these infections, such as nystatin, fluconazole (Diflucan), and sulphamethoxazole-trimethoprim.

Viral infections, including CMV, Epstein-Barr virus, herpes simplex virus (HSV), varicella-zoster virus, and polyomavirus (e.g., BK virus) can be primary or reactivation of existing disease (Hoffart, 2014; Trevitt et al., 2012). Primary infections occur as new infections after transplantation from an exogenous source such as the donated organ or blood transfusion. Reactivation occurs when a virus exists in a patient and becomes reactivated after transplantation because of immuno-suppression.

CMV is one of the most common viral infections. If a recipient has never had CMV and receives an organ from a donor with a history of CMV, antiviral prophylaxis will be administered (IV ganciclovir, valganciclovir). If a primary active CMV infection is diagnosed or there is symptomatic reactivation of CMV, IV ganciclovir will be given along with an immune globulin that contains CMV antibodies. To prevent HSV infections, oral acyclovir is given for several months after the transplantation.

Cardiovascular Disease.

Transplant recipients have an increased incidence of atherosclerotic vascular disease. Cardiovascular disease is the leading cause of death after renal transplantation (Parnham, Gleadle, Leong, et al., 2015). Hypertension, dyslipidemia, diabetes mellitus, smoking, rejection, infections, and increased homocysteine levels can all contribute to

cardiovascular disease. Immuno-suppressants can worsen hypertension and dyslipidemia. It is important that the patient be taught to control risk factors such as elevated cholesterol, triglycerides, and blood glucose and weight gain. Adherence to the prescribed antihypertensive and dyslipidemia regimen is essential not only to prevent cardiovascular events but also to prevent damage to the new kidney. (Hypertension is discussed in Chapter 35.)

Malignancies.

The overall incidence of malignancies in kidney transplant recipients is about 6%, which is 100 times greater than in the general population. The primary cause of this increased incidence is the immuno-suppressive therapy. Not only do immuno-suppressants suppress the immune system, but they also suppress the ability to fight infection and the production of abnormal cells such as cancer cells. The malignancies include cancers of the skin, lips, kidney, hepato-biliary system, vulva, and perineum; lymphomas; and Kaposi's sarcoma and other sarcomas. Regular screening for cancer is an important part of the transplant recipient's preventive care. The patient must also be advised to avoid sun exposure by using protective clothing and sunscreens to minimize the incidence of skin cancers and to check the skin regularly and report any suspicious lesions.

Recurrence of Original Renal Disease.

Recurrence of the original disease that destroyed the native kidneys occurs in some kidney transplant recipients. It is most common with certain types of glomerulo-nephritis, immunoglobulin A nephropathy, diabetes mellitus, and focal segmental sclerosis. Disease recurrence can result in the loss of a functioning kidney transplant. Patients must be advised before transplantation if they have a disease known to recur.

Corticosteroid-Related Complications.

Aseptic necrosis of the hips, the knees, and other joints can result from chronic corticosteroid therapy and renal osteodystrophy. Most transplant recipients receive calcium supplements, vitamin D, and bisphosphonates in an effort to prevent or minimize the bone disorders associated with corticosteroid use. Patient teaching should include the importance of regular bone mineral density testing, weight-bearing exercise, smoking cessation, and limiting alcohol consumption. Other significant problems related to corticosteroids include peptic ulcer disease, glucose intolerance and diabetes, cataracts, dyslipidemia, and an increased incidence of

infections and malignancies. In the first year after transplantation, corticosteroid doses are usually decreased to 5 to 10 mg a day. The use of tacrolimus and cyclosporin has allowed for the corticosteroid doses to be much lower than they were in the past. Some patients have been successfully withdrawn from corticosteroids 1.5 to 2 years after transplantation, thus eliminating these problems. Vigilant monitoring for adverse effects of corticosteroids and early treatment are essential.

Age-Related Considerations

Chronic Kidney Disease

The incidence of stage 5 CKD in Canada is increasing most rapidly in older-adult patients. At the end of 2012, 41 252 Canadians were living with stage 5 CKD. Since 2003, this number has grown 40% from 29 540. More than half (53%) of newly diagnosed patients with CKD were 65 years of age or older as compared to 33% in 1990 (CIHI, 2014). The most common diseases leading to renal failure in older adults are diabetes and hypertension. HD is the predominant RRT for older-adult patients starting dialysis. In 2012, 84% of those age 65 years or older were started with HD compared to other RRTs (CIHI, 2014). Expenditures can be expected to increase as the CKD-affected population ages and has a correspondingly greater number of comorbid conditions.

The care of the older adult with CKD is particularly challenging, not only because of the normal physiological changes of aging that occur but also because of the number of comorbid conditions that develop (Stevens, Lamb, & Levin, 2015). Physiological changes of clinical importance in the older-adult patient with CKD include diminished cardiopulmonary function, bone loss, immunodeficiency, altered protein synthesis, impaired cognition, and altered drug metabolism. Malnutrition is common in the older-adult patient with CKD for a variety of reasons, including lack of mobility, lack of understanding of basic nutritional requirements, social isolation, physical disability, impaired cognitive function, and malabsorption problems (Stevens, Lamb, & Levin, 2015).

The older-adult patient needs to consider the best option for treatment modality based on his or her health, personal preferences, and the support available. Home PD allows the patient to be more mobile and to enjoy an increased sense of control over the illness. PD causes less hemodynamic instability than HD but does require self-care or assistance from another person. The older adult may not have adequate help in the home to provide assistance. Establishing vascular access for HD may be difficult in an older-adult patient because of atherosclerotic changes. Travel to and from the HD unit may also be problematic if the patient does not drive or have access to reliable public transportation. Although transplantation is an option, older-adult patients must be carefully screened to ensure that the benefits outweigh the risks. A living donor is preferable so that there is not a prolonged waiting time.

The most common cause of death in the older-adult patient with CKD is cardiovascular disease (myocardial infarction, stroke), followed by withdrawal from dialysis. If a competent patient decides to withdraw from dialysis, it is essential to support the patient and the family. Ethical issues (see the "Ethical Dilemmas" box) to be considered in this situation include patient competency, benefit versus burden of treatment, and futility of treatment. Withdrawal from treatment is not a failure if the patient is well informed and comfortable with the decision.

The increasing number of debilitated older-adult patients with CKD receiving dialysis has raised a number of ethical concerns about the use of scarce resources in a population with a limited life expectancy. Substantial evidence exists showing success of dialysis (especially PD) in older adults. Quality of life has also been reported to be good to excellent in many older-adult patients with CKD. There appears to be no justification for excluding older adults from dialysis programs. Rationing dialysis on the basis of age alone is not supported based on current outcome and quality-of-life data.

Ethical Dilemmas

Withdrawing Treatment

Situation

A 70-year-old patient with diabetes mellitus and chronic renal failure who has been receiving dialysis for 10 years tells the nurse that he wants to discontinue his dialysis. His quality of life has diminished during the past 2 years since his wife died. He is not a prospective transplantation patient.

Important Points for Consideration

- Quality of life is an important consideration for patients when evaluating whether to begin or discontinue treatment.
- Quality-of-life decisions often weigh the benefit of treatment against the burden of treatment. When a treatment becomes too burdensome, the patient (if competent) may request to withdraw the treatment.
- A determination must be made whether there is some other treatable problem such as depression that may be clouding the patient's judgement.

- Patient autonomy, or the patient's right to self-determination regarding treatment decisions, applies to both initiating and discontinuing treatment.
- If a decision is made to withdraw treatment, the health care team, the patient, and the family should develop an appropriate follow-up plan that includes palliative care and hospice support.

Clinical Decision-Making Questions

1. How should the nurse respond to the patient's request?
2. What is the position of the Canadian Nurses Association (CNA) on withdrawing or withholding treatment that no longer benefits the patient or causes suffering?

Case Study

Chronic Kidney Disease

Source: iofoto/Shutterstock.com.

Patient Profile

Natalia Battong, a 42-year-old schoolteacher, has been treated for type 2 diabetes mellitus since the age of 25. Her nephrologist has observed her for the past several years for manifestations of progressive chronic kidney disease. Eight weeks ago, she had an arteriovenous fistula created in preparation for starting hemodialysis. Over the past week, she has experienced anorexia, nausea, vomiting, problems with concentration, and pruritus.

Subjective Data

- Complains of swelling in her feet and hands
- Has gained 4.5 kg in the past 2 weeks
- Complains of dyspnea and weakness when walking

Objective Data

Laboratory Data

- Estimated glomerular filtration rate (eGFR): 8.0 mL/min/1.73 m^2
- Serum creatinine: 560 mmol/L
- Blood urea nitrogen (BUN): 32 mmol/L
- Potassium: 6 mmol/L
- Hemoglobin: 95 g/L

Chest Radiograph

- Pulmonary edema

Discussion Questions

1. Explain the basic pathophysiological changes that resulted in the development of Mrs. Battong's diabetic nephropathy.
2. What are the indications for dialysis in this patient?
3. Identify the abnormal diagnostic study results, and explain why each would occur.
4. Explain why Mrs. Battong developed each of the clinical manifestations she shows.
5. ***Priority decision:*** What are the priority nursing interventions for Mrs. Battong and her family?
6. ***Priority decision:*** Based on the assessment data provided, what are the priority nursing diagnoses? Are there any collaborative problems?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Which of the following characterizes acute kidney injury? *(Select all that apply)*
   a. Primary cause of death is infection.
   b. An abrupt decline in kidney function with a rise in serum creatinine
   c. Disease course is potentially reversible.
   d. Cardiovascular disease is the most common cause of death
2. The RIFLE Criteria define three stages of AKI based on changes in which of the following?
   a. Blood pressure (BP) and urine osmolality
   b. Urine output and urinary creatinine
   c. Fractional excretion of urinary sodium and glomerular filtration rate (GFR)
   d. Baseline serum creatinine and urine output
3. In the oliguric phase of acute kidney injury (AKI), for which symptoms does the nurse monitor the client?
   a. Hypotension
   b. Pulmonary edema
   c. Hypernatremia
   d. Hypokalemia
4. The nurse monitors the client in the diuretic phase of AKI for which serum electrolyte imbalances?
   a. Hyperkalemia and hyponatremia
   b. Hyperkalemia and hypernatremia
   c. Hypokalemia and hyponatremia
   d. Hypokalemia and hypernatremia
5. Which systemic effect best characterizes chronic kidney disease (CKD)?
   a. Progressive irreversible damage of the kidneys
   b. Rapid decrease in urinary output with an elevated blood urea nitrogen (BUN)
   c. Progressive increase in creatinine clearance

d. Rapid rise in serum creatinine from baseline

6. Nurses need to educate clients at risk for developing CKD. Which of the following individuals are considered to be at increased risk? *(Select all that apply)*
   a. Older-adult Canadians who are Black
   b. People who are older than 60 years
   c. Clients with a history of pancreatitis
   d. Individuals who are obese
7. Clients with CKD experience an increased incidence of cardiovascular disease related to which of the following? *(Select all that apply)*
   a. Vascular calcification
   b. Genetic predisposition
   c. Hypertension
   d. Increased high-density lipoproteins
8. Clients with CKD stages 3–4 require a collaborative approach to care that focuses on delaying the progression of CKD by which of the following?
   a. Educating clients and caregivers about BP control
   b. Instructing clients to significantly restrict protein in their diet
   c. Instructing clients that radiocontrast agents are not harmful at this stage of CKD
   d. Educating clients to restrict their sodium intake to 3.5 g/day
9. Which of the following interventions should the nurse undertake to assess the patency of a newly placed arteriovenous graft for dialysis?
   a. Irrigate the graft daily with low-dose heparin.
   b. Monitor for any increase in blood pressure in the affected arm.
   c. Listen with a stethoscope over the graft for the presence of a bruit.
   d. Frequently monitor the pulses and the neuro-vascular status distal to the graft.
10. Following a kidney transplantation, which signs of rejection would the nurse include in her or his client education?
    a. Fever, weight loss, increased urinary output, increased BP
    b. Fever, weight gain, increased urinary output, increased BP
    c. Fever, weight loss, decreased urinary output, decreased BP

d. Fever, weight gain, decreased urinary output, increased BP

1. a, b, c; 2. d; 3. b; 4. c; 5. a; 6. a, b, & d; 7. a & c; 8. a; 9. c; 10. d.

CHAPTER 50

Nursing Assessment

Endocrine System

Written by, Katherine A. Kelly

Adapted by, Daphne Connolly

LEARNING OBJECTIVES

1. Describe the common characteristics and the functions of hormones.
2. Identify the locations of the endocrine glands.
3. Describe the functions of hormones secreted by the pituitary, thyroid, parathyroid, and adrenal glands and the pancreas.
4. Describe the locations and the roles of hormone receptors.
5. Identify the significant subjective and objective assessment data related to the endocrine system that should be obtained from a patient through an interview, examination, and review of the relevant documentation.
6. Identify the appropriate technique to use in the physical assessment of the thyroid gland.
7. Relate age-related changes in the endocrine system to differences in assessment findings.
8. Differentiate normal from common abnormal findings in the physical assessment of the endocrine system.
9. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the endocrine system.

KEY TERMS

aldosterone, p. 1242

antidiuretic hormone (ADH), p. 1240

catecholamines, p. 1241

corticosteroid, p. 1242

cortisol, p. 1242

glucagon, p. 1242

growth hormone (GH), p. 1239

hormone, p. 1236

insulin, p. 1242

islets of Langerhans, p. 1242

negative feedback, p. 1236

positive feedback, p. 1238

thyroxine (T_4), p. 1241

triiodothyronine (T_3), p. 1241

tropic hormones, p. 1239

The endocrine system and the nervous system are two of the primary communicating and coordinating systems in the body. The nervous system communicates through nerve impulses; the endocrine system communicates through chemical substances known as *hormones,* and it plays a role in reproduction, growth and development, and regulation of energy. The endocrine glands include the hypothalamus, pituitary gland, thyroid, parathyroids, adrenal glands, pancreas, ovaries, testes, and pineal gland (Figure 50-1). The pineal gland secretes melatonin and is involved in regulation of gonadal function and development, as well as chronobiological rhythms (Ben-Moshe, Foulkes, & Gothilf, 2014). In addition to the endocrine glands, other body organs secrete hormones. For example, the kidneys secrete erythropoietin, the heart secretes atrial natriuretic peptide, and the gastro-intestinal tract secretes numerous peptide hormones (e.g., gastrin). These hormones are discussed in their respective assessment chapters.

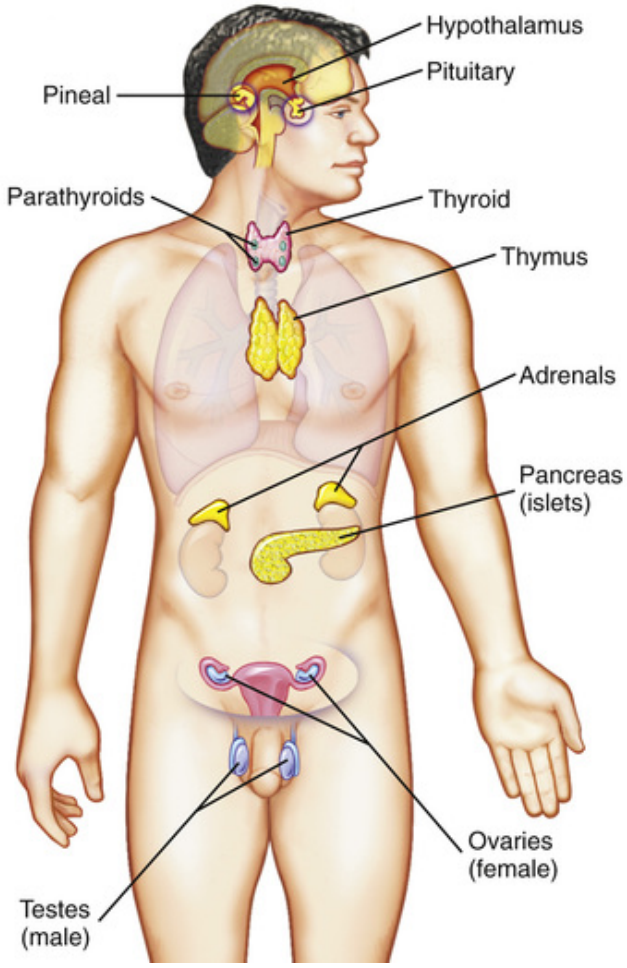

FIGURE 50-1 Location of the major endocrine glands. The parathyroid glands lie on the posterior surface of the thyroid. Source: Modified from Patton, K. T., & Thibodeau, G. A. (2013). *Anatomy and physiology*. (8th ed., p. 564, Figure 25-2). St Louis: Mosby.

Structures and Functions of the Endocrine System

Glands

The organs of the endocrine system are referred to as *glands.* Endocrine glands produce chemical substances called *hormones* and secrete them into the blood, by which they eventually affect specific target tissues. A *target tissue* is the body tissue or organ on which the hormone has its effect. For example, the thyroid (the gland) synthesizes thyroxine (the hormone), which influences all body tissues (target tissue). It is important to note that not all glands in the body belong to the endocrine system. There are two types of glands: *Exocrine glands* secrete their substances into ducts that then empty into a body cavity or onto a surface (e.g., skin). For example, salivary glands produce saliva, which is secreted through salivary ducts into the mouth. *Endocrine glands,* in contrast, secrete their substances directly into the blood, not into ducts.

Hormones

Classifications and Functions.

A **hormone** is a chemical substance synthesized and secreted by a specific organ or tissue. Most hormones have common characteristics, including (a) secretion in small amounts at variable but predictable rates, (b) circulation through the blood, and (c) binding to specific cellular receptors either in the cell membrane or within the cell.

Hormones are classified by their chemical structure: *lipid-soluble hormones* and *water-soluble* (protein-based) *hormones.* Lipid-soluble hormones include steroid hormones (all hormones produced by the adrenal cortex and the sex glands) and thyroid hormones. All other hormones are water soluble (Ojeda & Kovacs, 2012). The differences in solubility are important for understanding how the hormone interacts with the target cell.

Hormones control a number of physiological activities. Important hormonal functions are related to reproduction, response to stress and injury, electrolyte balance, energy metabolism, growth, maturation, and aging. Hormones also play a role in the function of the nervous system. Some hormones have a regulatory effect on nervous tissue. For example,

catecholamines are hormones when they are secreted by the adrenal medulla, but they act as neurotransmitters when secreted by nerve cells in the brain and the peripheral nervous system. When epinephrine travels through the blood, it is a hormone and affects target tissues. When it travels across synaptic junctions, it acts as a neurotransmitter (Barnes, Carson, & Nair, 2015). Hormones can also influence behaviour. For example, excess growth hormone, cortisol, and parathyroid hormone can cause mood swings. Depression has been associated with adrenal insufficiency and hypothyroidism. Table 50-1 summarizes the major hormones, glands, or tissues from which they are synthesized, target organs or tissues, and functions.

TABLE 50-1
MAJOR ENDOCRINE GLANDS AND HORMONES

Hormones	Target Tissue	Functions
Anterior Pituitary (Adenohypophysis)		
Growth hormone (GH) or somatotropin	All body cells	Promotes protein anabolism (growth, tissue repair) and lipid mobilization and catabolism
Thyroid-stimulating hormone (TSH) or thyrotropin	Thyroid gland	Stimulates synthesis and release of thyroid hormones, growth and function of thyroid gland
Adrenocorticotrophic hormone (ACTH)	Adrenal cortex	Fosters growth of adrenal cortex; stimulates secretion of corticosteroids
Gonadotropic hormones • Follicle-stimulating hormone (FSH) • Luteinizing hormone (LH)*	Reproductive organs	Stimulates sex hormone secretion, reproductive organ growth, reproductive processes
Melanocyte-stimulating hormone (MSH)	Melanocytes in skin	Increases melanin production in melanocytes to make skin darker in colour
Prolactin	Ovary and mammary glands in girls and women	Stimulates milk production in lactating women; increases response of follicles to LH and FSH.
	Testes in men	Stimulates testicular function in men.
Posterior Pituitary (Neurohypophysis)		
Oxytocin	Uterus; mammary glands	Stimulates milk secretion, uterine contractility
Antidiuretic hormone (ADH; vasopressin)	Renal tubules, vascular smooth muscle	Promotes reabsorption of water, vasoconstriction
Thyroid		
Thyroxine (T_4)	All body tissues	Precursor to T_3
Triiodothyronine (T_3)	All body tissues	Regulates metabolic rate of all cells and processes of cell growth and tissue differentiation
Calcitonin	Bone tissue	Regulates calcium and phosphorus blood levels; decreases serum Ca^{2+} levels
Parathyroids		
Parathyroid hormone (PTH), or parathormone	Bone, intestine, kidney tissues	Regulates calcium and phosphorus blood levels; promotes bone demineralization and increases intestinal absorption of Ca^{2+}; increases serum Ca^{2+} levels
Adrenal Medulla		
Epinephrine (adrenaline)	Sympathetic effectors	Increases in response to stress; enhances and prolongs effects of sympathetic nervous system
Norepinephrine (noradrenaline)	Sympathetic effectors	Increases in response to stress; enhances and prolongs effects of sympathetic nervous system
Adrenal Cortex		
Corticosteroids (e.g., cortisol, hydrocortisone)	All body tissues	Promotes metabolism, response to stress; anti-inflammatory
Androgens (e.g., DHEA androsterone) and estradiol	Reproductive organs	Promotes masculinization in men, growth and sexual activity in women
Mineralocorticoids (e.g., aldosterone)	Kidney	Regulates sodium and potassium balance and thus water balance
Pancreas (Islets of Langerhans)		

Hormones	Target Tissue	Functions
Insulin (from beta cells)	General	Promotes movement of glucose out of blood and into cells
Amylin (from beta cells)	Liver, stomach	Decreases gastric motility, glucagon secretion, and endogenous glucose release from liver; increases satiety
Glucagon (from alpha cells)	General	Stimulates glycogenolysis and gluconeogenesis
Somatostatin	Pancreas	Inhibits insulin and glucagon secretion
Pancreatic polypeptide	General	Influences regulation of pancreatic exocrine function and metabolism of absorbed nutrients
Gonads		
Women: Ovaries		
Estrogen	Reproductive system, breasts	Stimulates development of secondary sex characteristics, preparation of uterus for fertilization, and fetal development; stimulates bone growth
Progesterone	Reproductive system	Maintains lining of uterus necessary for successful pregnancy
Men: Testes		
Testosterone	Reproductive system	Stimulates development of secondary sex characteristics, spermatogenesis

*In men, sometimes referred to as interstitial cell-stimulating hormone (ICSH).

DHEA, dehydroepiandrosterone.

Hormone Transport.

Hormones are carried by the blood to other sites in the body where their actions are exerted. Some hormones (e.g., steroids and thyroid hormones) are not water soluble. Therefore, these types of hormones are bound to plasma proteins for transport in the blood. Although hormones are inactive when bound to plasma proteins, they can be released when appropriate and immediately exert their action at the target tissue. Water-soluble hormones (e.g., protein hormones, catecholamines) circulate freely in the blood and are not dependent on proteins for transport.

Targets and Receptors.

As mentioned, hormones exert their effects on target tissue. The hormone recognizes the target tissue by attaching to receptors (the site that interacts with the hormone) in the cell membrane (e.g., protein-type hormone receptors) or within cells of the target tissue (e.g., thyroid and steroid hormone receptors). The specificity of hormone–target cell interaction is determined by receptors in a "lock-and-key" type of mechanism. Thus, a hormone acts only on cells that have a receptor specific for that hormone (Figure 50-2). The location of the receptor sites affects the mechanism of action for the hormone.

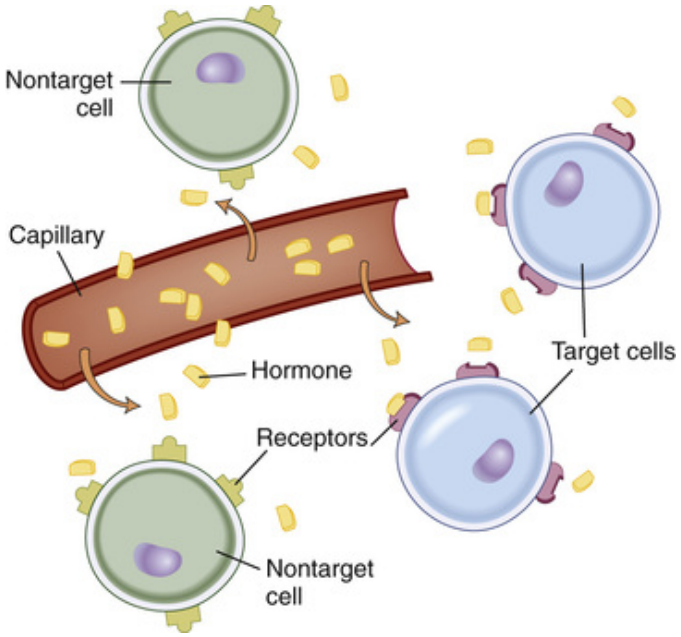

FIGURE 50-2 The target cell concept. Hormones act only on cells that have receptors specific to that hormone because the shape of the receptor determines which hormone can react with it. This is an example of the lock-and-key model of biochemical reactions.

Protein Hormone Receptors.

Protein hormone action is a two-step process. The receptor is located in the target cell membrane; thus the hormone itself acts as a "first messenger." The hormone–receptor interaction stimulates the production of a "second messenger" such as cyclic adenosine monophosphate (cAMP). cAMP works by activating enzymes to regulate intracellular activity (Figure 50-3).

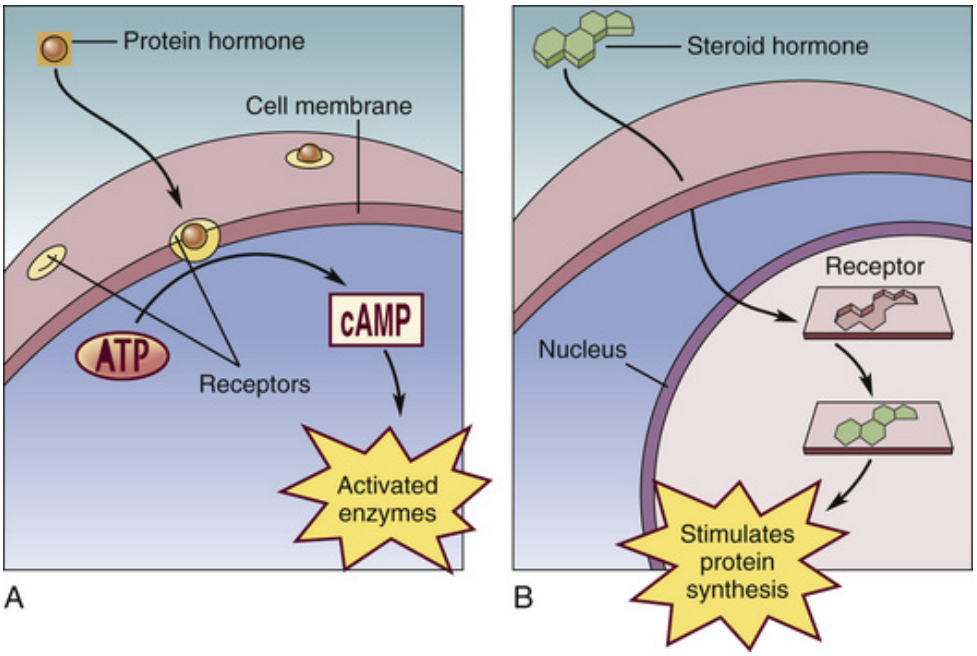

FIGURE 50-3 Actions of protein and steroid hormones. **A,** Protein hormones bind to receptors located on the surface of the cell membrane. The hormone–receptor interaction stimulates the formation of cyclic adenosine monophosphate (cAMP), thereby activating various cell processes. Source: Herlihy, B. (2014). *The human body in health and illness*. (5th ed., p. 261, Figure 14-2 B & C). St. Louis: Elsevier Saunders.

Steroid Hormone Receptors.

Steroid and thyroid hormone receptors are located inside the cell. Because these hormones are lipid soluble, they pass through the target cell membrane by passive diffusion and bind to receptor sites located in the cytoplasm or nucleus of the target cell (Molina, 2013). Intracellular hormone–receptor complexes, such as those observed in steroid hormone action, bind to specific sites on DNA to stimulate or inhibit the synthesis of messenger RNA. When new messenger RNA is synthesized, it migrates to the cytoplasm, where it stimulates the synthesis of new protein. These new proteins produce specific effects in the target cell (see Figure 50-3).

Regulation of Hormonal Secretion.

Endocrine activity is regulated by specific mechanisms of varying levels of complexity. These mechanisms stimulate or inhibit hormone synthesis and secretion and include simple feedback, complex feedback, nervous system control, and physiological rhythms.

Simple Feedback.

The regulation of hormone levels in the blood depends on a highly specialized mechanism called *feedback.* Feedback is based on the blood level of a particular substance. The substance may be a hormone or another chemical compound regulated by, or responsive to, a hormone. In **negative feedback,** the most common type of feedback system, the gland responds by increasing or decreasing the secretion of a hormone on the basis of feedback from various factors (Molina, 2013). Negative feedback is similar to the functioning of a thermostat in which cold air in a room activates the thermostat to release heat and hot air turns off the thermostat to prevent more hot air from entering the room.

The pattern of insulin secretion is a physiological example of negative feedback between glucose and insulin. Elevated blood glucose levels stimulate the secretion of insulin from the pancreas. As blood glucose levels decrease, the stimulus for insulin secretion also decreases. The homeostatic mechanism is considered negative feedback because it reverses the change in blood glucose level. Another example of negative feedback is the relationship between calcium and parathyroid hormone (PTH). Low blood levels of calcium stimulate the parathyroid gland to release PTH, which acts on bone, the intestine, and the kidneys to increase blood calcium levels. The increased blood calcium levels then inhibit further PTH release (Figure 50-4).

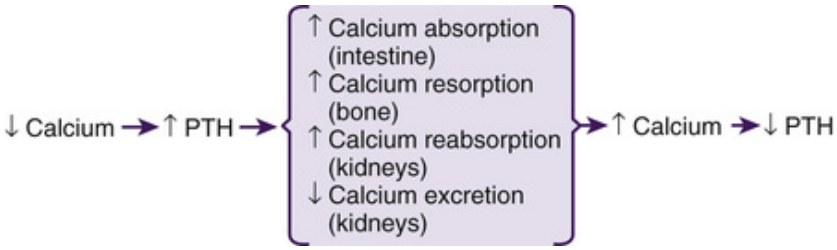

FIGURE 50-4 Feedback mechanism between parathyroid hormone (PTH) and calcium.

Positive feedback is a second method of regulation of hormone secretion. The positive feedback mechanism increases the target organ action beyond normal. The action of oxytocin during childbirth is an example. The hormone oxytocin from the posterior pituitary gland stimulates and increases uterine contractions. The release of oxytocin is stimulated by pressure receptors in the vagina. As the fetus enters the vagina during childbirth, the pressure receptors sense increased pressure

and signal the brain to release more oxytocin. Oxytocin release leads to stronger uterine contractions. When birth is finished, the stimulus to the pressure receptors in the vagina ends, and thus oxytocin secretion decreases.

Nervous System Control.

In addition to chemical regulation, some endocrine glands are directly affected by the activity of the nervous system. Pain, emotion, sexual excitement, and stress can stimulate the nervous system to modulate hormone secretion. Neural involvement is initiated by the central nervous system and implemented by the sympathetic nervous system. For example, stress is sensed by the central nervous system, and the sympathetic nervous system secretes catecholamines that increase heart rate and blood pressure to deal with stress more effectively. (Effects of stress are discussed further in Chapter 8.)

Rhythms.

Another regulatory mechanism affecting many hormonal secretions involves the rhythms of secretions. These rhythms originate in brain structures. A common physiological rhythm is the *circadian rhythm,* in which a hormone level fluctuates predictably during a 24-hour period (Markova-Car, Jurišić, Ilić, et al., 2014). These rhythms may be related to sleep–wake or dark–light cycles. For example, in a person who sleeps at night, the cortisol level rises early in the day, declines toward evening, and rises again toward the end of sleep to peak by morning (Figure 50-5). Secretion of growth hormone and prolactin peaks during sleep. Thyroid-stimulating hormone (TSH) secretion is also maximal during sleep and ebbs 3 hours after a person awakens in the morning. The menstrual cycle is an example of a body rhythm that is longer than 24 hours *(infradian).* These rhythms must be considered when hormone levels on laboratory results are interpreted. (See the Diagnostic Studies of the Endocrine System section in this chapter and additional diagnostic studies sections in Chapter 51.)

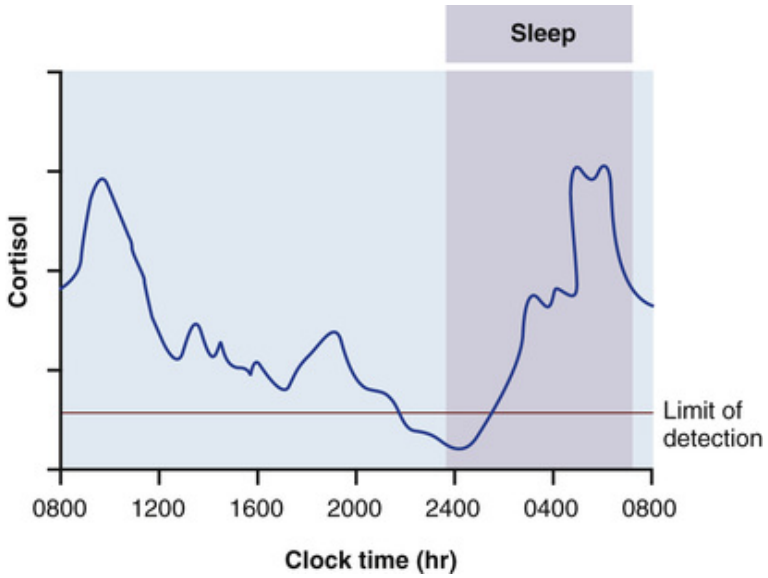

FIGURE 50-5 Circadian rhythm of cortisol secretion.

Hypothalamus

The relationship between the hypothalamus and the pituitary gland is one of the most important aspects of the endocrine system. Although the pituitary gland has been referred to as the "master gland," most of its functions rely on an interrelationship with the hypothalamus. The hypothalamus and the pituitary gland integrate communication between the nervous and endocrine systems. Thus, neuroendocrinology is the study of the interactions between these two systems (McEwen, Gray, & Nasca, 2015). The hypothalamus is located in the most central part of the diencephalon area of the brain (see Figure 50-1). Although it is part of the brain, the hypothalamus secretes many hormones. Two important groups of hormones from the hypothalamus are releasing hormones and inhibiting hormones (Molina, 2013). The function of these hormones is to either stimulate (release) or inhibit the secretion of hormones from the anterior pituitary (Table 50-2).

TABLE 50-2
HORMONES OF THE HYPOTHALAMUS

The following hormones from the hypothalamus target the anterior pituitary.
Releasing Hormones
• Corticotropin-releasing hormone (CRH) • Gonadotropin-releasing hormone (GnRH) • Growth hormone–releasing factor (GHRH), or somatotropin-releasing hormone • Prolactin-releasing hormone (PRF) • Thyrotropin-releasing hormone (TRH)
Inhibiting Hormones
• Prolactin-inhibiting hormone (PIH) • Somatostatin (inhibits growth hormone release)

The hypothalamus also contains neurons, which receive input from the brain stem and limbic system. These neurons influence the limbic system, brain stem, and spinal cord. This creates a circuit to facilitate the coordination of the endocrine system, the autonomic nervous system, and the expression of complex behavioural responses, such as anger and feelings of fear and pleasure.

Pituitary Gland

The pituitary gland *(hypophysis)* is very small: about the size of a pea. It is located in the sella turcica, under the hypothalamus, at the base of the brain above the sphenoid bone (see Figure 50-1). The pituitary gland is connected to the hypothalamus by the infundibular *(hypophyseal)* stalk. This stalk serves as a communication mechanism between the hypothalamus and the pituitary gland. The pituitary gland consists of two parts, the *anterior* lobe *(adenohypophysis)* and the *posterior* lobe *(neurohypophysis).* Hormones secreted from each of these pituitary lobes serve very different functions.

Anterior Pituitary Gland.

The anterior lobe accounts for 80% of the gland by weight. As mentioned previously, the anterior pituitary is regulated by the hypothalamus through releasing and inhibiting hormones. These hypothalamic hormones reach the anterior pituitary through a network of capillaries known as the *hypothalamus–hypophyseal portal system.* The releasing and inhibiting hormones in turn affect the secretion of six hormones from the anterior pituitary gland (Figure 50-6; see Table 50-2).

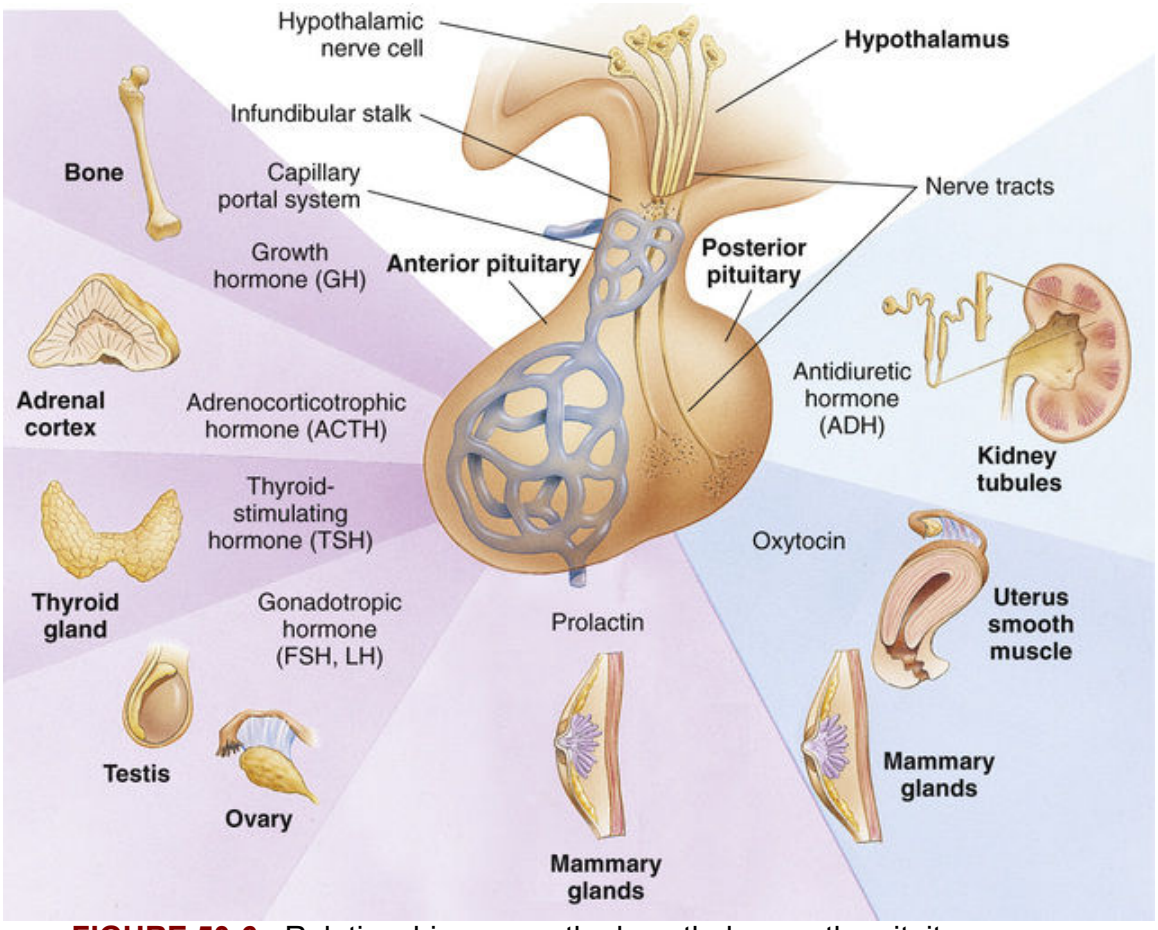

FIGURE 50-6 Relationship among the hypothalamus, the pituitary, and the target organs. The hypothalamus communicates with the anterior pituitary via a capillary system and with the posterior pituitary via nerve tracts. The anterior and posterior pituitary hormones are shown with their target tissues. *FSH,* follicle-stimulating hormone; *LH,* luteinizing hormone. Source: Adapted from Patton, K. T., Thibodeau, G. A., & Douglas, M. M. (2012). *Essentials of anatomy & physiology* (p. 332, Figure 15-8). St. Louis: Elsevier Mosby.

Tropic Hormones.

Several hormones secreted by the anterior pituitary gland are referred to as **tropic hormones.** These hormones control the secretion of hormones by other glands. TSH stimulates the thyroid gland to secrete thyroid hormones. Adrenocorticotrophic hormone (ACTH) stimulates the adrenal cortex to secrete corticosteroids. Follicle-stimulating hormone stimulates secretion of estrogen and the development of ova in the female and sperm in the male. Luteinizing hormone stimulates ovulation in girls and women and secretion of sex hormones in both sexes.

Growth Hormone.

Growth hormone (GH) has effects on all body tissue. GH, as its name suggests, affects the growth and development of skeletal muscles and long bones, thereby affecting a person's size and height. It also has numerous biological actions, including a role in the metabolism of protein, fat, and carbohydrate (Molina, 2013).

Prolactin.

Prolactin is a hormone that stimulates the breast development necessary for lactation after childbirth. Prolactin is also referred to as *lactogenic hormone.*

Posterior Pituitary Gland.

The posterior pituitary is composed of nerve tissue and is essentially an extension of the hypothalamus. The communication between the hypothalamus and the posterior pituitary gland occurs through nerve tracts known as the *median eminence.* The hormones secreted by the posterior pituitary gland—antidiuretic hormone and oxytocin—are actually produced in the hypothalamus. These hormones travel down the nerve tracts from the hypothalamus to the posterior pituitary gland and are stored until their release is triggered by the appropriate stimuli (see Figure 50-6).

Antidiuretic Hormone.

The major physiological role of **antidiuretic hormone (ADH)**—also called *vasopressin*—is regulation of fluid volume by stimulating reabsorption of water in the renal tubules. ADH is also a potent vasoconstrictor.

The most important stimulus of ADH secretion is *plasma osmolality,* a measure of solute concentration of circulating blood (Figure 50-7). Plasma osmolality increases when there is a decrease in extracellular fluid or an increase in solute concentration. The increased plasma osmolality activates osmoreceptors, which are extremely sensitive, specialized neurons in the hypothalamus. These activated osmoreceptors stimulate ADH release (Molina, 2013). Table 50-3 lists factors that affect ADH release. When ADH is released, the renal tubules reabsorb water, causing urine to be more concentrated. When ADH release is inhibited, renal tubules do not reabsorb water, causing urine to be more dilute.

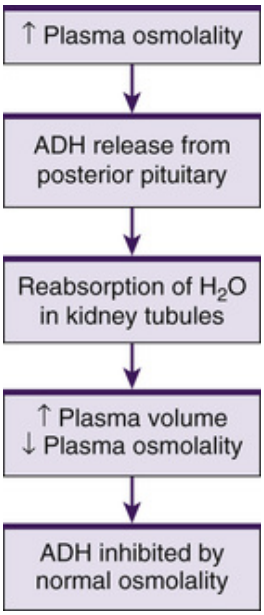

FIGURE 50-7 Relationship of plasma osmolality to antidiuretic hormone (ADH) release and action.

TABLE 50-3
FACTORS AFFECTING RELEASE OF ANTIDIURETIC HORMONE

Stimulate Release	Inhibit Release
• Decreased fluid volume • Hypotension • Increased plasma osmolality • Nausea and vomiting • Pain	• β-Adrenergic agonists • Alcohol • Decreased plasma osmolality • Increased fluid volume

Oxytocin.

Oxytocin stimulates both ejection of milk into mammary ducts and contraction of uterine smooth muscle. Oxytocin secretion is increased by stimulation of touch receptors in the nipples of lactating women and of vaginal pressure receptors.

Pineal Gland.

The pineal gland is located in the brain and is composed of photoreceptive cells. The secretion of the hormone melatonin is its primary function. Melatonin secretion is increased in response to exposure to the dark and decreased in response to light. The gland helps to regulate circadian rhythms and the reproductive system at the onset of puberty.

Thyroid Gland

The thyroid gland is located in the anterior portion of the neck, in front of the trachea. It consists of two encapsulated lateral lobes connected by a narrow isthmus (Figure 50-8). The thyroid is a highly vascular organ and is regulated by TSH from the anterior pituitary. The three hormones produced and secreted by the thyroid gland are thyroxine, triiodothyronine, and calcitonin.

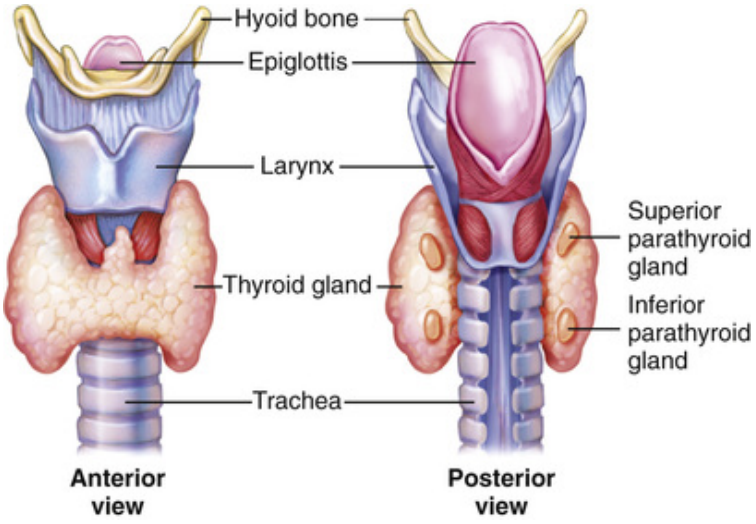

FIGURE 50-8 Thyroid and parathyroid glands. Note the surrounding structures. Source: Thibodeau, G. A., & Patton, K. T. (2010). *The human body in health and disease* (5th ed., p. 321, Figure 11-7). St. Louis: Mosby.

Thyroxine and Triiodothyronine.

The major function of the thyroid gland is the production, storage, and release of the thyroid hormones: **thyroxine (T_4)** and **triiodothyronine (T_3).** T_4 is by far the most abundant thyroid hormone, accounting for 90% of thyroid hormone produced by the thyroid gland. T_3, however, is much more potent and has greater metabolic effects. About 20% of circulating T_3 is secreted directly by the thyroid gland, and the remainder is obtained by peripheral conversion of T_4 (Molina, 2013). Iodine is necessary for the synthesis of thyroid hormones. T_4 and T_3 affect metabolic rate, caloric requirements, oxygen consumption, carbohydrate and lipid metabolism, growth and development, brain function, and nervous system activity. More than 99% of thyroid hormones are bound to plasma proteins,

especially T_4-binding globulin synthesized by the liver. Only the unbound "free" hormones are biologically active.

Thyroid hormone production and release is stimulated by TSH from the anterior pituitary gland. When circulating levels of thyroid hormone are low, the hypothalamus releases thyrotropin-releasing hormone (TRH), which in turn causes the anterior pituitary gland to release TSH. High levels of circulating thyroid hormone have an inhibitory effect on the secretion of both TRH from the hypothalamus and TSH from the anterior pituitary gland (Molina, 2013).

Calcitonin.

Calcitonin is a hormone produced by C cells (parafollicular cells) of the thyroid gland in response to high circulating calcium levels. Calcitonin inhibits calcium resorption (loss of substance) from bone, increases calcium storage in bone, and increases renal excretion of calcium and phosphorus, thereby lowering serum calcium levels. Although it provides a counter-mechanism to PTH, calcitonin does not play a critical role in calcium balance (Molina, 2013).

Parathyroid Glands

The parathyroid glands are small, oval structures usually arranged in pairs behind each thyroid lobe (see Figure 50-8). Most people have four such glands. The major cell type of the glands is epithelial, and the glands are richly supplied with blood from the inferior and superior thyroid arteries.

Parathyroid Hormone.

The parathyroids secrete parathyroid hormone (PTH) (also called *parathormone*). Its major role is to regulate the blood level of calcium. PTH acts on bone, the kidneys, and indirectly, the gastro-intestinal tract. In bone, PTH stimulates bone resorption and inhibits bone formation, which results in the release of calcium and phosphate into the blood. In the kidneys, PTH increases calcium reabsorption and phosphate excretion. In addition, PTH stimulates the renal conversion of vitamin D to its most active form (1,25-dihydroxyvitamin D_3). This active form then enhances the intestinal absorption of calcium.

The secretion of PTH is directly regulated by a feedback system (see Figure 50-4) and is not under pituitary and hypothalamic control. When the serum calcium level is low, PTH secretion increases; when the serum

calcium level rises, PTH secretion falls. In addition, high levels of active vitamin D inhibit PTH secretion, and low levels of magnesium stimulate PTH secretion.

Adrenal Glands

The adrenal glands are small, paired, highly vascularized glands located on the upper portion of each kidney. Each gland consists of two parts: the medulla and the cortex (Figure 50-9). Each part has distinct functions, and the glands act independently of one another.

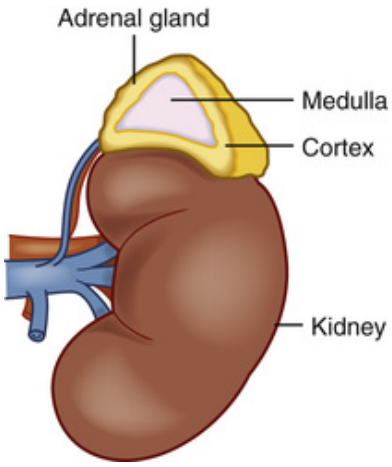

FIGURE 50-9 The adrenal gland is composed of the adrenal cortex and the adrenal medulla.

Adrenal Medulla.

The adrenal medulla is the inner part of the gland and consists of sympathetic postganglionic neurons. The medulla secretes the catecholamines *epinephrine* (adrenalin), *norepinephrine* (noradrenaline), and *dopamine*. **Catecholamines,** usually considered neurotransmitters, are hormones when secreted by the adrenal medulla because they are released into the circulation and transported to their target organs. Catecholamines exert their effects after binding to adrenergic receptors on cells, and they have widespread effects on all body systems. Catecholamines are an essential part of the body's response to stress (see Chapter 8).

Adrenal Cortex.

The adrenal cortex is the outer part of the adrenal gland. It secretes more than 50 steroid hormones, which are classified as *glucocorticoids, mineralocorticoids,* and *androgens*. Cholesterol is the precursor for steroid hormone synthesis. Glucocorticoids (e.g., cortisol) are named for their effects on glucose metabolism. Mineralocorticoids (e.g., aldosterone) are essential for the maintenance of fluid and electrolyte balance. Adrenal androgens are produced and secreted in small but significant amounts. The term **corticosteroid** refers to any of the hormones synthesized by the adrenal cortex (excluding androgens).

Cortisol.

Cortisol, the most abundant and potent glucocorticoid, is necessary to maintain life. One major function of cortisol is the regulation of blood glucose concentration. Cortisol increases blood glucose through stimulation of hepatic gluconeogenesis (conversion of amino acids to glucose) and inhibiting protein synthesis (Molina, 2013). Cortisol also decreases peripheral glucose use in the fasting state.

Another major effect of glucocorticoids is their anti-inflammatory action and supportive actions in response to stress. A marked increase in the rate of cortisol secretion by the adrenal cortex aids the body in coping more effectively with stressful situations (see Chapter 8). Cortisol decreases the inflammatory response by stabilizing the membranes of cellular lysosomes and preventing increased capillary permeability. The lysosomal stabilization reduces the release of proteolytic enzymes and thereby limits their destructive effect on surrounding tissue. Cortisol can also inhibit production of prostaglandins, thromboxanes, and leukotrienes and alter the cell-mediated immune response.

Cortisol helps maintain vascular integrity and fluid volume. It has a mineralocorticoid effect because it can bind to mineralocorticoid receptors.

Cortisol is secreted in a diurnal pattern (see Figure 50-5). The major control of cortisol is by means of a negative feedback mechanism that involves the secretion of corticotropin-releasing hormone from the hypothalamus. This hormone stimulates the secretion of ACTH by the anterior pituitary. Cortisol levels are also increased by surgical stress, burns, infection, fever, psychoses, acute anxiety, and hypoglycemia.

Aldosterone.

Aldosterone is a potent mineralocorticoid that maintains extracellular fluid volume. It acts at the renal tubule to promote renal reabsorption of sodium and excretion of potassium and hydrogen ions. Aldosterone

synthesis and secretion are stimulated by angiotensin II, hyponatremia, and hyperkalemia and inhibited by atrial natriuretic peptide and hypokalemia.

Adrenal Androgens.

The third class of steroids synthesized and secreted by the adrenal cortex are the androgens. Normally, the adrenal cortex secretes small amounts of androgens. Adrenal androgens stimulate pubic and axillary hair growth and sex drive in women. In girls and women, androgens are converted to estrogen in the peripheral tissues. In postmenopausal women, the major source of estrogen is from the peripheral conversion of adrenal androgen to estrogen. The effects of adrenal androgen in men are negligible in comparison with testosterone secreted by the testes.

Pancreas

The pancreas is a long, tapered, lobular, soft gland located behind the stomach and anterior to the first and second lumbar vertebrae. The pancreas has both exocrine and endocrine functions. The hormone-secreting portion of the pancreas is referred to as the **islets of Langerhans.** The islets account for less than 2% of the gland and consist of four types of hormone-secreting cells: α, β, delta, and F cells. α Cells produce and secrete the hormone glucagon. Insulin and amylin are produced and secreted by β cells. Somatostatin is produced and secreted by the delta cells. Pancreatic polypeptide is secreted by the F (or PP) cells.

Glucagon.

Glucagon is synthesized and released from pancreatic α cells in response to low levels of blood glucose, to protein ingestion, and to exercise. Glucagon increases blood glucose levels by stimulating glycogenolysis, gluconeogenesis, and ketogenesis. Usually, glucagon and insulin function in a reciprocal manner to maintain normal blood glucose levels. The exception is after ingestion of a high-protein, carbohydrate-free diet, in which case both hormones are secreted. In this instance, glucagon counteracts the inhibitory effect of insulin on gluconeogenesis, and normal blood glucose levels are maintained.

Insulin.

Insulin is the principal regulator of the metabolism and storage of ingested carbohydrates, fats, and proteins. Insulin facilitates glucose transport across cell membranes in most tissues. However, the brain, nerves, lens of the eye, hepatocytes, erythrocytes, and cells in the intestinal mucosa and kidney tubules are not dependent on insulin for glucose uptake. An increased blood glucose level is the major stimulus for insulin synthesis and secretion. Other stimuli to insulin secretion are increased amino acid levels and vagal stimulation. Insulin secretion is usually inhibited by low blood glucose levels and by glucagon, somatostatin, hypokalemia, and catecholamines (Table 50-4).

TABLE 50-4
FACTORS INFLUENCING SECRETION OF INSULIN

Stimulate Secretion	Inhibit Secretion
↑ Glucose levels	↓ Glucose levels
↑ Amino acid levels	↓ Amino acid levels
↑ Gastro-intestinal hormone levels	↓ Potassium levels
↑ Vagal stimulation	↑ Corticosteroid hormone levels
↑ Fats	↑ Catecholamine levels
	↑ Somatostatin levels
	↑ Glucagon levels (usually)
	↑ Insulin levels

A major effect of insulin on glucose metabolism occurs in the liver, where the hormone enhances glucose incorporation into glycogen and triglycerides by altering enzymatic activity and inhibiting gluconeogenesis. Another major effect occurs in peripheral tissues, where insulin facilitates glucose transport into cells, transport of amino acids across muscle membranes and their synthesis into protein, and transport of triglycerides into adipose tissue. Thus, insulin is a storage, or *anabolic,* hormone.

The endocrine system functions to regulate body processes and maintain internal homeostasis despite vastly changing substrates, as is observed in glucose homeostasis after food ingestion. After a meal, insulin is responsible for the storage of nutrients *(anabolism).* In the fasting state (during which ingested glucose is not readily available), hormones such as catecholamines, cortisol, and glucagon break down stored complex fuels *(catabolism)* to provide simple glucose as fuel for energy.

Age-Related Considerations

The Endocrine System

Normal aging has many effects on the endocrine system (Table 50-5). These include (a) decreased hormone production and secretion, (b) altered hormone metabolism and biological activity, (c) decreased responsiveness of target tissues to hormones, and (d) alterations in circadian rhythms.

TABLE 50-5

AGE-RELATED DIFFERENCES IN ASSESSMENT
Endocrine System

Changes	Clinical Significance
Thyroid	
Atrophy of thyroid gland; decrease in TSH and T_3 secretion; increased nodules	Increased incidence of hypothyroidism with aging; however, most older adults maintain adequate thyroid function. Thyroid hormone replacement dose lower in older adults.
Parathyroid	
Increased secretion of PTH and increased basal level of PTH	Increased calcium resorption from bone (demineralization); hypercalcemia, hypercalciuria (may reflect defective renal mechanism)
Adrenal Cortex	
Adrenal cortex: more fibrotic and slightly smaller Decreased metabolism of cortisol Decreased plasma levels of adrenal androgens and aldosterone	Decreased metabolic clearance rate for glucocorticoids
Adrenal Medulla	
Increased secretion and basal level of norepinephrine. No change in plasma epinephrine levels.	Decreased responsiveness to β-adrenergic agonists and receptor blockers
Decreased β-adrenergic receptor response to norepinephrine	May partly explain increased incidence of hypertension with aging
Pancreas	
Increase in fibrosis and fatty deposits in pancreas. Increased glucose intolerance and decreased sensitivity to insulin.	May partly contribute to increased incidence of diabetes mellitus with advanced aging
Gonads	
Women: decline in estrogen secretion Men: decline in testosterone secretion	Women experience symptoms associated with menopause and have increased risk for atherosclerosis and osteoporosis Men may or may not experience symptoms

PTH, parathyroid hormone; *T_3,* triiodothyronine; *T_4,* thyroxine; *TSH,* thyroid-stimulating hormone.

Assessment of the effects of aging on the endocrine system is difficult because the subtle changes of aging often mimic manifestations of endocrine disorders. Some endocrine changes associated with aging are obvious; others are subtle. The nurse must be aware that endocrine problems may manifest differently in an older adult than in a younger

person. Older adults may have multiple comorbid conditions and take multiple medications that alter the body's usual response to endocrine dysfunction. Symptoms of endocrine dysfunction such as fatigue, constipation, or mental impairment in older adults are often missed because they are attributed solely to aging. It is important that the nurse consider age-related endocrine changes when assessing an older adult (Saxon, Etten, & Perkins, 2014).

Assessment of the Endocrine System

Hormones affect every body tissue and system, causing great diversity in the signs and symptoms of endocrine dysfunction. Therefore, assessment of the endocrine system is often difficult, and keen clinical skills are required to detect manifestations of disorders. Endocrine dysfunction may result from deficient or excessive hormone secretion, transport abnormalities, an inability of the target tissue to respond to a hormone, or inappropriate stimulation of the target-tissue receptor.

Endocrine disorders may have specific or nonspecific (vague) clinical manifestations. When signs and symptoms are specific, such as the classic "polys" (polyuria, polydipsia, and polyphagia) in diabetes mellitus, the assessment is easier; nonspecific signs and symptoms, such as tachycardia, palpitations, fatigue, or altered mood, are more problematic. Nonspecific changes should alert the health care provider to the possibility of an endocrine disorder. The most common nonspecific symptoms, fatigue and depression, often are accompanied by other manifestations such as changes in energy level, alertness, sleep patterns, mood, affect, weight, skin, hair, personal appearance, and sexual function.

Subjective Data

The lack of clear-cut manifestations of endocrine problems necessitates a conscientious and detailed health history. A thorough health history yields data to help sort out possible causes and the effect of the problem on the person's life (Table 50-6).

TABLE 50-6

HEALTH HISTORY
Endocrine System: Questions for Obtaining Subjective Data

Past History
• Do you have any previous or current problems with your endocrine system (e.g., problems with thyroid, diabetes, changes in facial or body hair)? • Have you had any previous hospitalizations, surgical procedures, or treatments for endocrine problems? • Are you currently taking or have you ever taken medications for an endocrine problem such as a thyroid disorder or diabetes?
Family History
• Is there any family history of diabetes mellitus or insipidus; hyperthyroidism or hypothyroidism; goitre; hypertension or hypotension; obesity; infertility; growth problems; pheochromocytoma (neoplastic tumour of the adrenal medulla or sympathetic ganglia); autoimmune diseases (e.g., Addison's disease); or adrenal hyperplasia? • Have any other members of your family ever had a problem similar to your problem today?
Review of Systems
Overall Health Status
• How do you feel generally? Have you had any changes recently to your health? • Have there been any changes in your appetite or weight?* • Have you noticed any changes in your ability to perform your usual activities in comparison with last year? Five years ago?* • Do you experience fatigue with or without activity?*
Eyes, Ears, Nose, Mouth, and Throat
• Have you experienced any blurring or double vision?* When was your last eye examination? • Have you noticed any difficulty swallowing?* • Are your shirts harder to button at the neck?
Cardiovascular System
• Do you experience heart palpitations?*
Musculo-Skeletal System
• Do you have difficulty holding things because of shakiness of your hands?*
Gastro-Intestinal System
• Describe your usual bowel pattern. Have you noted any bowel changes?* • Do you use anything, such as laxatives, to help you move your bowels?*
Genito-Urinary System
• Do you have to get up at night to urinate? If so, how many times? Do you keep water by your bed at night? • Have you ever had a kidney stone?*
Neurological System
• Do you feel more nervous than you used to? Do you notice your heart pounding or that you sweat at times when you do not think you should be sweating? • How is your memory? Have you noticed any changes? • How long can you concentrate on any one thing? Has this changed lately?
Endocrine System
• Do you feel that most rooms are too hot or too cold? Do you frequently have to put on a sweater, or do you feel as though you need to open windows when others in the room seem comfortable?*
Integumentary System
• Have you noticed any changes in the distribution of the hair anywhere on your body?* • Have you noticed any changes in the colour of your skin, particularly on your face, neck, hands, or body creases?* • Has the texture of your skin changed? For example, does it seem thicker and drier than it used to?*
Sexual and Reproductive History
Women
• When did you start to menstruate? Was this earlier or later than other women in your family? If you still menstruate, do you have scant, heavy, or irregular menstrual flows? • How many children have you had? How much did they weigh at birth? Were you told you had diabetes during any pregnancy?* • Were you able to nurse your children if you wanted to?

• Are you menopausal? If so, for how long? • Are you attempting to get pregnant but cannot?* Are you in treatment to become pregnant? * Are you using birth control? * • Are you postmenopausal? If so, do you have any vaginal bleeding?
Men
• Have you noticed any changes in your ability to have an erection?* • Are you trying to have children but cannot?*
Functional Assessment (Including Activities of Daily Living)
Activity and Mobility
• Do you have a planned exercise program? If yes, what is it, and have you had to make any changes in this routine lately? If so, why and what kinds of changes?
Sleep and Rest
• How many hours do you sleep at night? Do you feel rested on awakening? • Are you ever awakened by sweating during the night?* • Do you have nightmares?* • Does anyone in your family complain about your snoring?*
Nutrition and Elimination
• What is your weight and height? • How much do you want to weigh? • Have there been any changes in your appetite or weight?*
Interpersonal Relationships
• Are you in a relationship? Are you able to take care of any significant others that need your assistance? Are you able to take care of your home? If not, why not?
Coping and Stress Management
• What kind of stressors do you have? • How do you deal with stress or problems? • What is your support system? To whom do you turn when you have a problem? • Do you feel sad or uninterested in life?*
Occupational Health
• Where do you work? What kind of work do you do? Are you able to do what is expected of you and what you expect of yourself? • If you are retired, what do you do with your time? What did you do before you retired? • If you are unemployed, are you looking for work?
Self-Care and Health Promotion Activities
• Women: Have you had a mammogram or Pap smear recently? • Men: Have you had a prostate examination recently? • Both: If so, what were the results and dates of these tests? How often do you have these tests?

*If yes, describe.

Important Health Information

Past Health History.

During an assessment, the patient should be questioned about the general state of health and whether any changes in it have occurred. In addition, the patient or significant other should be specifically questioned about previous or current endocrine abnormalities and abnormal patterns of growth and development.

Case Study

Patient Introduction

Source: aastock/Shutterstock.com.

Lydia Mollon is a 35-yr-old woman who comes to the clinic complaining of "just not feeling well." She is accompanied by her partner, Holly. She states that she has gained a lot of weight despite trying to watch her diet and just seems to be getting more and more tired. Holly voices concerns about changes in her partner's energy level.

Critical Thinking

Throughout this assessment chapter, think about Ms. Mollon's concerns with the following questions in mind:

1. What are the possible causes of Ms. Mollon's weight gain, fatigue, and irritability?
2. What would be the priority assessment of Ms. Mollon?
3. What questions should be asked of Ms. Mollon?
4. What should be included in the physical assessment? What should be looked for?
5. What diagnostic studies should be ordered?

Ms. Mollon and her condition will be followed throughout this assessment chapter. See below and pp. 1247 and 1254 for more information on Ms. Mollon.

Family History.

Heredity can play a major role in the occurrence of endocrine problems. The patient should be questioned about conditions in family members such as diabetes mellitus or insipidus; hyperthyroidism or hypothyroidism; or goiter (see Table 50-6 for more examples). Such questioning frequently elicits information about a familial tendency.

Medications.

The patient should be questioned about the use of all medications (both prescription and over-the-counter drugs) and the use of herbs and dietary supplements. The patient should be asked the reason for taking the drug, the dosage, and the length of time taken. The patient should specifically be asked about the use of hormone replacements. Information that the patient is currently taking hormone replacements such as insulin, thyroid hormone, or corticosteroids (e.g., prednisone) helps direct the nurse in regard to possible problems associated with the use of these agents. For example, corticosteroids may cause glucose intolerance in susceptible patients by increasing glycogenolysis and insulin resistance. The adverse effects of many nonhormone medications can contribute to problems affecting endocrine function. For example, many drugs can affect blood glucose levels.

Surgery and Other Treatments.

The nurse should inquire about previous hospitalizations, surgery, chemotherapy, and radiation therapy (especially irradiation of the neck). Surgery of the brain or a severe blow to the head could have resulted in pituitary or hypothalamic alterations.

Objective Data

Most endocrine glands are inaccessible for direct examination. With the exception of the thyroid and the male gonads, the glands are deeply encased in the body, protected against injury and trauma. However, assessment can be accomplished with a variety of objective data. The nurse must understand the actions of hormones so that by monitoring the target tissue, he or she can assess the function of a gland.

Case Study

Subjective Data

Source: aastock/Shutterstock.com.

A focused subjective assessment of Lydia Mollon revealed the following information.

Past Medical History: Denies any medical or surgical history. Has not seen a health care provider (HCP) for 8 years.

Medications: None.

Overall Health Management: Ms. Mollon works as a receptionist for a local law firm and states it is all she can do some days to make it through the workday.

Functional Assessment

Sleep and Rest: Ms. Mollon states that she frequently wakes up with a headache and goes to bed with the same headache, describing it as a dull, throbbing ache between her eyes. She sleeps 10+ hr at night but does not feel rested on awakening.

She definitely does not have the energy she had 5 yr ago or even 6 mo ago. She used to enjoy gardening and going out with their friends but now can barely manage work and coming home.

Ms. Mollon states that she has no ambition to exercise. She is just too tired at the end of the workday and has no energy on the weekends either. She also complains of leg cramps with walking.

Nutrition, Elimination and Metabolic History: Ms. Mollon reports a steady weight gain over the past 6 mo, mainly in her abdominal area. She feels as if she looks pregnant but knows that is not possible. Her appetite has actually decreased but she has not been able to lose any weight. She says she feels "bloated." She also complains of facial hair growth and has noticed that she bruises easily. Whenever she gets a bug bite, it seems to take forever to heal. Ms. Mollon denies difficulty with swallowing, hoarseness, palpitations, or tremors. She also denies any changes or difficulty with urination or bowel movements.

Coping and Stress Management: Ms. Mollon is worried she is going crazy. She finds herself easily angered and irritable, frequently snapping at co-workers and her partner. She states this is not her usual self and she at first thought it was because she was dealing with a constant, dull headache.

Lately, she has noticed that her vision is blurry and that is making work and life even more difficult and stressful. When asked about her headache, she states it hurts between her eyes. She rates the pain as a 4 on a scale of 0 to 10 and states that acetaminophen or ibuprofen does not alleviate the pain. The pain is typically worse on arising in the morning and slowly decreases during the day.

Ms. Mollon hates the way she looks. She says when she looks in the mirror, she can't believe what she sees. She feels as if she has aged 10 yr over the past 6 mo and has gained weight in her face, neck, and trunk. She is concerned that her scalp hair is thinning and she is growing a beard. She states that she is beginning to wonder if she is "turning into a man!"

Ms. Mollon states that she is finding it more and more difficult to cope with the stresses of her job, her relationship with her partner, and life in general. She believes her emotions are very "raw and labile," totally different from the easy-going, smiling person she had once prided herself in being.

See pp. 1247 and 1254 for more information on Ms. Mollon.

Physical Examination.

The nurse must remember that the endocrine system affects every body system. Clinical manifestations of endocrine function vary significantly, depending on the gland involved. Specific clinical findings for the various endocrine problems are discussed in Chapters 51 and 52. Regardless of the type of endocrine dysfunction, the following general examination procedure should be followed.

Vital Signs.

All vital signs are measured at the beginning of the examination. Variations in temperature may be associated with thyroid dysfunction. Cardiovascular changes such as tachycardia, bradycardia, hypotension, or hypertension may occur with a variety of endocrine-related problems.

Height and Weight.

Assessment of the endocrine system includes a history of growth and development patterns, weight distribution and changes, and comparisons of these factors with normal findings. Growth pattern abnormalities are suggestive of problems associated with growth hormone. Changes in weight also may be associated with endocrine dysfunction. Thyroid disorders and diabetes mellitus are examples of endocrine disorders that can affect body weight. Body mass index is a height-to-weight ratio used to assess nutritional status (see Chapter 43, Figure 43-1).

It may also be helpful to compare the patient's current body weight to the usual body weight in order to assess changes. Weight change (percentage) is calculated by subtracting the current body weight from the usual weight, dividing by the usual body weight, and multiplying by 100.

Mental–Emotional Status.

Throughout the examination, the patient's orientation, alertness, memory, affect, personality, anxiety, appropriateness of dress, and speech pattern should be assessed objectively. Endocrine disorders can commonly cause changes in mental and emotional status.

Integument.

The nurse should note the colour and the texture of skin, hair, and nails. The overall skin colour should be noted, as should pigmentation, and any ecchymosis should be documented. Hyperpigmentation, or "bronzing," of the skin (particularly on knuckles, elbows, knees, genitalia, and palmar creases) is a classic finding in Addison's disease but also is present with ACTH-producing tumours and acromegaly (Jarvis, Browne, MacDonald-Jenkins, et al., 2014). The nurse should palpate the skin for texture and presence of moisture. The nurse should also examine the hair distribution, not only on the head but also on the face, the trunk, and the extremities. The appearance and texture of the hair should be examined. Dull, brittle hair; excessive hair growth; or hair loss may indicate endocrine dysfunction.

Head.

The size and contour of the head are inspected. Facial features should be symmetrical. Inspect the eyes for position, symmetry, shape, movement, opacity over the lens, eyelid lag, and edema. Visual acuity should also be checked because changes may be associated with a pituitary tumour or diabetic retinopathy. In the mouth, the buccal mucosa, the condition of the teeth (malocclusion and mottling), and tongue size should be inspected,

and fasciculations (localized, uncoordinated, uncontrollable twitching of a single muscle group) documented.

Neck.

When inspecting the thyroid gland, the nurse should make observations first in the normal position (preferably with side lighting), then with the patient's neck in slight extension, and then as the patient swallows some water. The trachea should be midline, and the neck should appear symmetrical. Any unusual bulging over the thyroid area should be noted. If enlargement of the thyroid gland is not noticeable, palpation can be performed. (Because palpation can trigger the release of thyroid hormones, palpation should be deferred in patients with a visibly enlarged thyroid gland.) When the thyroid is enlarged, the lateral lobes should be auscultated with the stethoscope bell to determine the presence of a bruit.

The thyroid gland is difficult to palpate. Thyroid palpation requires considerable practice, as well as validation by a more experienced examiner. Water should always be available for the patient to swallow as part of this examination. There are two acceptable approaches to thyroid palpation: anterior and posterior. For *anterior palpation,* the nurse stands in front of the patient, with the patient's neck flexed (Figure 50-10, *B*). The nurse places a thumb horizontally with the upper edge along the lower border of the patient's cricoid cartilage. The thumb is then moved over the isthmus as the patient swallows water. The fingers are then placed laterally to the anterior border of the sternocleidomastoid muscle, and each lateral lobe is palpated before and while the patient swallows water.

FIGURE 50-10 Palpation of the thyroid gland. **A,** Posterior approach. **B,** Anterior approach. Source: Wilson, S., & Giddens, J. F. (2013). *Health assessment for nursing practice* (5th ed., p. 177, Figure 19-53). St. Louis: Mosby Elsevier.

For *posterior palpation,* the nurse stands behind the patient (Figure 50-10, *A*). With the thumbs of both hands resting on the nape of the patient's neck, the nurse uses the index and middle fingers of both hands to feel for the thyroid isthmus and for the anterior surfaces of the lateral lobes. To facilitate the examination of each lobe and to relax the neck muscles, the nurse asks the patient to flex the neck slightly forward and to the right. The thyroid cartilage is displaced to the right by the nurse's left hand and fingers. The nurse palpates with the right hand after placing the thumb deep and behind the sternocleidomastoid muscle with the index and middle fingers in front of it; the area is palpated with the right hand (Figure 50-10). While this is done, the patient is asked to swallow water. This procedure is repeated on the left side. The thyroid is palpated for its size, shape, symmetry, and tenderness and for any nodules.

The thyroid is often not palpable. If palpable, it usually feels smooth, with a firm consistency, and is not tender with gentle pressure. Nodules, enlargement, asymmetry, or hardness is abnormal, and the patient should be referred for further evaluation.

Thorax.

The thorax should be inspected for shape and characteristics of the skin. The presence of gynecomastia in men should be noted. The nurse auscultates lung sounds and heart sounds, noting the presence of adventitious lung sounds or extra heart sounds.

Case Study

Objective Data: Physical Examination

Source: aastock/Shutterstock.com.

A focused assessment of Lydia Mollon reveals the following:

Ms. Mollon is sitting on the edge of the examination table. She appears somewhat anxious. Her BP is 190/80, heart rate 84, respiratory rate 20, temp 37°C. Her weight is 82.6 kg, and she is 160 cm tall.

Ms. Mollon's face is reddened and puffy, and she appears to have a lump on the back of her neck and shoulders. She has some acne on her face, along with some hair growth on her upper lip and chin area. Her abdomen is protruding but her arms and legs are thin. She has +1 edema in her ankles bilaterally. There are several ecchymotic areas on her upper and lower extremities, as well as purple stretch marks on her abdomen.

Throughout this chapter, consider which diagnostic studies would likely be performed for Ms. Mollon.

See pp. 1245 and 1254 for more information on Ms. Mollon.

Abdomen.

No abdominal examination findings are specific for endocrine dysfunction other than skin characteristics and hyperactive or hypoactive bowel sounds.

Extremities.

The nurse assesses the size, shape, symmetry, and general proportion of hands and feet. The skin is inspected for changes in pigmentation and presence of lesions and edema. Muscle strength is evaluated, as are deep tendon reflexes. In the upper extremities, the nurse assesses for the

presence of tremors by placing a piece of paper in the patient's outstretched fingers, palm down.

Genitalia.

The nurse inspects the hair distribution pattern. A diamond pubic hair distribution pattern in women or a triangular pattern in men are abnormal findings and might indicate endocrine dysfunction. For men, the testes should be palpated; for women, any clitoral enlargement should be noted.

Common assessment abnormalities related to the endocrine system are presented in Table 50-7. A focused assessment is used to evaluate the status of previously identified endocrine problems and to monitor for signs of new problems (see Chapter 3, Table 3-6). A focused assessment of the endocrine system is described in the "Focused Assessment" box at right.

TABLE 50-7

ASSESSMENT ABNORMALITIES
Endocrine System

Finding	Description	Possible Etiology and Significance
Integument		
Hyperpigmentation	Darkening of the skin, particularly in creases and skinfolds	Addison's disease, caused by increased secretion of melanocyte-stimulating hormone
Depigmentation (vitiligo)	Patchy areas of light skin	May be a marker of autoimmune endocrine disorders
Striae	Purplish-red marks below the skin surface, usually observed on abdomen, breasts, and buttocks (see Chapter 51, Figure 51-11)	Cushing's syndrome
Changes in skin texture	Thick, cold, dry skin	Hypothyroidism
	Thick, leathery, oily skin	Growth hormone excess (acromegaly)
	Warm, smooth, moist skin	Hyperthyroidism
Changes in hair distribution	Hair loss	Hypothyroidism, hyperthyroidism, decreased pituitary secretion
	Diminished axillary and pubic hair	Cortisol deficiency
	Hirsutism (excessive facial hair on women)	Cushing's syndrome, prolactinoma (a pituitary tumour)
Skin ulceration	Areas of ulcerated skin, most commonly observed on legs and feet	Peripheral neuropathy and peripheral vascular disease, which are contributory factors in the development of diabetic foot ulcers
Edema	Generalized edema	Mucopolysaccharide accumulation in tissue in hypothyroidism
Head and Neck		
Visual changes	Decreased visual acuity or decreased peripheral vision	Pituitary gland enlargement or tumour, which leads to pressure on optic nerve
Exophthalmos	Protrusion of eyeballs from orbits	Hyperthyroidism; results from fluid accumulation in eye and retro-orbital tissue
Moon facies	Periorbital edema and facial fullness	Increased cortisol secretion as a result of Cushing's syndrome
Myxedema	Puffiness, periorbital edema, masklike affect	Infiltration of dermis by hydrophilic mucopolysaccharides in hypothyroidism
Goitre	Generalized enlargement of thyroid gland	Hyperthyroidism, hypothyroidism, iodine deficiency
Thyroid nodule (one or more)	Localized enlargement of thyroid gland	May be benign or malignant
Cardiovascular		
Chest pain	Angina caused by increased metabolic demands	Hyperthyroidism, hypothyroidism
Dysrhythmias	Tachycardia, atrial fibrillation	Hypothyroidism or hyperthyroidism, hypoparathyroidism or hyperparathyroidism, pheochromocytoma
Hypertension	Elevation in blood pressure caused by increased metabolic demands and catecholamines	Hyperthyroidism, pheochromocytoma, Cushing's syndrome
Musculo-Skeletal		
Changes in muscular strength or muscle mass	Generalized weakness, fatigue, or both	Common symptoms associated with many endocrine problems, including pituitary, thyroid, parathyroid, and adrenal dysfunction; diabetes mellitus; diabetes insipidus
	Decreased muscle mass	Specifically observed in growth hormone deficiency and in Cushing's syndrome secondary to protein wasting

Finding	Description	Possible Etiology and Significance
Enlargement of bones and cartilage	Coarsening of facial features; increases in size of hands and feet over a period of several years	Growth hormone excess in adults, as in acromegaly
Nutrition		
Changes in weight	Weight loss	Hyperthyroidism; caused by increases in metabolism, diabetic ketoacidosis
Altered glucose levels	Weight gain	Hypothyroidism, Cushing's syndrome, type 2 diabetes mellitus
	Increased serum glucose level	Diabetes mellitus, Cushing's syndrome, growth hormone excess
Neurological		
Lethargy	State of mental sluggishness or somnolence	Hypothyroidism
Tetany	Intermittent involuntary muscle spasms, usually involving the extremities	Severe calcium deficiency that can occur with hypoparathyroidism
Seizure	Sudden involuntary contraction of muscles	Consequence of a pituitary tumour; fluid and electrolyte imbalance associated with excessive ADH secretion; complications of diabetes mellitus; severe hypothyroidism
Increased deep tendon reflexes	Hyper-reflexia	Hyperthyroidism, hypoparathyroidism
Gastro-Intestinal		
Constipation	Passage of infrequent, hard stools	Hyperthyroidism or calcium imbalances caused by hyperparathyroidism
Reproductive		
Changes in reproductive function	Menstrual irregularities, decreased libido, decreased fertility, erectile dysfunction	Various endocrine abnormalities, including pituitary hypofunction, growth hormone excess, thyroid dysfunction, and adrenocortical dysfunction
Other		
Polyuria	Excessive urinary output	Diabetes mellitus (secondary to hyperglycemia) or diabetes insipidus (associated with decreased ADH secretion)
Polydipsia	Excessive thirst	Extreme water losses in diabetes mellitus (with severe hyperglycemia) or diabetes insipidus (associated with decreased ADH)
Decreased urine output	ADH leading to reabsorption of water from kidney tubules	Syndrome of inappropriate antidiuretic hormone (SIADH)
Thermoregulation	Cold sensitivity Heat intolerance	Hypothyroidism caused by a slowing of metabolic processes Hyperthyroidism caused by excessive metabolism

ADH, antidiuretic hormone.

Focused Assessment

Endocrine System

Use this checklist to ensure the key assessment steps have been performed.

Subjective

Ask the patient about experiencing any of the following, and note responses.

Excessive or increased thirst	Y	N
Excessive or decreased urination	Y	N
Excessive hunger	Y	N
Intolerance of heat or cold	Y	N
Excessive sweating	Y	N
Recent weight gain or loss	Y	N

Objective: Diagnostic

Check the following laboratory results for critical values

Potassium level	✓
Glucose level	✓
Sodium level	✓
Glycosylated hemoglobin (A_{1C}) level	✓
Thyroid studies: TSH, (T_3, and T_4 levels [if ordered])	✓

Objective: Physical Examination

Inspect/Measure

Body temperature	✓
Height and weight	✓
Alertness and emotional state	✓
Skin, for changes in colour and texture	✓
Hair, for changes in colour, texture, and distribution	✓

Auscultate

Heart rate, blood pressure	✓

Palpate

Extremities, for edema	✓
Skin, for texture and temperature	✓
Neck, for thyroid size, shape	✓

TSH, thyroid-stimulating hormone; *T_3,* triiodothyronine; *T_4,* thyroxine.

Diagnostic Studies of the Endocrine System

Accurately performed laboratory tests and radiological examinations contribute to the diagnosis of an endocrine problem. Laboratory tests usually involve blood and urine testing. Ultrasonography may be used as a screening tool to localize endocrine growths such as thyroid nodules. Radiological tests include regular radiography, computed tomography, and magnetic resonance imaging. For all diagnostic testing, the nurse is responsible for explaining the procedure to the patient and family. Diagnostic studies common to the endocrine system are described in Table 50-8.

TABLE 50-8

DIAGNOSTIC STUDIES
Endocrine System

Study	Description and Purpose	Normal Values	Nursing Responsibility
Pituitary Studies			
Blood Studies			
Growth hormone (GH) (somatotropin)	Evaluation of GH secretion Used to identify GH deficiency or excess; GH levels are affected by time of day, food intake, and stress	Male: <5 mcg/L Female: <10 mcg/L	Make sure that patient has been fasting and has not recently been emotionally or physically stressed. Indicate patient fasting status and recent activity level on the laboratory slip. Send blood sample to laboratory immediately.
Somatomedin C (insulin-like growth factor [IGF-1])	Evaluation of GH secretion Provides an accurate reflection of mean plasma concentration of GH because it is not subject to circadian rhythm and fluctuations	5.5–14.4 nmol/L Low levels indicate GH deficiency; high levels indicate GH excess	Note if patient has fasted overnight, as overnight fasting is preferred.
Growth hormone (GH) stimulation	Needed to adequately diagnose GH deficiency Measurement of GH secretion in response to stimulation (insulin, arginine) For insulin, baseline blood levels for GH, glucose, and cortisol are obtained; insulin is then administered IV; blood samples for GH are obtained at 0, 60, and 90 min after insulin is administered; blood glucose levels are monitored at 15- to 30-min intervals; blood glucose should drop to less than 2.2 mmol/L for effective test results, and GH level should rise two-fold to three-fold over baseline levels Response is subnormal or absent in GH deficiency	Growth hormone levels >10 mcg/L	Ensure that patient or family understands this procedure. Patient must be on NPO status after midnight. Water is permitted on morning of the test. IV access is established for administration of medications and frequent blood sampling. Continually assess for hypoglycemia and hypotension. After test, provide a sweet snack or IV glucose infusion as physician orders.
Gonadotropins • Follicle-stimulating hormone (FSH) • Luteinizing hormone (LH)	Useful in distinguishing primary gonadal problems from pituitary insufficiency Normal levels vary according to age and sex Levels are low in pituitary insufficiency and high in primary gonadal failure	*FSH* Male: <22 IU/L Female: • Follicular phase: <20 IU/L • Ovulatory peak: <40 IU/L • Luteal phase: <20 IU/L • Postmenopause levels: 40–160 IU/L *LH*	There is no special preparation of the patient. Note on the laboratory slip time of menstrual cycle or whether female patient is postmenopausal.

Study	Description and Purpose	Normal Values	Nursing Responsibility
		Male: 1–9 IU/L Female: • Follicular phase: 1–18 IU/L • Ovulatory peak: 20–80 IU/L • Luteal phase: 0.5–18 IU/L • Postmenopause levels: 12–55 IU/L	
Water deprivation (restriction) (ADH stimulation)	Used to differentiate causes of polyuria, including neurogenic DI, nephrogenic DI, and psychogenic polydipsia ADH or vasopressin is administered subcutaneously	Neurogenic DI: >9% increase in urine osmolality Nephrogenic DI: <9% increase in urine osmolality Psychogenic polydipsia: <9% increase in osmolality	Caution: Severe dehydration may occur with neurogenic or nephrogenic DI during this test. Test lasts 6 hr, usually from 0600 to 1200 hours. Obtain baseline weight and urine and plasma osmolality. Send hourly samples for measuring urine osmolality. Discontinue test and rehydrate if patient's weight drops more than 2 kg at any time. Rehydrate with oral fluids. Check orthostatic BP and pulse after rehydration to ensure adequate fluid volume.
Prolactin level	Diagnose and monitor prolactin-secreting pituitary adenomas	Male: <20 mcg/L Female: • Nonlactating: <25 mcg/L • Pregnant: 20–400 mcg/L Levels above normal reflect potential pituitary tumour; levels below may be pituitary apoplexy	Draw blood within 3–4 hr after patient awakens. Specimen must be sent to the laboratory immediately. If there is a delay, the specimen is placed in water and crushed ice.
Radiology			
Magnetic resonance imaging (MRI)	Most common uses are visualization of the CNS, bony spine, joints, extremities, and breasts	—	Inform patient of the need to lie as still as possible during the test; explain that tests are painless and noninvasive.
Computed tomographic (CT) scan with contrast media	Used to detect presence and size of tumour Oral or IV contrast medium (or both) may be used	—	Inform patient of the need to lie still during the procedure. If IV contrast medium is to be used, check for iodine allergy before test.
Thyroid Studies			

Study	Description and Purpose	Normal Values	Nursing Responsibility
Blood Studies			
Thyroid-stimulating hormone (TSH)	Measurement of TSH levels Considered the most sensitive method for evaluating thyroid disease Generally recommended as first diagnostic test for thyroid dysfunction	2–10 mIU/L	Explain blood collection procedure to patient. No specific preparations are necessary.
Thyroxine (T_4), total	Measurement of total serum level of T_4 Useful in evaluating thyroid function and monitoring thyroid therapy	Male: 51–154 nmol/L Female: 64–154 nmol/L	Same as for TSH measurement.
Triiodothyronine (T_3)	Measurement of serum levels of T_3 Helpful in diagnosing hyperthyroidism if T_4 levels are normal	Adult: 1.7–5.2 pmol/L	Same as for TSH measurement.
Free T_4	Measurement of active component of total T_4 Because level remains constant, this is considered better indication of thyroid function than total T_4	10–36 pmol/L	Same as for TSH measurement.
T_3 uptake (T_3RU)	Indirect measurement of binding capacity of thyroid-binding globulin	24%–34% uptake	Same as for TSH measurement.
Thyroid antibodies (Ab) • Thyroid peroxidase (TPO) Ab • Thyroglobulin Ab • Thyroid-stimulating Ab	Measurements of levels of thyroid antibodies Assists in the diagnosis of an autoimmune thyroid disease and distinguishes it from thyroiditis One or more antibody tests may be ordered, depending on symptoms	—	Same as for TSH measurement.
Thyroglobulin	Test to identify the presence of functioning thyroid tissue or thyroid cancer cells; result used primarily as a tumour marker for patients being treated for thyroid cancer	Male: 0.5–53 mcg/L Female: 0.5–43 mcg/L	Same as for TSH measurement.
Radiology			
Ultrasonography	Evaluation of thyroid nodule or nodules to determine whether they are fluid filled (cystic) or solid tumour	—	Explain that gel and a transducer will be used over the neck. Neither fasting nor sedation is required.

Study	Description and Purpose	Normal Values	Nursing Responsibility
Thyroid scan and uptake	Scan: Used to evaluate nodules of the thyroid. Radioactive isotopes are given PO or IV. Scanner passes over thyroid and makes graphic record of radiation emitted. Normal thyroid scan reveals homogeneous pattern with symmetrical lobes. Benign nodules appear as warm spots because they take up the radionuclide; malignant tumours appear as cold spots because they tend not to take up the radionuclide. Radioactive iodine uptake (RAIU): Provides direct measurement of thyroid activity. Useful for evaluation of functional activity of solitary thyroid nodules. Patient is given radioactive iodine either PO or IV. The uptake by the thyroid gland is measured with a scanner at several time intervals such as 2- to 4-hr intervals and at 24 hr. The values of RAIU are expressed in percentage of uptake.	—	Explain procedure to the patient. Check for iodine and shellfish allergy before test. Be sure patient understands that radioactive iodine taken orally is harmless. No special preparation is required. Patient should not have supplemental iodine for several weeks before the test. Thyroid medications interfere with test results.
Parathyroid Studies			
Blood Studies			
Parathyroid hormone (PTH)	Measurement of PTH level in serum to evaluate hypercalcemia or hypocalcemia Results must be interpreted in terms of concomitantly measured serum calcium level	Intact (whole): 10–65 ng/L	Fasting specimen preferred. Inform patient that blood sample will be collected. Sample may need to be kept on ice. Apply pressure to venipuncture site.
Total serum calcium	Measurement of total serum calcium to help detect bone and parathyroid disorders Hypercalcemia can indicate primary hyperparathyroidism, and hypocalcemia can indicate hypoparathyroidism	2.25–2.75 mmol/L	Inform patient that blood sample will be collected. Avoid prolonged tourniquet application. Apply pressure to venipuncture site.
Ionized calcium	Measurement of free form of calcium unaffected by variable serum albumin levels	1.05–1.3 mmol/L	Same as for total serum calcium.
Serum phosphate	Measurement of inorganic phosphorus Hyperphosphatemia indicates primary hypoparathyroidism or secondary causes (e.g., renal failure); hypophosphatemia indicates hyperparathyroidism Phosphorus and calcium levels are inversely related	0.97–1.45 mmol/L	Fasting preferred. Inform patient that blood sample will be collected. Take specimen to laboratory immediately. Apply pressure to venipuncture site.
Adrenal Studies			
Blood Studies			

Study	Description and Purpose	Normal Values	Nursing Responsibility
Cortisol	Measures amount of total cortisol in serum and evaluation of status of adrenal cortex function	138–635 nmol/L at 0800 hr 83–359 nmol/L at 1600 hr	Cortisol has diurnal variation: levels are higher in the morning than in evening. Sample should be collected in morning; evening samples may also be ordered. Mark time of blood collection on laboratory slip. Patient's anxiety should be minimized.
Aldosterone	Measurement of aldosterone levels to evaluate for hyperaldosteronism	Upright posture (at least 2 hr): <0.03–1.05 nmol/L Supine position: Peak 0.35 nmol/L Nadir 0.14 nmol/L	Usually, morning blood sample is preferred. On laboratory slip, indicate patient position (supine, sitting, standing) during venipuncture.
Adrenocorticotrophic hormone (ACTH) (corticotropin)	Measurement of the plasma level of ACTH Although ACTH is a pituitary hormone, it controls adrenal cortex secretion; this value helps determine whether underproduction or overproduction of cortisol is caused by dysfunction of the adrenal gland or pituitary gland	Morning: <18 pmol/L Evening: <11 pmol/L	Patient should be on NPO status after midnight before morning blood collection. Minimize patient's stress. Diurnal levels correspond with variation of cortisol levels; that is, levels are higher in morning, lower in evening. ACTH is very unstable; blood tube must be placed on ice and sent to laboratory immediately.
ACTH stimulation with cosyntropin	Used to evaluate adrenal function Baseline plasma cortisol levels are measured; IV cosyntropin (synthetic ACTH) is administered; samples are collected 30 and 60 min after bolus	For the rapid stimulation test, cortisol levels increase more than 267 nmol/L above baseline	Inject cosyntropin with a plastic syringe, and collect blood samples in plastic heparinized tubes. Ensure sample collection at appropriate times.
ACTH suppression (dexamethasone suppression)	Assessment of adrenal function; especially helpful if hyperactivity is suspected Useful in evaluation of Cushing's syndrome Dexamethasone is administered at 2300 hr to suppress secretion of corticotropin-releasing hormone; plasma cortisol sample is collected at 0800 hr	Cortisol level <138 nmol/L indicates normal adrenal response (50% decrease in cortisol production)	Ensure that patient has fasted. Inform patient that blood sample will be collected. Observe venipuncture site for bleeding and hematoma formation. Do not test acutely ill patients; those under stress are not tested. ACTH may override suppression. Screen patient for drugs such as estrogen and glucocorticoids, which may produce false-positive results. Ensure accurate timing of medication and sample collection.

Study	Description and Purpose	Normal Values	Nursing Responsibility
Metanephrine	Screening for pheochromocytoma; more accurate than urinary vanillylmandelic acid (VMA) and catecholamine measurements	12–60 pg/mL Normetanephrine: 18–111 pg/mL Results may vary by laboratory	Ask about recent history of vigorous exercise, high levels of stress, or starvation (may artificially ↑ levels). Ingestion of caffeine, alcohol, levodopa, lithium, nitroglycerin, acetaminophen, and medications containing epinephrine or norepinephrine can alter test results.
Urine Studies			
17-Ketosteroids	Measurement of androgen metabolites in urine and evaluation of adrenocortical and gonadal function	Male: 20–70 mcmol/day Female: 20–60 mcmol/day	Instruct patient regarding 24-hr urine collection. Tell patient that specimen must be kept refrigerated or on ice during collection. Determine whether preservative is required for method used.
Aldosterone	Measurement of urinary aldosterone level to diagnose hyperaldosteronism	0.11–0.86 nmol	Ensure that patient is on unrestricted diet with normal salt intake and no medication for 3 wk before collection. Instruct patient regarding 24-hr urine collection.
Cortisol, urine (free cortisol)	Measurement of free (unbound) cortisol for patients with suspected hyper- or hypofunction of the adrenal gland Preferred test for evaluating hypercortisolism	0800 hr: 138–635 nmol/L 1600 hr: 83–359 nmol/L	Instruct patient about 24-hr urine collection and avoidance of stressful situations and excessive physical exercise. Some drugs may alter levels. Ensure that patient is on low-sodium diet.
Vanillylmandelic acid (VMA)	Measurement of urinary excretion of catecholamine metabolite; helpful in diagnosing pheochromocytoma	<35 mcmol/24 hr Elevated values indicate pheochromocytoma	Collect specimen with a preservative. Keep on ice. Consult with laboratory or physician about whether patient should discontinue any drugs 3 days before urine collection and a VMA-restricted diet.
Radiology			
Abdominal computed tomographic (CT) scan	The radiological examination of choice for the adrenal gland Used to detect tumour and size of tumour mass or metastatic spread Oral or IV contrast medium, or both, may be used	—	Inform patient of the need to lie still during the procedure. If IV contrast medium is to be used, check for iodine and shellfish allergy before test.
Pancreatic Studies			
Blood Studies			

Study	Description and Purpose	Normal Values	Nursing Responsibility
Fasting blood glucose (FBG) level	Measurement of circulating glucose level	4–6 mmol/L	Ensure that patient fasts for at least 4–8 hr; water intake is permitted.
Oral glucose tolerance test (OGTT)	2-hr test: Used to diagnose diabetes mellitus if FBG result is equivocal; patient drinks 75 g of glucose. Samples for glucose are collected immediately and at 30, 60, and 120 min 5-hr test: Used to evaluate hypoglycemia. Patient drinks 100 g of glucose; samples of glucose are collected immediately and at 30, 60, 90, 120, 180, 240, and 300 min	<11.1 mmol/L at 30 and 60 min <7.8 mmol/L at 120 min <6.4 mmol/L at 3 and 4 hr	Instruct patient to fast (unless otherwise ordered), refrain from smoking and ingesting caffeine, and fast for 12 hr before test. Ensure that patient's diet 3 days before test included 150–300 g of carbohydrate. Simultaneously monitor glucose levels with capillary glucose monitoring if the patient is symptomatic. Encourage water during the test. Collect urine samples hourly. Allow patient to eat after test. Administer medications as ordered, after the test.
Capillary glucose monitoring	Provides immediate glucose values with glucose oxidase or electrochemical methods	Capillary values (whole blood): 10%–15% less than serum values Most capillary blood glucose meters automatically accommodate for this discrepancy	Obtain large drop of blood from clean finger, touch strip to drop of blood (not finger), time accurately, and compare colours in good lighting if visual method is used. Use digital readout if it is available. Use automatic finger-puncture device if it is available. Be sure to change section of device that touches patient's fingers between uses.
Glycosylated or hemoglobin (A_{1C})	Measurement of degree of glucose control during previous 3 mo (lifespan of hemoglobin molecule)	<6% for patients without diabetes <7% for patients with good diabetic control (values vary; check with laboratory)	Inform patient that fasting is not necessary and that blood sample will be collected. Observe venipuncture site for bleeding or hematoma formation.
Urine Studies			
Glucose	Estimation of amount of glucose in urine through use of an enzymatic method Dipstick is dipped into the urine and read for colour changes after 1 min	Random: negative 24-hr: <2.78 mmol/24 hr (<0.5 g/24 hr)	Use freshly voided urine specimen collected at appropriate time. Know that many different drugs alter glucose readings and that errors are great if directions for timing are not followed exactly. Follow package directions.

Study	Description and Purpose	Normal Values	Nursing Responsibility
Ketones	Measurement of amount of acetone excreted in urine as result of incomplete fat metabolism Tested with a dipstick as described for glucose study	Negative or trace amount of ketone is normal Positive result can indicate lack of insulin and diabetic ketoacidosis	Use freshly voided urine specimen. Test is often performed with glucose test. Directions must be followed exactly. Certain drugs can produce false-positive and false-negative results.
Radiology			
Abdominal computed tomographic (CT) scan	The radiological examination of choice for pancreas Used to identify tumours or cysts Oral or IV contrast medium (or both) may be ordered	—	Inform patient of the need to lie still during the procedure. If IV contrast is to be used, check for iodine allergy before test.

ADH, antidiuretic hormone; *AU,* arbitrary units (T_3RU). *BP,* blood pressure; *DI,* diabetes insipidus; *IV,* intravenous; *NPO,* nothing by mouth; *PO,* by mouth.

Laboratory Studies

Laboratory studies used to diagnose endocrine problems may include direct measurement of the hormone level or an indirect indication of gland function by evaluation of blood or urine components affected by the hormone (e.g., electrolytes).

Hormones with fairly constant basal levels (e.g., T_4) need be measured only once. Notation of sample time on the laboratory slip and sample is important for hormones with circadian or sleep-related secretion (e.g., cortisol). Evaluation of other hormones may require multiple blood sampling, as in suppression tests (e.g., dexamethasone) and stimulation tests (e.g., glucose tolerance). In these situations, it is often necessary to obtain intravenous access to administer medications and fluids and to collect multiple blood samples.

Pituitary Studies.

Disorders associated with the pituitary gland can manifest in a wide variety of ways because of the number of hormones produced. Many diagnostic studies are available to evaluate these hormones either directly or indirectly (see Table 50-8).

Thyroid Studies.

There are a number of tests available to evaluate thyroid function. The most sensitive and accurate laboratory test is measurement of TSH; thus it

is often recommended as a first diagnostic test for evaluation of thyroid function (Thyroid Foundation of Canada, 2015). Common additional tests ordered in the presence of abnormal TSH levels include measurements of total serum T_4, free T_4, and total serum T_3. The Canadian Society of Endocrinology and Metabolism (CSEM, 2015) in conjunction with Choosing Wisely Canada (2014) has recommended that free T_4 or T_3 not be used to screen for hypothyroidism or to monitor and adjust levothyroxine (L-T_4, Synthroid) dose in patients with known primary hypothyroidism.

Free T_4 is the unbound T_4, and its level is a more accurate reflection of thyroid function than that of total T_4. Less common tests that help in the differentiation of various types of thyroid disease include measurement of T_3, assessment of free T_3 resin uptake, measurement of thyroid autoantibodies, thyroid scanning, ultrasonography, and biopsy. CSEM (2015) does not recommend ultrasound as a routine evaluation of abnormal thyroid function tests. These tests are performed to help differentiate various types of thyroid disorders.

Case Study

Objective Data: Diagnostic Studies

Source: aastock/Shutterstock.com.

The health care provider orders the following initial diagnostic studies to be drawn in the morning after an 8-hr fast:

- CBC, basic metabolic panel (electrolytes, BUN, creatinine)
- Fasting blood glucose (FBG)

- TSH, free T_4
- Plasma cortisol levels
- Plasma ACTH levels

CBC results reveal a WBC of 12.2 × 10^9/L and a decreased lymphocyte count at 8 × 10^9/L. The rest of the CBC is within normal limits (WNL).

The FBG is 7.2 mmol/L. The plasma cortisol and ACTH levels are elevated. Thyroid studies are within normal limits. Based on findings, the health care provider diagnoses Ms. Mollon with Cushing's syndrome.

See pp. 1245 and 1247 for more information on Ms. Mollon.

Parathyroid Studies.

The only hormone secreted by the parathyroid glands is PTH. Because the function of PTH is to regulate serum calcium and phosphate levels, abnormalities in PTH secretion are reflected in the calcium and phosphate levels. For this reason, diagnostic tests for the parathyroid gland typically include measurements of PTH, serum calcium, and serum phosphate.

Adrenal Studies.

Diagnostic tests associated with the adrenal glands focus on the three types of hormones secreted: glucocorticoids, mineralocorticoids, and androgens. These hormone levels can be measured both in blood plasma and in urine. Urine studies are usually performed as 24-hour urine collections. The major advantage of a 24-hour urine sample is that the short-term fluctuations in hormone levels seen in plasma samples are eliminated (Pagana & Pagana, 2013).

Pancreatic Studies.

The tests found in Table 50-8 are geared toward evaluating the metabolism of glucose. They are important in the diagnosis and management of diabetes. (Diagnostic studies for diabetes are discussed in Chapter 52.)

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Which of the following is a characteristic common to all hormones?
   a. They circulate in the blood bound to plasma proteins.
   b. They influence cellular activity of specific target tissues.
   c. They accelerate the metabolic processes of all body cells.
   d. They enter cells to alter the cell's metabolism or gene expression.
2. A client is receiving radiation therapy for cancer of the kidney. The nurse monitors the client for signs and symptoms of damage to which of the following organ(s)?
   a. Pancreas
   b. Thyroid
   c. Adrenal glands
   d. Posterior pituitary gland
3. A client has a serum sodium level of 152 mmol/L. What is the normal hormonal response to this situation?
   a. Release of ADH
   b. Release of renin
   c. Secretion of aldosterone
   d. Secretion of corticotropin-releasing hormone
4. All cells in the body are believed to have intracellular receptors for which of the following?
   a. Insulin
   b. Glucagon
   c. Growth hormone
   d. Thyroid hormone
5. When obtaining subjective data from a client during assessment of the endocrine system, the nurse asks specifically about which of the following?
   a. Energy level
   b. Intake of vitamin C
   c. Employment history

d. Frequency of sexual intercourse

6. What is an appropriate technique to use during physical assessment of the thyroid gland?
   a. Ask the client to hyperextend the neck during palpation.
   b. Percuss the neck for dullness to define the size of the thyroid.
   c. Have the client swallow water during inspection and palpation of the gland.
   d. Use deep palpation to determine the extent of a visibly enlarged thyroid gland.
7. Why do endocrine disorders often go unrecognized in older adults?
   a. Symptoms are often attributed to aging.
   b. Older adults rarely have identifiable symptoms.
   c. Endocrine disorders are relatively rare in the older adult.
   d. Older adults usually have subclinical endocrine disorders that minimize symptoms.
8. Which of the following would the nurse consider an abnormal finding during an endocrine assessment? *(Select all that apply)*
   a. Blood pressure of 100/70
   b. Soft, formed stool every other day
   c. Excessive facial hair on a woman
   d. 1.5-kg weight gain over the last 6 months
   e. Hyperpigmented coloration in lower legs
9. A client has a total serum calcium level of 0.75 mmol/L. If this finding reflects hypoparathyroidism, what would the nurse expect further diagnostic testing to reveal?
   a. Decreased serum PTH
   b. Increased serum ACTH
   c. Increased serum glucose
   d. Decreased serum cortisol levels

1. b; 2. c; 3. a; 4. d; 5. a; 6. c; 7. a; 8. c, e; 9. a.

CHAPTER 51

Nursing Management

Endocrine Problems

Written by, Katherine A. Kelly

Adapted by, Daphne Connolly

LEARNING OBJECTIVES

1. Describe the pathophysiology, clinical manifestations, collaborative care, and nursing management of the patient with an imbalance of hormones produced by the anterior pituitary gland.
2. Describe the pathophysiology, clinical manifestations, collaborative care, and nursing management of the patient with an imbalance of hormones produced by the posterior pituitary gland.
3. Describe the pathophysiology, clinical manifestations, collaborative care, and nursing management of the patient with thyroid dysfunction.
4. Describe the pathophysiology, clinical manifestations, collaborative care, and nursing management of the patient with an imbalance of the hormone produced by the parathyroid glands.
5. Describe the pathophysiology, clinical manifestations, collaborative care, and nursing management of the patient with an imbalance of hormones produced by the adrenal cortex.
6. Describe the pathophysiology, clinical manifestations, collaborative care, and nursing management of the patient with an excess of

hormones produced by the adrenal medulla.
7. Explain the adverse effects of corticosteroid therapy.
8. Describe common nursing assessments, interventions, rationales, and expected outcomes related to patient teaching for management of chronic endocrine problems.

Disorders of the Anterior Pituitary Gland

Acromegaly

Etiology and Pathophysiology

Acromegaly is a condition caused by excessive secretion of growth hormone (GH) and characterized by an overgrowth of the bones and soft tissues in the hands, feet, and face. It occurs most often as a result of a benign pituitary tumour (adenoma). Because the problem develops after epiphyseal closure, the bones of the arms and legs do not grow longer. Acromegaly is relatively rare. The estimated annual incidence is about 3 to 4 cases per 1 million population (Puig, 2015). Both sexes are affected in equal numbers.

Clinical Manifestations

Manifestations of acromegaly begin gradually, usually in the third and fourth decades of life. Typically, the time between the initial onset of symptoms and the final diagnosis is an average of 7 to 10 years (Miller, Learned-Miller, Trainer, et al., 2011). Individuals experience enlargement of the hands and feet. The enlargement of the bones and cartilage may cause symptoms that range from mild joint pain to deforming, crippling arthritis. Changes in physical appearance occur, with thickening and enlargement of bony and soft tissue on the face and head (Figure 51-1). Enlargement of the mandible causes the jaw to jut forward. The paranasal and the frontal sinuses enlarge, as does the bony tissue of the forehead. Enlargement of soft tissue around the eyes, nose, and mouth results in a coarsening of facial features. Enlargement of the tongue results in speech difficulties, and the voice deepens as a result of hypertrophy of the vocal cords.

FIGURE 51-1 Example of progressive changes in facial features in acromegaly. Source: Courtesy Linda Haas, Seattle, Washington.

Sleep apnea may also occur and is thought to be related to upper airway narrowing that results from changes in pharyngeal soft tissues (Melmed & Kleinberg, 2016). The skin becomes thick, leathery, and oily. People with acromegaly may also experience peripheral neuropathy and proximal muscle weakness. Women may develop menstrual disturbances. Individuals with acromegaly are more likely to develop polyps in the colon and colon cancer.

The enlarged pituitary gland can exert pressure on surrounding structures within the brain, leading to visual disturbances and headaches. Because GH mobilizes stored fat for energy, it increases free fatty acid levels in the blood, which predisposes patients to atherosclerosis. The hormone also antagonizes the action of insulin and causes hyperglycemia. Manifestations of diabetes mellitus may occur, including *polydipsia* (increased thirst) and *polyuria* (increased urination). Prolonged secretion of GH leads to glucose intolerance.

Untreated acromegaly leads to a number of changes in the body. Effects on the cardiovascular system include cardiomegaly, left ventricular hypertrophy, angina pectoris, and hypertension. For this reason, disease of the cardiovascular system is associated with increased mortality rates among these individuals. Other systems that undergo changes include the gastro-intestinal (GI), genito-urinary, musculo-skeletal, and nervous systems.

Diagnostic Studies

In addition to the history and physical examination, diagnosis of GH excess requires evaluation of plasma insulin-like growth factor (IGF-1) levels and GH response to an oral glucose tolerance test (OGTT). A single measurement of serum GH is of limited value in the diagnosis of acromegaly because GH levels normally fluctuate. IGF-1 levels are more constant and thus provide a more reliable measure. A preferred test for acromegaly is the OGTT. Normally, GH concentration falls during an OGTT. In acromegaly, these levels do not fall (Turbow & Patterson, 2014).

Magnetic resonance imaging (MRI) is indicated for the identification and the localization of the pituitary tumour and the determination of its extension into surrounding tissue. High-resolution computed tomographic (CT) scan with contrast media may also be used to localize the tumour. A complete ophthalmological examination, including evaluation of visual fields, is performed if the tumour lies adjacent to the optic chiasm or the optic nerves (Katznelson, Laws, Jr., Melmed, et al., 2014).

Collaborative Care

The therapeutic goal in acromegaly is to return GH levels to normal. This is accomplished by surgery, radiation therapy, drug therapy, or a combination of these therapies. The prognosis depends on age at onset, age when treatment is initiated, and tumour size. Usually, bone growth can be arrested and soft tissue hypertrophy can be reversed. However, sleep apnea and diabetic and cardiac complications may persist in spite of treatment.

Surgical Therapy.

Surgery is the treatment of choice and offers the best hope for a cure, especially for smaller tumours. The *trans-sphenoidal approach* is recommended (Katznelson et al., 2014; Figure 51-2). Surgery produces an immediate reduction in GH levels, followed by a drop in IGF-1 levels within a few weeks. Patients with larger tumours or those with GH levels higher than 50 mcg/L may require adjuvant radiation or drug therapy.

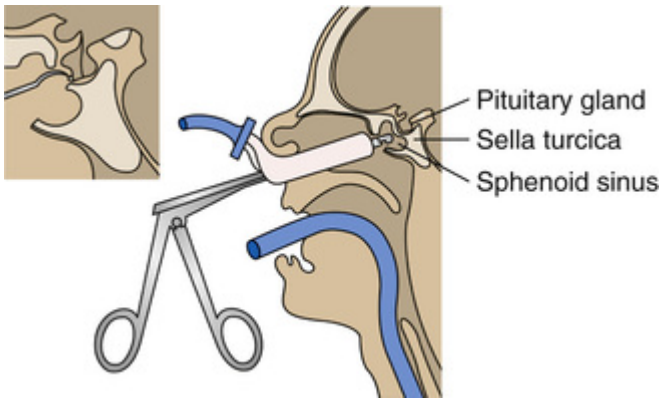

FIGURE 51-2 Surgery on the pituitary gland is most commonly performed with the trans-sphenoidal approach. An incision is made in the inner aspect of the upper lip and gingiva. The sella turcica is entered through the floor of the nose and the sphenoid sinuses.

When the entire pituitary gland is removed during surgery *(hypophysectomy),* the loss of pituitary hormones is permanent. Rather than replacing the pituitary (tropic) hormones, which requires parenteral administration, the essential hormones produced by target organs (glucocorticoids, thyroid hormone, and sex hormones) can be replaced orally. Hormone replacement must be continued throughout life.

Radiation Therapy.

Radiation therapy is considered when surgery has failed to produce complete remission and for patients considered to be at high risk for surgical complications. The long delay before GH levels normalize limits its usefulness in treating symptoms (Turbow & Patterson, 2014). Radiation therapy is usually offered in combination with drugs that reduce GH levels. Radiation therapy has also been used to reduce the size of a tumour before surgery. (Radiation therapy is discussed in Chapter 18.) Hypopituitarism commonly results from radiation therapy and necessitates hormone therapy.

Stereotactic radiosurgery (gamma-knife surgery, proton beam, linear accelerator) may be used for small, surgically inaccessible pituitary tumours (see Chapter 59). This procedure consists of a single dose of radiation delivered to one site from multiple angles.

Drug Therapy.

Three groups of drugs are used in the treatment of acromegaly: somatostatin analogues, dopamine agonists, and GH-receptor antagonists. These drugs reduce GH levels and can be used as initial treatment or as adjunct therapy with surgery or radiation. The most common drug used for acromegaly is octreotide (Sandostatin), a somatostatin analogue that reduces GH levels to within the normal range in many patients. Octreotide is given by subcutaneous injection three times a day. Two long-acting analogues, octreotide (Sandostatin LAR), and lanreotide (Somatuline Autogel), are available as intramuscular (IM) injections every 2 to 4 weeks. Dopamine agonists, such as cabergoline (Dostinex) and bromocriptine mesylate (Apo-bromocriptine), may also be used in the treatment of acromegaly to suppress GH secretion. They are not commonly used as sole therapy; rather, they are combined with somatostatin analogues. A GH receptor antagonist, pegvisomant (Somavert), has been developed for use in the treatment of acromegaly and directly blocks GH action, resulting in decreased levels of IGF-1. It is recommended for patients in whom surgery, somatostatin analogues, and dopamine agonists have failed (Puig, 2015).

Nursing Management Acromegaly

Nursing Assessment

The nurse must assess for signs and symptoms of abnormal tissue growth and evaluate changes in the physical size of each patient. Patients should be questioned about increases in hat, ring, glove, and shoe sizes and about changes in appearance. Photographs are helpful for evaluating any changes (Figure 51-1). Because physical changes occur slowly and over a long time, it is possible that the individual is not even aware of them.

Nursing Implementation

After surgery in which a trans-sphenoidal approach has been used, the head of the patient's bed should be elevated at a 30-degree angle at all times. This elevation prevents pressure on the sella turcica and decreases the incidence of headaches, a frequent postoperative problem. Neurological status, including pupillary response, should be monitored in order to detect neurological complications. Patients should be instructed to avoid vigorous coughing, sneezing, and straining at stool (Valsalva manoeuvre) to prevent leakage of cerebro-spinal fluid from the point at which the sella turcica was entered.

Any clear nasal drainage should be sent to the laboratory to be tested for glucose. A glucose level higher than 1.67 mmol/L indicates leakage of cerebro-spinal fluid from an open connection to the brain. If this happens, the patient is at an increased risk for meningitis. Complaints of persistent and severe generalized or supraorbital headache may indicate leakage of cerebro-spinal fluid into the sinuses. A cerebro-spinal fluid leak usually resolves within 72 hours when treated with head elevation and bedrest. If the leak persists, daily spinal taps may be performed to reduce pressure to below-normal levels and allow the fossa to heal. When a patient has a cerebro-spinal fluid leak, intravenous (IV) antibiotics should be administered as ordered to prevent meningitis. If the leak does not

respond to treatment within 72 hours, surgical intervention may be required.

Mild analgesics are given for headaches. The nurse should perform mouth care every 4 hours to keep the surgical area clean and free of debris and to promote patient comfort. Tooth brushing should be avoided for at least 10 days to prevent disrupting the suture line and to avoid discomfort.

If stereotactic radiosurgery is performed, the patient is usually moved from the specialized radiation centre to the neurosurgical nursing unit for overnight observation. The patient is in a stereotactic head frame. Vital signs, neurological status, and fluid volume status must be carefully monitored. Possible complications include increased headaches, seizures, nausea, and vomiting. A patient with a history of seizures is at increased risk for seizures for at least 24 hours after the procedure. All staff should know how to remove a stereotactic frame in case of an emergency. The patient may experience discomfort at the pin sites. Pin site care should be performed according to institutional policy. Family members can be instructed in pin site care if the patient is discharged with pins in place.

A possible postoperative complication is transient diabetes insipidus (DI). This complication may occur because of the loss of antidiuretic hormone (ADH), which is stored in the posterior lobe of the pituitary gland, or because of cerebral edema related to manipulation of the pituitary gland during surgery. To assess for DI, urine output and serum and urine osmolarity must be closely monitored. Clinical manifestations and treatment of DI are discussed in more detail later in this chapter.

If a hypophysectomy is performed or the pituitary gland is damaged, replacement of ADH, cortisol, and thyroid hormone is necessary. These medications must be taken for life; therefore, careful patient teaching is essential.

Surgery may result in permanent loss or deficiencies in follicle-stimulating hormone (FSH) and luteinizing hormone (LH). This can lead to decreased fertility for both sexes. The nurse should assist patients in working through the grieving process associated with these losses.

The need for continued drug therapy reduces the patient's perception of independence and requires considerable emotional adjustment. The teaching plan should include self-administration of subcutaneous injections if prescribed. Cost issues related to the expense of ongoing medication, as well as other therapies, may be another area for nursing intervention.

The nurse must consider the emotional impact of a hypophysectomy when counselling patients and planning the educational program related to hormone replacement. Serial photographs to show improvement may be helpful. Psychological support from the nurse and from the patient's family and friends is needed to promote positive mental health outcomes for a patient with acromegaly. Patients with acromegaly may be at higher risk for colon polyps and colorectal cancer, and screening for colon neoplasia with colonoscopy at diagnosis is suggested (Katznelson et al., 2014).

Excesses of Other Tropic Hormones

Excesses of tropic hormones and overproduction of a single anterior pituitary hormone usually cause syndromes related to hormone excess from the target organ. If the adrenocorticotrophic hormone (ACTH) level is increased, Cushing's disease results; if the thyroid-stimulating hormone (TSH) level is excessive, hyperthyroidism develops.

Prolactinomas (prolactin-secreting adenomas) are the most frequently occurring pituitary tumours (Turbow & Patterson, 2014). Common manifestations experienced by women with prolactinomas include galactorrhea, ovulatory dysfunction (anovulation, infertility), menstrual dysfunction (oligomenorrhea or amenorrhea), decreased libido, and hirsutism. In men, erectile dysfunction and decreased libido and sperm density may result. Headaches and visual problems may also occur. The visual problems are secondary to pressure on the optic chiasm. Because prolactinomas do not typically enlarge, drug therapy is usually the first-line treatment (Yang, Hong, Lee, et al., 2011). Dopamine agonists such as cabergoline (Dostinex) and bromocriptine have been used successfully to treat this disorder. Surgery with the trans-sphenoidal

approach discussed previously may be considered, depending on the size and extent of the tumour. Radiation therapy for treatment of prolactinomas has been used to a somewhat limited degree, mainly in patients in whom the tumour has failed to respond to medical or surgical therapy.

Hypofunction of the Pituitary Gland

Hypopituitarism is a rare disorder that involves a decrease in one or more of the pituitary hormones; signs and symptoms relate to the underlying disorder and to the specific pituitary hormones that are deficient or absent. The anterior pituitary gland secretes ACTH, TSH, FSH, LH, GH, and prolactin; the posterior pituitary gland secretes ADH and oxytocin. A deficiency of only one pituitary hormone is referred to as *selective hypopituitarism.* Total failure of the pituitary gland results in deficiency of all pituitary hormones; this condition is referred to as *panhypopituitarism.* The hormone deficiencies most commonly associated with hypopituitarism involve GH and the gonadotropins (e.g., LH, FSH).

Etiology and Pathophysiology

The most common cause of pituitary hypofunction is a pituitary tumour. Autoimmune disorders, infections, pituitary infarction (Sheehan's syndrome), or destruction of the pituitary gland (as a result of trauma, irradiation, or surgical procedures) can also cause hypopituitarism. *Sheehan's syndrome* is a postpartum condition of pituitary necrosis and hypopituitarism after circulatory collapse resulting from uterine hemorrhaging.

Hormone deficiencies involving anterior pituitary hormones lead to end-organ failure; thus the effects of hypopituitarism depend on the specific pituitary hormone or hormones that are lacking. For example, infertility may be the first indication of pituitary hypofunction associated with a pituitary tumour. Deficiencies of TSH and ACTH are life-threatening. ACTH deficiency causes a tendency toward shock and may result in an episode of acute adrenal insufficiency (refractory and life-threatening shock from

sodium and water depletion). (Adrenal shock is discussed later in this chapter.)

Clinical Manifestations and Diagnostic Studies

The manifestations associated with pituitary hypofunction vary with the type and degree of dysfunction. Early manifestations associated with a space-occupying lesion include headaches, visual changes (decreased visual acuity or decreased peripheral vision), loss of smell, nausea and vomiting, and seizures. Manifestations associated with hyposecretion of the target glands vary widely (Table 51-1).

TABLE 51-1

CLINICAL MANIFESTATIONS OF HYPOPITUITARISM

Hormone Deficiency	Clinical Manifestations
Growth hormone (GH)	Subtle, nonspecific findings. Truncal obesity, decreased muscle mass and strength, weakness, fatigue, depression or flat affect
Follicle-stimulating hormone (FSH) and luteinizing hormone (LH)	*Women:* Menstrual irregularities, loss of libido, changes in secondary sex characteristics such as decreased breast size *Men:* Testicular atrophy, diminished spermatogenesis, loss of libido, impotence, decreased facial hair and muscle mass
Thyroid-stimulating hormone (TSH)	Mild form of primary hypothyroidism: fatigue, cold intolerance, constipation, lethargy, weight gain
Adrenocorticotrophic hormone (ACTH)	Involves a deficiency of cortisol: weakness, fatigue, headache, dry and pale skin, diminished axillary and pubic hair, lowered resistance to infection, fasting hypoglycemia

In addition to a history and physical examination, diagnostic studies such as MRI and CT are used to identify a pituitary tumour. Laboratory tests for diagnosing hypopituitarism vary widely but generally involve the direct measurement of pituitary hormones (e.g., TSH) or an indirect determination of the target organ hormones (e.g., triiodothyronine [T_3], thyroxine [T_4]). (See Chapter 50 for more information regarding diagnostic studies.)

Nursing and Collaborative Management Hypopituitarism

Treatment of hypopituitarism consists of surgery or radiation therapy for tumour removal, followed by permanent hormone replacement. Surgery and radiation therapy for pituitary tumours are discussed earlier in this chapter. Hormone therapy is carried out with the appropriate pituitary hormone (e.g., GH, corticosteroids, thyroid hormone, and sex hormones). Hormone therapies for thyroid hormone and corticosteroids are discussed later in this chapter.

A primary nursing role in anterior pituitary insufficiency is the assessment and recognition of signs and symptoms associated with hypopituitarism. Nursing management is directed at problems that result from hormone deficiency. The nurse also plays a pivotal role in teaching patients about diagnostic procedures, the disease process, and collaborative care options. Because the need for hormone therapy is lifelong, patient teaching must cover hormonal administration, adverse drug effects, and follow-up therapy.

Somatropin (Humatrope) is used for GH replacement therapy. Adults with GH deficiency respond well to GH replacement and experience increased energy, increased lean body mass, a feeling of well-being, and improved body image. The adverse drug effects most commonly reported by adults include swelling in the feet and the hands, pain in the joints, and headache. Somatropin is given as a subcutaneous injection. The dosage and administration is variable because it is adjusted according to the degree of relief from symptoms, IGF-1 levels, and the development of adverse effects.

Although gonadal deficiency is not life-threatening, replacement therapy is offered to improve sexual function and general well-being. This therapy, however, is contraindicated in individuals with certain medical conditions, such as breast cancer, phlebitis, pulmonary embolism in women, and prostate cancer in men. Estrogen and progesterone replacement therapy may be indicated for hypogonadal women to treat hot flashes, vaginal dryness, and

decreased libido. Hormone therapy for women is discussed in greater detail in Chapter 56. Testosterone is used to treat men with gonadotropin deficiency. The benefits achieved with testosterone therapy include a return of male secondary sex characteristics; improvement in libido; and increased muscle mass, bone mass, and bone density.

Disorders of the Posterior Pituitary Gland

The hormones secreted by the posterior pituitary—ADH and oxytocin—are actually produced in the hypothalamus and then transported to and stored in the posterior pituitary gland. ADH, also referred to as *arginine vasopressin* (AVP) or *vasopressin*, plays a major role in the regulation of water balance and osmolarity (see Chapter 50).

The two primary conditions associated with ADH secretion are a result of either overproduction or underproduction of ADH. Overproduction or oversecretion of ADH results in the **syndrome of inappropriate antidiuretic hormone (SIADH).** Underproduction or undersecretion of ADH results in a condition referred to as *diabetes insipidus.*

Syndrome of Inappropriate Antidiuretic Hormone

Etiology and Pathophysiology

SIADH occurs when ADH is released despite normal or low plasma osmolarity (Figure 51-3). SIADH results from an abnormal production or sustained secretion of ADH and is characterized by fluid retention, serum hypo-osmolality, dilutional hyponatremia, hypochloremia, concentrated urine in the presence of normal or increased intravascular volume, and normal renal function. This syndrome occurs more commonly in older adults (Runkle, Gomez-Hoyos, Cuesta-Hernández, et al., 2015).

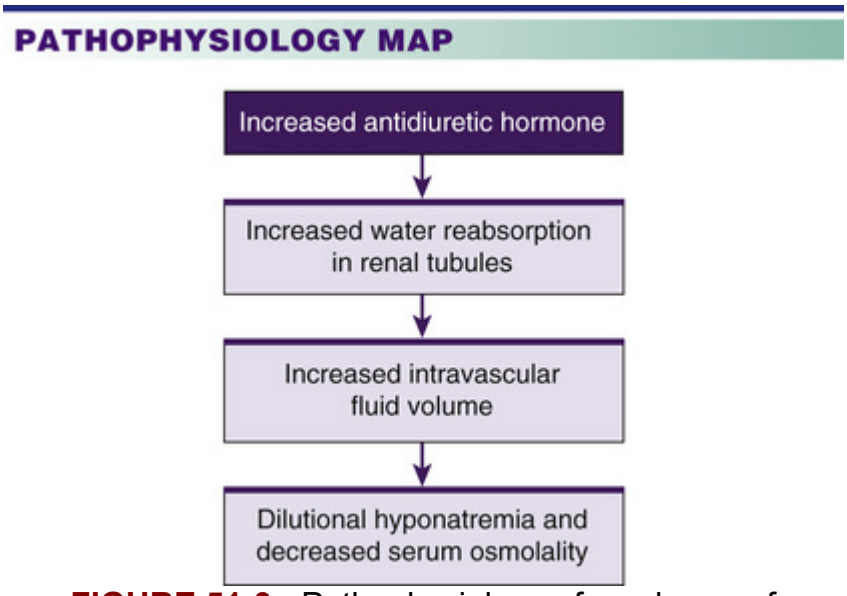

FIGURE 51-3 Pathophysiology of syndrome of inappropriate antidiuretic hormone (SIADH). Source: Redrawn from Urden, L. D., Stacy, K. M., & Lough, M. E. (2014). *Critical care nursing: Diagnosis and management* (7th ed., p. 838, Figure 33-6). St. Louis: Mosby.

The abnormal production or sustained secretion of ADH that leads to SIADH has various causes (Table 51-2). The most common cause is malignancy, especially small cell lung cancer. SIADH tends to be self-limiting when caused by head trauma or drugs but is chronic in nature when associated with tumours or metabolic diseases.

TABLE 51-2

CAUSES OF SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE

Malignant Tumours	Drug Therapy
• Colorectal cancer • Lymphoid cancers (Hodgkin's disease, non-Hodgkin's lymphoma, lymphocytic leukemia) • Pancreatic cancer • Prostate cancer • Small cell carcinoma of the lung • Thymus cancer **Central Nervous System Disorders** • Brain tumours • Cerebral atrophy • Cerebro-vascular injury • Guillain-Barré syndrome • Head injury (skull fracture, subdural hematoma, subarachnoid hemorrhage) • Infection (encephalitis, meningitis) • Systemic lupus erythematosus	• Antineoplastic agents (vincristine, vinblastine, cyclophosphamide [Procytox]) • Carbamazepine (Tegretol) • Chlorpropamide • General anaesthetic agents • Opioids • Oxytocin • SSRI antidepressants • Thiazide diuretics • Tricyclic antidepressants **Miscellaneous Conditions** • Adrenal insufficiency • Chronic obstructive pulmonary disease • HIV infection • Hypothyroidism • Lung infection (pneumonia, tuberculosis, lung abscess) • Positive pressure mechanical ventilation

HIV, human immunodeficiency virus; *SSRI*, selective serotonin reuptake inhibitor.

Clinical Manifestations and Diagnostic Studies

Excess ADH increases both permeability of the distal tubules and collecting ducts and reabsorption of water into the circulation. Consequently, extracellular fluid volume expands, plasma osmolality declines, the glomerular filtration rate (GFR) increases, and sodium levels decline (dilutional hyponatremia) (Hong, 2012). Hyponatremia causes muscle cramps and weakness. Patients with SIADH experience low urinary output and increased body weight (Robinson & Verbalis, 2016). As the serum sodium level falls (usually to less than 120 mmol/L), manifestations become more severe and include vomiting, abdominal cramps, muscle twitching, and seizures. As plasma osmolality and serum sodium levels continue to decline, cerebral edema may occur, leading to lethargy, anorexia, confusion, headache, seizures, and coma.

SIADH is diagnosed from simultaneous measurements of urine and serum osmolality. The dilutional hyponatremia is indicated by a serum sodium level of less than 134 mmol/L, serum osmolality of

less than 280 mmol/kg, and a urine specific gravity greater than 1.005. A serum osmolality much lower than the urine osmolality indicates the inappropriate excretion of concentrated urine in the presence of dilute serum.

Collaborative Care

Once SIADH is identified, treatment is directed at the underlying cause of the disorder. Medications that stimulate the release of ADH should be avoided or discontinued (see Table 51-2). The immediate treatment goal is to restore normal fluid volume and osmolality. If symptoms are mild and the serum sodium level exceeds 125 mmol/L, the only treatment may be restriction of fluids to between 800 and 1 000 mL/day. This restriction should result in gradual, daily reductions in weight, a progressive rise in serum sodium concentration and osmolality, and improvement in symptoms.

In cases of severe hyponatremia (serum sodium level <120 mmol/L), especially in the presence of neurological symptoms such as seizures, IV hypertonic saline solution (3% to 5%) may be administered. Hypertonic saline must be administered very slowly on an infusion pump to avoid too rapid a rise in sodium. A diuretic such as furosemide (Lasix) may be used to promote diuresis, but only if the serum sodium level is at least 125 mmol/L because it may promote further loss of sodium. Because furosemide increases potassium, calcium, and magnesium losses, supplements may be needed. A fluid restriction of 500 mL/day is also indicated for patients with severe hyponatremia.

In chronic SIADH, water restriction of between 800 and 1 000 mL/day is recommended. Because this degree of restriction may not be tolerated, agents that block the effect of ADH on the renal tubules may be prescribed, thereby allowing more dilution of urine. Tolvaptan (Samsca), a vasopressin receptor antagonist, is used to treat euvolemic hyponatremia in hospitalized patients. This medication should be initiated in a closely monitored setting to prevent rapid correction of the serum sodium level.

Nursing Management Syndrome of Inappropriate Antidiuretic Hormone

The nurse can be instrumental in the early detection and treatment of SIADH. An appropriate nursing assessment (Table 51-3) should be conducted for patients at risk for SIADH and those who have confirmed SIADH. Specifically, the nurse should be alert for low urinary output with a high specific gravity, a sudden weight gain, or a decline in serum sodium level. Nursing management of acute onset of SIADH is presented in Table 51-3.

TABLE 51-3

NURSING ASSESSMENT
Syndrome of Inappropriate Antidiuretic Hormone

Assessment
• Daily weight measurement • Frequent measurement of intake (oral and parenteral) and output • Frequent measurement of urine specific gravity • Frequent measurement of vital signs • Monitoring of heart and lung sounds • Monitoring of level of consciousness • Observation for signs of hyponatremia (e.g., decreased neurological function, seizures, nausea and vomiting, muscle cramping)
Management
• Frequent oral hygiene • Frequent turning, positioning, and range of motion exercise (if patient is bedridden) • Positioning of head of bed flat or with no more than 10 degrees of elevation to enhance venous return to heart and increase left atrial filling pressure, thereby reducing ADH release • Protection from injury (e.g., assist with ambulation, bed alarm) because of potential alterations in mental status • Provision of distractions to decrease the discomfort of thirst related to fluid restrictions • Provision of support for patient and significant others regarding diagnosis and any mental status changes • Restricting total fluid intake to no more than 1 000 mL/day (including that taken with medications) • Seizure precautions

ADH, antidiuretic hormone.

When SIADH is chronic, patients must learn to self-manage treatment regimens. Fluids are restricted to between 800 and 1 000 mL/day. Ice chips or sugarless chewing gum can help decrease thirst. If drinking liquids is an aspect of socialization, patients should

be assisted in planning fluid intake so that liquid allowances are saved for social occasions. Patients may be treated with a diuretic to remove excess fluid volume. The diet should be supplemented with sodium and potassium, especially if diuretics are prescribed. Solutions of these electrolytes must be well diluted to prevent gastro-intestinal irritation or damage. They are best taken at mealtime to allow mixing with and dilution by food. Patients should be taught the symptoms of fluid and electrolyte imbalances, especially those involving sodium and potassium, so that responses to treatment can be monitored (see Chapter 19).

Diabetes Insipidus

Etiology and Pathophysiology

Diabetes insipidus (DI) is a group of conditions associated with a deficiency of production or secretion of ADH or with a decreased renal response to ADH caused by injury to the neurohypophyseal system. The decrease in ADH results in fluid and electrolyte imbalances caused by increased urinary output and increased plasma osmolality (Figure 51-4). Depending on the cause, DI may be transient or a chronic lifelong condition.

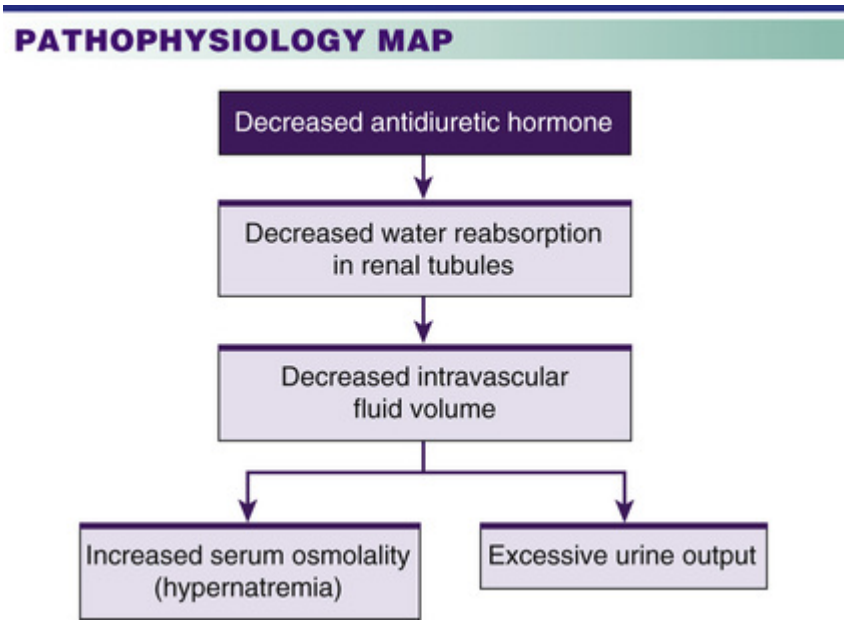

FIGURE 51-4 Pathophysiology of diabetes insipidus. Source: Redrawn from Urden, L. D., Stacy, K. M., & Lough, M. E. (2014). *Critical care nursing: Diagnosis and management* (7th ed., p. 833, Figure 33-5). St. Louis: Mosby.

Diabetes insipidus has several classifications (Table 51-4). *Central DI* is the most common form.

TABLE 51-4

TYPES AND CAUSES OF DIABETES INSIPIDUS

Types	Causes
Central (neurogenic) DI	Results from an interference with ADH synthesis or release. Multiple causes include brain tumour, head injury, brain surgery, CNS infections.
Nephrogenic DI	Results from inadequate renal response to ADH despite presence in adequate levels. Causes include drug therapy (especially lithium), renal damage, or hereditary renal disease.
Primary DI	Results from excessive water intake. Causes are structural lesion in thirst centre and psychological disorder.

ADH, antidiuretic hormone; *CNS,* central nervous system; *DI,* diabetes insipidus.

Clinical Manifestations

DI is characterized by increased thirst (polydipsia) and increased urination (polyuria; see Figure 51-4) (John & Day, 2012). The primary

characteristic of DI is the excretion of large quantities of urine (5–20 L per day) with a very low specific gravity (<1.005) and urine osmolality of less than 100 mmol/kg. Serum osmolality is elevated (usually >300 mmol/kg) as a result of hypernatremia caused by pure water loss in the kidneys. Most affected patients compensate for fluid loss by drinking great amounts of water so that serum osmolality is normal or only moderately elevated. Patients may be fatigued from nocturia and may experience generalized weakness.

Central DI usually occurs suddenly with excessive fluid loss. After intracranial surgery, DI usually has a triphasic pattern: the acute phase, with abrupt onset of polyuria; an interphase, in which urine volume apparently normalizes; and a third phase, in which central DI is permanent. The third phase is usually apparent within 10 to 14 days postoperatively. Central DI that results from head trauma is usually self-limiting and improves with treatment of the underlying problem. DI following cranial surgery is more likely to be permanent. Although the clinical manifestations of nephrogenic DI are similar, the onset and the amount of fluid losses are less dramatic.

If oral fluid intake cannot keep up with urinary losses, a severe fluid volume deficit results. This deficit is manifested by weight loss, constipation, poor tissue turgor, hypotension, tachycardia, and shock. In addition, affected patients show central nervous system (CNS) manifestations, ranging from irritability and mental dullness to coma. These manifestations are related to increasing serum osmolality and hypernatremia. Because of the polyuria, severe dehydration and hypovolemic shock may occur.

Diagnostic Studies

Because DI may be central, nephrogenic, or psychogenic in origin, identification of the cause is the initial step. A complete history is documented, and a thorough physical examination is performed. Primary or psychogenic DI is associated with overhydration and hypervolemia rather than with the dehydration and hypovolemia seen in other forms of DI. A water deprivation test is usually performed to confirm the diagnosis of central DI. Before the water

deprivation test, the patient's baseline weight, pulse, urine and plasma osmolalities, specific gravity of urine, and blood pressure (BP) are measured. All fluids are withheld for 8 to 16 hours. Patients may be anxious and should be reassured that the test will be stopped if fluid volume deficit becomes severe. Patients should be observed throughout the test because of the craving to drink. During the test, the patient's BP, weight, and urine osmolality are assessed hourly. The test continues until urine osmolality stabilizes (hourly increase of <30 mmol/kg in 3 consecutive hours), body weight declines by 3%, or orthostatic hypotension develops. ADH is then given, and urine osmolality is measured 1 hour later. In central DI, the rise in urinary osmolality after vasopressin administration exceeds 9%. Individuals with nephrogenic DI will have no response (Pagana & Pagana, 2013).

Collaborative Care

Determining and treating the primary cause is central in the collaborative management of DI. The therapeutic goal is maintenance of fluid and electrolyte balance.

For central DI, fluid and hormonal replacement is the cornerstone of treatment. In acute DI, hypotonic saline is administered IV and titrated to replace urinary output (Gardner, 2011). Hormone replacement is necessary because of the lack of ADH production or secretion. Desmopressin acetate (DDAVP), an analogue of ADH, is the hormone replacement of choice for central DI. DDAVP can be administered orally, IV, or as a nasal spray. Another drug available for ADH replacement is vasopressin. Several drugs can be used for the treatment of partial central DI, including carbamazepine (Tegretol).

Hormone replacement has little effect in the treatment of nephrogenic DI because the kidney is unable to respond to ADH. Instead, the treatment for nephrogenic DI revolves around dietary measures (low-sodium diet) and thiazide diuretics. Limiting sodium intake to no more than 3 g per day is thought to help decrease urine output. Thiazide diuretics (e.g., hydrochlorothiazide) are able to slow the GFR and allow the kidneys to reabsorb more water in the loop of Henle and the distal tubules. When low-sodium diet and

thiazides are not effective, indomethacin (Indocin) may be prescribed. Indomethacin, a nonsteroidal anti-inflammatory drug (NSAID), helps increase renal responsiveness to ADH.

Nursing Management Diabetes Insipidus

Nursing management of patients with DI revolves around early detection, maintenance of adequate hydration, and patient teaching for long-term management.

Acute DI is treated with fluids and hormone replacement. Fluids are replaced orally or IV, depending on the patient's condition and ability to drink copious amounts of fluids. Adequate amounts of fluids should be kept at the patient's bedside. If IV glucose solutions are used, the serum glucose level should be monitored because hyperglycemia and glucosuria can lead to osmotic diuresis, which increases the fluid volume deficit. Monitoring of blood pressure (BP), heart rate, and urine output and specific gravity is essential and may be required hourly in the patient who is acutely ill. Level of consciousness must also be monitored, as well as signs of acute dehydration, by assessing alertness, response to stimuli, mucous membranes, tachycardia, and skin turgor. Accurate records of intake and output, urine specific gravity, and daily weights are mandatory in the assessment of fluid volume status.

Nursing interventions also include the administration of DDAVP. Patients should be assessed for weight gain, headache, restlessness, and signs of hyponatremia and water intoxication. By monitoring fluid intake and output and the urine specific gravity, the nurse can assess the adequacy of treatment. The health care provider should be notified immediately if the patient with DI develops increased urine volume with a low specific gravity because this may indicate the need to change the dosage of DDAVP.

The patient with chronic DI requiring long-term ADH replacement needs instruction in self-management. DDAVP can be taken orally or intranasally. Nasal irritation may result from nasal administration. Headache, nausea, and other signs of hyponatremia may indicate overdosage, whereas failure to improve may indicate underdosage. The patient should be instructed to report any of these symptoms. Patients taking DDAVP should be instructed to monitor

their weight daily; increases in weight may indicate fluid retention. The need for close follow-up, including laboratory studies, is an essential part of the teaching plan.

Table 51-5 compares diabetes insipidus and SIADH.

TABLE 51-5

COMPARISON OF DIABETES INSIPIDUS AND SIADH

Feature	Diabetes Insipidus	SIADH
Definition	Deficiency of ADH results in inability to conserve water.	Excessive amounts of ADH are secreted from posterior pituitary and other ectopic sources.
Pathophysiological features	With ADH deficiency, permeability of water is diminished, which results in excretion of large volumes of hypotonic fluid. Three patterns may develop: (a) transient diabetes insipidus—abrupt onset within first few days after neurosurgery, resolves; (b) permanent diabetes insipidus—abrupt and early onset, persists for several weeks or for life; (c) triphasic diabetes insipidus—an acute phase with abrupt onset of polyuria; an interphase, in which urine volume apparently normalizes; and a third phase, in which central diabetes insipidus is permanent.	Key features of ADH excess are (a) water retention, (b) hyponatremia, and (c) hypo-osmolality. Continual release of ADH causes water retention from renal tubules and collecting ducts; extracellular fluid volume increases with dilutional hyponatremia; and hyponatremia suppresses renin and aldosterone secretions, which causes decrease in proximal tubule reabsorption of Na^+.
Clinical manifestations	Genito-urinary: polyuria: 5 to 18 L/day; clear urine; urinary frequency; nocturia Gastro-intestinal: weight loss; polydipsia (if thirst mechanism intact) Integumentary: dry skin and mucous membranes Neurological: mentation changes as electrolyte imbalance and hypotension worsen	Related to degree of hyponatremia: confusion, lethargy, irritability, seizures, coma Gastro-intestinal: decreased motility with anorexia, nausea, vomiting; abrupt weight gain *without edema* in 5%-10% of affected patients

ADH, antidiuretic hormone; *SIADH,* syndrome of inappropriate antidiuretic hormone.

Disorders of the Thyroid Gland

The thyroid hormones—thyroxine (T_4) and triiodothyronine (T_3)—regulate energy metabolism, growth, and development. Disorders of the thyroid gland include enlargement, benign and malignant nodules, inflammation, and hyperfunctioning and hypofunctioning states (Figure 51-5).

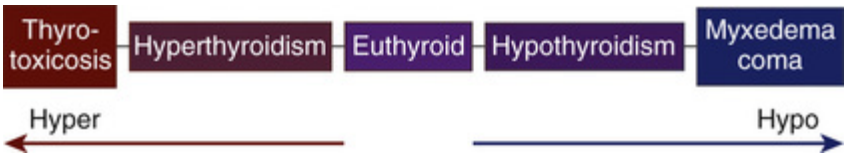

FIGURE 51-5 Continuum of thyroid dysfunction.

Goitre

A **goitre** is an enlarged thyroid gland. In a person with a goitre, the thyroid cells are stimulated to grow, which may result in an overactive thyroid (hyperthyroidism) or an underactive one (hypothyroidism). Goitres are common in patients with Graves' disease (Figure 51-6). A goitre that produces excess thyroid hormone is called a *toxic goitre.* A nontoxic goitre produces normal levels of thyroid hormone. Goitre as a clinical manifestation of thyroid disorders is further discussed in the following sections.

FIGURE 51-6 Exophthalmos and goitre of Graves' disease.

Source: Forbes, C. D., & Jackson, W. F. (2003). *Color atlas and text of clinical medicine* (3rd ed., p. 309, Figure 7.55). London: Mosby.

The most common cause of goitre worldwide is a lack of iodine in the diet. In Canada, where most people use iodized salt, goitre is more often caused by the overproduction or underproduction of thyroid hormones or by nodules that develop in the gland itself. Foods or drugs that contain thyroid-inhibiting substances (goitrogens) can cause goitre (Table 51-6).

TABLE 51-6
GOITROGENS

Thyroid Inhibitors	Other Drugs	Foods*
• Iodine in large doses • Methimazole (Tapazole) • Propylthiouracil	• Amiodarone • Lithium • Para-aminosalicylic acid • Salicylates • Sulphonamides	• Broccoli • Brussels sprouts • Cabbage • Cauliflower • Kale • Mustard • Peanuts • Turnips

*List is not all-inclusive.

In a person with a goitre, TSH and T_4 levels are measured to determine whether a goitre is associated with hyperthyroidism, hypothyroidism, or normal thyroid function. Thyroid antibodies are measured to assess for thyroiditis (inflammation of the thyroid). Treatment with thyroid hormone may prevent further thyroid enlargement. Large goitres are removed surgically.

Thyroid Nodules and Cancer

A *thyroid nodule,* a palpable deformity of the thyroid gland, may be benign or malignant. More than 95% of all thyroid nodules are benign. The incidence of thyroid nodules increases with age. Benign nodules are usually not dangerous, but they can cause tracheal compression if they become too large. Nodules should be assessed and evaluated (discussed in the section Diagnostic Studies).

Thyroid cancer is the most common endocrine-related carcinoma. It was estimated that 5 600 new cases of thyroid cancer would be diagnosed in Canada in 2012 (Canadian Cancer Society's Steering Committee on Cancer Statistics, 2012), the majority of these in women. The primary sign of thyroid cancer is the presence of a painless, palpable nodule or nodules in an enlarged thyroid gland. Patients or health care providers discover most of these nodules during routine palpation of the neck.

Types of Thyroid Cancer

The four main types of thyroid cancer include papillary, follicular, medullary, and anaplastic. *Papillary* thyroid cancer is the most common type, accounting for about 70% to 80% of all thyroid cancers. Papillary cancer tends to grow slowly and spreads initially to lymph nodes in the neck.

Follicular thyroid cancer, which accounts for approximately 10% to 15% of all thyroid cancers, tends to occur in older adults. Follicular cancer first grows into the cervical lymph nodes. Follicular cancer is more likely than papillary cancer to grow into blood vessels and, from there, to spread to the lungs and bones.

Medullary thyroid cancer, which accounts for 5% to 10% of all thyroid cancers, is more likely to occur in families and to be associated with other endocrine problems. It can be diagnosed through genetic testing for a proto-oncogene called *RET*. In family members of a person with medullary thyroid cancer, a positive finding of the *RET* proto-oncogene can enable early diagnosis and treatment of medullary thyroid cancer.

Anaplastic thyroid cancer, which accounts for less than 5% of all thyroid cancers, is the most advanced and aggressive thyroid cancer. It is the least likely to respond to treatment.

Diagnostic Studies

Nodular enlargement of the thyroid gland or palpation of a mass usually necessitates radiological evaluation. Ultrasonography is often the first radiological test used in the diagnostic workup of a thyroid nodule. CT, MRI, and ultrasonography-guided fine-needle aspiration (FNA) are other diagnostic options. FNA is indicated when a tissue sample is necessary for pathological examination. A thyroid scan may also be performed to evaluate for possible malignancy. The scan shows whether nodules on the thyroid are "hot" or "cold." Thyroid tumours may or may not take up radioactive iodine (RAI). Tumours that take up the RAI are called "hot" nodules and are nearly always benign. If the nodule does not take up the radioactive iodine, it appears as "cold" and has a higher risk of being malignant. Measurement of serum calcitonin is also

helpful in diagnosis because increased levels are associated with medullary thyroid carcinoma.

Nursing and Collaborative Care Thyroid Cancer

Surgical removal of the tumour is usually indicated in the treatment of thyroid cancer. Surgical procedures may range from unilateral total lobectomy to total thyroidectomy with bilateral lobectomy. RAI may be given to some patients to destroy any remaining cancer cells after surgery but is not commonly used (Lamartina, Durante, Filetti, et al., 2015). In addition, many thyroid cancers are TSH dependent, and thyroid hormone in high doses is often prescribed to inhibit pituitary secretion of TSH. Radiation therapy is rarely used (Thyroid Foundation of Canada, 2016). Chemotherapy may be used in advanced disease. Nursing care for patients with thyroid tumours is similar to care for patients who have undergone thyroidectomy and should also include general nursing measures for patients with cancer (see Chapter 18 and NCPs 18-1 and 18-2 for the care of patients undergoing radiation and chemotherapy, available on the Evolve website).

Multiple Endocrine Neoplasia

Multiple endocrine neoplasia is an inherited condition characterized by hormone-secreting tumours (Clark, 2015). Multiple endocrine neoplasia is caused by the mutation of one of two genes, *MEN1* or *RET,* that normally control cell growth. Tumours may develop in childhood or later in life.

The two major types of multiple endocrine neoplasia are type 1 and type 2. Both types are commonly inherited as autosomal dominant disorders. People with type 1 neoplasia commonly show signs of parathyroid gland hyperactivity (hyperparathyroidism). Other signs may include hyperactivity of the pituitary gland (prolactinoma) and pancreas (gastrinomas). In most cases, the tumours are initially benign, and some tumours later become malignant. People with type 2 neoplasia often have clinical manifestations of medullary thyroid carcinoma. They may also

develop pheochromocytoma (tumour of the adrenal glands). (Pheochromocytoma is discussed later in this chapter.)

Treatment of the tumour(s) may include conservative management (watchful waiting), medication to block the effects of excess hormone, and surgical removal of the gland or tumour (or both). It is important for patients with multiple endocrine neoplasia to have regular screening visits with their health care provider so that new tumours may be detected early and existing tumours carefully monitored.

Thyroiditis

Thyroiditis is an inflammation of the thyroid gland that can have several causes. *Subacute granulomatous thyroiditis* is thought to be caused by a viral infection. *Acute thyroiditis* is caused by a bacterial or fungal infection. Subacute and acute forms of thyroiditis have abrupt onsets and usually a recent viral infection. The thyroid gland is tender and enlarged, and the patient often has neck pain and fatigue (Lian-Xi, Xing, Bing, et al., 2014). *Chronic autoimmune thyroiditis* (Hashimoto's thyroiditis) can lead to hypothyroidism. *Hashimoto's thyroiditis* is a chronic autoimmune disease in which thyroid tissue is replaced by lymphocytes and fibrous tissue (Figure 51-7). It is the most common cause of goitrous hypothyroidism and is most common in women. *Silent thyroiditis,* a form of lymphocytic thyroiditis, has a variable onset and no apparent symptoms. *Postpartum thyroiditis* occurs frequently in women with a history of thyroid disease who have recently given birth. In most respects, silent and postpartum thyroiditis resemble Hashimoto's thyroiditis, except that the gland tends to recover and thyroid hormone treatment needs to be administered for only a few weeks (Thyroid Foundation of Canada, 2016).

FIGURE 51-7 Appearance of the neck in Hashimoto's thyroiditis. Source: Belchetz, P. E., & Hammond, P. (2003). *Mosby's color atlas and text of diabetes and endocrinology*. London: Mosby.

T_4 and T_3 levels are initially elevated in subacute, acute, and silent thyroiditis but may become depressed over time. TSH levels are initially low and then elevated. Thyroid hormone levels are usually low in chronic Hashimoto's thyroiditis, but the TSH level is high. Radioactive iodine uptake (RAIU) is suppressed in subacute and silent thyroiditis. Antithyroid antibodies are present in patients with Hashimoto's thyroiditis.

Recovery from thyroiditis may be complete in weeks or months without treatment. If the condition is bacterial in origin, treatment may include specific antibiotics or surgical drainage. In subacute and acute forms, salicylates and NSAIDs are administered. If patients do not respond to these drugs in 48 hours, corticosteroids are administered. Propranolol (Inderal) or atenolol (Tenormin) may be used for the cardiovascular symptoms of a hyperthyroid condition. Thyroid hormone replacement is indicated if a patient is hypothyroid.

Nursing care of patients with thyroiditis involves teaching about treatment and encouraging adherence to the treatment regimen. Patients are instructed to remain under close health care supervision so that progress can be monitored and any change in symptoms can be reported immediately to the health care provider.

Patients with thyroiditis of autoimmune origin may be susceptible to other autoimmune disorders such as Addison's disease, pernicious anemia, premature gonadal failure, or Graves' disease

(Hubbard, 2011). Patients should be taught the signs and symptoms of these disorders, particularly Addison's disease. A patient receiving thyroid hormone replacement must be taught the expected adverse effects of these drugs and how to manage them. Patients treated surgically need care similar to that given to patients undergoing thyroidectomy.

Hyperthyroidism

Hyperthyroidism is hyperactivity of the thyroid gland with sustained increase in synthesis and release of thyroid hormones. **Thyrotoxicosis** is the clinical syndrome of hypermetabolism caused by excess circulating levels of T_4, T_3, or both. Hyperthyroidism and thyrotoxicosis usually occur together, as in Graves' disease. However, in some forms of thyroiditis, thyrotoxicosis may occur without hyperthyroidism (Vaidya & Pearce, 2014).

Hyperthyroidism is more prevalent among women than among men; the frequency is highest among people 20 to 40 years old. The most common form of hyperthyroidism is Graves' disease. Other causes include toxic nodular goitre, thyroiditis, exogenous iodine excess, pituitary tumours, and thyroid cancer.

Etiology and Pathophysiology

Graves' Disease.

Graves' disease is an autoimmune disease of unknown etiology marked by diffuse thyroid enlargement and excessive thyroid hormone secretion. Precipitating factors such as insufficient iodine supply, infections, and stressful life events may interact with genetic factors to cause Graves' disease. In Canada, Graves' disease accounts for 90% of the cases of hyperthyroidism and is more common in females (Thyroid Foundation of Canada, 2016). Cigarette smoking increases the risk for the development of eye problems associated with the disease (Strianese, Piscopo, Elefante, et al., 2013). Patients with this disease develop antibodies to the TSH receptor. These antibodies attach to the receptors and stimulate the thyroid gland to

release T_3, T_4, or both. The excessive release of thyroid hormones leads to the clinical manifestations associated with thyrotoxicosis. The disease is characterized by remissions and exacerbations, with or without treatment. It may progress to destruction of thyroid tissue, which causes hypothyroidism.

Toxic Nodular Goitres.

Nodular goitres are characterized by thyroid hormone–secreting nodules that are independent of TSH stimulation. If associated with signs of hyperthyroidism, a nodule is termed *toxic.* A goitre may have multiple nodules (multinodular goitre) or a single nodule (solitary autonomous nodule). The nodules are usually benign follicular adenomas. Toxic nodular goitres occur equally in men and women. Although they can appear at any age, the frequency of toxic multinodular goitre is highest among people older than 40 years.

Clinical Manifestations

The clinical manifestations of hyperthyroidism are related to the effects of excess amounts of thyroid hormones. Excess amounts of circulating thyroid hormone directly increase metabolism. They also increase tissue sensitivity to stimulation by the sympathetic nervous system.

Palpation of the thyroid gland may reveal a goitre. When the thyroid gland is excessively large, a goitre may be visible. Auscultation of the thyroid gland may reveal bruits, a reflection of increased blood supply. Another common finding associated with hyperthyroidism is *ophthalmopathy,* a term used to describe abnormal eye appearance or function. A classic finding in Graves' disease is **exophthalmos,** a protrusion of the eyeballs from the orbits (see Figure 51-6). Exophthalmos is a type of infiltrative ophthalmopathy that results from impairment of venous drainage from the orbit, which causes increased fat deposits and fluid (edema) in the retro-orbital tissues. Because of increased pressure, the eyeballs are forced outward and protrude. This sign is seen in 20% to 50% of patients with Graves' disease. It is usually bilateral but can be unilateral or asymmetrical. In ophthalmopathy, the upper eyelids are usually

retracted and elevated, with the sclera visible above the iris. When the eyelids do not close completely, the exposed corneal surfaces become dry and irritated. Serious consequences, such as corneal ulcers and eventual loss of vision, can occur. The changes in the ocular muscles result in muscle weakness, causing diplopia.

Other common manifestations of thyroid hyperfunction are summarized in Table 51-7. A patient with advanced disease may exhibit many of the manifestations, whereas a patient in the early stages of hyperthyroidism may exhibit only weight loss and increased nervousness. Manifestations of hyperthyroidism (e.g., palpitations, tremors, weight loss) in older adults do not differ significantly from those in younger adults. In some instances in which confusion and agitation are reported, dementia may be suspected and may delay the diagnosis. In Table 51-8, features of hyperthyroidism in younger- and older-adult patients are compared.

TABLE 51-7
CLINICAL MANIFESTATIONS OF THYROID DYSFUNCTION

Hypofunction	Hyperfunction
Cardiovascular System	
• Anemia • Cardiac hypertrophy • Decreased rate and force of cardiac contractions • Distant heart sounds • Increased capillary fragility • Tendency to develop heart failure, angina, myocardial infarction • Varied changes in blood pressure	• Angina • Atrial fibrillation (more common in older adults) • Bounding, rapid pulse • Cardiac hypertrophy • Dysrhythmias • Increased cardiac output • Increased rate and force of cardiac contractions • Palpitations • Systolic hypertension • Systolic murmurs
Respiratory System	
• Decreased breathing capacity • Dyspnea	• Dyspnea on mild exertion • Increased respiratory rate
Gastro-Intestinal System	
• Celiac disease • Constipation • Decreased appetite • Distended abdomen • Enlarged, scaly tongue • Nausea and vomiting • Weight gain	• Diarrhea, frequent defecation • Hepatomegaly • Increased appetite, thirst • Increased bowel sounds • Increased peristalsis • Splenomegaly • Weight loss
Integumentary System	
• Decreased sweating • Dry, sparse, coarse hair • Dry, thick, inelastic, cold skin • Generalized interstitial edema • Pallor • Poor turgor of mucosa • Puffy face • Thick, brittle nails	• Clubbing of fingers (thyroid acropachy) • Diaphoresis • Fine, silky hair • Hair loss (may be patchy) • Palmar erythema • Premature greying (in men) • Pretibial myxedema (infiltrative dermopathy) • Thin, brittle nails detached from nail bed (onycholysis) • Warm, smooth, moist skin
Musculo-Skeletal System	
• Arthralgia • Fatigue • Muscular aches and pains • Slow movements • Weakness	• Dependent edema • Fatigue • Muscle weakness • Osteoporosis • Proximal muscle wasting
Nervous System	

Hypofunction	Hyperfunction
• Anxiety, depression • Apathy • Delayed relaxation of deep tendon reflexes • Fatigue • Forgetfulness • Hoarseness • Lethargy • Paresthesias • Polyneuropathy • Slow, slurred speech • Slowed mental processes • Stupor, coma	• Depression, fatigue, apathy (in older adults) • Difficulty in focusing eyes • Exhaustion • Fine tremor (of fingers and tongue) • Hyper-reflexia of tendon reflexes • Inability to concentrate • Insomnia • Lability of mood, delirium • Nervousness • Personality changes: irritability, agitation • Restlessness • Stupor, coma
Reproductive System	
• Decreased libido • Infertility • Prolonged menstrual periods or amenorrhea	• Amenorrhea • Decreased fertility • Decreased libido • Erectile dysfunction in men • Gynecomastia in men • Menstrual irregularities
Other	
• Decreased hearing • Goitre • Increased sensitivity to opioids, barbiturates, anaesthetics • Increased susceptibility to infection • Intolerance of cold • Sleepiness	• Elevated basal temperature • Exophthalmos • Eyelid lag, stare • Eyelid retraction • Goitre • Increased sensitivity to stimulant drugs • Intolerance of heat • Rapid speech

Complications

Thyrotoxic crisis (also called *thyroid storm*) is a rare, acute condition in which all hyperthyroid manifestations are intensified. Although thyrotoxic crisis is considered a life-threatening emergency, death is rare when treatment is initiated early. The cause is thought to be stressors (e.g., infection, trauma, surgery) in a patient with pre-existing hyperthyroidism, either diagnosed or undiagnosed. Heart and nerve tissues become more sensitive to sympathetic nervous system activation because more binding sites for epinephrine and norepinephrine are present.

Manifestations include severe tachycardia, heart failure, shock, hyperthermia (temperature up to 40.7°C), restlessness, agitation, seizures, abdominal pain, nausea, vomiting, diarrhea, delirium, and coma. Treatment is aimed at reducing circulating thyroid hormone levels and the clinical manifestations of this disorder by appropriate

drug therapy. Supportive therapy is directed at managing respiratory distress, fever reduction, fluid replacement, and elimination or management of the initiating stressor or stressors.

Diagnostic Studies

The two primary laboratory findings used to confirm the diagnosis of hyperthyroidism are decreased TSH levels and elevated free T_4 levels. Total T_3 and T_4 levels may also be assessed, but these are not as definitive. Measurements of total T_3 and T_4 include both free and bound (to protein) hormone levels. The free hormone is the only form of the hormone that is biologically active.

The radioactive iodine uptake test is indicated to differentiate Graves' disease from other forms of thyroiditis. The 24-hour test of radioiodine uptake in patients with Graves' disease reveals a diffuse, homogeneous uptake of 35% to 90%, whereas in patients with thyroiditis, the amount of uptake is less than 20%. Patients with nodular goitre demonstrate uptake in the high-normal range (see Table 51-8).

TABLE 51-8

COMPARISON OF HYPERTHYROIDISM IN YOUNGER AND OLDER ADULTS

Features	Younger Adults	Older Adults
Common causes	Graves' disease in >90% of cases	Graves' disease or toxic nodular goitre
Common symptoms	Nervousness; irritability; weight loss; heat intolerance; warm, moist skin	Anorexia, weight loss, apathy, lassitude, depression, confusion
Goitre	Present in >90% of cases	Present in ~50% of cases
Ophthalmopathy	Exophthalmos present in 20%–50% of cases	Occasional exophthalmos
Cardiac features	Tachycardia and palpitations common, but without heart failure	Angina, dysrhythmias (especially atrial fibrillation), or heart failure may occur

Collaborative Care

The overall goal in the treatment of hyperthyroidism is to block the adverse effects of thyroid hormones and stop their oversecretion. The three primary treatment options for patients with hyperthyroidism are antithyroid medications, radioactive iodine

therapy, and subtotal thyroidectomy (Table 51-9). However, the choice of treatment is influenced by the patient's age, the severity of the disorder, complicating features (including pregnancy), and the patient's preferences.

TABLE 51-9
COLLABORATIVE CARE
Hyperthyroidism

Diagnostic
• History and physical examination
• Electrocardiography
• Laboratory tests
  • Serum free T_4, TSH levels
  • TRH stimulation test
• Ophthalmological examination
• Radioactive iodine uptake (RAIU)
Collaborative Therapy
Drug Therapy
• Antithyroid drugs
  • Methimazole (Tapazole)
  • Propylthiouracil (Propyl-Thyracil)
	• Iodine
	• β-Adrenergic blockers (e.g., propranolol [Inderal])
	Radiation Therapy
	• Radioactive iodine
	Surgical Therapy
	• Subtotal thyroidectomy
	Nutritional Therapy
	• Frequent meals
	• High-calorie diet
	• High-protein diet

T_4, thyroxine; *TRH,* thyrotropin-releasing hormone; *TSH,* thyroid-stimulating hormone.

Drug Therapy.

Drugs used in the treatment of hyperthyroidism include antithyroid drugs, iodine, and β-adrenergic blockers. It is important to note that although these drugs are useful in the treatment of thyrotoxic states, they are not considered curative. Radiation therapy or surgery may ultimately be required.

Antithyroid Drugs.

The first-line antithyroid drugs used in the treatment of hyperthyroidism are thioamides, such as propylthiouracil (Propyl-Thyracil) and methimazole (Tapazole). These drugs inhibit the synthesis of thyroid hormones. Propylthiouracil also blocks peripheral conversion of T_4 to T_3. Individual response is considerably varied; however, improvement usually begins 1 to 2 weeks after the initiation of therapy, and good results are seen

within 4 to 8 weeks. Therapy is usually continued for 6 months to 2 years to allow for spontaneous remission. The major disadvantages of these drugs are possible nonadherence to the regimen and a high rate of recurrence of hyperthyroidism when the drugs are discontinued. Indications for use of antithyroid drugs include Graves' disease in young patients, hyperthyroidism during pregnancy, and the need to attain a euthyroid state before surgery or radiation therapy.

Iodine.

Iodine is used with other antithyroid drugs in the preparation of a patient for thyroidectomy or for treatment of thyrotoxic crisis. The administration of iodine in large doses rapidly inhibits synthesis of T_3 and T_4 and blocks the release of these hormones into the circulation. It also decreases the vascularity of the thyroid gland, which makes surgery safer and easier. The effect of iodine is usually maximal within 1 to 2 weeks. Because the therapeutic effect lessens, long-term iodine therapy is not effective in controlling hyperthyroidism. Iodine is available in the form of Lugol's solution (Health Canada, 2016).

β-Adrenergic Blockers.

β-Adrenergic blockers are used for symptomatic relief of thyrotoxicosis that results from increased β-adrenergic receptor stimulation caused by excess thyroid hormones. Propranolol (Inderal) is usually administered with other antithyroid agents and rapidly provides symptomatic relief. Atenolol (Tenormin) is the preferred β-adrenergic blocker for use in hyperthyroid patients with asthma or heart disease.

Radioactive Iodine Therapy.

Radioactive iodine (RAI) therapy is the treatment of choice for most nonpregnant adults. (Before initiation of therapy, a pregnancy test is performed on all women who menstruate.) RAI damages or destroys thyroid tissue, thus limiting thyroid hormone secretion. Patients should be instructed that radiation-related thyroiditis and parotiditis are possible and may cause dryness and irritation of the mouth and

throat. Relief may be obtained with frequent sips of water, ice chips, or the use of normal saline or a baking soda solution (e.g., 10 mL of baking soda in 250 mL of water) to gargle three or four times per day. The discomfort should subside in 3 to 4 days. If dryness and irritation persist, patients should contact the health care provider. The response to radioactive iodine is delayed, and the effect may not be maximal for 2 to 3 months. For this reason, patients are usually treated with antithyroid drugs and propranolol before and during the first 3 months after the initiation of RAI, until the effects of irradiation become apparent. Although this method of treatment is usually effective, there is a high incidence of post-treatment hypothyroidism, which results in the need for lifelong thyroid hormone replacement. Patients and the family or caregiver should be taught about the symptoms of hypothyroidism and instructed to seek medical help if these symptoms occur.

Surgical Therapy.

Thyroidectomy is indicated when a large goitre causes tracheal compression, when patients do not respond to antithyroid therapy, and in patients with thyroid cancer. In addition, surgery may be performed when an individual is not a candidate for RAI. One advantage of thyroidectomy over RAI is a more rapid reduction in T_3 and T_4 levels. A *subtotal thyroidectomy* is the preferred surgical procedure and involves the removal of a significant portion (90%) of the thyroid gland. If too much tissue is taken, the gland does not regenerate after surgery, and hypothyroidism results.

Endoscopic thyroidectomy is a minimally invasive procedure. In this procedure, several small incisions are made through which an endoscope and other instruments can be passed to remove thyroid tissue or nodules. It is an appropriate procedure for patients with small nodules (<3 cm in diameter) in whom there is no evidence of malignancy. Advantages of endoscopic thyroidectomy over the traditional approach are less scarring, less pain, and a faster return to normal activity.

Before surgery, antithyroid drugs, iodine, and β-adrenergic blockers may be administered to achieve a euthyroid state and to control symptoms. Iodine reduces vascularization of the gland,

thereby reducing the risk for hemorrhage. Postoperative complications include hypothyroidism, damage to or inadvertent removal of parathyroid glands (causing hypoparathyroidism and hypocalcemia), hemorrhage, injury to the recurrent or the superior laryngeal nerve, thyrotoxic crisis, and infection.

Nutritional Therapy.

The potential for nutritional deficits is high when the metabolic rate is increased. A high-calorie diet (4 000 to 5 000 kcal/day) may be ordered to satisfy hunger and prevent tissue breakdown. This is accomplished with six full meals a day and snacks high in protein, carbohydrates, minerals, and vitamins, particularly vitamin A, thiamine, vitamin B_6, and vitamin C. The protein allowance should be 1 to 2 g/kg of ideal body weight. Increased carbohydrates should compensate for disturbed metabolism, provide energy, and spare body protein stores. Highly seasoned and high-fibre foods should be avoided because they can further stimulate the already hyperactive GI tract. Substitutes should be provided for caffeine-containing beverages such as coffee, tea, and cola because their stimulating effects increase restlessness and sleep disturbances. The nurse should consult a dietitian for guidance in meeting the nutritional needs of a patient with hyperthyroidism.

Nursing Management Hyperthyroidism

Nursing Assessment

Subjective and objective data that should be obtained from an individual with hyperthyroidism are presented in Table 51-10.

TABLE 51-10

NURSING ASSESSMENT
Hyperthyroidism

Subjective Data
Important Health Information
Past health history: Pre-existing goitre; recent infection or trauma; immigration from iodine-deficient area; autoimmune disease; positive family history of thyroid or autoimmune disorders *Medications:* Use of thyroid hormones or herbal therapies that may contain thyroid hormone
Symptoms
• Chest pain; dyspnea on exertion; palpitations • Decreased libido; erectile dysfunction, gynecomastia (in men); amenorrhea (in women) • Diarrhea; polyuria • Emotional lability, irritability, restlessness, personality changes, delirium, nervousness • Heat intolerance; pruritus; sweating • Insomnia • Insufficient iodine intake; weight loss; increased appetite or thirst; nausea • Muscle weakness, fatigue
Objective Data
General Observation
Agitation, rapid speech and body movements; hyperthermia, enlarged or nodular thyroid gland
Eyes
Exophthalmos, eyelid retraction; infrequent blinking
Integumentary
Warm, diaphoretic, velvety skin; thin, loose nails; fine, silky hair and hair loss; palmar erythema; digital clubbing; white pigmentation of skin (vitiligo); diffuse edema of legs and feet
Respiratory
Tachypnea
Cardiovascular
Tachycardia, bounding pulse, systolic murmurs, dysrhythmias, hypertension
Gastro-Intestinal
Increased bowel sounds; hepatosplenomegaly
Neurological
Hyper-reflexia; diplopia; fine tremors of hands, tongue, eyelids; stupor; coma
Musculo-Skeletal
Muscle wasting
Reproductive
Menstrual irregularities, infertility in women; erectile dysfunction, gynecomastia in men
Possible Findings
↑ T_3 level, ↑ T_4 level; ↑ T_3 resin uptake; ↓serum TSH level; chest radiograph showing enlarged heart, findings of tachycardia, atrial fibrillation on ECG

ECG, electrocardiogram; T_3, triiodothyronine; T_4, thyroxine; *TSH*, thyroid-stimulating hormone.

Nursing Diagnoses

Nursing diagnoses for patients with hyperthyroidism include, but are not limited to, the following:

- *Activity intolerance* related to *physical deconditioning* (fatigue, exhaustion, heat intolerance secondary to hypermetabolism)
- *Imbalanced nutrition: less than body requirements* related to *insufficient dietary intake* (hypermetabolism)

Additional information on nursing diagnoses for the patient with hyperthyroidism are presented in Nursing Care Plan (NCP) 51-1, available on the Evolve website.

Planning

The overall goals are that patients with hyperthyroidism will (a) experience relief from symptoms, (b) have no serious complications related to the disease or treatment, (c) maintain nutritional balance, and (d) adhere to the therapeutic plan.

Nursing Implementation

Acute Intervention.

Individuals who have hyperthyroidism are usually treated in an outpatient setting. However, patients who develop acute thyrotoxicosis and those who undergo thyroidectomy require hospitalization and acute care.

Acute Thyrotoxicosis.

Acute thyrotoxicosis is a systemic syndrome that necessitates aggressive treatment, often in a critical care unit. Medications that block thyroid hormone production and the sympathetic nervous system (see previous discussion) should be administered. Supportive therapy includes monitoring for cardiac dysrhythmias and decompensation, ensuring adequate oxygenation, and administering IV fluids to replace fluid and electrolyte losses. This is especially important in patients who develop vomiting and diarrhea.

The patient's room should be kept calm and quiet because increased metabolism causes sleep disturbances. Provision of adequate rest may be a challenge because of the patient's irritability and restlessness. Specific interventions may include (a) placing the patient in a cool room, away from very ill patients and noisy, high-traffic areas; (b) using lightweight bed coverings and changing the linen frequently if the patient is diaphoretic; (c) encouraging and assisting with exercise involving large muscle groups (tremors can interfere with small-muscle coordination) to allow the release of nervous tension and restlessness; and (d) establishing a supportive, trusting relationship to help the patient cope with aggravating events and to lessen anxiety.

Exophthalmos, when present, incurs a potential for corneal injury related to irritation and dryness. Affected patients may also have orbital pain. Nursing interventions to relieve eye discomfort and prevent corneal ulceration include applying artificial tears to soothe and moisten conjunctival membranes. Salt restriction may help reduce periorbital edema. Elevation of the patient's head promotes fluid drainage from the periorbital area—the patient should sit upright as much as possible. Dark glasses reduce glare and prevent irritation from air currents, dust, and dirt. If the eyelids cannot be closed, they should be lightly taped shut for sleep. To maintain flexibility, the patient should be taught to exercise the intraocular muscles several times a day by turning the eyes in the complete range of motion. Good grooming can be helpful in reducing the loss of self-esteem that can result from an altered body image. If the exophthalmos is severe, corticosteroids, radiation of retro-orbital tissues, orbital decompression, or corrective eyelid or muscle surgery may be helpful.

Thyroid Surgery.

When subtotal thyroidectomy is the treatment of choice, patients must be adequately prepared in order to avoid postoperative complications. To alleviate thyrotoxicosis, iodine treatment or propylthiouracil may be given before surgery. Iodine is mixed with water or juice and sipped through a straw after meals. The nurse assesses patients for signs of iodine toxicity, such as swelling of

buccal mucosa and other mucous membranes, excessive salivation, nausea and vomiting, and skin reactions. If toxicity occurs, iodine administration should be discontinued and the physician notified.

Preoperative teaching should include comfort and safety measures in which patients can participate. Coughing, deep breathing, and leg exercises should be practised and their importance explained. Patients should be taught how to support the head manually while turning in bed because this manoeuvre minimizes stress on the suture line after surgery. Range-of-motion exercises of the neck should be practised. The nurse should explain routine postoperative care such as IV infusions. Patients should be told that talking is likely to be difficult for a short time after surgery.

Safety Alert

- Airway obstruction, although not common, may occur postoperatively.
- Airway obstruction is an emergency situation.
- Oxygen, suction equipment, and a tracheostomy tray should be readily available in the patient's room.

Recurrent laryngeal nerve damage leads to vocal cord paralysis. If both cords are paralyzed, spastic airway obstruction may occur, necessitating an immediate tracheostomy.

Respiration may also become difficult because of excess swelling of the neck tissues, hemorrhage, hematoma formation, and laryngeal stridor. *Laryngeal stridor* (harsh, vibratory sound) may occur during inspiration and expiration as a result of edema of the laryngeal nerve. Laryngeal stridor may also be related to tetany, which occurs if the parathyroid glands are removed or damaged during surgery, which leads to hypocalcemia. To treat tetany, calcium salts such as calcium gluconate and calcium chloride should be readily available for IV administration. After a thyroidectomy, the patient should be cared for as follows:

1. Assessment every 2 hours for 24 hours for signs of hemorrhage or tracheal compression, such as irregular breathing, neck swelling, frequent swallowing, sensations of fullness at the incision site, choking, and blood on the dressings.
2. Placement in a semi-Fowler's position, and support of the patient's head with pillows, with care to avoid flexion of the neck and any tension on the suture lines.
3. Monitoring of vital signs. The nurse completes the initial assessment by checking for signs of hypocalcemia and tetany secondary to hypoparathyroidism (e.g., tingling sensation in toes, in fingers, or around the mouth; muscular twitching; apprehension) and by evaluating difficulty in speaking and hoarseness. The nurse should also check for the presence of Trousseau's and Chvostek's signs for 72 hours (see Chapter 19, Figure 19-15). Some hoarseness is to be expected for 3 to 4 days after surgery because of edema.
4. Control of postoperative pain with medication.

If postoperative recovery is uneventful, patients are ambulated within hours after surgery, are permitted to take fluid as soon as tolerated, and may eat soft foods the day after surgery.

The appearance of the incision may be distressing to patients. They can be reassured that the scar will fade and eventually look like a normal neck wrinkle. A scarf, jewellery, a high collar, or other covering can effectively camouflage a fresh scar.

Ambulatory and Home Care

Postoperative Care.

Patients and family members need to be aware that thyroid hormone balance should be monitored periodically to ensure that normal function has returned. Most patients experience a period of relative hypothyroidism soon after surgery because of the substantial reduction in the size of the thyroid. The remaining tissue usually hypertrophies, recovering the capacity to produce the hormone

needed by the body, but this takes time. Thyroid hormone is not administered because exogenous hormone inhibits pituitary production of TSH and delays or prevents the restoration of normal gland function and thyroid tissue regeneration.

To prevent weight gain, caloric intake must be reduced substantially below the amount that was required before surgery. Adequate iodine is necessary to promote thyroid function, but excesses inhibit the thyroid. Seafood once or twice a week or normal use of iodized salt should provide sufficient iodine intake. Regular exercise stimulates the thyroid gland and should be encouraged. High environmental temperature should be avoided because it inhibits thyroid regeneration.

Regular follow-up care is necessary. Patients should be seen biweekly for a month and then at least semiannually to assess for the development of hypothyroidism. If a complete thyroidectomy has been performed, patients need instruction in lifelong thyroid replacement. Patients should be taught the signs and symptoms of progressive thyroid failure and instructed to seek medical care if these develop. Hypothyroidism is relatively easy to manage with oral administration of thyroid replacement.

Evaluation

The following are expected outcomes for patients with hyperthyroidism:

- Relief from symptoms
- No serious complications related to the disease or the treatment
- Adherence to the therapeutic plan

Hypothyroidism

Etiology and Pathophysiology

Hypothyroidism affects approximately 2 per 100 people (Thyroid Foundation of Canada, 2016). Hypothyroidism results from

insufficient circulating thyroid hormone as a result of various abnormalities. Hypothyroidism can be primary (related to destruction of thyroid tissue or defective hormone synthesis) or secondary (related to pituitary disease with decreased secretion of TSH or hypothalamic dysfunction with decreased secretion of thyrotropin-releasing hormone [TRH]). It may also be transient, related to thyroiditis or discontinuation of thyroid hormone therapy.

Iodine deficiency is the most common cause of hypothyroidism worldwide. In Canada, the most common cause of primary hypothyroidism in the adult is atrophy of the thyroid gland. This atrophy is the end result of Hashimoto's thyroiditis and Graves' disease. These autoimmune diseases destroy the thyroid gland. Hypothyroidism also may develop as a result of treatment for hyperthyroidism, specifically the surgical removal of the thyroid gland or radioactive iodine therapy. Drugs such as amiodarone (which contains iodine) and lithium (which blocks hormone production) are known to produce hypothyroidism.

Cretinism, hypothyroidism that develops in infancy, is caused by thyroid hormone deficiencies during fetal or early neonatal life. All infants in Canada are screened for decreased thyroid function at birth.

Clinical Manifestations

Regardless of the cause, hypothyroidism has common features. It has systemic effects, characterized by an insidious and nonspecific slowing of body processes. The clinical presentation can range from no symptoms to classic symptoms and physical changes easily detected on examination. Unless hypothyroidism occurs after thyroidectomy or thyroid ablation, or during treatment with antithyroid drugs, the onset of symptoms may occur unnoticed over months to years. The severity of symptoms experienced depends on the degree of thyroid hormone deficiency and the long-term physiological effects of thyroid hormone deficiency. Long-term effects may involve any body system but are more pronounced in neurological, cardiovascular, GI, reproductive, and hematological systems.

Many affected patients are fatigued and lethargic and experience personality and mental changes. The mental changes observed in hypothyroidism include impaired memory, slowed speech, decreased initiative, and somnolence. Many individuals with hypothyroidism appear depressed.

Hypothyroidism is associated with decreased cardiac output and decreased cardiac contractility. The patient may experience low exercise tolerance and shortness of breath on exertion. In patients with a pre-existing cardiovascular condition, hypothyroidism may cause significant hemodynamic compromise (Grais & Sowers, 2014).

Anemia is a common feature of hypothyroidism. Erythropoietin levels may be low or normal. Oxygen demand is decreased, and the bone marrow is hypocellular; the result is a low hematocrit. Other hematological problems are related to cobalamin, iron, and folate deficiencies. The patient may bruise easily. Increased serum cholesterol and triglyceride levels and the accumulation of mucopolysaccharides in the intima of small blood vessels can result in coronary atherosclerosis. This accumulation is seldom symptomatic (i.e., characterized by angina) because of the decreased myocardial oxygen consumption that has been observed in hypothyroidism.

GI motility is decreased in hypothyroidism, and achlorhydria (absence or decrease of hydrochloric acid) is common. Constipation, which is a common complaint, may progress to obstipation and, in rare cases, to intestinal obstruction. Other physical changes include cold intolerance, hair loss, dry and coarse skin, brittle nails, hoarseness, muscle weakness and swelling, and weight gain. Weight gain is probably a result of decreased metabolic rate.

Patients with severe, longstanding hypothyroidism may display **myxedema,** the accumulation of hydrophilic mucopolysaccharides in the dermis and other tissues (Figure 51-8). This mucinous edema causes the characteristic facies of hypothyroidism (i.e., puffiness, periorbital edema, and masklike affect). Individuals with hypothyroidism may describe impaired self-image in regard to their disabilities and altered appearance.

FIGURE 51-8 Patient with myxedema, displaying the characteristic facies of hypothyroidism (i.e., puffiness, periorbital edema, and masklike affect). Source: Seidel, H. M., Ball, J., Dains, J., et al. (2015). *Mosby's guide to physical examination* (8th ed., p. 190, Figure 10-10). St. Louis: Mosby. (Originally from Lemmi, F. O., Lemmi, C. A. E. [2000]. *Physical assessment findings.* [CD-ROM]. Philadelphia: Saunders.)

Women with hypothyroidism frequently complain of menorrhagia. In addition, cycles may be anovulatory, and subsequent infertility may occur (Dittrich, Beckmann, Oppelt, et al., 2011).

In older adults, the typical manifestations of hypothyroidism (including fatigue, cold and dry skin, hoarseness, hair loss, constipation, and cold intolerance) may be attributed to normal aging. For this reason, these symptoms may not raise suspicion about an underlying condition. Older adults who have confusion, lethargy, and depression should be evaluated for thyroid disease.

Complications

The mental sluggishness, drowsiness, and lethargy of hypothyroidism may progress gradually or suddenly to a notable impairment of consciousness or coma. This situation, **myxedema coma,** constitutes a medical emergency. Myxedema coma can be precipitated by infection, drugs (especially opioids, tranquilizers, and barbiturates), exposure to cold, and trauma. It is characterized by subnormal temperature, hypotension, and hypoventilation. For patients experiencing myxedema to survive, vital functions must be supported and IV thyroid hormone replacement must be administered.

Diagnostic Studies

The most common and reliable laboratory tests used to evaluate thyroid function are measurements of TSH and free T_4. These values, when correlated with symptoms evident in the history and physical examination, confirm the diagnosis. Serum TSH levels help determine the cause of hypothyroidism—they are high when the defect is in the thyroid and low when it is in the pituitary gland or hypothalamus. An increase in TSH level after injection of TRH suggests hypothalamic dysfunction, whereas no change suggests anterior pituitary dysfunction (Table 51-11). The presence of thyroid peroxidase antibodies suggests an autoimmune origin of the problem. Other abnormal laboratory findings are elevated cholesterol and triglyceride levels, anemia, and increased creatine kinase level.

TABLE 51-11
COLLABORATIVE CARE
Hypothyroidism

Diagnostic Studies	Collaborative Therapy
• History and physical examination • Serum T_3 and serum T_4 levels (if ordered) • Serum TSH and free T_4 levels • Thyroid peroxidase antibodies • TRH stimulation test	• Monitoring thyroid hormone levels and adjusting dosage (if needed) • Nutritional therapy to promote weight loss • Patient and caregiver teaching (see Table 51-12) • Thyroid hormone replacement (e.g., levothyroxine)

T_3, triiodothyronine; *T_4,* thyroxine; *TRH,* thyrotropin-releasing hormone; *TSH,* thyroid-stimulating hormone.

Collaborative Care

The overall goal for treatment in a patient with hypothyroidism is restoration of a euthyroid state as safely and rapidly as possible with hormone replacement therapy. A low-calorie diet is indicated to promote weight loss.

Levothyroxine (Synthroid, Eltroxin) is the drug of choice to treat hypothyroidism. In young and otherwise healthy patients, the maintenance replacement dose is adjusted according to the patients' response and laboratory findings. In older-adult patients and in patients with compromised cardiac status, a lower initial dosage is recommended because the usual dosage may increase myocardial oxygen demand. The increased oxygen demand may cause angina and cardiac dysrhythmias. Any chest pain experienced by a patient starting thyroid replacement should be reported immediately; electrocardiography (ECG) must be performed and serum cardiac enzymes measured. In patients without adverse effects, the dose is increased at 4- to 6-week intervals. It is important that patients take replacement medication regularly. Lifelong thyroid replacement therapy is usually required.

Drug Alert

Levothyroxine (Synthroid)

- Patients with cardiovascular disease who take this drug must be carefully monitored.
- Heart rate must be monitored and pulse greater than 100 beats/min or an irregular heartbeat must be reported.
- Chest pain, weight loss, nervousness, tremors, or insomnia must be promptly reported.
- Multiple levothyroxine preparations are currently available. Patients taking levothyroxine must have serum TSH levels checked 4 to 6 weeks after changing levothyroxine preparation.

Nursing Management Hypothyroidism

Nursing Assessment

Careful assessment of patients suspected of having hypothyroidism may reveal the early and subtle changes that indicate dysfunction. Assessment should include questions about weight gain, mental changes, fatigue, slowed and slurred speech, cold intolerance, skin changes such as increased dryness or thickening, constipation, and dyspnea. Patients should be questioned about recent introduction of iodine-containing medications. They should be assessed for bradycardia; distended abdomen; dry, thick, cold skin; thick, brittle nails; paresthesias; and muscular aches and pains.

Nursing Diagnoses

Nursing diagnoses for patients with hypothyroidism may include, but are not limited to, the following:

- *Activity intolerance* related to *physical deconditioning* (weakness and fatigue)
- *Constipation* related to *decrease in gastro-intestinal motility*

Additional information on nursing diagnoses for the patient with hypothyroidism is presented in Nursing Care Plan (NCP) 51-2, available on the Evolve website.

Planning

The overall goals are that patients with hypothyroidism will (a) experience relief from symptoms, (b) maintain a euthyroid state, (c) maintain a positive self-image, and (d) adhere to a lifelong regimen of thyroid replacement therapy.

Nursing Implementation

Health Promotion.

There is currently no consensus regarding thyroid function screening. Although hypothyroidism is relatively common, particularly among women older than 50, screening of the general population is not strongly justified (Premawardhana, 2015). Research suggests that populations at high risk for thyroid dysfunction should be screened for subclinical (asymptomatic) thyroid disease. Individuals at risk include those with a family history of thyroid disease, those with a history of neck irradiation, women older than 50, and women who have just given birth.

Acute Intervention.

Most individuals with hypothyroidism do not require acute nursing care. However, a patient who develops myxedema coma does require acute nursing care, often in a critical care setting. Mechanical respiratory support and cardiac monitoring are frequently necessary. Thyroid hormone replacement therapy and all other medications should be administered IV because paralytic ileus may be present with myxedema coma. If the patient is hyponatremic, hypertonic saline may be administered until the serum sodium level reaches at least 130 mmol/L. Core temperature should be monitored because many patients with myxedema coma are hypothermic.

The nurse monitors a patient's progress by assessing vital signs, body weight, fluid intake and output, and visible edema. Cardiac assessment is especially important because the cardiovascular response to the hormone determines the medication regimen. Energy level and mental alertness should be noted. These should increase within 2 to 14 days and continue to rise steadily to normal levels.

Ambulatory and Home Care.

Patient and caregiver teaching is essential for patients with hypothyroidism (Table 51-12). Initially, patients with

hypothyroidism need more time than usual to comprehend all the necessary information. It is important to provide written instructions, repeat the information often, and assess the patient's comprehension level regularly.

TABLE 51-12

PATIENT & CAREGIVER TEACHING GUIDE
Hypothyroidism

The following instructions should be included when teaching the patient and caregiver about management of hypothyroidism. The nurse should:

1. Explain the nature of thyroid hormone deficiency and self-care practices necessary to prevent complications. Patient and family caregivers must understand thyroid replacement therapy. It is especially important to emphasize the need for lifelong replacement, the need to take the medication continually, and the need for regular follow-up care.
2. Emphasize the need for a comfortable, warm environment because of intolerance of cold.
3. Teach measures to prevent skin breakdown. Soap should be used sparingly and lotion applied to skin.
4. Caution patients, especially older adults, to avoid sedatives. If sedatives must be used, suggest that the lowest dose be used. Caregivers should closely monitor patient's mental status, level of consciousness, and respiration.
5. Discuss with patients measures to minimize constipation. Suggestions should include a gradual increase in activity and exercise, increased fibre in diet, use of stool softeners, and maintenance of a regular bowel elimination time. Enemas should not be used because they produce vagal stimulation, which can be hazardous if cardiac disease is present.

The need for lifelong drug therapy must be stressed. Patients should be taught expected and unexpected adverse drug effects. Specifically, the signs and symptoms of hypothyroidism or hyperthyroidism that indicate hormone imbalance should be included in the teaching plan. Toxic symptoms should be clearly defined. Table 51-7 lists signs of hyperthyroidism that are the same as toxic symptoms of thyroid hormone replacement.

Patients must be taught to contact a health care professional immediately if signs of overdose—such as orthopnea, dyspnea, rapid pulse, palpitations, nervousness, or insomnia—appear. A patient with diabetes mellitus should test his or her capillary blood glucose level at least daily because return to the euthyroid state frequently increases insulin requirements. In addition, thyroid preparations potentiate the effects of anticoagulants and decrease the effect of digitalis compounds. Thus, the patient should be taught the toxic signs and symptoms of these medications and should remain under close medical observation until his or her condition is stable.

It is sometimes difficult for patients to recognize signs of overdosage or underdosage of drug therapy; therefore, a family member or friend should also receive instructions. Handouts for patients should be written in understandable language and should accompany verbal instruction. The handouts should be reviewed with patients and the family to assess understanding, and information should be clarified when necessary.

With treatment, striking transformations occur in both appearance and mental function. In most adults, both return to normal. Cardiovascular conditions and (occasionally) psychosis may persist despite corrections of the hormonal imbalance. Relapses occur if treatment is interrupted.

Evaluation

The following are expected outcomes for patients with hypothyroidism:

- Relief from symptoms
- Maintenance of a euthyroid state as evidenced by normal thyroid hormone and TSH levels
- Avoidance of complications of therapy
- Adherence to lifelong therapy

Ethical Dilemmas

Alternative Healers

Situation

The nurse is caring for an Indigenous woman with thyroid disease. Thyroid replacement therapy is the planned treatment. The patient's traditional healer tells her not to take the medication and suggests that she should begin a herbal regimen instead. Should the nurse intervene?

Important Points for Consideration

- Culturally competent nursing care should incorporate the patient's cultural and religious values and beliefs.
- Patient autonomy, the patient's right to choose a treatment plan, should be respected.
- Having adequate, understandable information about available treatment options and their possible consequences facilitates an informed choice.

Clinical Decision-Making Questions

1. What information should the nurse obtain from the patient? What information should the nurse provide for the patient?
2. How should the nurse proceed? Should the nurse try to incorporate the healer's herbal regimen into the plan of care while attempting to persuade the woman of the need for the thyroid replacement therapy?

Disorders of the Parathyroid Glands

Hyperparathyroidism

Etiology and Pathophysiology

Hyperparathyroidism is a condition involving increased secretion of parathyroid hormone (PTH). PTH helps regulate calcium and phosphate levels by stimulating bone resorption of calcium, renal tubular reabsorption of calcium, and activation of vitamin D. Thus oversecretion of PTH is associated with increased serum calcium levels. Hyperparathyroidism affects approximately 0.1% to 0.4% of the general population, it occurs more frequently among women, and the incidence increases with age (Pallan, Rahman, & Khan, 2012).

Hyperparathyroidism is classified as primary, secondary, or tertiary. *Primary hyperparathyroidism* results from an increased secretion of PTH, which leads to disorders of calcium, phosphate, and bone metabolism. The most common cause is a benign neoplasm or a single adenoma in the parathyroid gland. Primary hyperparathyroidism usually occurs between the ages of 30 and 70 years. The incidence peaks in the fifth and sixth decades of life. Patients who have previously undergone head and neck irradiation may have an increased risk of developing a parathyroid adenoma.

Secondary hyperparathyroidism appears to be a compensatory response to states that induce or cause hypocalcemia, the main stimulus of PTH secretion. Disease conditions associated with secondary hyperparathyroidism include vitamin D deficiencies, malabsorption, chronic renal failure, and hyperphosphatemia.

Tertiary hyperparathyroidism occurs when the parathyroid glands become hyperplastic and negative feedback is lost from circulating calcium levels; thus, PTH is secreted autonomously, even with normal calcium levels. This condition is observed in patients who have undergone kidney transplantation after a long period of dialysis treatment for chronic renal failure. (Chapter 49 discusses parathyroid hormone and kidney function.)

Excessive levels of circulating PTH usually lead to hypercalcemia and hypophosphatemia, creating a multisystem effect (Table 51-13). In the skeleton, decreased bone density, cyst formation, and general weakness can occur as a result of the effect of PTH on osteoclastic activity (bone resorption) and osteoblastic activity (bone formation). In the kidneys, the excess calcium cannot be reabsorbed; as a result, levels of calcium in the urine increase (hypercalciuria). This urinary calcium level, along with a large amount of urinary phosphate, can lead to calculi formation (Cipriani, Biamonte, Costa, et al., 2015). In addition, PTH stimulates the synthesis of a biologically active form of vitamin D, a potent stimulator of calcium transport in the intestine. In this way, PTH indirectly increases GI absorption of calcium, contributing further to the high serum calcium levels.

TABLE 51-13
CLINICAL MANIFESTATIONS OF PARATHYROID DYSFUNCTION

Hypofunction	Hyperfunction
Cardiovascular	
• Decreased cardiac output • Decreased contractility of heart muscle • Dysrhythmias • Prolongation of Q–T and ST intervals on ECG	• Dysrhythmias • Hypertension • Shortened Q–T interval on ECG
Gastro-Intestinal	
• Abdominal cramps • Fecal incontinence (in older adults) • Malabsorption	• Anorexia • Cholelithiasis • Constipation • Nausea and vomiting • Pancreatitis • Peptic ulcer disease • Vague abdominal pain • Weight loss
Integumentary	
• Brittle nails, transverse ridging • Changes in developing teeth, lack of tooth enamel • Dry, scaly skin • Hair loss on scalp and body	• Moist skin • Skin necrosis
Musculo-Skeletal	
• Difficulty in walking • Fatigue • Painful muscle cramps • Skeletal radiograph changes, osteosclerosis • Soft tissue calcification • Weakness	• Backache • Compression fractures of spine • Decreased muscle tone, muscle atrophy • Osteoporosis • Pain on weight bearing • Pathological fractures of long bones • Skeletal pain • Weakness, fatigue
Neurological	
• Disorientation, confusion (in older adults) • Headache • Hyperactive deep tendon reflexes • Irritability • Memory impairment • Paresthesias of perioral area, hands, and feet • Personality changes • Positive Chvostek's or Trousseau's sign • Psychiatric manifestations of depression, anxiety, psychosis • Seizures • Tremor	• Abnormalities of gait • Delirium, confusion, coma • Emotional irritability • Headache • Hyperactive deep tendon reflexes • Memory impairment • Paresthesias • Personality disturbances • Poor coordination • Psychomotor retardation • Psychosis, depression
Renal	
• Urinary frequency • Urinary incontinence	• Hypercalciuria • Kidney stones (nephrolithiasis) • Polyuria • Urinary tract infections
Other	
• Eye changes, including lenticular opacities, cataracts, papilledema	• Corneal calcification on slit-lamp examination

ECG, electrocardiogram.

Clinical Manifestations and Complications

Clinical manifestations of hyperparathyroidism range from no symptoms (the condition is diagnosed through testing for unrelated problems) to overt symptoms. Clinical manifestations are associated with hypercalcemia and are summarized in Table 51-13. The major manifestations include muscle weakness, loss of appetite, constipation, fatigue, emotional disorders, and shortened attention span. Major signs include loss of calcium from bones (osteoporosis), fractures, and kidney stones (nephrolithiasis). Neuro-muscular abnormalities are characterized by muscle weakness, particularly in the proximal muscles of the lower extremities. Asymptomatic cases are often identified through routine calcium screening. Serious complications of hyperparathyroidism are renal failure; pancreatitis; cardiac changes; and fractures of long bones, ribs, and vertebrae.

Diagnostic Studies

PTH levels are elevated in hyperparathyroidism. Serum calcium levels usually exceed 2.75 mmol/L. Because of its inverse relation with the calcium level, the serum phosphorus level is usually below 0.1 mmol/L. Elevations occur in other laboratory values: urine calcium, serum chloride, uric acid, creatinine, amylase (if pancreatitis is present), and alkaline phosphatase (if bone disease is present). Bone density measurements may also be used to detect bone loss. Imaging studies, such as MRI, CT, and ultrasonography, may help localize the adenoma.

Collaborative Care

The treatment objectives for hyperparathyroidism are to relieve the manifestations and prevent complications caused by excess PTH. The choice of therapy depends on the urgency of the clinical situation, the degree of hypercalcemia, and the underlying cause of the disorder.

Surgical Therapy.

The most effective treatment of primary and secondary hyperparathyroidism is surgical intervention. Parathyroidectomy leads to rapid reduction of chronically high calcium levels. Criteria for surgery include serum calcium levels higher than 0.25 mmol/L above normal level; creatinine clearance rate of less than 60 mL/min; *T*-score lower than –2.5 at any site on bone mineral density testing, previous fracture fragility, or both; and age younger than 50 (Callender & Udelsman, 2014). The surgical procedure involves partial or complete removal of the parathyroid glands. The most common procedure involves use of an endoscope and is performed on an outpatient basis. Successful removal of the parathyroid glands is facilitated by preoperative nuclear scanning with technetium-99m (99mTc) (Callender & Udelsman, 2014).

Autotransplantation of normal parathyroid tissue in the forearm or near the sternocleidomastoid muscle may be performed, which allows PTH secretion to continue with normalization of calcium levels. If autotransplantation is not possible, or if it fails, patients need to take calcium supplements for the rest of their lives.

Nonsurgical Therapy.

A conservative approach is often used in patients who are asymptomatic or have mild symptoms of hyperparathyroidism. This approach includes an annual examination with tests for serum calcium and creatinine clearance and evaluation of bone density every 1 to 2 years (three sites). Continued ambulation and the avoidance of immobility are critical aspects of management. Dietary measures also include maintenance of a high fluid intake and a moderate calcium intake.

Phosphorus intake is usually supplemented unless this is contraindicated by an increased risk for urinary calculi formation. Several drugs currently used in the treatment of hyperparathyroidism are helpful in lowering calcium levels but do not treat the underlying problem. Bisphosphonates (e.g., alendronate [Fosamax]) inhibit osteoclastic bone resorption and rapidly normalize serum calcium levels. Estrogen or progestin therapy can reduce serum and urinary calcium levels in postmenopausal women

and may slow the demineralization of the skeleton. Oral phosphate may be used to inhibit the calcium-absorbing effects of vitamin D in the intestine. Phosphates should be used only if a patient has normal renal function and low serum phosphate levels. Calcimimetic agents (e.g., cinacalcet [Sensipar]) are a class of drugs that increase the sensitivity of the calcium receptor on the parathyroid gland, resulting in decreased PTH secretion and calcium blood levels and thus sparing calcium stores in the bone. Drugs in this class are currently indicated for secondary hyperparathyroidism in individuals with chronic kidney disease who are undergoing dialysis, for patients with parathyroid cancer, and for patients with symptomatic hypercalcemia in primary hyperparathyroidism.

Nursing Management Hyperparathyroidism

Nursing care for patients after a parathyroidectomy is similar to that for patients after a thyroidectomy. The major postoperative complications are associated with hemorrhage and fluid and electrolyte disturbances. *Tetany,* a condition of neuro-muscular hyperexcitability associated with a sudden decrease in calcium levels, is another concern. It is usually apparent early in the postoperative period but may develop over several days. Mild tetany, characterized by an unpleasant tingling sensation of the hands and around the mouth, may be present but should abate without problems. If tetany becomes more severe (e.g., muscular spasms or laryngospasms develop), IV calcium may be given. IV calcium gluconate should be readily available for patients after parathyroidectomy in case acute tetany occurs.

The nurse monitors intake and output to evaluate fluid status. Calcium, potassium, phosphate, and magnesium levels are assessed frequently, as are Chvostek's and Trousseau's signs (see Chapter 19, Figure 19-15). The nurse also encourages mobility to promote bone calcification.

If surgery is not performed, treatment to relieve symptoms and prevent complications is initiated. The nurse can assist patients with hyperparathyroidism to adapt the meal plan to their lifestyle. A referral to a dietitian may be useful. Because immobility can aggravate the bone loss, the nurse must stress to patients the importance of an exercise program. Patients should be encouraged to keep the regular appointments, and the tests being performed should be explained. Patients should also be instructed in the symptoms of hypocalcemia or hypercalcemia and to report them, should they occur. Hypocalcemia and hypercalcemia are discussed in Chapter 19.

Hypoparathyroidism

Etiology and Pathophysiology

Hypoparathyroidism is an uncommon condition associated with inadequate levels of circulating PTH. It is characterized by hypocalcemia that results from a lack of PTH to maintain serum calcium levels. PTH resistance at the cellular level may also occur (pseudohypoparathyroidism). This condition is caused by a genetic defect that results in hypocalcemia in spite of normal or high PTH levels and is often associated with hypothyroidism and hypogonadism.

The most common cause of hypoparathyroidism is iatrogenic. This may include accidental removal of the parathyroid glands or damage to the vascular supply of the glands during neck surgery (e.g., thyroidectomy, radical neck surgery) (Gupta, Chaudhary, Durga, et al., 2015). Idiopathic hypoparathyroidism resulting from the absence, fatty replacement, or atrophy of the glands is a rare disease that usually occurs early in life and may be associated with other endocrine disorders. Affected patients may have antiparathyroid antibodies. Severe hypomagnesemia also leads to a suppression of PTH secretion (Famularo, Minisola, Bravi, et al., 2012).

Clinical Manifestations

The clinical features of acute hypoparathyroidism result from a low serum calcium level (see Table 51-13). Sudden decreases in calcium concentration cause tetany. This state is characterized by tingling sensations in the lips, the fingertips, and occasionally the feet and by increased muscle tension, which escalates to paresthesias and stiffness. Painful tonic spasms of smooth and skeletal muscles can cause dysphagia, a constricted feeling in the throat, and laryngospasms that can compromise breathing. Patients are usually anxious and apprehensive. Abnormal laboratory findings include decreased serum calcium and PTH levels and increased serum phosphate levels. Other causes of chronic hypocalcemia include chronic renal failure, vitamin D deficiency, and hypomagnesemia.

Nursing and Collaborative Management Hypoparathyroidism

The primary treatment goals for a patient with hypoparathyroidism are to treat acute complications such as tetany, maintain normal serum calcium levels, and prevent long-term complications. Emergency treatment of tetany requires the administration of IV calcium. IV calcium chloride or calcium gluconate should be infused slowly because high blood levels of calcium can cause hypotension, serious cardiac dysrhythmias, or cardiac arrest; thus ECG monitoring is indicated when calcium is administered. Patients who take digoxin are particularly vulnerable. IV calcium can cause venous irritation and inflammation. Extravasation may cause cellulitis, necrosis, and tissue sloughing. IV patency should be assessed before administration.

Rebreathing may partially alleviate acute neuro-muscular symptoms associated with hypocalcemia, such as generalized muscle cramps or mild tetany. Patients who can cooperate should be instructed to breathe in and out of a paper bag or breathing mask. This reduces carbon dioxide excretion from the lungs, increases carbonic acid levels in the blood, and lowers the pH.

A lower pH (acidic environment) enhances the degree of ionization of calcium, causing an increase in the proportion of total body calcium available in the active form. This then temporarily alleviates the manifestations of hypocalcemia.

Patients with hypoparathyroidism need instruction in the management of long-term drug therapy and nutrition. Oral calcium supplements of at least 1.5 to 3 g/day in divided doses are usually prescribed. PTH replacement is not a recommended drug therapy because of the expense and the need for parenteral administration. Vitamin D is administered to patients with chronic and resistant hypocalcemia to enhance intestinal calcium absorption and bone resorption. The primary preparation is calcitriol (Rocaltrol). This drug raises calcium levels rapidly and is quickly metabolized. Rapid

metabolism is desired because vitamin D is a fat-soluble vitamin, and toxicity can cause irreversible renal impairment.

A high-calcium meal plan includes foods such as dark green vegetables, soybeans, and tofu. Patients should be told to avoid foods containing oxalic acid (e.g., spinach, rhubarb), phytic acid (e.g., bran, whole grains), and phosphorus (e.g., protein-rich foods such as meats, poultry, fish, nuts, beans, and dairy products) because they reduce calcium absorption.

Patients should be instructed about the need for lifelong treatment and follow-up care, including the monitoring of calcium levels three to four times a year.

Disorders of the Adrenal Cortex

There are three main classifications of adrenal steroid hormones. *Glucocorticoids* regulate metabolism, increase blood glucose levels, and are critical in the physiological stress response. In humans, the primary glucocorticoid is cortisol. *Mineralocorticoids* regulate sodium and potassium balance. The primary mineralocorticoid is aldosterone. *Androgens* contribute to growth and development in both genders and to sexual desire and satisfaction in women. The term *corticosteroid* refers to any one of these three types of hormones produced by the adrenal cortex.

Cushing's Syndrome

Etiology and Pathophysiology

Cushing's syndrome is a spectrum of clinical abnormalities caused by excess levels of corticosteroids, particularly glucocorticoids (Lacroix, Feelders, Stratakis, et al., 2015). Several conditions can cause this metabolic disorder (Table 51-14). The most common causes are iatrogenic administration of exogenous corticosteroids (e.g., prednisone) in large doses for several weeks or longer and the chronic and excessive production of cortisol by the adrenal cortex. Approximately 85% of cases of endogenous Cushing's syndrome result from an ACTH-secreting pituitary tumour (Cushing's disease). Other causes of Cushing's syndrome include adrenal tumours and ectopic ACTH production by tumours outside the hypothalamic-pituitary-adrenal axis (usually of the lung or the pancreas). Cushing's disease and primary adrenal tumours are most common in women age 20 to 40 years; ectopic ACTH production is more common in men.

TABLE 51-14
CAUSES OF CUSHING'S SYNDROME

• ACTH-secreting pituitary tumour (Cushing's disease) • Cortisol-secreting neoplasm within the adrenal cortex that can be either carcinoma or adenoma • Excess secretion of ACTH from carcinoma of the lung or other malignant growth outside the pituitary or the adrenal glands • Prolonged administration of high doses of corticosteroids

ACTH, adrenocorticotrophic hormone.

Clinical Manifestations

The clinical manifestations of Cushing's syndrome can occur in most body systems and are related to excess levels of corticosteroids (Table 51-15). Although manifestations of glucocorticoid excess usually predominate, symptoms of mineralocorticoid and androgen excess may also appear.

TABLE 51-15

CLINICAL MANIFESTATIONS: ADRENOCORTICAL HORMONE DYSFUNCTION

Category	Hypofunction (Addison's Disease)	Hyperfunction (Cushing's Syndrome)
Glucocorticoids		
Cardiovascular	Hypotension, tendency to develop refractory shock, vasodilation	Hypervolemia, hypertension, edema of lower extremities
Fluids and electrolytes	Hyponatremia, hypovolemia, dehydration, hyperkalemia	Sodium and water retention, edema, hypokalemia
Gastro-intestinal	Anorexia, nausea and vomiting, cramping abdominal pain, diarrhea	Increase in secretion of pepsin and hydrochloric acid; anorexia
General appearance	Weight loss	Centripetal (truncal) obesity, thin extremities, rounding of face (moon facies), fat deposits on back of neck and on shoulders (buffalo hump)
Hematological system	Anemia, lymphocytosis	Leukocytosis, lymphopenia, polycythemia, increased coagulability
Immune system	Tendency for coexisting autoimmune diseases	Inhibition of immune response, suppression of allergic response, inhibition of inflammation
Integumentary system	Bronzed or smoky hyperpigmentation of face, neck, hands (especially creases), buccal membranes, nipples, genitalia, and scars (if pituitary function is normal); vitiligo, alopecia	Thin, fragile skin; purplish red striae (see Figure 51-11); petechial hemorrhages; bruises; florid cheeks (facial plethora); acne; poor wound healing
Mental and emotional state	Neurasthenia, depression, exhaustion or irritability, confusion, delusions	Euphoria, irritability, hypomania to depression, emotional lability
Metabolism	Hypoglycemia, insulin sensitivity, fever	Hyperglycemia, negative nitrogen balance, dyslipidemia
Musculo-skeletal	Fatigability	Muscle wasting in extremities, proximal muscle weakness, fatigue, osteoporosis, awkward gait, back and joint pain, weakness
Renal/urinary	—	Glycosuria, hypercalciuria, kidney stones
Mineralocorticoids		
Cardiovascular	Hypovolemia, tendency toward shock, decreased cardiac output, decrease in heart size	Hypertension, hypervolemia
Fluids and electrolytes	Sodium loss, decreased volume of extracellular fluid, hyperkalemia, salt craving	Marked sodium and water retention, tendency toward edema, marked hypokalemia, alkalosis
Androgens		
Integumentary	Decreased axillary and pubic hair (in women)	Hirsutism, acne, hyperpigmentation
Musculo-skeletal	Decrease in muscle size and tone	Muscle wasting and weakness
Reproductive	No effect in men; decreased libido in women	Menstrual irregularities and enlargement of clitoris in women; gynecomastia and testicular atrophy in men

Corticosteroid excess causes pronounced changes in physical appearance (Figure 51-9). Weight gain, the most common feature, results from the accumulation of adipose tissue in the trunk, the face, and the cervical area (see Figure 51-9). Transient weight gain from sodium and water retention may be present because of the mineralocorticoid effects of cortisol. Hyperglycemia occurs because of glucose intolerance (associated with cortisol-induced insulin resistance) and increased gluconeogenesis by the liver.

FIGURE 51-9 Cushing's syndrome. Facies include a rounded face (moon facies) with thin, reddened skin. Hirsutism may also be present. Source: Seidel, H. M., Ball, J., Dains, J., et al. (2006). *Mosby's guide to physical examination* (6th ed., p. 272, Figure 10-17). St. Louis: Mosby.

The catabolic effects of cortisol on peripheral tissue cause protein wasting. Muscle wasting leads to muscle weakness, especially in the extremities. Loss of protein matrix in bone leads to osteoporosis with subsequent pathological fractures (e.g., vertebral compression fractures) and bone and back pain. Loss of collagen makes the skin

weaker and thinner; therefore, the skin bruises more easily. Catabolic processes predominate, and wound healing is delayed. Mood disturbances (e.g., irritability, anxiety, euphoria), insomnia, irrationality, and occasionally psychosis may occur.

Mineralocorticoid excess may cause hypertension (secondary to fluid retention), whereas adrenal androgen excess may cause pronounced acne, masculinization in women, and feminization in men. Menstrual disorders and hirsutism in women and gynecomastia and erectile dysfunction in men occur more commonly with adrenal carcinomas.

The clinical presentation is the first indication of Cushing's syndrome (Figure 51-10). Of particular importance are (a) centripetal (truncal) obesity or generalized obesity; (b) so-called moon facies (fullness of the face) with facial plethora; (c) purplish red striae, which are usually depressed below the skin surface, on the abdomen, the breasts, or the buttocks (Figure 51-11); (d) hirsutism in women; (e) menstrual disorders in women; (f) hypertension; and (g) unexplained hypokalemia.

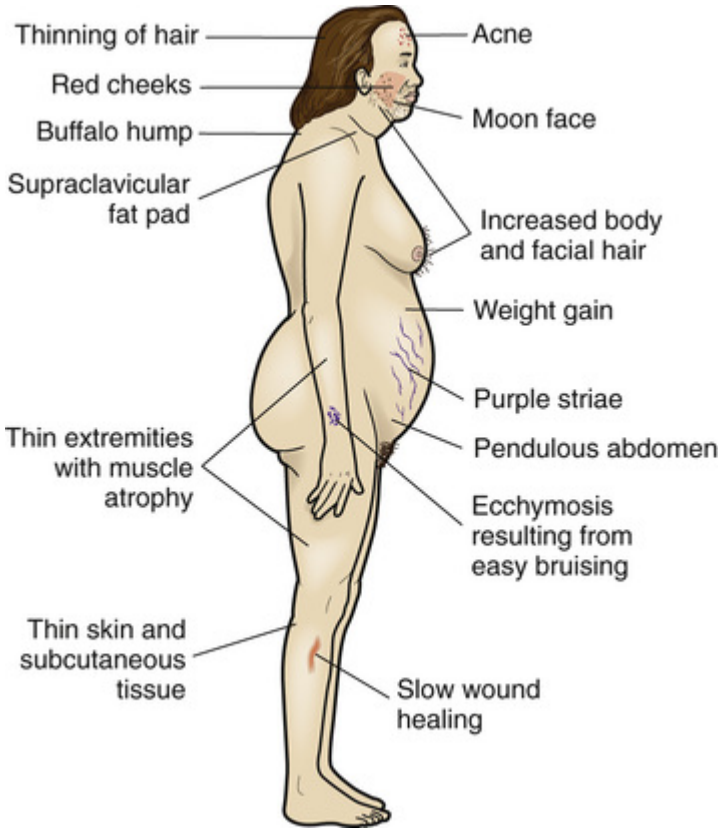

FIGURE 51-10 Common characteristics of Cushing's syndrome.

FIGURE 51-11 Cushing's syndrome. Truncal obesity; broad, purple striae; and easy bruising (left antecubital fossa). Source: Chew, S. L., & Leslie, D. (2006). *Clinical endocrinology and diabetes: An illustrated colour text.* (1st ed., p. 28, Figure 2). Edinburgh: Churchill Livingstone.

Diagnostic Studies

When Cushing's syndrome is suspected, a 24-hour urine sample is collected to measure free cortisol (see Chapter 50). If the free cortisol results are borderline, a low-dose dexamethasone suppression test is performed. Plasma cortisol (the primary glucocorticoid) levels may be elevated, with loss of diurnal variation. Elevation in the midnight serum cortisol level confirms the diagnosis of Cushing's syndrome with 100% sensitivity (Juszczak & Grossman, 2012). False-positive results can occur in patients with depression, those under acute stress, and those who are actively alcoholic. CT and MRI of the pituitary and adrenal glands may be used.

Plasma ACTH levels may be low, normal, or elevated, depending on the underlying problem. High or normal levels indicate ACTH-dependent Cushing's disease, whereas low or undetectable levels indicate an adrenal or exogenous etiology. Other findings on diagnostic tests associated with, but not diagnostic of, Cushing's syndrome include granulocytosis, lymphopenia, eosinopenia, hyperglycemia, glycosuria, hypercalciuria, and osteoporosis.

Hypokalemia and alkalosis occur in ectopic ACTH syndrome and adrenal carcinoma.

Collaborative Care

The primary goal of treatment for Cushing's disease is to normalize hormone secretion. The specific treatment is dependent on the underlying cause (Table 51-16). If the underlying cause is a pituitary adenoma, the standard treatment is surgical removal of the tumour through the trans-sphenoidal approach (Dallapiazza & Jane, Jr., 2015). (The trans-sphenoidal approach is discussed earlier in this chapter.) Irradiation of the pituitary adenoma may be necessary if surgical outcomes are not optimal or if a patient is at high risk for surgical complications. Adrenalectomy is indicated for Cushing's syndrome caused by adrenal tumours or hyperplasia. On occasion, bilateral adrenalectomy is necessary.

TABLE 51-16

COLLABORATIVE CARE
Cushing's Syndrome

Diagnostic	Collaborative Therapy*

• History and physical examination
• 24-hour urine collection for free cortisol measurement
• Blood chemistry evaluation for sodium, potassium, and glucose
• Complete blood cell count
• CT, MRI
• Dexamethasone suppression test
• Examination of visual field
• Measurement of plasma ACTH level
• Measurement of plasma cortisol levels for diurnal variations
• Mental status examination
	Adrenocortical Adenoma, Carcinoma, or Hyperplasia
	• Adrenalectomy (open or laparoscopic)
	• Drug therapy
	  • Ketoconazole (Nizoral)
	  • Mitotane (Lysodren)
	Pituitary Adenoma
	• Radiation therapy
	• Trans-sphenoidal resection
	Ectopic ACTH-Secreting Tumour
	• Treatment of the tumour responsible (surgical removal or radiation therapy)
	Exogenous Corticosteroid Therapy
	• Discontinuance of or alteration in administration of exogenous corticosteroids

*Treatment is based on underlying cause.

ACTH, adrenocorticotrophic hormone; *CT,* computed tomographic (scan); *MRI,* magnetic resonance imaging.

Laparoscopic adrenalectomy is considered an appropriate surgical approach except for patients with known or suspected malignant

adrenal tumours. An open surgical adrenalectomy is the treatment of choice for adrenal cancer. Patients with ectopic ACTH-secreting tumours are managed by treating the primary neoplasm.

Drug therapy is used when surgery is contraindicated or as an adjunct to surgery. The goal of drug therapy is the inhibition of adrenal function (medical adrenalectomy). Mitotane (Lysodren) suppresses cortisol production, alters peripheral metabolism of cortisol, and decreases plasma and urine corticosteroid levels. Ketoconazole can be used to inhibit cortisol synthesis. These drugs are used cautiously because they are often toxic at doses needed to reduce corticosteroid synthesis.

If Cushing's syndrome has developed during the course of prolonged administration of corticosteroids (e.g., prednisone), one or more of the following alternatives may be tried: (a) gradual discontinuance of corticosteroid therapy, (b) reduction of the corticosteroid dose, and (c) conversion to an alternate-day regimen. Gradual tapering of the corticosteroids is necessary to avoid potentially life-threatening adrenal insufficiency. An alternate-day regimen is one in which twice the daily dosage of a shorter-acting corticosteroid is given every other morning to minimize hypothalamic-pituitary-adrenal suppression, growth suppression, and altered appearance.

Nursing Management Cushing's Syndrome

Nursing Assessment

Subjective and objective data that should be obtained from a patient with Cushing's syndrome are presented in Table 51-17.

TABLE 51-17

NURSING ASSESSMENT
Cushing's Syndrome

Subjective Data
Important Health Information
Past health history: Pituitary tumour (Cushing's disease); adrenal, pancreatic, or pulmonary neoplasms; GI bleeding; frequent infections *Medications:* Use of corticosteroids
Symptoms
• Amenorrhea, erectile dysfunction, decreased libido • Anxiety, mood disturbances, emotional lability, psychosis • Headache; back, joint, bone, and rib pain; poor concentration and memory • Insomnia, poor sleep quality • Malaise, weakness, fatigue • Negative feelings regarding changes in personal appearance • Polyuria • Prolonged wound healing, easy bruising • Weight gain, anorexia
Objective Data
General
Centripetal (truncal) obesity, supraclavicular fat pads, buffalo hump, moon facies
Integumentary
Facial plethora; hirsutism of body and face, thinning of head hair; thin, friable skin; acne; petechiae; purpura; hyperpigmentation; purplish red striae on breasts, buttocks, and abdomen; edema of lower extremities
Cardiovascular
Hypertension
Musculo-Skeletal
Muscle wasting, thin extremities, awkward gait
Reproductive
Gynecomastia, testicular atrophy (in men); enlarged clitoris (in women)
Possible Findings
Hypokalemia, hyperglycemia, dyslipidemia; polycythemia, granulocytosis, lymphocytopenia, eosinopenia; ↑ plasma cortisol level; high, low, or normal ACTH levels; abnormal result of dexamethasone suppression test; ↑ levels of urine free cortisol and 17-ketosteroids; glycosuria, hypercalciuria; osteoporosis on radiograph

ACTH, adrenocorticotrophic hormone; *GI*, gastro-intestinal.

Nursing Diagnoses

Nursing diagnoses for patients with Cushing's syndrome may include, but are not limited to, the following:

- *Risk for infection* as evidenced by *insufficient knowledge to avoid exposure to pathogens*

(suppression of immune system)
- *Risk for overweight* as evidenced by *energy expenditure below energy intake based on standard assessment* (increased appetite, high caloric content of foods, inactivity)
- *Disturbed body image* related to alteration in self-perception (change in appearance)
- *Impaired skin integrity* related to *chemical injury agent* (excess corticosteroids)

Additional information on nursing diagnoses for the patient with Cushing's syndrome is presented in Nursing Care Plan (NCP) 51-3, available on the Evolve website.

Planning

The overall goals are that the patient with Cushing's syndrome will (1) experience relief of symptoms, (2) avoid serious complications, (3) maintain a positive self-image, and (4) actively participate in the therapeutic plan.

Nursing Implementation

Health Promotion.

Health promotion is focused on identifying patients at risk for Cushing's syndrome. Patients receiving long-term, exogenous cortisol for a variety of diseases are at risk. Teaching patients about medication use and monitoring of adverse drug effects are important preventive measures.

Acute Intervention.

Patients with Cushing's syndrome are seriously ill. Because the therapeutic interventions produce many adverse drug effects, the

focus of daily assessment is on signs and symptoms of hormone and drug toxicity and complicating conditions such as cardiovascular disease, diabetes mellitus, and infection. Nursing assessment should include monitoring of vital signs, daily weighing, and measuring glucose levels. Because signs and symptoms of inflammation such as fever and redness may be minimal or absent, the nurse must assess for pain, loss of function, and purulent drainage as signs of possible infection. The nurse also monitors for signs and symptoms of thrombo-embolic events (pulmonary emboli) such as sudden chest pain, dyspnea, or tachypnea.

Another important focus of nursing care is emotional support. Changes in appearance such as centripetal obesity, multiple bruises, hirsutism in women, and gynecomastia in men can be distressing. Patients may feel unattractive or unwanted. The nurse can help by remaining sensitive to patients' feelings and offering respect and unconditional acceptance. Patients can be reassured that the physical changes and much of the emotional lability will resolve when hormone levels return to normal.

If treatment involves surgical removal of a pituitary adenoma, an adrenal tumour, or one or both adrenal glands, nursing care has an additional focus on preoperative and postoperative care.

Preoperative Care.

Before surgery, the patient should be brought to optimal physical condition. Hypertension and hyperglycemia must be controlled, and hypokalemia is corrected with diet and potassium supplements. A high-protein meal plan helps correct the protein depletion. Preoperative teaching depends on the type of surgical approach planned (hypophysectomy or adrenalectomy) but should include information regarding the postoperative care that patients should anticipate. Patients should be told that in the postoperative period (for both open and laparoscopic adrenalectomy), they will probably have a nasogastric tube, urinary catheter, IV therapy, central venous pressure monitoring, and leg sequential compression devices to prevent emboli. Preoperative management for patients undergoing a hypophysectomy is discussed earlier in this chapter.

Postoperative Care.

Surgery on the adrenal glands poses risks beyond those of other types of operations. Because the glands are highly vascular, the risk for hemorrhage is increased. Manipulation of glandular tissue during surgery may cause the release of large amounts of hormone into the circulation that produce marked fluctuations in the metabolic processes affected by these hormones. After surgery, BP, fluid balance, and electrolyte levels tend to be unstable because of these hormone fluctuations.

High doses of corticosteroids (e.g., hydrocortisone [Solu-Cortef]) are administered IV during surgery and for several days afterward to ensure adequate responses to the stress of the procedure. If large amounts of endogenous hormone have been released into the systemic circulation during surgery, hypertension is likely to develop, increasing the risk for hemorrhage. High levels of corticosteroids also increase susceptibility to infection and delay wound healing.

Any significant changes in BP, respirations, or heart rate should be reported to the physician. Fluid intake and output should be monitored carefully and assessed for potential imbalances. The critical period for circulatory instability ranges from 24 to 48 hours after surgery. IV corticosteroids are given, and the dosage and the rate of flow are adjusted to the patient's clinical manifestations and fluid and electrolyte balances. Oral doses are given as tolerated. The IV line may be kept in place after IV corticosteroids are withdrawn to maintain access for quick administration of corticosteroids or vasopressors. Morning urine levels of cortisol (assessed at the same time each morning) are measured to evaluate the effectiveness of the surgery.

If the corticosteroid dosage is tapered too rapidly after surgery, acute adrenal insufficiency may develop. Vomiting, increased weakness, dehydration, and hypotension may indicate hypocortisolism. In addition, patients may complain of painful joints, pruritus, or peeling skin and may experience severe emotional disturbances. These signs and symptoms should be reported so that drug doses can be adjusted. The nurse must constantly be alert for signs of corticosteroid imbalance. After surgery, the patient is

usually maintained on bedrest until the BP stabilizes. Because the usual inflammatory responses are suppressed, the nurse must be alert for subtle signs of postoperative infections. The nurse must use meticulous care when changing the dressing and during any other procedures that necessitate access to body cavities, circulation, or areas under the skin, so that infection is prevented. A nursing care plan for patients with Cushing's syndrome (NCP 51-3) is available on the Evolve website for this chapter.

Ambulatory and Home Care.

Discharge instructions are based on the patient's lack of endogenous corticosteroids and resulting inability to react to stressors physiologically. The nurse should consider a referral for a visiting nurse, especially for older adults, because of the need for ongoing evaluation and education. Patients should wear medical alert bracelets at all times and carry medical identification and instructions in a wallet or purse. Exposure to extremes of temperature, infections, and emotional disturbances should be avoided as much as possible. Stress may produce or precipitate acute adrenal insufficiency because the remaining adrenal tissue cannot meet an increased hormonal demand. Many patients can be taught to adjust their corticosteroid replacement therapy in accordance with their stress levels. The nurse should consult with each patient's health care provider to determine the parameters for dosage changes if this plan is feasible. If a patient cannot adjust his or her own medication or if weakness, fainting, fever, or nausea and vomiting occur, the patient should contact the health care provider for a possible adjustment in corticosteroid dosage. Many patients require lifetime replacement therapy; however, it may take several months to adjust the hormone dose satisfactorily, and patients should be prepared for this.

Evaluation

The expected outcomes for patients with Cushing's syndrome are as follows:

- No signs or symptoms of infection
- Appropriate weight for height
- Increased acceptance of appearance
- Healing and maintenance of intact skin

Adrenocortical Insufficiency

Etiology and Pathophysiology

Adrenocortical insufficiency (hypofunction of the adrenal cortex) may have a primary cause (known as *Addison's disease*) or a secondary cause (lack of pituitary ACTH secretion). In **Addison's disease,** the supply of all three classes of adrenal corticosteroids (glucocorticoids, mineralocorticoids, and androgens) is reduced. In secondary adrenocortical insufficiency, levels of corticosteroids and androgens are deficient, but those of mineralocorticoids rarely are. ACTH deficiency may be caused by pituitary disease or suppression of the hypothalamic-pituitary-adrenal axis as a result of the administration of exogenous corticosteroids.

The most common cause of Addison's disease in industrialized nations is an autoimmune response (Puttana, Cunningham, & Dainty, 2013). Adrenal tissue is destroyed by antibodies against the patient's own adrenal cortex. Susceptibility genes for Addison's disease are beginning to be identified (Napier, Mitchell, Gan, et al., 2015). Often, other endocrine conditions are present, and Addison's disease is considered a component of polyglandular autoimmune syndrome (Puttana, Cunningham, & Dainty, 2013). Tuberculosis causes Addison's disease worldwide, but it is now an uncommon cause in Canada. Other causes include infarction, fungal infections (e.g., histoplasmosis), acquired immune deficiency syndrome (AIDS), and metastatic cancer. Iatrogenic Addison's disease may be caused by adrenal hemorrhage, often related to anticoagulant therapy, antineoplastic chemotherapy, ketoconazole therapy for AIDS, or bilateral adrenalectomy. Adrenal insufficiency most often occurs in adults younger than 60 years and affects both sexes equally. Addison's disease, if caused by an autoimmune response, is most common in White women.

Clinical Manifestations

Because manifestations do not tend to become evident until 90% of the adrenal cortex is destroyed, the disease is often advanced before it is diagnosed. The manifestations have a very slow (insidious) onset and include progressive weakness, fatigue, weight loss, and anorexia as primary features. Skin hyperpigmentation, a striking feature, is observed primarily in sun-exposed areas of the body, at pressure points, over joints, and in creases (Figure 51-12); it is most likely caused by increased secretion of β-lipotropin (which contains melanocyte-stimulating hormone [MSH]). Secretion of this tropic hormone is increased because of decreased negative feedback and subsequent low corticosteroid levels. Other frequent manifestations of primary adrenal hypofunction are hypotension, hyponatremia, hyperkalemia, nausea and vomiting, and diarrhea. Irritability and depression may also occur.

FIGURE 51-12 Hyperpigmentation typically observed in Addison's disease. Source: Chew, S. L., & Leslie, D. (2006). *Clinical endocrinology and diabetes: An illustrated colour text*. Edinburgh: Churchill Livingstone.

Secondary adrenocortical hypofunction shares many signs and symptoms in common with Addison's disease, but hyperpigmentation is not characteristic because ACTH and related peptide levels are low.

Complications

Patients with adrenocortical insufficiency are at risk for an acute adrenal insufficiency *(addisonian crisis),* a life-threatening emergency caused by insufficient adrenocortical hormones or a sudden sharp decrease in these hormones. Addisonian crisis is triggered by stress (e.g., from infection, surgery, trauma, hemorrhage, or psychological distress); by sudden withdrawal of corticosteroid hormone therapy (which often occurs when a patient who lacks knowledge of the importance of replacement therapy stops following the regimen); by adrenal surgery; or by sudden pituitary gland destruction.

During acute adrenal insufficiency, manifestations of glucocorticoid and mineralocorticoid deficiencies are severe and include hypotension (particularly postural), tachycardia, dehydration, hyponatremia, hyperkalemia, hypoglycemia, fever, weakness, and confusion. Hypotension may lead to shock. Circulatory collapse associated with adrenal insufficiency is often unresponsive to the usual treatment (vasopressors and fluid replacement). GI manifestations include nausea, vomiting, diarrhea, and pain in the abdomen. Pain may also occur in the lower back or the legs.

Diagnostic Studies

In addition to clinical features, cortisol levels that are subnormal or fail to rise over basal levels with an ACTH stimulation test can be diagnostic for Addison's disease. A failure of cortisol levels to rise in response to ACTH stimulation indicates primary adrenal disease. A positive response to ACTH stimulation indicates that the adrenal gland is functioning and that the probable cause is pituitary disease (see Chapter 50).

Other abnormal laboratory findings include hyperkalemia, hypochloremia, hyponatremia, hypoglycemia, anemia, and increased blood urea nitrogen levels. Urine levels of free cortisol are low, as is the urine level of aldosterone (Pagana & Pagana, 2013). An ECG may show low voltage and a vertical QRS axis. In addition, peaked T-waves caused by hyperkalemia may be evident. CT and MRI are used to localize tumours or identify adrenal calcifications or enlargement (Table 51-18).

TABLE 51-18
COLLABORATIVE CARE
Addison's Disease

Diagnostic	Collaborative Therapy
• History and physical examination • ACTH stimulation test • CT, MRI • Measurement of plasma cortisol levels • Measurement of serum electrolytes • Measurement of urine cortisol and aldosterone levels	• Daily glucocorticoid (e.g., hydrocortisone) replacement (two-thirds on awakening in morning, one-third in late afternoon)* • Daily mineralocorticoid (fludrocortisone acetate) replacement in morning* • Increased dose of cortisol for stress situations (e.g., surgery, hospitalization) • Salt additives for excess heat or humidity

*For conditions of normal daily stress, in individuals with usual daytime activity.

ACTH, adrenocorticotrophic hormone; *CT,* computed tomographic (scan); *MRI,* magnetic resonance imaging.

Collaborative Care

Treatment of adrenocortical insufficiency is focused on management of the underlying cause when possible. The mainstay of treatment for adrenocortical insufficiency is replacement therapy (see Table 51-18). Hydrocortisone, the most commonly used form of replacement therapy, has both glucocorticoid and mineralocorticoid properties. During situations associated with physiological stress, glucocorticoid dosage must be increased to prevent addisonian crisis. Mineralocorticoid replacement with fludrocortisone acetate is administered daily, with increased salt in the diet.

Addisonian crisis is a life-threatening emergency requiring aggressive management. Treatment must be directed toward shock management and high-dose hydrocortisone replacement. Large volumes of 0.9% saline solution and 5% dextrose are administered to reverse hypotension and electrolyte imbalances until BP returns to normal.

Nursing Management Addison's Disease

Nursing Implementation

Acute Intervention.

When the patient with Addison's disease is hospitalized—whether for diagnosis, an acute crisis, or some other health problem—nursing management focuses on monitoring the patient while correcting fluid and electrolyte balance. Vital signs and signs of fluid volume deficit and electrolyte imbalance are assessed. Trends in serum glucose, sodium, and potassium are monitored. Baseline data are established regarding mental status, vital signs, and weight. A complete medication history is obtained to determine drugs that can potentially interact with corticosteroids. These drugs include oral hypoglycemics, cardiac glycosides, oral contraceptives, anticoagulants, and NSAIDs.

Changes are noted in BP, weight gain, weakness, or other manifestations of Cushing's syndrome. In addition, the patient must be protected against exposure to infection and assisted with daily hygiene. The patient must also be protected from noise, light, and environmental temperature extremes—the patient cannot cope with these stresses because of the inability to produce corticosteroids.

The patient who is hospitalized because of adrenal crisis usually responds by the second day and can start oral corticosteroid replacement. The patient must be instructed about the importance of keeping scheduled follow-up appointments.

Ambulatory and Home Care.

The nurse has an important role in the long-term management of Addison's disease. The serious nature of the disease and the need for lifelong replacement therapy necessitate a well-organized and carefully presented teaching plan. Table 51-19 outlines the major areas that must be included in the teaching plan.

TABLE 51-19

PATIENT & CAREGIVER TEACHING GUIDE
Addison's Disease

The following information should be included when teaching the patient and caregiver about management of Addison's disease:

1. Names, dosages, and actions of drugs
2. Symptoms of overdosage and underdosage
3. Conditions necessitating increased medication (e.g., trauma, infection, surgery, emotional crisis)
4. Course of action to take in regard to changes in medication
    - Increase in dose of corticosteroid
    - Administration of large dose of corticosteroid intramuscularly, including demonstration and return demonstration
    - Consultation with health care provider
5. Prevention of infection and need for prompt and vigorous treatment of existing infections
6. Need for lifelong replacement therapy
7. Need for lifelong medical supervision
8. Need for medical identification device
9. Prevention of falls
10. Adverse effects of corticosteroid therapy and prevention techniques
11. Special instruction for patients who are diabetic, and management of blood glucose when taking corticosteroids

Glucocorticoids are usually given in divided doses, two-thirds in the morning and one-third in the afternoon. Mineralocorticoids are given once daily, preferably in the morning. This dosage schedule reflects normal circadian rhythm in endogenous hormone secretion and decreases the intensity of adverse effects associated with corticosteroid replacement therapy. Because the aim of replacement therapy is to return hormone levels to normal, nursing care is designed to help patients maintain hormone balance and manage the medication regimen.

Because the patient with Addison's disease is unable to tolerate physical or emotional stress without additional exogenous corticosteroids, long-term care revolves around recognizing the need for extra medication and techniques for stress management. The need for corticosteroid hormone is proportional to stress levels. A patient who cannot produce endogenous hormone must adjust the dose of exogenous hormone to the stress level. Examples of situations requiring corticosteroid adjustment are fever, influenza, extraction of teeth, and rigorous physical activity, such as playing tennis on a hot day or running a marathon. Doses are usually doubled in situations of minor stress (e.g., a respiratory infection,

dental work) and tripled in situations of major stress (e.g., divorce, loss of parent). When the stress level is in doubt, it is better to err on the side of over-replacement. If vomiting or diarrhea occurs, as may happen with influenza, the health care provider must be notified immediately because electrolyte replacement may be necessary. In addition, these manifestations may be early indicators of crisis. Overall, patients who take their medications consistently can anticipate a normal life expectancy.

The patient must be taught the signs and symptoms of corticosteroid deficiency and excess and to report these signs to the health care provider so the dosage can be adjusted to each patient's needs. It is critical that patients wear a medical alert bracelet and carry a wallet card stating that they have Addison's disease so that appropriate therapy can be initiated in case of an unexpected stressful event. The patient should be instructed and given handouts related to other medications that cause a need to increase glucocorticoid dosage (e.g., phenytoin [Dilantin], barbiturates, rifampin [Rifadin], and antacids). Estrogen inhibits steroid metabolism. The nurse should instruct patients receiving mineralocorticoid therapy (fludrocortisone acetate) (a) on how to measure their BP, (b) to increase salt intake, and (c) to report significant changes to their health care provider. Changes may indicate a need for dosage adjustment.

Patients should carry an emergency kit at all times. The kit should consist of 100 mg of intramuscular (IM) hydrocortisone, syringes, and instructions for use. The patient and significant others should be instructed in how to administer an IM injection in case the replacement therapy cannot be taken orally. Patients should verbalize instructions, practise IM injections with saline, and receive written instructions about when to alter the dose (Quinkler, Beuschlein, Hahner, et al., 2013).

Corticosteroid Therapy

Corticosteroids are used to relieve the signs and symptoms associated with many diseases (Table 51-20). The long-term administration of corticosteroids in therapeutic dosages often leads

to serious complications and adverse effects (Table 51-21). For this reason, corticosteroid therapy is not recommended for minor chronic conditions. Therapy should be reserved for diseases in which there is a risk for death or permanent loss of function and conditions in which short-term therapy is likely to produce remission or recovery. The potential benefits of treatment must always be weighed against the risks.

TABLE 51-20

DRUG THERAPY
Diseases and Disorders Treated With Corticosteroids

Hormone Replacement	***Endocrine Diseases***
• Adrenal insufficiency	• Hashimoto's thyroiditis
• Congenital adrenal hyperplasia	• Hypercalcemia

TABLE 51-21

DRUG THERAPY
Effects and Adverse Effects of Corticosteroids

• BP increases because of excess blood volume and potentiation of vasoconstrictor effects. Hypertension predisposes to heart failure. • Fat from extremities is redistributed to trunk and face. • Glucose intolerance predisposes to diabetes mellitus. • Healing is delayed, and patient is at increased risk for wound dehiscence. • Hypocalcemia related to anti–vitamin D effect may occur. • Hypokalemia may develop. • Manifestations of inflammation, including redness, tenderness, heat, swelling, and local edema, are suppressed. • Mood and behaviour changes may be observed. • Patient is predisposed to peptic ulcer disease. • Protein depletion decreases bone formation, density, and strength; patient is thus predisposed to pathological fractures, especially compression fractures of the vertebrae (osteoporosis). • Skeletal muscle atrophy and weakness occur. • Suppression of pituitary ACTH synthesis occurs. Corticosteroid deficiency is likely if hormone treatment is withdrawn abruptly. Corticosteroid doses should be tapered. • Susceptibility to infection is increased. Infection develops more rapidly and spreads more widely.

ACTH, adrenocorticotrophic hormone; *BP*, blood pressure.

Effects of Corticosteroid Therapy

Corticosteroid therapy has multiple effects. Although these actions can prove to be beneficial and therapeutic in some situations, they can contribute to adverse effects as well. The expected effects of corticosteroid therapy include the following:

1. *Anti-inflammatory action.* Corticosteroids decrease the number of circulating lymphocytes, monocytes, and eosinophils. They enhance the release of polymorphonuclear leukocytes from bone marrow, inhibit the accumulation of leukocytes at the site of inflammation, and inhibit the release of substances involved in the inflammatory response (e.g., kinins, prostaglandins, histamine) from the leukocytes. As a result, manifestations of inflammation, including redness, tenderness, heat, swelling, and local edema, are suppressed.
2. *Immuno-suppression.* Corticosteroids cause atrophy of lymphoid tissue, suppress the cell-mediated immune responses, and decrease the production of antibodies.

3. *Maintenance of normal blood pressure.* Corticosteroids potentiate the vasoconstrictor effect of norepinephrine and act on the renal tubules to increase sodium reabsorption and enhance potassium and hydrogen excretion. Retention of sodium (and subsequently water) increases blood volume and helps maintain BP. Mineralocorticoids have a direct effect on sodium reabsorption in the distal tubules of the kidneys; as a result, sodium retention and water retention are increased.
4. *Carbohydrate and protein metabolism.* Corticosteroids antagonize the effects of insulin and can induce glucose intolerance by increasing hepatic glycogenolysis and insulin resistance. They also stimulate the breakdown of protein for gluconeogenesis, which can lead to skeletal muscle wasting. Although corticosteroids mobilize free fatty acids and cause redistribution of fat in Cushingoid patterns, the mechanism underlying this process is unknown.

Complications Associated With Corticosteroid Therapy

A beneficial effect in one situation may be a harmful one in another. For example, the vasopressive effect of a hormone is critical in enabling the organism to function in stressful situations, but it can produce hypertension when used for drug therapy. Suppression of inflammation and the immune response may help save the life of someone experiencing anaphylaxis or receiving a transplant, but it causes reactivation of latent tuberculosis and greatly reduces resistance to other infections and cancers. In addition, corticosteroids inhibit the antibody response to vaccines.

Drug Alert

Corticosteroids

The nurse should do the following:

- Instruct patients not to discontinue therapy abruptly.
- Monitor patients for signs of infection.
- Instruct patients with diabetes to closely monitor blood glucose levels.

Nursing and Collaborative Management Corticosteroid Therapy

Many patients receive corticosteroid therapy, particularly glucocorticoid therapy, for nonendocrine reasons (see Table 51-20). Thorough instruction is necessary to ensure patient adherence to the regimen. When corticosteroids are used as nonreplacement therapy, they are taken once daily or once every other day. They should be taken early in the morning with food to decrease gastric irritation. Because exogenous corticosteroid administration may suppress endogenous ACTH and therefore endogenous cortisol (suppression is time and dose dependent), the danger of abrupt cessation of corticosteroid therapy must be emphasized to patients and significant others. When taken for longer than 1 week, corticosteroids suppress adrenal production, and oral steroids should be tapered. In acute care or home care situations, nurses must ensure that increased doses of steroid are prescribed with increased physical or emotional stress.

Because patients often receive corticosteroid treatment for prolonged periods (>3 months), corticosteroid-induced osteoporosis is an important concern (Clarke, 2012). Therapies to reduce the resorption of bone may include increased calcium intake, vitamin D supplementation, administration of bisphosphonates (e.g., alendronate [Fosamax]), and institution of a low-impact exercise program. Further instruction and interventions to minimize the adverse effects and complications of corticosteroid therapy are listed in Table 51-22.

TABLE 51-22

PATIENT & CAREGIVER TEACHING GUIDE
Corticosteroid Therapy

The following instructions should be included when teaching the patient and caregiver about management of corticosteroid therapy.

1. Plan a diet high in protein, calcium, and potassium but low in fat and concentrated simple carbohydrates such as sugar, honey, syrups, and candy.
2. Identify measures to ensure adequate rest and sleep, such as daily naps and avoidance of caffeine late in the day.
3. Develop and maintain an exercise program to help maintain bone integrity.
4. Recognize edema and ways to restrict sodium intake to less than 2 000 mg/day if edema occurs.
5. Monitor glucose levels and recognize symptoms and signs of hyperglycemia (e.g., polydipsia, polyuria, blurred vision) and glycosuria (glucose in the urine). Patients should be instructed to report hyperglycemic symptoms or capillary glucose levels higher than 10 mmol/L or urine findings that are positive for glucose.
6. Notify health care provider if patients are experiencing postprandial heartburn or epigastric pain that is not relieved by antacids.
7. See an eye specialist yearly to assess possible development of cataracts.
8. Use safety measures such as getting up slowly from a bed or a chair, and use good lighting to prevent accidental injury.
9. Maintain good hygiene practices and avoid contact with people with colds or other contagious illnesses to prevent infection.
10. Inform all health care providers about long-term corticosteroid use.
11. Realize that doses of corticosteroids may need to be increased in times of physical and emotional stress.
12. Never abruptly stop taking the corticosteroids because this could lead to addisonian crisis and possibly death.

Hyperaldosteronism

Etiology and Pathophysiology

Hyperaldosteronism is characterized by excessive aldosterone secretion. The main effects of aldosterone are retention of sodium and excretion of potassium and hydrogen ion. Thus the hallmark of this disease is hypertension with hypokalemic alkalosis. *Primary hyperaldosteronism* (PA) is most commonly caused by a small, solitary adrenocortical adenoma. On occasion, multiple lesions are involved and are associated with bilateral adrenal hyperplasia. PA affects both sexes equally and occurs most frequently between the ages of 30 and 50 years. It is estimated that approximately 1% of cases of hypertension are caused by PA. *Secondary hyperaldosteronism* occurs in response to a nonadrenal cause of elevated aldosterone levels such

as renal artery stenosis, renin-secreting tumours, or chronic renal disease.

Clinical Manifestations

Elevations in aldosterone levels are associated with retention of sodium and elimination of potassium. Sodium retention leads to hypernatremia, hypertension, and headache. Edema does not usually occur because the rate of sodium excretion increases, which prevents more severe sodium retention. The potassium wasting leads to hypokalemia, which causes generalized muscle weakness, fatigue, cardiac dysrhythmias, glucose intolerance, and metabolic alkalosis that may lead to tetany.

Diagnostic Studies

The diagnosis of hyperaldosteronism should be suspected in all hypertensive patients with hypokalemia that are not being treated with diuretics. PA is associated with elevations in plasma aldosterone levels and decreased plasma renin activity, elevated sodium levels, and decreased serum potassium levels. Adenomas are localized by means of CT or MRI. If a tumour is not found, plasma 18-hydroxycorticosterone is measured after overnight bedrest. A level higher than 1.38 nmol/L indicates the presence of an adenoma.

Nursing and Collaborative Management Primary Hyperaldosteronism

The preferred treatment for PA is surgical removal of the adrenal gland that has the adenoma (adrenalectomy). A laparoscopic approach is most often used. Before surgery, patients should be treated with a low-sodium diet, potassium-sparing diuretics (spironolactone [Aldactone] or eplerenone [Inspra]), and antihypertensive agents to normalize serum potassium levels and BP. Spironolactone and eplerenone block the binding of aldosterone to the mineralocorticoid receptor in the terminal distal tubules and collecting ducts of the kidneys, thus increasing the excretion of sodium and water and the retention of potassium. Oral potassium supplements and sodium restrictions may also be necessary. Potassium supplementation and a potassium-sparing diuretic should not be started simultaneously because of the danger of hyperkalemia. Patients taking eplerenone should be instructed to avoid grapefruit juice.

Patients with bilateral adrenal hyperplasia are treated with a potassium-sparing diuretic. Calcium channel blockers may also be used to control BP. Dexamethasone may be used to decrease the hyperplasia.

Nursing care includes careful assessment for signs of fluid and electrolyte imbalance (especially potassium imbalance) and cardiovascular status. BP should be monitored frequently before and after surgery because unilateral adrenalectomy is successful in controlling hypertension in only 80% of patients with adenoma. Patients receiving maintenance therapy with spironolactone need instruction about the possible adverse effects (gynecomastia, erectile dysfunction, and menstrual disorders), as well as knowledge about the signs and symptoms of hypokalemia and hyperkalemia. Patients should be taught how to monitor their own BP and the need for

frequent monitoring. The need for continued health supervision should be stressed.

Disorders of the Adrenal Medulla

Pheochromocytoma

Etiology and Pathophysiology

Pheochromocytoma is a rare condition characterized by a tumour of the adrenal medulla that arises from the chromaffin cells and produces excessive amounts of catecholamines (epinephrine, norepinephrine). The secretion of excessive catecholamines results in severe hypertension (Li, Spiler, Fahey, 3rd, et al., 2013). If left untreated, it may lead to hypertensive encephalopathy, diabetes mellitus, cardiomyopathy, and death. It is most commonly seen in young to middle-aged adults. Pheochromocytoma may be inherited in persons with multiple endocrine neoplasia.

Clinical Manifestations

The most striking clinical features of pheochromocytoma include severe, episodic hypertension accompanied by the classic manifestations of severe, pounding headache; tachycardia with palpitations; profuse sweating; and unexplained abdominal or chest pain. Such "attacks" may be provoked by many medications, including antihypertensives, opioids, radiological contrast media, and tricyclic antidepressants. The duration of the episodes varies from a few minutes to several hours.

Diagnostic Studies

Although pheochromocytoma is associated with a number of symptoms, the correct diagnosis is often missed. Pheochromocytoma is an uncommon cause of hypertension, accounting for only 0.1% of all cases. This condition should be considered in patients who do not respond to traditional hypertensive treatments.

The simplest and most reliable diagnostic test for pheochromocytoma is measurement of urinary fractionated metanephrines (catecholamine metabolites) and fractionated

catecholamines and creatinine, usually done as a 24-hour urine collection. Serum catecholamines may be elevated during an "attack." CT scans and MRI are used for diagnosing tumours. Health care providers should avoid palpating the abdomen of a patient with suspected pheochromocytoma, since it may cause the sudden release of catecholamines and severe hypertension.

Nursing and Collaborative Management Pheochromocytoma

The primary treatment for pheochromocytoma consists of surgical removal of the tumour. Treatment with α- and β-adrenergic receptor blockers is required preoperatively to control BP and prevent an intraoperative hypertensive crisis. The α-adrenergic receptor blocker prazosin (Minipress) is given up to 2 weeks preoperatively to reduce BP and alleviate other symptoms of catecholamine excess, but calcium channel blockers may also be effective (Shah & Ruan, 2014) After adequate α-adrenergic blockade, β-adrenergic receptor blockers (e.g., propranolol) are used to decrease tachycardia and other dysrhythmias. If beta blockers are started too early, unopposed α-adrenergic stimulation could precipitate a hypertensive crisis. Sympathetic blocking agents may result in orthostatic hypotension. Patients must be advised to make postural changes cautiously.

Surgery is more commonly performed via laparoscopic adrenalectomy than via open abdominal incision. Complete removal of the adrenal tumour cures the hypertension in the majority of affected individuals, but hypertension persists in approximately 10% to 30% of patients. For these individuals, BP management involves standard antihypertensive drug therapy. If surgery is not an option, medication is used to diminish catecholamine production by the tumour and simplify chronic management.

Case finding is an important nursing function. Any patient with hypertension accompanied by symptoms of sympathoadrenal discharge should be referred to a health care provider for definitive diagnosis. An important part of the nursing assessment is observation of patients for the classic triad of symptoms of pheochromocytoma—severe, pounding headache; tachycardia; and profuse sweating. BP should be monitored immediately if a patient is experiencing an attack. The nurse should be prepared to check BP when any of the drugs that might precipitate an attack are administered.

The nurse should attempt to make patients with pheochromocytoma as comfortable as possible. All diagnostic samples should be collected appropriately. Capillary blood glucose levels should be monitored to assess for diabetes mellitus. Patients need rest, nourishing food, and emotional support during this period.

Preoperative and postoperative care is similar to that for any patient undergoing adrenalectomy, except that BP fluctuations from catecholamine excesses tend to be severe and must be carefully monitored. Because hypertension may persist even when the tumour is removed, the nurse should stress the importance of follow-up care and routine BP monitoring. Patients taking catecholamine synthesis inhibitors should be instructed to rise slowly while holding on to a secure object because this medication can cause orthostatic hypotension.

Case Study

Graves' Disease

Source: JPagetRFPhotos/Shutterstock.com.

Patient Profile

Ruth Delaware, a 47-year-old woman, was admitted to the hospital with a high fever. After an endocrine workup, she received a diagnosis of Graves' disease.

Subjective Data

- Reports recent job loss because of inability to cope with job stress
- Reports symptoms including fatigue, unintentional weight loss, insomnia, palpitations, and heat intolerance

Objective Data

Physical Examination

- Fever of 40°C
- BP of 150/78, pulse of 118, and respiratory rate of 24
- Hot, moist skin
- Fine tremors of the hands
- Grade 4+ deep tendon reflexes and muscle strength of grades 1 to 2

Collaborative Care

- Subtotal thyroidectomy planned for 2 months later
- Started on propylthiouracil and propranolol (Inderal)

Discussion Questions

1. What is the cause of Ms. Delaware's symptoms?
2. What diagnostic studies were probably ordered? What results have established the diagnosis of Graves' disease?
3. Why was surgery delayed?
4. What was the purpose of drug therapy for Ms. Delaware?
5. ***Priority decision:*** What are Ms. Delaware's priority learning needs? What teaching strategies would the nurse use if Ms. Delaware could not read?

6. What are the nursing interventions for successful long-term management of Ms. Delaware after the subtotal thyroidectomy?
7. ***Priority decision:*** On the basis of the assessment data presented, what are the priority nursing diagnoses pertinent to Ms. Delaware while she is hospitalized? Are there any collaborative problems?
8. ***Evidence-informed practice:*** Why is Ms. Delaware counselled to give up her longstanding cigarette smoking habit?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. After a hypophysectomy for acromegaly, which of the following should be the focus of postoperative nursing care?
   a. Frequent monitoring of serum and urine osmolarity
   b. Parenteral administration of a GH-receptor antagonist
   c. Keeping the client in a recumbent position at all times
   d. Client teaching regarding the need for lifelong hormone therapy
2. A client with a head injury develops SIADH. Which of the following manifestations of SIADH would the nurse expect to find?
   a. Hypernatremia and edema
   b. Muscle spasticity and hypertension
   c. Low urine output and hyponatremia
   d. Weight gain and decreased glomerular filtration rate (GFR)
3. The health care provider prescribes levothyroxine (Synthroid) for a client with myxedema. After teaching regarding this drug, the nurse determines that further instruction is needed when the client says which of the following?
   a. "I can expect the medication dose may need to be adjusted."
   b. "I only need to take this drug until my symptoms are improved."
   c. "I can expect to return to normal function with the use of this drug."
   d. "I will report any chest pain or difficulty breathing to the doctor right away."
4. Which of the following symptoms would lead the nurse to suspect damage or removal of the parathyroid glands after thyroid surgery?
   a. Muscle weakness and weight loss

b. Hyperthermia and severe tachycardia

c. Hypertension and difficulty swallowing

d. Laryngospasms and tingling in the hands and feet

5. Which of the following are important nursing intervention(s) when caring for a client with Cushing's syndrome? *(Select all that apply)*

a. Restricting protein intake

b. Monitoring blood glucose levels

c. Observing for signs of hypotension

d. Administering medication in equal doses

e. Protecting the client from exposure to infection

6. Which of the following is an important preoperative nursing intervention before an adrenalectomy for hyperaldosteronism?

a. Monitor blood glucose levels

b. Restrict fluid and sodium intake

c. Administer potassium-sparing diuretics

d. Advise the client to make postural changes slowly

7. How does the nurse instruct the client who is taking corticosteroids to control the adverse effects of drug therapy?

a. Increase calcium intake to 1 500 mg/day

b. Perform glucose monitoring for hypoglycemia

c. Obtain immunizations due to high risk for infections

d. Avoid abrupt position changes because of orthostatic hypotension

8. What does the nurse teach the client regarding the best time to take corticosteroids for replacement purposes?

a. Once a day at bedtime

b. Every other day on awakening

c. On arising and in the late afternoon

d. At consistent intervals every 6 to 8 hours

1. a, 2. c, 3. b, 4. d, 5. b, e, 6. c, 7. a, 8. c.

CHAPTER 52

Nursing Management

Diabetes Mellitus

Written by, Jane K. Dickinson

Adapted by, Tess Montada-Atin

LEARNING OBJECTIVES

1. Describe the pathophysiology and clinical manifestations of diabetes mellitus.
2. Describe the differences between type 1 and type 2 diabetes mellitus.
3. Describe the collaborative care of the patient with diabetes mellitus.
4. Describe the role of nutrition and exercise in the management of diabetes mellitus.
5. Describe the nursing management of a patient with newly diagnosed diabetes mellitus.
6. Describe the nursing management of the patient with diabetes mellitus in the ambulatory and home care settings.
7. Identify the pathophysiology and clinical manifestations of acute and chronic complications of diabetes mellitus.
8. Explain the collaborative care and nursing management of the patient with acute and chronic complications of diabetes mellitus.

KEY TERMS

diabetes mellitus (DM), p. 1287
diabetic ketoacidosis (DKA), p. 1311
diabetic nephropathy, p. 1318
diabetic neuropathy, p. 1318
glycemic index (GI), p. 1302
hyperosmolar hyperglycemic state (HHS), p. 1313

insulin resistance, p. 1290
lipodystrophy, p. 1298
prediabetes, p. 1290
Somogyi effect, p. 1298

Diabetes Mellitus

Diabetes mellitus (DM) is a multisystem disease related to abnormal insulin production, impaired insulin utilization, or both. DM is a serious health problem throughout the world. According to the World Health Organization (WHO), 347 million people have DM (WHO, 2015). By 2030, this figure is expected to top 366 million. Canadian data indicate that the estimated prevalence of diagnosed DM in adults is 9.3% (~3.4 million people) (Canadian Diabetes Association [CDA], 2015).

Approximately 65% to 80% of people with DM will die as a result of heart disease or stroke (Poirier, Dufour, Carpentier, et al., 2013). DM is a contributing factor in the deaths of approximately 41 500 Canadians each year. Canadian adults with DM are twice as likely as people without DM to die prematurely. For example, a 35-year-old Canadian with DM is four times more likely to die at that age than a 35-year-old without DM. Life expectancy for people with type 2 DM may be shortened by 5 to 10 years (Stone, Fitchett, Grover, et al., 2013). The financial burden of DM and its complications on people with the disease and on the Canadian health care system is enormous. A person with DM incurs medical costs that are two to three times higher than those of a person without DM. A person with DM can face direct costs for medication and supplies ranging from $1 000 to $15 000 per year. DM and its complications cost the Canadian health care system an estimated $11.7 billion in 2010 and this figure will rise to $16 billion by 2020 (CDA and Diabetes Quebec [DQ], 2011).

Approximately 10% of people with DM have type 1 DM. However, the number of people with type 2 DM is increasing dramatically owing to a number of factors —in the Western world, people are living longer, obesity rates are rising, and lifestyles are becoming increasingly sedentary. There is increased immigration from high-risk populations, with 77% of Canadians coming from populations that are at higher risk for type 2 DM. These populations include people of Latin American, Asian, South Asian, and African descent (CDA and DQ, 2011) (see Determinants of Health box). Risk levels for these groups are between two and six times higher than for White Canadians.

Determinants of Health

Diabetes

Income and Social Status

- Low income and food insecurity appear to be associated with a higher prevalence of diabetes and diabetes-related complications.*

Biology and Genetics

- Indigenous people are among the highest risk populations for developing diabetes in Canada.†
- Almost 80% of new Canadians come from populations at high risk for developing type 2 DM (e.g., people of Latin American, Asian, South Asian, or African descent).‡

Personal Health Practices and Coping Skills

- Progression to type 2 DM can be prevented or delayed through lifestyle modifications such as weight loss and weight control, consuming a healthy diet, and exercising.¶
- Electronic mobile devices can be used to deliver educational and motivational text messages about lifestyle modification.¶

There are three recognized groups of Indigenous people in Canada: First Nations, Inuit, and Métis. These populations are three to five times more likely than the general population to develop type 2 DM (CDA, 2013a). An estimated 25% of individuals in First Nations communities on reserves who are over age 45 have DM. According to the CDA Clinical Practice Guidelines Expert Committee (CDA, 2013a), the prevalence of type 2 DM in Canadian Indigenous children 5 to 18 years of age is noted to be as high as 1%, with the highest in the Plains Cree people of Central Canada. Screening every 2 years should also be considered from age 10 or established puberty in Indigenous children with more than one additional risk factor (CDA, 2013a).

DM is a serious problem for the Métis, more frequently affecting women, older adults, people who are obese, and those with lower levels of education. The disease has a negative impact on quality of life and is associated with significant comorbidities in this population (Shah, Cauch-Dudek, & Pigeau, 2011; Martens et al., 2011). It has been documented that Indigenous communities in Canada experience prevalence rates of DM that are among the highest in the world (CDA and DQ, 2011). Comparing First Nations with non–First Nations people in Manitoba, it was found that rates of DM and diabetes-related lower-limb amputations were higher (Martens, Barlett, Prior, et al., 2011).

Etiology and Pathophysiology

Current theories link the causes of DM, singly or in combination, to genetic, autoimmune, viral, and environmental factors (e.g., obesity, sedentary lifestyle, stress). Regardless of its cause, DM is primarily a disorder of glucose metabolism related to absent or insufficient insulin supply or poor utilization of the insulin that is available.

Although the *CDA 2013 Clinical Practice Guidelines* recognize 11 different classifications of the disease, most of these types are rarely encountered in routine nursing practice (CDA, 2013a). The two most common types of DM are classified as type 1 and type 2 DM (Table 52-1). Gestational diabetes mellitus (GDM), prediabetes, and secondary DM (discussed later in this chapter) are other classifications of DM commonly seen in clinical practice.

TABLE 52-1

CHARACTERISTICS OF TYPE 1 AND TYPE 2 DIABETES MELLITUS

Factor	Type 1 Diabetes Mellitus	Type 2 Diabetes Mellitus
Age at onset	More common in young people but can occur at any age	Usually ≥35 yr but can occur at any age Incidence is increasing in children
Type of onset	Signs and symptoms abrupt, but disease process may be present for several years	Insidious; may go undiagnosed for years
Prevalence	Accounts for 5%–10% of all types of diabetes	Accounts for 90% of all types of diabetes
Environmental factors	Viruses, toxins	Obesity, lack of exercise
Primary defect	Absent or minimal insulin production due to an autoimmune process	Insulin resistance, decreased insulin production over time, and alterations in production of adipokines
Islet-cell antibodies	Often present at onset	Absent
Endogenous insulin	Minimal or absent	Possibly excessive; adequate but delayed secretion or reduced utilization; secretions diminish over time
Nutritional status	Thin, normal, or obese	Obese or normal
Symptoms	Thirst, polyuria, polyphagia, fatigue, weight loss	Frequently none, fatigue, recurrent infections
Ketosis	Prone at onset or during insulin deficiency	Resistant except during infection or stress
Nutritional therapy	Essential	Essential
Insulin	Required for all	Required for some
Oral antihyperglycemic agents	Not indicated	Usually beneficial
Vascular and neurological complications	Frequent	Frequent

Normal Insulin Metabolism.

Insulin is a hormone produced by the beta cells in the islets of Langerhans of the pancreas. Under normal conditions, insulin is continuously released into the bloodstream in small pulsatile increments (a basal rate), with increased release (bolus) when food is ingested (Figure 52-1). The activity of released insulin lowers blood glucose and facilitates a stable, normal glucose range of approximately 4 to 6 mmol/L. The average amount of insulin secreted daily by an adult is approximately 40 to 50 units, or 0.6 units/kg of body weight.

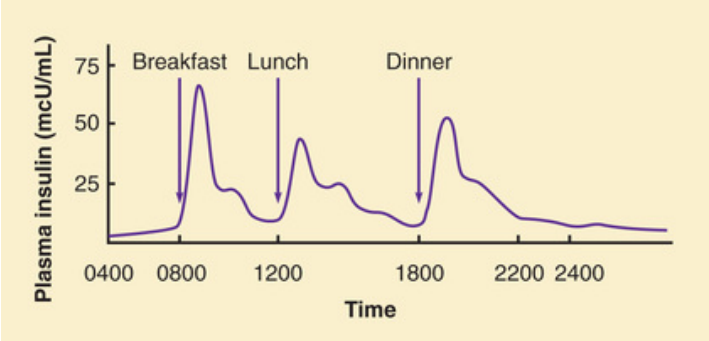

FIGURE 52-1 Normal endogenous insulin secretion. In the first hour or two after meals, insulin concentrations rise rapidly in blood and peak at about 1 hour. After meals, insulin concentrations promptly decline toward preprandial values as carbohydrate absorption from the gastro-intestinal tract declines. After carbohydrate absorption from the gastro-intestinal tract is complete and during the night, insulin concentrations are low and fairly constant, with a slight increase at dawn.

Other hormones (glucagon, epinephrine, growth hormone, and cortisol) work to oppose the effects of insulin and are often referred to as *counter-regulatory hormones.* These hormones work to increase blood glucose levels by stimulating glucose production and output by the liver and by decreasing the movement of glucose into the cells. Insulin and these counter-regulatory hormones provide a sustained but regulated release of glucose for energy during food intake and periods of fasting and usually maintain blood glucose levels within the normal range. An abnormal production of any or all of these hormones may be present in DM.

Insulin is released from the pancreatic beta cells as its precursor, proinsulin, and is then routed through the liver. Proinsulin is composed of two polypeptide chains, chain A and chain B, which are linked by the C-peptide chain. Insulin is formed when enzymes cleave C off, leaving the A and B chains. The presence of C peptide in serum is a useful indicator of beta-cell function.

Insulin facilitates glucose transport from the bloodstream across the cell membrane to the cytoplasm of the cell. The rise in plasma insulin after a meal stimulates storage of glucose as glycogen in liver and muscle, inhibits gluconeogenesis, enhances fat deposition in adipose tissue, and increases protein synthesis. The fall in insulin level during normal overnight fasting facilitates the release of stored glucose from the liver, protein from muscle, and fat from adipose tissue. For this reason, insulin is known as the *anabolic* or *storage hormone*.

Skeletal muscle and adipose tissue have specific receptors for insulin and are considered insulin-dependent tissues. Other tissues (e.g., brain, liver, blood cells) do not directly depend on insulin for glucose transport but require an adequate glucose supply for normal function. Although liver cells are not considered insulin-dependent tissue, insulin receptor sites on the liver facilitate the hepatic uptake of glucose and its conversion to glycogen.

Type 1 Diabetes Mellitus.

Formerly known as "juvenile-onset" or "insulin-dependent" DM, *type 1 DM* most often occurs in people who are younger than 30 years, with a peak onset between ages 11 and 13. The rate of type 1 DM in children is highest in Europe (Finland and Sweden) (International Diabetes Federation [IDF], 2015). Most cases of type 1 DM are sporadic; only 10% to 15% of affected individuals have a first-degree relative with type 1 DM at the time of diagnosis. Typically, it is seen in people with a lean body type, although it can occur in people who are overweight. This form includes *latent autoimmune diabetes mellitus in adults* (LADA); the term is used to describe the small number of people with apparent type 2 DM who appear to have immune-mediated loss of pancreatic beta cells (CDA, 2013a).

Etiology and Pathophysiology.

Type 1 DM results from progressive destruction of pancreatic beta cells owing to an autoimmune process in susceptible individuals. Autoantibodies to the islet cells cause a reduction of 80% to 90% of normal beta-cell function before hyperglycemia and other manifestations occur (Figure 52-2). A genetic predisposition and exposure to a virus are factors that may contribute to the pathogenesis of type 1 DM. Occasionally, type 1 DM may be caused by nonimmune factors of unknown (idiopathic) etiologies. This type of DM is known as *type 1B DM.* When type 1 DM is caused by an immune mechanism, the disease is known as *type 1A.*

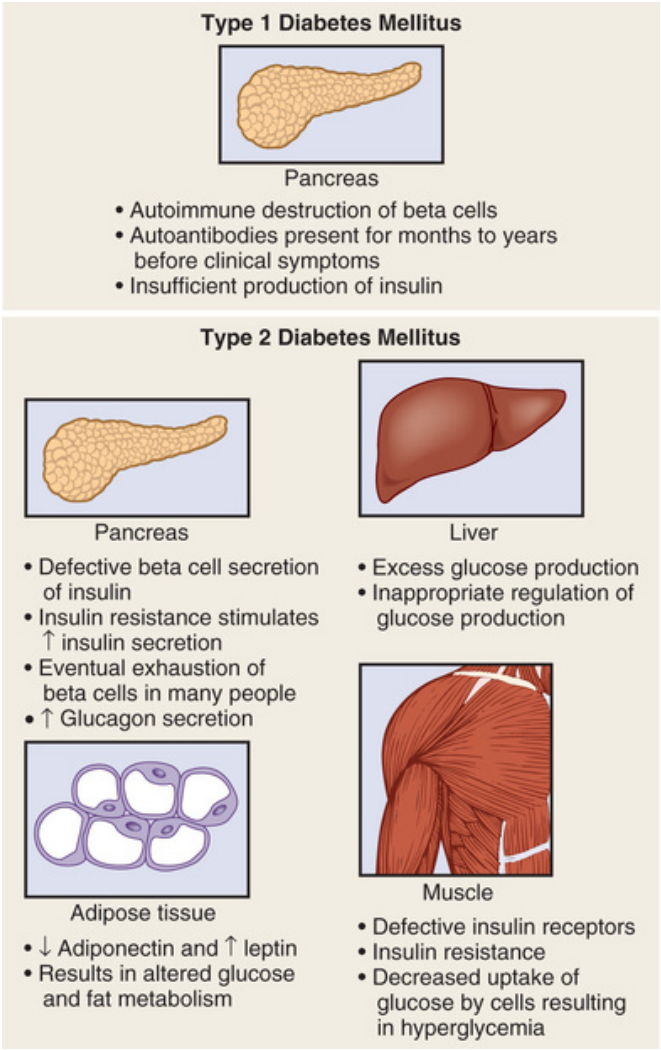

FIGURE 52-2 Altered mechanisms in type 1 and type 2 diabetes mellitus.

Predisposition to type 1 DM is believed to be related to human leukocyte antigens (HLAs) (see Chapter 16 for a discussion of HLAs and disease associations). Theoretically, when an individual with certain HLA types is exposed to viral infections, the beta cells of the pancreas are destroyed, either directly or through an autoimmune process. The HLA types associated with an increased risk for type 1 DM include HLA-DR3 and HLA-DR4 (see the Genetics in Clinical Practice box, Types 1 and 2 Diabetes Mellitus).

Onset of Disease.

Type 1 DM is associated with a long preclinical period. The islet-cell autoantibodies responsible for beta-cell destruction are present for months to years before the onset of symptoms. Manifestations of type 1 DM develop when the person's pancreas can no longer produce insulin. Once this occurs, the onset of symptoms is usually rapid, and the patient comes to the emergency department with impending or actual ketoacidosis. The patient usually has a history of recent

and sudden weight loss as well as the classic symptoms of *polydipsia* (excessive thirst), *polyuria* (frequent urination), and *polyphagia* (excessive hunger).

The individual with type 1 DM requires a supply of insulin from an outside source *(exogenous insulin),* such as an injection, in order to sustain life. Without insulin, the patient will develop diabetic ketoacidosis (DKA), a life-threatening condition resulting in metabolic acidosis that, if untreated, could be fatal. Newly diagnosed patients with type 1 DM may experience a remission, or "honeymoon period," soon after treatment is initiated. During this time, the patient requires very little injected insulin because beta-cell mass remains sufficient for glucose control as the progressive destruction continues to occur. Eventually, as more beta cells are destroyed, blood glucose levels increase, more insulin is needed, and the honeymoon period ends. It is critical for the patient to monitor blood glucose very closely during this period. The honeymoon period usually lasts 3 to 12 months, after which the person will require insulin on a permanent basis.

Prediabetes.

Prediabetes, also known as *impaired glucose tolerance* (IGT) or *impaired fasting glucose* (IFG), is noted when a fasting or a 2-hour plasma glucose level is higher than normal (6.1–6.9 mmol/L for IFG and 7.1–11 mmol/L for IGT) but lower than that considered diagnostic for DM. Up to 6 million Canadians have prediabetes, putting them at risk of developing DM and its complications, particularly cardiovascular disease. About 50% of Canadians with prediabetes develop type 2 DM in their lifetime (CDA and DQ, 2011).

Long-term damage to the body, especially the heart and blood vessels, may already be occurring in patients with prediabetes. People with prediabetes usually do not have symptoms. Individuals with prediabetes should have their blood glucose and A_{1c} tested regularly and should watch for the symptoms of DM, such as polyuria, polyphagia, or polydipsia. If action is taken to manage blood glucose, patients with prediabetes can delay or prevent the development of type 2 DM. Maintaining a healthy weight, exercising regularly, eating a healthy diet, and using medication when required are measures found to reduce the risk of developing DM in people with prediabetes by almost 60% (CDA, 2013a).

Type 2 Diabetes Mellitus.

Type 2 DM is, by far, the most prevalent type of DM, accounting for over 90% of patients with DM. Type 2 DM usually occurs in people older than 35 years, and 80% to 90% of patients are overweight at the time of diagnosis. The most powerful risk factor is believed to be obesity, specifically abdominal and visceral adiposity. Visceral adipocytes release an excess amount of free fatty acids, which are associated with insulin resistance at the level of the liver, as well as several adipocytokines, which cause insulin resistance in the muscle (Neeland, Turer, Ayers, et al., 2012). Obesity has a tendency to run in families and probably has a genetic basis (see the Genetics in Clinical Practice box, Types 1 and 2 Diabetes Mellitus).

Other risk factors for type 2 DM are membership in a high-risk population (e.g., people of Indigenous, Latin American, South Asian, Asian, or African descent), history of IGT or IFG, presence of complications associated with DM, vascular disease, history of GDM, and history of delivery of an infant with macrosomia. Hypertension, dyslipidemia, being overweight, abdominal obesity, polycystic ovary syndrome (PCOS), and acanthosis nigricans are associated with insulin resistance and are also risk factors for type 2 DM. Insulin resistance with compensatory hyperinsulinemia is a common feature of PCOS, in both lean and obese women. The exact mechanisms for abnormalities of insulin action in PCOS are not fully understood (Rojas, Chavez, Olivar, et al., 2014). Acanthosis nigricans is a cutaneous sign of an underlying condition and is characterized by a velvety, light brown to black hyperpigmented thickening of the skin, usually on the back, the sides of the neck, the axillae, and flexural surfaces (Atwa, Emaraz, Balata, et al., 2014). The pathways that lead to acanthosis nigricans are not well known. However, the association of acanthosis nigricans with disorders such as DM characterized by insulin resistance suggests that hyperinsulinemia plays a key role in the development of acanthosis nigricans (Atwa et al., 2014). The incidence of type 2 DM is at least three times higher in people with schizophrenia than in the general population and is thought to be related to antipsychotic medications (CDA, 2013a; Moisan, Turgeon, Desjardins, et al., 2013) These medications have contributed to the prevalence of obesity in patients with schizophrenia, which is a known risk factor for insulin resistance and type 2 DM.

Prevalence of type 2 DM increases with age, with about half of the people diagnosed being older than 55. In the past, type 2 DM was known as "adult-onset" DM. This term is no longer considered appropriate because the disease is now being seen in a rapidly growing number of children and adolescents, particularly in the Indigenous population. In a large study, people at risk for type 2 DM were able to cut that risk by 58% by exercising moderately for 30 minutes a day and by losing 5% to 7% of their body weight (CDA, 2013a). Other large studies have shown similar results in reducing risk.

Etiology and Pathophysiology.

In type 2 DM, the pancreas usually continues to produce some *endogenous* (self-made) insulin. However, the insulin that is produced is either insufficient for the needs of the body, poorly utilized by the tissues, or both. In contrast, there is a virtual absence of endogenous insulin in type 1 DM. The presence of endogenous insulin is the major pathophysiological distinction between type 1 and type 2 DM.

Genetic mutations that lead to insulin resistance and a higher risk for obesity have been found in many people with type 2 DM. It is likely that multiple genes are involved in this complex, multifactorial disorder (see the Genetics in Clinical Practice box).

Genetics in Clinical Practice

Types 1 and 2 Diabetes Mellitus

	Type 1 Diabetes Mellitus	Type 2 Diabetes Mellitus	Maturity-Onset Diabetes of the Young (MODY)
Genetic basis	Associations between specific human leukocyte antigens (HLA-DR3, HLA-DR4)	Majority of cases are polygenic	Autosomal dominant, monogenic (single gene)
	As many as 40 genes (and maybe more) influence susceptibility	As many as 25 genes influence susceptibility	Caused by mutations in any of the MODY genes (types 1–11)
Incidence	Accounts for about 5%–10% of cases in Canada	Accounts for about 90% of cases in Canada	Accounts for 1%–5% of people with diabetes
Risk to offspring and twins	Risk to offspring of mothers with diabetes is only 1%–4% Risk to offspring of diabetic fathers is 5%–6%	Risk to offspring is 8%–14%	If one parent has MODY, the offspring has a 50% chance of developing the disease If one parent has MODY, the offspring has a 50% chance of being a carrier
	Identical twin concordance is 30%–40%	Identical twin concordance often exceeds 60%–75%	
Clinical implications	Disease is a result of complex interaction of genetic, autoimmune, and environmental factors	Disease is a result of complex genetic interactions, which are modified by environmental factors such as body weight and exercise	Characterized by young age of onset (often before 25), not associated with obesity or hypertension

Four major metabolic abnormalities have a role in the development of type 2 DM. The first factor is **insulin resistance** in glucose and lipid metabolism, which is a condition in which body tissues do not respond to the action of insulin. This lack of response is owing to insulin receptors that are unresponsive to the action of insulin, insufficient in number, or both. Most insulin receptors are located on skeletal muscle, fat, and liver cells. Insulin mediates glucose uptake into fat tissue and skeletal muscle through GLUT4 glucose transporters. Insulin resistance in fat cells is associated with a decrease in the number of GLUT4 transporters and altered activity in individuals with type 2 DM (Ismail-Beigi, 2012). When insulin is not properly used, the entry of glucose into the cell is impeded, resulting in hyperglycemia. In the early stages of insulin resistance, the pancreas responds to high blood glucose by producing greater amounts of insulin (if beta-cell function is normal). This creates a temporary state of hyperinsulinemia that coexists with the hyperglycemia.

A second factor in the development of type 2 DM is a marked decrease in the ability of the pancreas to produce insulin, as the beta cells become fatigued from the compensatory overproduction of insulin or when beta-cell mass is lost. The resulting IFG and IGT place the individual at risk of developing DM and its complications. This does not necessarily mean that all people with prediabetes will progress to DM. A significant proportion will revert to normal blood glucose levels (CDA, 2013a). The underlying basis for the failure of beta cells to adapt is unknown. However, it may be linked to the adverse effects of chronic hyperglycemia or high circulating free fatty acids.

A third factor is inappropriate glucose production by the liver. Instead of properly regulating the release of glucose in response to blood levels, the liver does so in a haphazard way that does not correspond to the body's needs at the time. Furthermore, there is increased secretion of glucagon from the alpha cells of the pancreas that stimulates glucose production by the liver, adding to the increase in blood sugar. However, this is not considered a primary factor in the development of type 2 DM.

A fourth factor is alteration in the production of hormones and cytokines by adipose tissue *(adipocytokines).* Adipocytokines appear to play a role in glucose and fat metabolism and are likely to contribute to the pathophysiology of type 2 DM. The two main adipocytokines believed to affect insulin sensitivity are adiponectin and leptin. Others include tumour necrosis factor α (TNF-α), interleukin-6 (IL-6), and resistin. The role of resistin in the pathogenesis of obesity-mediated insulin resistance and type 2 DM, however, remains controversial (Beckers, De Freitas, Zegers, et al., 2011). Figure 52-2 depicts the altered mechanisms in type 1 and type 2 DM.

Metabolic syndrome (also known as *insulin resistance syndrome*) is a cluster of abnormalities that act synergistically to greatly increase the risk for cardiovascular disease. Metabolic syndrome is characterized by abdominal obesity, hypertension, dyslipidemia, insulin resistance, and dysglycemia. Patients with metabolic syndrome are at significant risk of developing DM and cardiovascular disease (CDA, 2013a). Lifestyle interventions have been shown to be highly effective in delaying or preventing the onset of DM in people with IGT. Risk factors for metabolic syndrome include, but are not limited to, abdominal obesity, sedentary lifestyle, urbanization and Westernization, and being Indigenous or of Latin American or African descent. Overweight individuals with metabolic syndrome can prevent or delay the onset of DM through a program of weight loss and regular physical activity. (Metabolic syndrome is discussed in further detail in Chapter 43.)

Onset of Disease.

Disease onset in type 2 DM is usually gradual. The person may go for many years with undetected hyperglycemia that might produce few, if any, symptoms. Many people are diagnosed on routine laboratory testing. If the patient with type 2 DM has marked hyperglycemia (e.g., 28–55 mmol/L), a sufficient endogenous insulin supply may prevent DKA from occurring. However, osmotic fluid and electrolyte loss related to hyperglycemia may become severe and lead to hyperosmolar hyperglycemic state. (Complications of DM are discussed later in this chapter.)

Gestational Diabetes.

Gestational diabetes mellitus (GDM) develops during pregnancy. In Canada, it occurs in about 3% of pregnancies in the non-Indigenous population (CDA, 2013a), and the rates are two to three times higher in Indigenous populations (CDA, 2013a). It is detected between 24 and 28 weeks of gestation, using a

sequential screening method with a 50-g oral glucose challenge test, followed by a 75-g oral glucose tolerance test (OGGT). Women with multiple risk factors should be offered screening at any time during pregnancy (CDA, 2013a). Treatment of GDM reduces perinatal death and neonatal complications such as birth trauma, hypoglycemia, hyperbilirubinemia, and respiratory distress syndrome (CDA, 2013a). Nutritional counselling is considered to be the first-line therapy. Physical activity should be encouraged as tolerated. If nutritional counselling alone does not achieve target fasting, or postprandial blood glucose levels, or both, insulin therapy is usually indicated. Approximately 10% of patients progress to DM soon after pregnancy. Although most women with GDM will have normal glucose levels within 6 weeks postpartum, their risk of developing type 2 DM in 5 to 10 years is increased. Women should be screened postpartum to determine their glucose status. The 2013 CDA guidelines recommend a 75-g OGTT be done between 6 weeks and 6 months postpartum. Education on lifestyle modifications to prevent DM should continue postpartum. GDM and management of the pregnant patient with DM is a specialized area not covered in detail in this chapter. The reader is advised to consult a DM and obstetrics text for information about this subject.

Secondary Diabetes.

In some people, DM occurs because of another medical condition or as a result of the treatment of a medical condition that causes abnormal blood glucose levels. Conditions that may cause secondary DM include schizophrenia, cystic fibrosis, Cushing's syndrome, hyperthyroidism, immuno-suppressive therapy, and the use of parenteral nutrition. Commonly used medications that can induce DM in some people include corticosteroids (prednisone), phenytoin (Dilantin), and atypical antipsychotics (e.g., clozapine [Clozaril]). Secondary DM may resolve when the underlying condition is treated or the medication is discontinued.

Clinical Manifestations

Type 1 Diabetes Mellitus.

Because the onset of type 1 DM is rapid, the initial manifestations are usually acute. The classic symptoms are *polyuria* (frequent urination), *polydipsia* (excessive thirst), and *polyphagia* (excessive hunger). The osmotic effect of glucose produces the manifestations of polydipsia and polyuria. Polyphagia is a consequence of cellular malnourishment when insulin deficiency prevents utilization of glucose for energy. Weight loss may occur because the body cannot get glucose and turns to other energy sources, such as fat and protein. Weakness and fatigue may also be experienced, because body cells lack needed energy from glucose. There may be pronounced changes in visual acuity owing to changes in the lens with hyperglycemia and fluid retention. Women may have vaginal yeast infections. Ketoacidosis, a complication associated with untreated type 1 DM, is associated with additional clinical manifestations that are discussed later in this chapter.

Type 2 Diabetes Mellitus.

The clinical manifestations of type 2 DM are often nonspecific, although it is possible that an individual with type 2 DM will experience some of the classic symptoms associated with type 1. Some of the more common manifestations associated with type 2 DM include fatigue, recurrent infections, prolonged wound healing, visual acuity changes, and painful peripheral neuropathy in the feet. Unfortunately, the clinical manifestations appear so gradually that, before the person knows it, he or she may have complications.

Complications

Complications of DM are discussed in detail later in this chapter.

Diagnostic Studies.

The 2013 CDA guidelines recommend any one of the following four methods and their criteria for the diagnosis of DM and a repeat confirmatory test on another day in the absence of symptomatic hyperglycemia:

1. Glycated hemoglobin (A_{1c}) ≥6.5% (in adults), using a standardized, validated assay, in the absence of conditions that affect the accuracy of the A_{1c} and not for suspected type 1 DM or
2. Fasting blood glucose (FBG) level ≥7.0 mmol/L. (*Fasting* is defined as no caloric intake for at least 8 hours.) or
3. Random plasma glucose (RPG) measurement ≥11.1 mmol/L. (*Random* is defined as any time of day without regard to the interval since the last meal.) or
4. Two-hour plasma glucose (PG) level in a 75 g OGTT ≥11.1 mmol/L

It is preferable that the same test be repeated for confirmation, but an RPG level in an asymptomatic individual should be confirmed with any of the other tests (A_{1c}, FBG, or 2-hr PG in 75-g OGTT). When overt symptoms of hyperglycemia (polyuria, polydipsia, and polyphagia) are present, the diagnosis has been made and a confirmatory test is not required before treatment is initiated.

IFG, IGT, or A_{1c} of 6.0% to 6.4% each represent an intermediate stage between normal glucose homeostasis and DM. The stage is called *prediabetes* (see discussion on prediabetes earlier in this chapter). When the FBG level is 6.1 to 6.9 mmol/L, the individual is considered to have IFG. IGT is classified when a 2-hour PG in a 75-g OGTT level is 7.8 to 11.0 mmol/L (CDA, 2013a). The combination of IFG and an A_{1c} of 6.0% to 6.4% is predictive of 100% progression to type 2 DM over a 5-year period.

Measurement of glycated hemoglobin, also known as the *A_{1c} test*, is not only used for diagnosing diabetes but is also useful in determining glycemic control

over time. The test works by showing the amount of glucose that has been attached to hemoglobin molecules, which are attached to the red blood cell (RBC) for the life of the cell (~120 days). Therefore, an A_{1c} test indicates the overall glucose control for the previous 90 to 120 days. All patients with DM should have regular assessments of A_{1c} every 3 to 6 months. Major studies have demonstrated that people with DM who can maintain near-normal A_{1c} levels over time have a greatly reduced risk for the development of retinopathy, nephropathy, and neuropathy. For most people with DM, the ideal A_{1c} goal is 7% or less. Normal range is 6% or less. A target A_{1c} of less than 6.5% can be considered in some patients with type 2 DM to further lower the risk for nephropathy but must be balanced against the risk for hypoglycemia and increased mortality in those at an elevated risk for cardiovascular disease (CDA, 2013a). Diseases affecting RBCs (e.g., sickle cell anemia, thalassemia trait) or recent blood transfusions can affect the A_{1c} results and should be taken into consideration in the interpretation of this test result. It is important to know where an individual is on the glucose continuum (Figure 52-3).

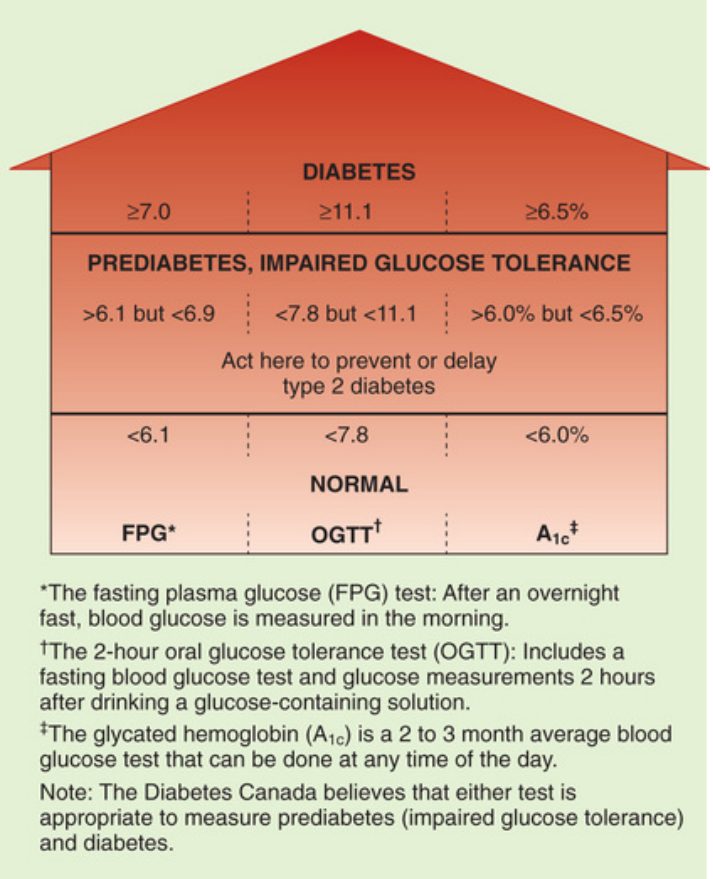

FIGURE 52-3 The glucose continuum. Numbers represent blood glucose levels in millimoles per litre (mmol/L).

Collaborative Care

The goals of DM management are to promote well-being, reduce symptoms, prevent acute complications of hyperglycemia and hypoglycemia, and delay the onset and progression of long-term complications. These goals are most likely to be met when patients are able to maintain blood glucose levels as near to normal as possible. Patient teaching, which enables patients to become the most active participants in their own care, is essential for a successful treatment plan. Nutritional therapy, exercise, self-monitoring of blood glucose, and drug therapy are the tools used in the management of DM (Table 52-2). All individuals with type 1 DM require insulin from the time of diagnosis. For some people with type 2 DM, lifestyle modifications, including healthy eating, regular physical activity, and maintenance of desirable body weight will be sufficient to attain an optimal level of blood glucose control. For the majority, however, drug therapy with oral antihyperglycemic agents (OHAs), noninsulin injectable agents, or insulin, will be necessary.

TABLE 52-2
COLLABORATIVE CARE
Diabetes Mellitus

Diagnostic
• History and physical examination • Blood pressure • Blood tests: including FBG, postprandial blood glucose, glycated hemoglobin (A_{1c}), fasting lipid profile, serum creatinine, electrolytes, calculation of creatinine clearance, TSH • Dental examination • Doppler scan—ankle-brachial index (if indicated) • ECG (if indicated) • Foot (podiatric) examination • Fundoscopic examination—dilated eye examination • Monitoring of weight • Neurological examination, including monofilament test for sensation to lower extremities • Random urine for microalbuminuria (MAU), complete urinalysis, and acetone if indicated
Collaborative Therapy

• Oral antihyperglycemic agents and noninsulin injectable agents (see Table 52-7)
• Angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockers (ARBs) (high risk for a cardiovascular event) (see Chapter 35, Table 35-8)
• Blood pressure control
  • Target <130/80 mm Hg
• Drug therapy
  • Enteric-coated acetylsalicylic acid (ASA; Aspirin) (80 mg or 325 mg)
  • Insulin (see Figure 52-4 and Tables 52-3 and 52-4)
  • Lipid-lowering therapy (high risk for a cardiovascular event) (see Chapter 36, Table 36-5)
• Exercise therapy (see Tables 52-9 and 52-10)
• Nutritional therapy (see Table 52-8)
• Patient and caregiver teaching and follow-up programs
• Self-monitoring of blood glucose (SMBG)
• Vascular protection

ECG, electrocardiogram; *FBG*, fasting blood glucose; *TSH*, thyroid-stimulating hormone.

Drug Therapy: Insulin

Exogenous (injected) insulin is needed when a patient has inadequate insulin to meet specific metabolic needs and a satisfactory blood glucose level cannot be maintained through the combination of nutritional therapy, exercise, and OHAs and noninsulin injectable agents. Exogenous insulin is always required for the management of type 1 DM. Individuals with type 2 DM may be treated with insulin alone or with insulin in combination with OHAs (CDA, 2013a). Insulin requirement may increase significantly during periods of severe stress, such as illness or surgery.

Types of Insulin.

In Canada, beef insulin was withdrawn in 1999 but can still be bought from international sources. Human biosynthetic insulin is now the most widely used insulin. Human insulin is derived from common bacteria (e.g., *Escherichia coli*) or yeast cells using recombinant DNA technology. Insulin analogues are made by

modifying the amino acid sequence of the insulin molecule (Cheng, 2011). Insulins differ in regard to onset, peak action, and duration (Figure 52-4). The specific properties and different combinations of these insulins can be used to tailor treatment to the patient's specific patterns of blood glucose levels, lifestyle, eating, and activity. Different types of insulin are listed in Table 52-3. Most insulin preparations start with regular insulin as a base. By adding zinc, acetate buffers, and protamine to insulin in various ways, the onset of activity, peak, and duration times can be manipulated. Zinc and protamine are added to make NPH (neutral protamine Hagedorn). In rare instances, these additives may cause an allergic reaction at the injection site. Switching the brand or the type of insulin may alleviate this localized reaction.

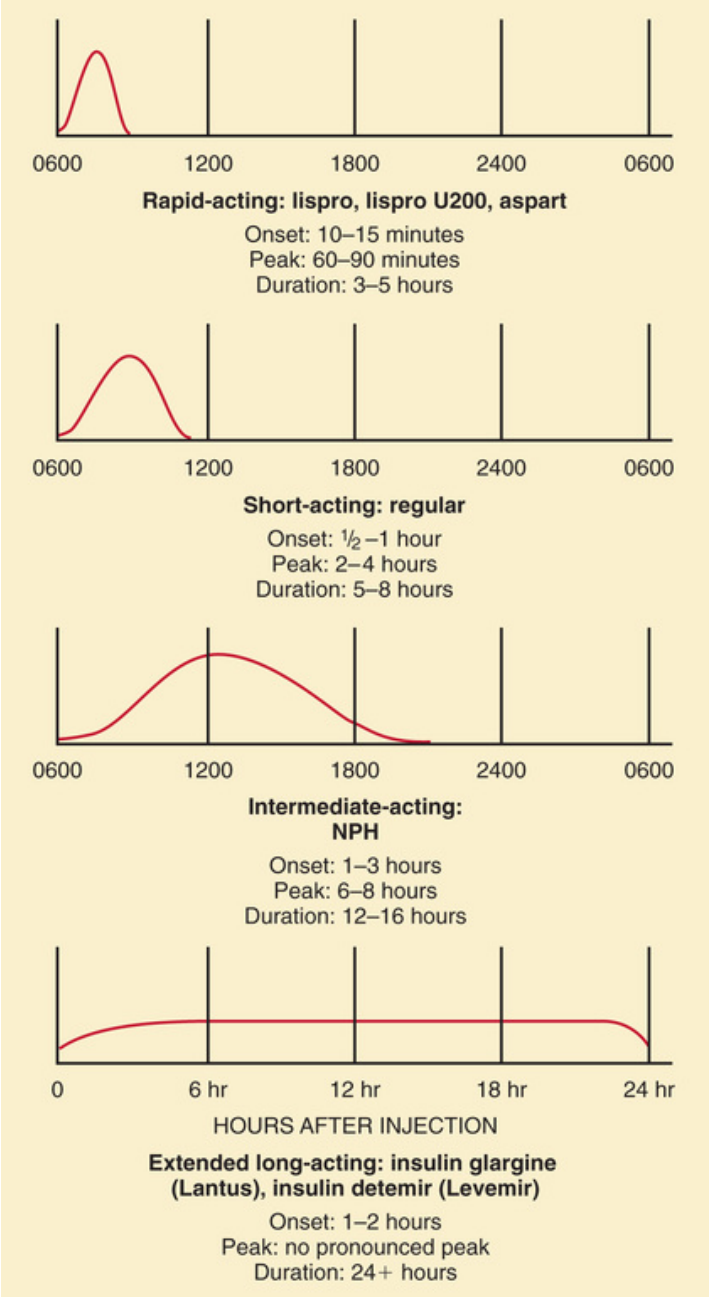

FIGURE 52-4 Commercially available insulin preparations showing onset, peak, and duration of action of relative plasma insulin level. *NPH,* neutral protamine Hagedorn.

TABLE 52-3

DRUG THERAPY
Types of Insulin*

Classification	Examples
Rapid-acting analogue (clear)	Lispro (Humalog) Lispro U200 (Humalog) Aspart (NovoRapid) Glulisine (Apidra)
Short-acting (clear)	Regular (Novolin ge Toronto, Humulin R)
Intermediate-acting (cloudy)	NPH (Humulin N, Novolin ge NPH)
Extended long-acting analogue (clear)	Glargine (Lantus) Glargine U300 (Toujeo) Detemir (Levemir)
Premixed (cloudy)	Regular/NPH 30/70† (Humulin 30/70, Novolin ge 30/70) Regular/NPH 50/50 and 40/60 Lispro/lispro protamine 25/75 (Humalog Mix 25); 50/50 (Humalog Mix 50) Aspart/aspart protamine 30/70 (NovoMix 30)

*Insulin preparations are clear solutions except for NPH and protamine-containing insulin, which are cloudy.

†These numbers refer to percentages of each type of insulin.

NPH, neutral protamine Hagedorn.

Health care providers should refer to the most current edition of *Compendium of Pharmaceuticals and Specialties* (Canadian Pharmacists Association, Ottawa, Ontario, Canada) and product monographs for detailed information.

Insulin Regimens.

Examples of insulin regimens ranging from one to four injections per day are presented in Table 52-4. The exogenous insulin regimen that most closely mimics endogenous insulin production is the basal–bolus regimen, which uses rapid- or short-acting (bolus) insulin before meals and intermediate- or long-acting (basal) background insulin once or twice a day. The basal–bolus regimen is *intensive insulin therapy,* which consists of multiple daily insulin (MDI). The goal is to achieve a near-normal glucose level of 4 to 7 mmol/L before meals, or 4 to 6 mmol/L if this can be reached safely without severe hypoglycemia. The Diabetes Control and Complications Trial (DCCT) Research Group demonstrated that people with type 1 DM who have tight glucose control through intensive management develop fewer and less severe complications (DCCT, 1993). Ideally, regimens should be collaboratively selected by the patient and the health care provider (CDA, 2013a). The criteria for selection are based on the type of DM and the required, desired, and feasible levels of glycemic control, in addition to economic factors and flexibility. Starting a multiple daily injection regimen with 3 to 4 injections per day may be overwhelming for patients. Depending on the patient's glycemic control, introducing a once or twice a day insulin regimen may be more manageable.

TABLE 52-4

DRUG THERAPY
Common Insulin Regimens

Regimen	Type of Insulin/Frequency	Action Profile*	Comments
Once a day Single dose	Intermediate (NPH) at bedtime *Or*		One injection should cover nighttime coverage.
	Long-acting (glargine [Lantus], detemir [Levemir]) *In morning or at bedtime*		One injection will last 24 hr with no peaks and less chance for hypoglycemia. Does not cover postprandial blood sugars.
Twice a day Split-mixed dose	NPH and regular *Or* NPH and rapid *Before breakfast and at dinner*		Two injections provide coverage for 24 hr. Patient must adhere to a set meal plan.
Three times a day Combination of mixed and single dose	NPH and regular *Or* NPH and rapid *Before breakfast* + Regular or rapid *Before dinner* + NPH *At bedtime*		Three injections provide coverage for 24 hr, particularly during early a.m. hours. Potential is reduced for hypoglycemia between 0200 and 0300 hours.
Basal-bolus Multiple dose	Regular or rapid *Before breakfast, lunch, and dinner* + NPH *Twice daily or at bedtime* Or		More flexibility is allowed at mealtimes and for amount of food intake. Good postprandial control. Premeal blood glucose checks and establishing and following individualized algorithms are necessary. Patients with type 1 DM will require basal insulin to cover 24 hr.

Regimen	Type of Insulin/Frequency	Action Profile*	Comments
Basal-bolus Multiple dose	Regular or rapid *Before breakfast, lunch, and dinner* + Long-acting (glargine or detemir) *Once a day, usually at bedtime*		Four injections required per day. Most physiological approach, except for pump.

*Key:

Rapid-acting (lispro, aspart, glulisine) insulin

Short-acting (regular) insulin

Intermediate-acting (NPH) or long-acting (glargine, detemir) insulin

NPH, neutral protamine Hagedorn.

Mealtime Insulin (Bolus).

Synthetic, rapid-acting insulins include lispro (Humalog), lispro U200 (Canadian Diabetes Association Clinical Practice Guidelines Expert Committee, 2016), aspart insulin (NovoRapid), and glulisine (Apidra). They have an onset of action of approximately 10 to 15 minutes (as compared with 30 to 60 minutes for regular insulin). Rapid-acting insulin is considered to be the type that best mimics natural insulin secretion in response to a meal. It should be administered 0 to 15 minutes before meals and can be given up to 15 minutes after meals. However, preprandial administration achieves better postprandial glycemic control. When rapid-acting insulin is used as mealtime coverage in people with type 1 DM, an additional and longer-acting insulin must also be used as basal background insulin because the duration of rapid-acting insulin is so short. Other benefits of rapid-acting insulin include decreased postmeal hyperglycemia, decreased hypoglycemic episodes, and increased flexibility compared with regular insulin (CDA, 2013a). Regular insulin is also a mealtime insulin and has an onset of action of 30 to 60 minutes; it should be injected 30 to 45 minutes before a meal to ensure that the onset of action coincides with meal absorption. Because timing an injection 30 to 45 minutes before a meal is difficult for people to incorporate into their lifestyles, the rapid-acting insulins are often preferred by people who take insulin with meals (CDA, 2013a).

Long- or Intermediate-Acting (Basal) Background Insulin.

Insulin glargine (Lantus) and detemir (Levemir) are extended long-acting basal insulins that are released steadily and continuously over 24 hours. The duration of insulin glargine U300 (Toujeo) is up to 30 hours. These long-acting insulins do not have a peak of action (see Figure 52-4). They may be used for once-daily subcutaneous administration at bedtime in patients with type 1 and type 2 DM

who require basal (long-acting) insulin for the control of hyperglycemia. Because they lack a peak action time, the risk for hypoglycemia is greatly reduced. They are clear, colourless insulins. The nurse should be aware of the potential danger of confusing glargine, glargine U300, and detemir with other clear insulins (rapid- or short-acting) (Registered Nurses' Association of Ontario [RNAO], 2009). Glargine, glargine U300, and detemir must not be diluted or mixed with any other insulin or solution as this action can change the time or action profile of these long-acting analogues and cause precipitation (Sanofi-Aventis Canada, 2015; NovoNordisk, 2016b).

Intermediate-acting insulin NPH is also used as a basal insulin that has a duration of 10 to 16 hours. The disadvantage is that it has a peak at 4 to 10 hours, which can result in hypoglycemia. It is the only basal insulin that can be mixed with the short- and rapid-acting insulins. NPH is a cloudy insulin that must be gently agitated before administration (Forum for Injection Technique [FIT] Canada, 2011).

Combination Therapy.

Two different insulin types are commonly used in combination to mimic normal endogenous insulin secretion (see Table 52-4). Short- or rapid-acting insulin is often mixed with an intermediate-acting insulin to provide both mealtime and basal coverage without having to administer two separate injections. Patients may mix the two types of insulin themselves or may use a commercially premixed formula (Figure 52-5; see also Table 52-3). It is important to teach patients to draw the clear (short- or rapid-acting) insulin first when mixing to avoid potential contamination with the cloudy (intermediate-acting) insulin. Introducing intermediate insulin into a rapid- or short-acting vial may increase its duration of action. The premixed formulas offer convenience to patients and are especially helpful to those who lack the visual, manual, or cognitive skills to mix insulin themselves. However, the convenience of these formulas sacrifices the potential for optimal blood glucose control because there is less opportunity for flexible dosage and administration based on need.

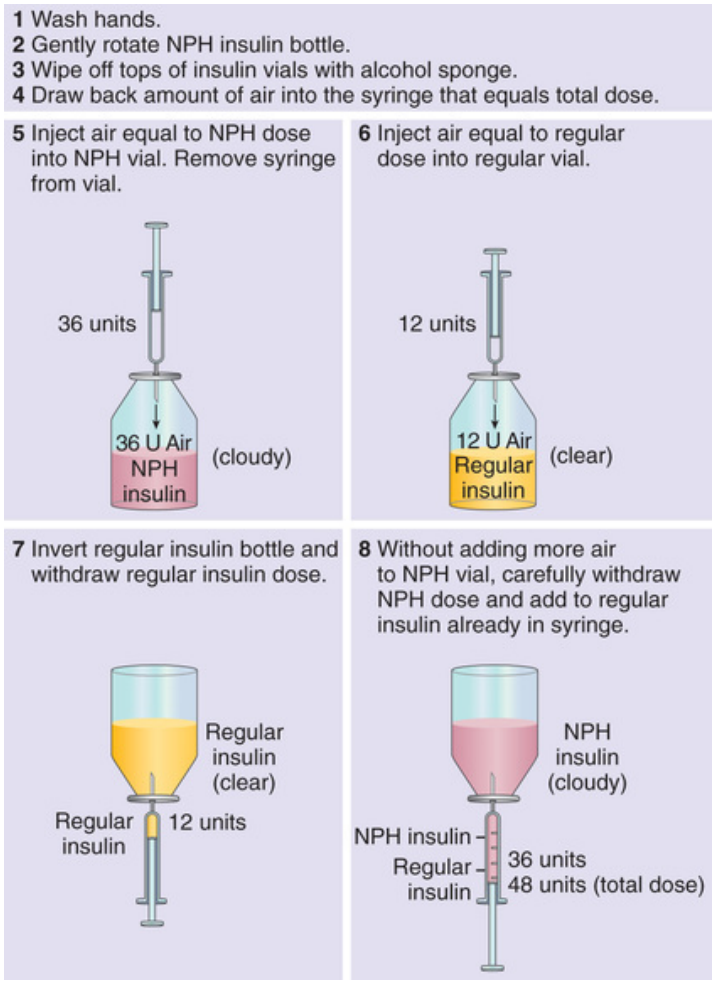

FIGURE 52-5 Mixing insulins. This stepwise process avoids the problem of contaminating regular insulin with intermediate-acting insulin. *NPH*, neutral protamine Hagedorn.

Storage of Insulin.

As a protein, insulin requires special storage considerations. Heat and freezing alter the insulin molecule. The insulin vial, cartridge, or disposable insulin pen that the patient is currently using may be left at room temperature for up to 4 weeks, unless the room temperature is higher than 30°C or below freezing (<2°C). Unopened vials, cartridges, and disposable insulin pens must be refrigerated. Prolonged exposure to direct sunlight should be avoided. Nondisposable insulin pens should not be stored in the refrigerator. The same principles apply for a patient who is travelling; insulin can be stored in a thermos or cooler to keep it cool (not frozen) if the patient is travelling in hot climates (RNAO, 2009).

Prefilled syringes containing two types of insulin are stable for up to 1 week when stored in the refrigerator, whereas syringes containing only one type of insulin are stable up to 30 days. Prefilled syringes may be beneficial to patients who are sight impaired or who lack the manual dexterity to fill their own syringes

at home. In these cases, family members, friends, and caregivers may prefill syringes on a periodic basis. These should be stored in a vertical position with the needle pointed up to avoid clumping of suspended insulin binders in the needle (RNAO, 2009). Some insulin combinations, such as insulin lispro and NPH, are not appropriate for prefilling and storage because the onset, action, and peak times of the mixture of the two can differ from those of either of the types. Pharmacy references should be consulted as needed when mixing and prefilling different types of insulin. Prefilled syringes should be gently rolled between the palms to warm the refrigerated insulin and to resuspend the particles before injecting (RNAO, 2009). Lantus insulin cannot be stored in a prefilled syringe (RNAO, 2009).

Administration of Insulin.

Because insulin is inactivated by gastric juices, it cannot be taken orally. The only route of administration currently approved for self-administration is subcutaneous injection by syringe or insulin pen or by continuous subcutaneous infusion (pump). Intravenous (IV) administration of regular insulin can be done with medical supervision when immediate onset of action is desired in the hospital setting.

Injection.

The steps in administering a subcutaneous insulin injection are outlined in Table 52-5. The technique should be taught to new insulin users and reviewed periodically with long-term users. It should never be assumed that, because insulin is being used, the patient knows and practises the correct insulin injection technique. Inaccurate preparation is often caused by poor eyesight. Air bubbles in the syringe may not be seen, or the scale on the syringe may be read improperly.

TABLE 52-5

PATIENT & CAREGIVER TEACHING GUIDE
Insulin Therapy

The following instructions should be included when teaching the patient and caregiver about insulin therapy.

1. Wash hands thoroughly.
2. Check insulin type and expiration date.
3. If a cloudy insulin is used, gently roll container to resuspend insulin. It should look uniformly milky.
4. Remove the cover from the needle.
5. Pull the plunger down until the tip of the plunger is at the line for the number of units required. Put the needle into the vial and push the air into the vial.
6. Turn the vial upside down and slowly push plunger up and down to get rid of air bubbles and then pull plunger down until it is at the line for the correct dose of insulin.
7. Check that the amount of insulin is correct and that there are no large air bubbles in the syringe. Remove the syringe.
8. Select proper injection site (see Figure 52-6) and inject into a skin lift (pinched skin) at 90 degrees. To prevent possible intramuscular injections, slim individuals may need to inject into the skin lift at 45 degrees. (The use of 8-mm needles is recommended.)
9. After injecting insulin, leave needle in place for 5 sec to ensure that all insulin has been injected and then remove needle and release skin lift.
10. Dispose of single-use syringe safely. *Note:* When instructing patient to self-inject insulin, use the following guidelines (if appropriate):
    - Inspect insulin for any changes before each use (i.e., clumping, precipitation, change in clarity or colour).
    - Aspiration does not need to be done before injection. The injection site does not need to be cleansed with alcohol.

The patient receiving mixed insulins (e.g., regular and an intermediate-acting insulin) needs to learn the proper technique for combining both in the same syringe if commercially prepared premixed insulins are not used (see Figure 52-5).

The speed with which peak serum concentrations are reached varies with the anatomical site used for injection. The fastest absorption is from the abdomen, followed by the arm, the thigh, and the buttock. Appropriate sites for insulin injection are noted in Figure 52-6, although the abdomen is the preferred site. The patient should be cautioned about injecting into a site that is to be exercised. For example, the patient should not inject insulin into the thigh and then go jogging. Exercise of the area containing the injection site together with the increased body heat generated by the exercise may increase the rate of absorption and speed the onset of insulin action.

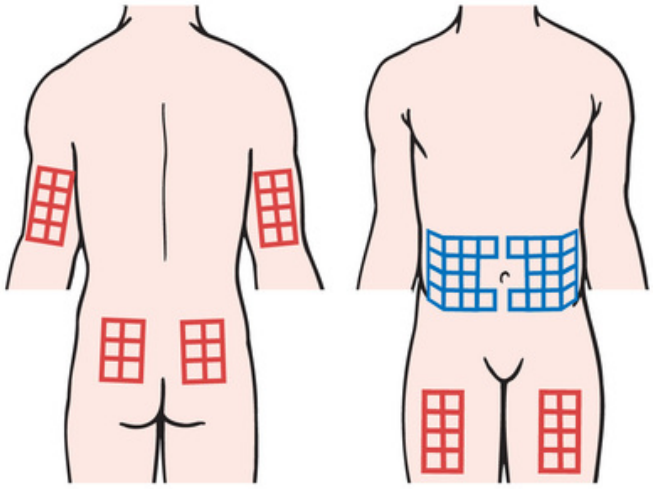

FIGURE 52-6 Injection sites for insulin. The abdomen is the preferred site.

Before purified human insulins were widely used, patients were advised to rotate anatomical injection sites to prevent *lipodystrophy,* a condition that produces lumps and dents in the skin from repeated injection in the same spot. The use of human insulin reduces the risk for lipodystrophy. Because of this, and because rotating sites causes variability in insulin absorption, rotation of injection sites to different anatomical sites is no longer the recommended practice. Instead, patients are advised to rotate the injection within one particular site, such as the abdomen. Sometimes, it is helpful to think of the entire abdomen as a checkerboard, with each square representing an injection site as the patient rotates sites systematically across the board.

Most commercial insulin is available as U100, indicating that 1 mL contains 100 units of insulin. U100 insulin must be used with a U100-marked syringe. Disposable, plastic insulin syringes are available in a variety of sizes, including 1, 0.5, and 0.3 mL. The 0.5-mL size may be used for doses of 50 units or less, and the 0.3-mL syringe can be used for doses of 30 units or less. Smaller syringes offer a number of advantages. The major benefit is increased accuracy and reliability when delivering smaller doses because wider line markings are easier to see. Patients should be cautioned to check dosage lines carefully when changing syringe types because some use a scale of 1-unit increments and others use 2-unit increments.

Recapping should be done only by the person using the syringe. The nurse must never recap a needle that has been used by a patient. The use of an alcohol swab on the site before self-injection is no longer recommended. Routine hygiene such as washing with soap and rinsing with water is adequate. This recommendation applies primarily to patient self-injection technique. When injection occurs in a health care facility, policy may dictate site preparation with alcohol to prevent hospital-acquired infection. Injection should be performed at a 45- to 90-degree angle, depending on the thickness of the patient's fat pad.

An insulin pen is a compact portable device that serves the same function as a needle and syringe but is handier to use (Figure 52-7). The insulin pen uses 300-unit cartridges, which are packaged in a box of five, for a total of 1 500 units. One of the advantages of insulin pens is that they are less "medical" looking. The insulin pen has a numerical dial-up device that clicks for each unit being dialled. The pen can dial up to a maximum of 60 to 70 units, depending on the device. This is a safer and more convenient option for most patients, especially those with visual impairment, dexterity problems, and peripheral neuropathy. Pen-needle tips are finer than syringe tips and must be changed with every injection. They are manufactured in a variety of sizes—4, 5, 6, 8, and 12 to 12.7 mm—for a variety of body-fat types (FIT Canada, 2011).

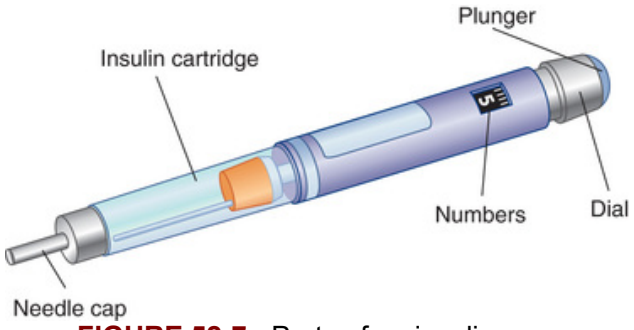

FIGURE 52-7 Parts of an insulin pen.

Alternate Delivery Methods.

Continuous subcutaneous insulin infusion can be administered using an insulin pump, a small battery-operated device that holds and delivers insulin (Figure 52-8). Usually worn on the belt, under clothing, or directly affixed to the body, the pump is connected to a catheter inserted into the subcutaneous tissue in the abdominal wall. Every 2 to 3 days, the insertion site is changed and the pump is refilled with insulin and reprogrammed. The device is programmed to deliver a continuous infusion of rapid-acting insulin 24 hours a day, known as the *basal rate.* Basal insulin can be temporarily increased or decreased based on activity level changes or illness. At mealtime, the user programs the pump to deliver a bolus infusion of insulin appropriate to the amount of carbohydrate ingested and to bring down high premeal blood glucose, if necessary. A major advantage of the insulin pump is the reduction of hypoglycemia episodes. Pumps also offer the benefit of a more normal lifestyle, allowing users more flexibility with meal and activity patterns as insulin delivery becomes very similar to the normal physiological pattern. The insertion site should be checked daily for redness and swelling (Pickup, 2012; American Association of Diabetes Educators [AADE], 2011).

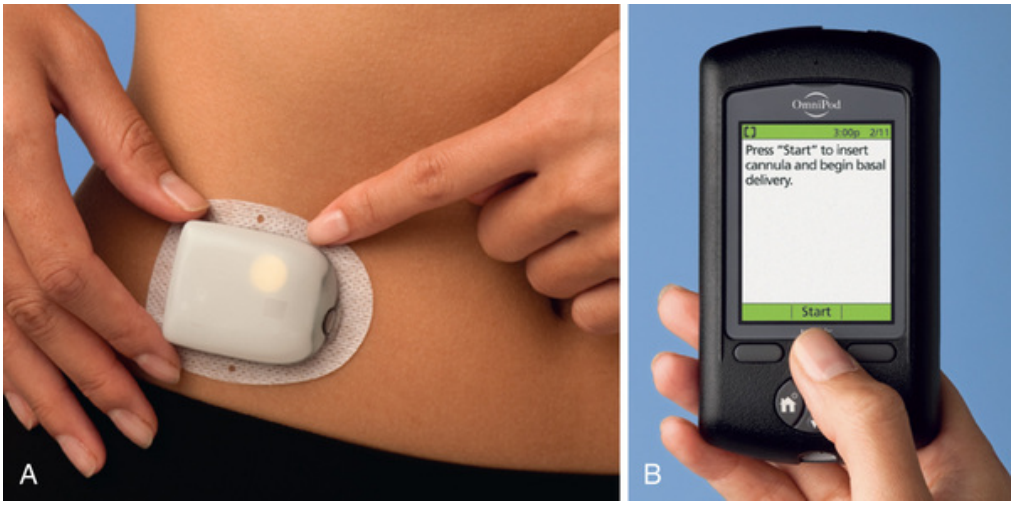

FIGURE 52-8 **A,** The Omnipod® Insulin Management System is a tubeless, wireless, and waterproof pump that is affixed directly to the body and holds and delivers insulin. **B,** The Personal Diabetes Manager (PDM) wirelessly programs insulin delivery via the Pod. The PDM has a built-in glucose meter.

Problems With Insulin Therapy.

Hypoglycemia, allergic reactions, lipodystrophy, and Somogyi effect are the problems associated with insulin therapy. Hypoglycemia is discussed in detail later in this chapter. (Guidelines for assessing patients treated with insulin are presented in Table 52-6.)

TABLE 52-6
ASSESSING THE PATIENT TREATED WITH ANTIHYPERGLYCEMIC AGENTS

For Patient With Newly Diagnosed Diabetes or Re-Evaluation of Medication Regimen	
Cognitive	Is patient or responsible other able to understand antihyperglycemic agents are being used as part of diabetes management? Is patient or responsible other able to understand concepts of asepsis, combining insulins, insulin–OHA actions, and adverse effects? Is patient able to remember to take >1 dose/day? Does patient take medications at right times in relation to meals?
Psychomotor	Is patient or responsible other physically able to prepare and administer accurate doses of the medication?
Affective	What emotions and attitudes are patient and responsible others displaying in regard to diagnosis of diabetes and antihyperglycemic treatment? Is the patient displaying acceptance of diagnosis of DM and readiness to learn?
For Follow-Up of Patient Treated With Antihyperglycemic Agents	
Effectiveness of therapy	Is patient having symptoms of hyperglycemia or hypoglycemia? Does blood glucose record show good or poor control? Is glycated hemoglobin (A_{1c}) consistent with glucose records?
Adverse effects of therapy	Has patient had hypoglycemic episodes? If so, how often? What time of day? What was the precipitating event? Inconsistent meal timing, meal carbohydrate content, alcohol, or exercise? Are there complaints of nightmares, night sweats, or early-morning headaches? Has patient had skin rash, gastro-intestinal upset, ankle edema, or weight gain since taking the antihyperglycemic agent? Is atrophy or hypertrophy present at injection sites?
Self-management behaviours	If patient is having hypoglycemic episodes, how are those episodes managed? Has the patient analyzed episodes to determine the cause? How much insulin, OHA, or noninsulin injectable is the patient taking and at what time of day? Is patient adjusting the medication dose? Under what circumstances and by how much? Has exercise pattern changed? Is patient adhering to healthy eating recommendations? Are meals taken at times corresponding to peak insulin action? Is patient performing SMBG?

GI, gastro-intestinal; *OHA*, oral antihyperglycemic agent; *SMBG*, self-monitoring of blood glucose.

Allergic Reactions.

Local inflammatory reactions to insulin, such as itching, erythema, and burning around the injection site, may occur. Local reactions may be self-limiting within 1 to 3 months or may improve with a low dose of antihistamine. A true insulin allergy is a systemic response with urticaria and possibly anaphylactic shock, generally resulting from the use of animal insulins. Fortunately, this type of allergy is rare, particularly since human insulin has become available. Zinc and protamine—used as preservatives in the insulin and the latex rubber stoppers on the vials—have been implicated in insulin reactions.

Lipodystrophy.

Lipodystrophy (hypertrophy or atrophy of subcutaneous tissue) may occur if the same injection sites are used frequently. Hypertrophy, a thickening of the subcutaneous tissue, eventually regresses if the patient does not use the site for at least 6 months. The use of hypertrophied sites may result in erratic insulin absorption. Lipodystrophies have been most commonly associated with beef, or beef and pork, insulin and rarely with human insulin.

Somogyi Effect and Dawn Phenomenon.

Wide differences in early-morning (low) and fasting (high) glucose levels characterize the Somogyi effect. Usually occurring during the hours of sleep, the **Somogyi effect** produces a decline in blood glucose level in response to too much insulin. Counter-regulatory hormones are released, stimulating lipolysis, gluconeogenesis, and glycogenolysis, which in turn produce rebound hyperglycemia and ketosis. The danger of this effect is that, when blood glucose levels are measured in the morning, hyperglycemia is apparent, and the patient (or the health care provider) may, therefore, increase the insulin dose. The Somogyi effect is associated with the occurrence of undetected hypoglycemia during sleep, although it can happen at any time.

The patient may report headaches on awakening and may recall night sweats or nightmares. If the Somogyi effect is suspected as a cause for early-morning high blood glucose, the patient may be advised to check blood glucose levels between 0200 and 0400 hours to determine whether hypoglycemia is present at that time. If it is, the insulin dosage of administration affecting the early-morning blood glucose is reduced.

The *dawn phenomenon* is characterized by hyperglycemia that is present on awakening in the morning, owing to the release of counter-regulatory hormones in the predawn hours. It has been suggested that growth hormone and cortisol are possible factors in this occurrence. The dawn phenomenon affects the majority of people with DM and tends to be most severe when growth hormone is at its peak in adolescence and young adulthood.

Careful assessment is required to document each phenomenon because the treatment for each differs. The treatment for Somogyi effect is reduction of insulin dosage. The treatment for dawn phenomenon is an adjustment in the timing of insulin administration or an increase in insulin. The assessment must include insulin dose, injection sites, and variability in the time of meals or insulin administration. In addition, the patient is asked to measure and document bedtime, nighttime (between 0200 and 0400 hours), and morning FBG levels on several occasions. If the predawn levels are below 3.3 mmol/L and signs and symptoms of hypoglycemia are present, the insulin dosage should be reduced. If the 0200 to 0400–hour blood glucose level is high, the insulin dosage should be increased. In addition, the patient should be counselled on appropriate bedtime snacks.

Drug Therapy: Antihyperglycemic Agents

Oral antihyperglycemic agents and noninsulin injectables work to improve the mechanisms by which insulin and glucose are produced and used by the body. These medications work on three defects of type 2 diabetes: (1) insulin resistance, (2) decreased insulin production, and (3) increased hepatic glucose production. Oral antihyperglycemic agents and noninsulin injectables may be used in combination with agents from several classes or with insulin to achieve blood

glucose targets. Guidelines for assessing patients receiving these medications are shown in Table 52-6.

Currently, many classes of antihyperglycemics are available to improve DM control for patients with type 2 DM (CDA, 2013a). These agents are listed in Table 52-7.

TABLE 52-7

DRUG THERAPY
Antihyperglycemic Agents for Diabetes Mellitus

Type	Mechanism of Action	Adverse Effects
Insulin Secretagogues: Sulphonylureas		
Gliclazide (Diamicron, Diamicron MR) Glimepiride (Amaryl) Glyburide (Diabeta) (chlorpropamide and tolbutamide are available in Canada but rarely used)	Stimulate release of insulin from beta cells; decrease glycogenolysis and gluconeogenesis; glimepiride may improve insensitivity in tissues	Weight gain, hypoglycemia
Meglitinide		
Repaglinide (GlucoNorm)	Stimulates a rapid and short-lived release of insulin from the pancreas	Less weight gain, decreased incidence of hypoglycemia compared with glyburide
Biguanide		
Metformin (Glucophage, Glumetza)	Inhibits hepatic glucose production; increases peripheral and liver sensitivity to insulin	Nausea, upset stomach, diarrhea; less weight gain than sulphonylureas and does not cause hypoglycemia; potential lactic acidosis in renal or hepatic impairment; has to be held at the time of or before procedures and held for 48 hr after administration of IV contrast media
α-Glucosidase Inhibitors		
Acarbose (Glucobay)	Delays absorption of glucose and digestion of CHO in small intestine, lowering after-meal blood glucose levels	Flatulence, abdominal pain, diarrhea
Thiazolidinediones		
Pioglitazone (Actos) Rosiglitazone (Avandia)	↑ Glucose uptake in muscle and fat; inhibit hepatic glucose production	Edema, weight gain, heart failure; causes ovulation in premenopausal women with PCOS; not recommended for patients with heart failure
Dipeptidyl Peptidase-4 Inhibitors		
Sitagliptin (Januvia) Saxagliptin (Onglyza) Linagliptin (Trajenta) Alogliptin (Nesina)	Enhance the incretin system, stimulate release of insulin from pancreatic beta cells, and inhibit hepatic glucose production	Upper respiratory tract infection, sore throat, headache, diarrhea
Noninsulin Injectable Agents: GLP-1 Receptor Agonists		
Liraglutide (Victoza) Exenatide (Byetta) Albiglutide (Eperzan) Dulaglutide (Trulicity)* Exenatide QW (Bydureon)*	Stimulate release of insulin; decrease glucagon secretion, increase satiety, decrease gastric emptying	Nausea, vomiting, hypoglycemia, diarrhea, headache
Sodium-Glucose Cotransporter Type 2 (SGLT2) Inhibitors		
Canagliflozin (Invokana) Dapagliflozin (Forxiga) Empagliflozin (Jardiance)	Enhance urinary glucose excretion	Genital infections, urinary tract infections, hypotension, increased lipids
Combination Therapy		

Type	Mechanism of Action	Adverse Effects
Avandamet (rosiglitazone [Avandia] and metformin [Glucophage]) Janumet/Janumet XR (sitagliptin [Januvia] and metformin/metformin XR [Glucophage/Glucophage XR]) Jentadueto (linagliptin [Trajenta] and metformin [Glucophage]) Kazano (alogliptin [Nesina] and metformin [Glucophage]) Komboglyze (metformin [Glucophage] and saxagliptin [Onglyza]) Oseni (alogliptin [Nesina] and pioglitazone [Actos])	See mechanism of action for individual drugs, above	See adverse effects for individual drugs, above

CHO, carbohydrates; *GI*, gastro-intestinal; *IV,* intravenous; *PCOS,* polycystic ovarian syndrome.

Insulin Secretagogues.

Sulphonylureas have been widely used to treat type 2 DM since the 1950s. The primary action of the sulphonylureas is to increase beta-cell insulin production from the pancreas. Caution must be exercised in dosage determination in older adults and patients with renal impairment owing to the increased risk for hypoglycemia. Therapy with sulphonylureas is generally more effective early in the course of type 2 DM. According to one study, up to a third of patients on monotherapy with a sulphonylurea will require a second agent within 5 years (Kahn, Haffner, Heise, et al., 2006).

Meglitinides.

Like the sulphonylureas, meglitinides (repaglinide [GlucoNorm]) increase insulin production from the pancreas. But because they are more rapidly absorbed and eliminated, they offer a reduced potential for hypoglycemia. When meglitinides are taken just before meals, pancreatic insulin production increases during and after the meal, mimicking the normal blood glucose response to eating. Patients should be instructed to take meglitinides anytime from 30 minutes before each meal right up to the time of the meal, and not to take a dose if they are not eating. They are safer to use in patients with irregular mealtimes.

Biguanides.

Metformin (Glucophage) is the only biguanide glucose-lowering agent available worldwide. It can be used alone or with sulphonylureas, other OHAs, or insulin to treat type 2 DM. The primary action of metformin is to reduce glucose

production by the liver. It also enhances insulin sensitivity at the tissue level and improves glucose transport into the cells. Metformin is recommended as the first-line medication for most people with type 2 DM (CDA, 2013a). Besides being an effective blood glucose–lowering agent, metformin has other advantages. Unlike insulin secretagogues and insulin, metformin does not promote weight gain. It also has beneficial effects on plasma lipids. Metformin is also used to treat prediabetes, especially in individuals who are obese and have impaired fasting glucose.

Patients who are undergoing surgery or any radiological procedures that involve the use of a contrast medium are instructed to temporarily discontinue metformin before surgery or the procedure. They should not resume the metformin until 48 hours afterward, once their serum creatinine has been checked and is found to be normal.

Drug Alert

Metformin

- Do not use in patient with kidney disease, liver disease, or heart failure. Lactic acidosis is a rare complication of metformin accumulation.
- IV contrast media that contain iodine pose a risk for acute kidney injury, which could exacerbate metformin-induced lactic acidosis.
- Avoid use in people who drink excessive amounts of alcohol.

α-Glucosidase Inhibitors.

Also known as *starch blockers,* glucosidase inhibitors work by slowing down the absorption of carbohydrate in the small intestine. Acarbose (Glucobay) is the available drug in this class. Taken with the first bite of each main meal, they are most effective in lowering postprandial blood glucose. Effectiveness of these medications is measured by checking 2-hour postprandial glucose levels. Medications from this class are not effective against fasting hyperglycemia (CDA, 2013a).

Thiazolidinediones.

Sometimes referred to as *insulin sensitizers,* thiazolidinediones include pioglitazone (Actos) and rosiglitazone (Avandia). They are most effective for people who have insulin resistance. They improve insulin sensitivity, transport, and utilization at target tissues.

Because they do not increase insulin production, thiazolidinediones will not cause hypoglycemia when used alone, but the risk is still present when a thiazolidinedione is used in combination with insulin or an insulin secretagogue.

Patients taking these medications may experience a secondary benefit of improved triglyceride, high-density lipoprotein (HDL), and blood pressure levels (CDA, 2013a). Use with insulin is not approved in Canada because the combination potentiates the adverse effect of edema and subsequent weight gain.

Dipeptidyl Peptidase-4 Inhibitors.

A newer class of glucose-lowering drugs available in Canada is the dipeptidyl peptidase-4 (DPP-4) inhibitors. This class of drugs includes sitagliptin (Januvia), saxagliptin (Onglyza), linagliptin (Trajenta) and alogliptin (Nesina). The incretin hormones, which are part of the physiological process that regulates glucose homeostasis, are normally inactivated by DPP-4. By inhibiting DDP-4, these medications slow the inactivation of incretin hormones. Incretin hormones are released by the intestines throughout the day, but levels increase in response to a meal. When glucose levels are normal or elevated, incretins increase insulin synthesis and release from the pancreas as well as decrease hepatic glucose production. DPP-4 inhibitors manage type 2 DM by increasing and prolonging increased incretin levels. These drugs are glucose-dependent (i.e., they respond to the presence of elevated glucose and result in insulin release only when needed), and therefore, they lower the potential for hypoglycemia. The main benefit of these drugs over other medications for DM with similar effects is the absence of weight gain as an adverse effect. These drugs may be taken alone or in combination with other OHAs (CDA, 2013a; Bristol-Myers Squibb [BMS] Canada, 2011).

Sodium-Glucose Cotransporter Type 2 (SGLT2) Inhibitors.

Canagliflozin (Invokana), dapagliflozin (Forxiga) and empagliflozin (Jardiance) are the medications in a new class of drugs known as sodium-glucose cotransporter Type 2 (SGLT2) inhibitors available in Canada. These drugs work by blocking the reabsorption of glucose by the kidney, increasing glucose excretion, and lowering blood glucose levels (Harper, Clement, Goldenberg, et al., 2015).

Combination Therapy.

Many combination drugs are currently available. These drugs combine two different classes of medications to treat DM. These agents are listed in Table 52-7. One advantage of combined therapy is improved patient compliance.

Glucagon-Like Peptide (GLP)-1 Receptor Agonists (Incretin Mimetics).

Liraglutide (Victoza), exenatide (Byetta), exenatide QW (Bydureon), albiglutide (Eperzan), and dulaglutide (Trulicity) are the GLP-1 receptor agonists available in Canada. These drugs stimulate GLP-1 (one of the incretin hormones), which is found to be decreased in people with type 2 DM. The mechanisms of action of these drugs are similar to those performed by the incretin hormone it mimics. They stimulate the release of insulin from the pancreatic beta cells. Other mechanisms of actions are (1) suppression of glucagon secretion from the

pancreatic beta cells, which reduces glucose output from the liver; (2) reduction of food intake by increasing satiety, thereby reducing caloric intake; and (3) slowing gastric emptying. These drugs are not indicated for use with insulin. GLP-1 receptor agonists are administered using a subcutaneous injection in a prefilled pen (NovoNordisk, 2016a; Eli Lilly Canada, 2011).

Drug Alert

Exenatide (Byetta)

- Acute pancreatitis and kidney problems have been associated with its use.

Drug Alert

Liraglutide (Victoza)

- Avoid use in patients with a personal or family history of medullary thyroid cancer
- Acute pancreatitis has been associated with its use.

Other Drugs Affecting Blood Glucose Levels.

Both the patient and the health care provider must be aware of drug interactions that can potentiate hypoglycemic and hyperglycemic effects. For example, β-adrenergic blockers can mask symptoms of hypoglycemia and prolong the hypoglycemic effects of insulin. Thiazide and loop diuretics can potentiate hyperglycemia by inducing potassium loss, although low-dose therapy with a thiazide is usually considered safe.

Nutritional Therapy

Although nutritional therapy is the cornerstone of care for the person with DM, it is also its most challenging aspect. Nutritional therapy can reduce A_{1c} by an absolute 1% to 2% with the greatest impact at the initial stages of DM (CDA, 2013a). Achieving nutritional goals requires a coordinated team effort that takes into account the behavioural, cognitive, socioeconomic, cultural, and spiritual aspects of the person. Because of these complexities, it is recommended that a DM nurse educator and a registered dietitian, with expertise in DM management, be members of the team.

Nutritional therapy for the management of DM is based on a plan of healthy eating that is appropriate and beneficial for all members of the general population, whether they have DM or not. In an institutional setting, the prescribed diet is often labelled "diabetic diet" or "no added sugar," indicating that the meal plan follows the CDA's current nutritional recommendations.

Eating Well With Canada's Food Guide (see Chapter 42, Figure 42-1) summarizes and illustrates nutritional guidelines and nutrient needs. These are appropriate in guiding the food choices of people with DM. Nutritional therapy and meal planning should be individualized to accommodate the person's preferences, age, needs, culture, lifestyle, and readiness to change. Tools used to measure the effectiveness of nutritional therapy include blood glucose, A_{1c}, and lipid values; tests of renal status; and clinical measurements such as body weight, body mass index, waist circumference, and blood pressure (CDA, 2013a). Table 52-8 describes nutritional therapy for type 1 and type 2 DM.

TABLE 52-8

NUTRITIONAL THERAPY
Diabetes Mellitus

Factor	Type 1 Diabetes Mellitus	Type 2 Diabetes Mellitus
Total calories	Increase in caloric intake possibly necessary to achieve desirable body weight and restore body tissues	Reduction in caloric intake desirable for overweight or obese patient
Effect of diet	Diet and insulin necessary for glucose control	Diet alone possibly sufficient for glucose control
Distribution of calories	Equal distribution of carbohydrates through meals or adjustment of carbohydrates for insulin activity	Equal distribution recommended; low-fat diet desirable; consistency of carbohydrate at meals desirable
Consistency in daily intake	Necessary for glucose control	Desirable for weight reduction and moderation of blood glucose levels
Uniform timing of meals	Crucial for NPH insulin programs; flexibility with multidose rapid-acting insulin	Desirable but not essential, unless using insulin or sulphonylureas
Intermeal and bedtime snacks	Frequently necessary	Is based on patient's eating habits and preferences; may be necessary if using insulin or sulphonylureas
Nutritional supplement for exercise programs	Carbohydrates 20 g/hr for moderate physical activities	May be necessary if patient's blood glucose levels are controlled on sulphonylureas or insulin

NPH, neutral protamine Hagedorn.

The Canadian Diabetes Association was renamed Diabetes Canada in 2017; it continues to provide a variety of nutrition teaching tools to assist health care providers. These are accessible online at the Diabetes Canada website or through the Diabetes Canada office. The resource entitled *Just the Basics: Healthy Eating for Diabetes Management and Prevention* is an example of such a tool (CDA, 2013b). It provides tips for healthy eating, DM prevention, and management for support until the person can see a dietitian. This tool highlights the need for the following:

1. Eating three meals per day at regular times and eating at intervals no more than 6 hours apart

2. Limiting sugars and sweets such as sugar, regular pop, desserts, candies, jam, and honey
3. Limiting the amount of high-fat food such as fried foods, chips, and pastries
4. Eating more high-fibre foods (whole-grain breads and cereals, lentils, dried beans and peas, brown rice, fruits, and vegetables)
5. Drinking water if thirsty
6. Adding physical activity to the lifestyle (CDA, 2013a)

Type 1 Diabetes Mellitus.

Meal planning should be based on the individual's usual food intake and balanced with insulin and exercise patterns. The insulin regimen should be developed with the patient's eating habits and activity pattern in mind. Patients using rapid-acting insulin can make adjustments in dosage before the meal, based on the current blood glucose level and the carbohydrate content of the meal or snack. Intensified insulin therapy, such as multiple daily injections or the use of an insulin pump, allows considerable flexibility in food selection and can be adjusted for deviations from usual eating and exercise habits. All people with type 1 DM should be seen by a registered dietitian to learn about carbohydrate-counting strategies.

Type 2 Diabetes Mellitus.

The emphasis for nutritional therapy in type 2 DM should be placed on achieving glucose, lipid, and blood pressure goals. Because 80% to 90% of people with type 2 DM are overweight, calorie and fat reduction is a goal. Weight loss has been shown to improve glycemic control by increasing insulin sensitivity and glucose uptake and decreasing hepatic glucose output (CDA, 2013a).

There is no one proven strategy or method that can be uniformly recommended. A nutritionally adequate meal plan with a reduction of total fat (especially saturated fats), an increase of fibre, and a decrease in simple sugars can bring about decreased calorie and carbohydrate consumption. Eating many small meals is another strategy that can be adopted to spread nutrient intake throughout the day. A weight loss of 5% to 7% of body weight often improves glycemic control, even if desirable body weight is not achieved. Weight loss is best attempted by a moderate decrease in calories and an increase in caloric expenditure. Regular exercise and learning new behaviours and attitudes can help facilitate long-term lifestyle changes. Monitoring of blood glucose levels, A_{1c}, lipids, and blood pressure provides feedback on how well the goals of nutritional therapy are being met.

Food Composition.

DM has been called a disease of carbohydrate metabolism, but it is actually a general metabolic disorder involving three categories of energy-providing

nutrients: carbohydrates, fats, and proteins. Therefore, the nutrient balance of a diabetic diet is essential to maintenance of blood glucose levels. The nutritional energy intake should be constantly balanced with the energy output of the individual, taking into account exercise and metabolic work of the body. The following are general recommendations for nutrient balance; each patient's individual meal plan should be developed with a dietitian and with her or his lifestyle and health goals in mind and is based on Canada's food guide (Health Canada, 2011; CDA, 2013a; American Diabetes Association [ADA], 2013):

- *Protein:* 15% to 20% of energy. There is no evidence that usual protein intake (15%–20% of energy) should be modified. Those with diabetic nephropathy should limit protein intake to 15% of energy and be monitored closely by a registered dietitian.
- *Fat:* less than 35% of energy. Combined saturated fats and trans-fatty acids should be reduced to less than 7% of energy intake. Polyunsaturated fat should be limited to less than 10% of energy intake. Foods rich in polyunsaturated omega-3 fatty acids and plant oils should be included.
- *Fibre:* approximately 25 to 50 g/day from a variety of food sources, including soluble and cereal fibres.
- *Carbohydrate:* 45% to 60% of energy. Carbohydrates should include whole grains, fruits, vegetables, and low-fat milk. Patients should try to consume higher-fibre sources of carbohydrate. Less than 10% of daily energy should come from sucrose (sugar). Low-carbohydrate diets are not recommended for DM management.

Glycemic index (GI) is the term used to describe the rise in blood glucose levels after a person has consumed carbohydrate-containing food. The GI of foods was developed to compare the postprandial responses of the body with carbohydrate-containing foods. A GI of 100 refers to the response to 50 g of glucose or white bread in a normal person without DM. All other food with an equivalent carbohydrate value is measured against this standard. For example, the GI of an apple is 52, regular milk 27, baked potato 93, cornflake cereal 119, and baked beans 69 (ADA, 2008) (see the Resources at the end of this chapter for an online calculator for GI).

The GI of carbohydrates should be considered when choosing them in a meal plan. Foods with a high GI (e.g., potatoes, white bread) will cause a sharp rise in blood glucose, whereas those with a low GI (e.g., brown rice) steadily increase blood glucose over a longer period. Although the GI affects blood glucose, the total amount of carbohydrates is more important than the source (CDA, 2013a).

Nutritive and nonnutritive sweeteners may be included in a healthy meal plan, in moderation. Nonnutritive sweeteners approved by Health Canada include the sugar substitutes, saccharin, aspartame, sucralose, acesulphame-K, steviol glycosides, tagatose, thaumatin, and cyclamate (CDA, 2013a).

Alcohol.

Alcohol is high in calories, has no nutritive value, and can be a partner in contributing to hypertriglyceridemia. In addition, it has detrimental effects on the liver (see Chapter 46). The inhibitory effect of alcohol on glucose production by the liver can cause severe hypoglycemia in patients taking insulin or OHAs that increase insulin secretion. Hypoglycemia may occur up to 24 hours after alcohol consumption in those with type 1 DM. Because alcohol consumption can make blood glucose more difficult to control, patients should be encouraged to discuss the use of alcohol honestly with their health care providers (CDA, 2013a).

Alcohol can also cause other serious adverse effects when used in conjunction with certain OHAs used to treat DM. For example, there is a risk for lactic acidosis in patients who have alcohol dependency and use metformin. Alcohol consumption should be limited to 1 to 2 standard drinks per day (e.g., 1 glass or 142 mL wine) or fewer than 14 standard drinks per week for men and fewer than 9 for women (CDA, 2013a). Alcohol can sometimes be incorporated into healthy eating if blood glucose is well controlled and if the patient is not on medications that will cause adverse effects. A patient can reduce the risk for alcohol-induced hyperglycemia or hypoglycemia by consuming alcohol with food, using sugar-free mixes, and drinking dry, light wines (CDA, 2013a).

Healthy Eating Education.

Dietitians are the primary source of nutrition education. However, all members of the interdisciplinary team should be prepared to answer basic questions about healthy eating and DM. Access to a dietitian may not be possible for patients who live in remote areas, and nurses often assume responsibility for teaching basic dietary management. *Eating Well With Canada's Food Guide* (see Chapter 42, Figure 42-1) is a simple, accessible, and appropriate tool for health care team members to use to educate people with DM about nutrition.

An effective method of presenting the basics of meal planning is the *plate method.* This simple method helps the patient visualize the amount of vegetables, starch, and protein that should fill a dinner plate (CDA, 2013a). For lunch and dinner, one-half of the plate is filled with vegetables, one-fourth is filled with a starch, and one-fourth is filled with 60 to 90 g (2–3 oz) of lean meat or other protein source. A glass of low-fat milk and a small piece of fresh fruit complete

the meal. The breakfast plate is filled halfway with starch, and one-fourth of the plate contains an optional protein. Low-fat milk and fresh fruit complete the breakfast. Assuming low-fat and nonfat foods are selected, following the plate method will provide a well-balanced diet.

Nutrition education should include the patient's family and significant others, and it is most effective to teach the person who will be cooking. However, it is important that the responsibility for making healthy food choices falls to the patient with DM. A support network of family and friends is the key to making successful and sustainable nutritional and lifestyle changes.

In an acute health care facility, the nutritional needs of the patient with DM vary slightly from the normal meal plans. Previously, standardized calorie-level meal patterns were used, but new alternatives are now being used, such as the consistent-carbohydrate DM meal plan. Under this system, meal plans are not created according to calorie levels, but instead are created with consistent carbohydrate content. For example, every day, each breakfast contains the same amount of carbohydrates as the previous day; the same method is used for lunch and dinner (CDA, 2013a).

Exercise

Regular, consistent exercise is considered an essential part of DM and prediabetes management. Exercise increases insulin sensitivity and can have a direct effect on lowering blood glucose levels. It also contributes to weight loss, which also decreases insulin resistance. The therapeutic benefits of regular physical activity may result in a decreased need for DM medicines in order to reach target blood glucose goals. Regular exercise may also help reduce triglyceride and low-density lipoprotein (LDL) cholesterol levels, reduce blood pressure, and improve circulation (CDA, 2013a; ADA, 2015). Any new exercise program in the person with DM should be started only after medical clearance and should be started slowly, with gradual progression toward the desired goal. People with type 2 DM should accumulate at least 150 minutes of moderate-intensity aerobic activity—such as brisk walking, cycling, or dancing—each week, spread over at least 3 separate days. Performance of resistance exercises three times per week should also be encouraged in addition to aerobic exercise (CDA, 2013a).

Before starting an exercise program, all patients with DM should undergo a pre-exercise assessment by a medical doctor and should be started slowly with gradual progression toward the desired goal (CDA, 2013a). Patients who use insulin and insulin secretagogues, such as sulphonylureas or meglitinides, are at increased risk for hypoglycemia when there is an increase in physical activity, especially if the patient exercises at the time of peak drug action or if food intake has not been sufficient to maintain adequate blood glucose levels. Hypoglycemia can also occur if a normally sedentary patient with DM has an unusually active day. The glucose-lowering effects of exercise can last up to 48 hours after the activity, so it is possible for hypoglycemia to occur during that time. It is

recommended that patients who use medications that can cause hypoglycemia schedule exercise about 1 hour after a meal or have a 10- to 15-g carbohydrate snack before exercising. Several small carbohydrate snacks can be taken every 30 minutes during exercise to prevent hypoglycemia. Patients using medications that place them at risk for hypoglycemia should always carry a fast-acting source of carbohydrate, such as juice, glucose tablets, or hard candies, when exercising. Table 52-9 gives guidelines on the number of calories burned per hour for different activities.

TABLE 52-9

ACTIVITIES THAT AFFECT CALORIC EXPENDITURE

Light Activity (100–200 Kcal/Hr)	Moderate Activity (200–350 Kcal/Hr)	Vigorous Activity (400–900 Kcal/Hr)
• Driving a car • Fishing • Light housework • Secretarial work • Teaching • Walking casually	• Active housework • Bicycling (light) • Bowling • Dancing • Gardening • Golfing • Roller skating • Walking briskly	• Aerobic exercise • Bicycling (vigorous) • Hard labour • Ice skating • Outdoor sports • Running • Soccer • Tennis • Wood chopping

Although exercise is generally beneficial to blood glucose levels, strenuous activity can be perceived by the body as a stress, causing a release of counter-regulatory hormones, which results in a temporary elevation of blood glucose. As a result, hyperglycemia may occur in cases of poorly controlled type 2 DM or in patients with type 1 DM who exercise at a time of day when insulin action is waning. Some patients may have to inject a small bolus of rapid-acting or regular insulin if the blood glucose level is elevated before exercising to prevent progressive hyperglycemia. Furthermore, patients should exercise with caution if the blood glucose is elevated and there are no ketones. However, exercise should be postponed and the patient should take additional insulin when the blood sugar is elevated and urine ketones are present (CDA, 2013a).

Monitoring Blood Glucose

Self-monitoring of blood glucose (SMBG) is a cornerstone of DM management. By providing a "real-time" blood glucose reading, SMBG enables the patient to make self-management decisions regarding diet, exercise, and medication. SMBG is also important for detecting episodic hyperglycemia and hypoglycemia.

Portable blood glucose monitors are used at the hospital bedside and by patients who perform SMBG independently. A wide variety of blood glucose monitors are available (Figure 52-9). Usually, disposable lancets are used to obtain a small drop of capillary blood (usually from a finger stick) that is placed onto a glucose testing strip. After a specified time, the monitor displays a digital reading of the blood glucose. The technology of SMBG is a rapidly changing field, with

more convenient systems being introduced every year. Newer systems allow the user to collect blood from alternative sites such as the forearm or the palm but will not register rapidly changing blood glucose readings. Therefore, finger sticks are still recommended if symptoms of low blood glucose are present. The most advanced systems require 4 seconds to provide results with only 0.3 μL of capillary blood.

FIGURE 52-9 A blood glucose monitor (Accu-Chek Aviva) is used to measure blood glucose levels. Source: Courtesy Roche Diagnostics Canada, Laval, QC.

Continuous glucose monitoring (CGM) systems provide another route for monitoring glucose. They measure glucose concentrations in the interstitial fluid. There are two devices available—the real-time CGM (personal) and the retrospective CGM (professional). The real-time CGM available in Canada is the Medtronic MiniMed Paradigm REAL-Time System (Figure 52-10). Using a sensor inserted under the skin, it displays glucose values continuously, with the values updating every 5 minutes. The sensor is inserted by the patient, using an automatic insertion device. Data are sent from the sensor to a transmitter, which displays the glucose value on an insulin pump. The patient is alerted during episodes of hypoglycemia and hyperglycemia, allowing corrective action to be taken quickly. The retrospective CGM captures data but does not display. CGMs assist patients and health care providers to identify trends and track patterns. These data are particularly useful for the management of insulin therapy. These systems still require finger-stick measurements using a blood glucose monitor to calibrate the sensor and to make treatment decisions.

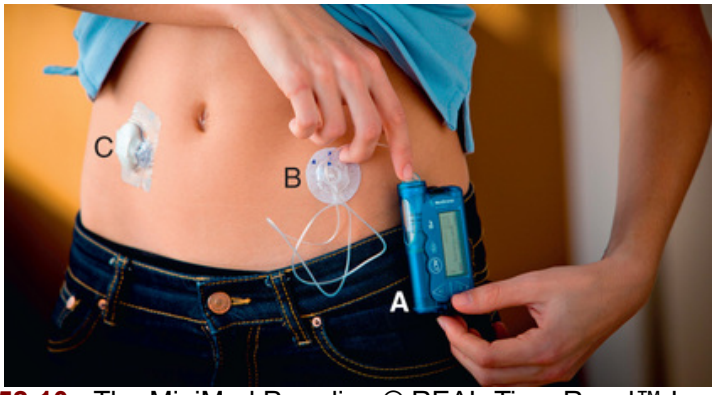

FIGURE 52-10 The MiniMed Paradigm® REAL-Time Revel™ Insulin Pump (A) delivers insulin through a thin plastic tubing to an infusion set, which has a cannula (B) that sits under the skin. Continuous glucose monitoring occurs through a tiny sensor (C) inserted under the skin. Sensor data are sent continuously to the insulin pump through wireless technology, giving a more complete picture of glucose levels, which can lead to better treatment decisions and better glucose control. Source: Phanie/Alamy Stock Photo.

The blood glucose level reported by a laboratory is sometimes higher than that reported on the patient's home glucose monitor or the hospital's portable monitor. This is because some monitors give capillary blood glucose values from whole blood (via finger stick), whereas venous samples taken in the laboratory provide plasma readings. Plasma samples, or venous samples, are approximately 10% to 12% higher. Most monitors are automatically calibrated to give a "plasma" test result (even though whole blood was used for the sample) so that the home readings can be more readily compared with laboratory values. The literature accompanying a monitor will identify whether that particular monitor is calibrated to give plasma or whole blood readings.

Instructions for using a blood glucose monitor accompany each product. Because errors in monitoring technique can cause errors in management strategies, thorough patient education is crucial. Initial education should be followed up at regular intervals with reassessment. In addition, patients must be taught to use and interpret control solutions. Control solution should be used when first using a glucometer, when a new bottle of strips is used or when there is a reason to believe that the readings are not correct. Lab-to-meter correlation should be done between SMBG and simultaneous venous FBG, at least annually or when A_{1c} does not match SMBG readings, to ensure accuracy of SMBG. At blood glucose levels >4.2 mmol/L, a difference of <20% is considered acceptable (CDA, 2013a). Table 52-10 lists the steps that should be taught to the patient learning to perform SMBG.

TABLE 52-10

PATIENT & CAREGIVER TEACHING GUIDE
Obtaining a Capillary Sample for Blood Glucose Testing

The following instructions should be included when teaching the patient and caregiver about SMBG.

1. Wash hands with soap and warm water. It is not necessary to clean the site with alcohol, and it may interfere with test results by artificially lowering them.
2. If it is difficult to obtain an adequate drop of blood for testing, do any or all of the following: warm the hands in warm water, let the arm hang down for a few minutes before the finger puncture is made, use a new lancet with every puncture, or use a higher setting on the lancing device.
3. If the puncture is made on the finger, use the side of the finger pad rather than near the centre. There are fewer nerve endings along the side of the finger pad. If an alternative site is used (e.g., forearm), special equipment may be needed. Alternative-site testing is not recommended after a meal or for people with erratic blood glucose control experiencing hypoglycemia. Refer to manufacturer's instructions for alternative-site use.
4. The puncture should be only deep enough to obtain a sufficiently large drop of blood. Unnecessarily deep punctures may cause pain and bruising.
5. Lancets should be disposed of in designated “sharps” containers obtained from drug stores. Lancets and needles should not be placed in garbage cans, recycling bins, toilets, or glass jars.

The primary advantage of SMBG is that it supplies immediate information about blood glucose levels that can be used to make adjustments in food intake, activity patterns, and medication dosages. It also produces accurate records of daily glucose fluctuations and trends as well as alerting the patient to acute episodes of hyperglycemia and hypoglycemia. Furthermore, it provides patients with a tool for achieving and maintaining specific glycemic goals. SMBG is recommended as an essential part of daily DM management for all people using insulin or OHAs. The frequency of monitoring depends on several factors, including the patient's glycemic goals, the type of DM the patient has, the patient's ability and willingness to perform the test independently, and the treatment regimen. It is recommended that patients with type 1 DM test at least three times per day and include both preprandial and postprandial testing. Those using an insulin pump may test more frequently. People with type 2 DM treated with OHAs or lifestyle alone will have more variable and individualized testing regimens. For patients with type 2 DM treated with once-daily insulin and OHAs, monitoring at least once daily is recommended (CDA, 2013a).

Blood glucose testing should also be performed whenever hypoglycemia is suspected so that immediate action can be taken if necessary. When the person with DM is ill, the blood glucose should be tested at 4-hour intervals to determine the effects of this stressor on the blood glucose level.

SMBG is an empowering tool that allows the patient to be an active partner in the treatment of DM. Achieving the desired level of patient participation does require time and effort from the health care provider. The nurse involved in this aspect of management should anticipate a close working relationship with patients as they refine their techniques and learn appropriate decision making about managing their DM. A patient who is visually impaired, cognitively impaired, or limited in manual dexterity needs careful evaluation of the degree to which SMBG can be performed independently. Nurses working in home health and outpatient settings may need to identify caregivers who can assume this responsibility. Adaptive devices are available to help patients with certain

limitations. These include "talking meters" and other equipment for people who are visually impaired as well as devices to stabilize insulin vials and syringes for those with limitations affecting dexterity.

Bariatric Surgery

Bariatric surgery may be considered for patients with type 2 diabetes who have a body mass index (BMI) >40.0 kg/m^2 (class III obesity) or BMI >35.0 to 39.9 kg/m^2 (class II obesity) and comorbidities, when lifestyle interventions are inadequate in achieving and maintaining healthy weight goals (CDA, 2013a) (see the "Evidence-Informed Practice" box). Patients with type 2 diabetes who have undergone bariatric surgery need lifelong monitoring and support. (Bariatric surgery is discussed in Chapter 43.)

Evidence-Informed Practice

Research Highlight

Bariatric Surgery for Adults With Type 2 Diabetes Who Are Obese

Clinical Question

In adults who are severely obese (P), how do gastric bypass and biliopancreatic diversion (I) compare with medical therapy (C) for remission from type 2 diabetes mellitus (O)?

Best Available Evidence

- Systematic review of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence

- Sixty adults with type 2 diabetes for ≥5 yr with a BMI ≥35 kg/m^2 and Hb A_{1c} ≥7.0%
- Roux-en-Y gastric bypass (n = 20), biliopancreatic diversion (n = 20), or medical therapy (n = 20)
- At 2 yr, more patients in the gastric bypass and biliopancreatic diversion groups achieved diabetes remission than in the medical therapy group
- Bypass and biliopancreatic diversion each reduced A_{1c}, glucose levels, and BMI more than medical therapy

Conclusion

- Bariatric surgery (gastric bypass and biliopancreatic diversion) decreases BMI, improves glycemic control, and increases remission from type 2 diabetes more than medical therapy does, in adults who are severely obese.

Implications for Nursing Practice

1. In addition to behavioural and medical approaches, bariatric surgery often normalizes blood glucose levels, reduces or avoids the need for drugs, and provides a potentially cost-effective approach to treating the disease.
2. Bariatric surgery is an appropriate treatment for people with type 2 diabetes and obesity who are not achieving recommended treatment targets with medical therapies, especially when there are other major comorbidities.

P, Patient population of interest; *I,* intervention or area of interest; *C,* comparison of interest or comparison group; *O,* outcomes of interest.

Culturally Competent Care

Diabetes Mellitus

Because culture can have a strong influence on dietary preferences and meal preparation practices, culturally competent care has special relevance for the patient with diabetes. This is especially pertinent when considering the prevalence of diabetes in diverse Canadian cultural groups such as people of Indigenous, Latin American, South Asian, Asian, or African descent. The influence of culture on food choices and meal planning should be explored with the patient as part of the health history. When giving diet instructions, efforts should be made to consider the food preferences of the cultural group. Nutritional resources specifically designed for members of different cultural groups are available from Diabetes Canada.

Nursing Management Diabetes Mellitus

Nursing Assessment

Table 52-11 provides initial subjective and objective data that might be obtained from a person with DM. After the initial assessment, periodic patient assessments should be done on a regular basis.

TABLE 52-11

NURSING ASSESSMENT
Diabetes Mellitus

Subjective Data
Important Health Information
Past health history: Mumps, rubella, coxsackievirus, or other viral infections; recent trauma, infection, or stress; pregnancy, gave birth to infant >4 kg; chronic pancreatitis; Cushing's syndrome, acromegaly; family history of type 1 or type 2 diabetes mellitus; obesity Date of last eye and dental examination, compliance with diet in patients with previously diagnosed diabetes *Medications:* Use of and compliance with insulin or OHAs; use of corticosteroids, diuretics, phenytoin (Dilantin) *Surgery or other treatments:* Any recent surgery
Symptoms
• Constipation or diarrhea; frequent urination, nocturia, urinary incontinence • Depression, irritability, apathy • Erectile dysfunction; frequent vaginal infections; decreased libido • Malaise • Muscle weakness, fatigue • Poor healing, especially involving the feet • Thirst, hunger, nausea and vomiting • Weight loss (type 1), weight gain (type 2)
Objective Data
Eyes
Vitreal hemorrhages; cataracts; soft, sunken eyeballs*
Integumentary
Dry, warm, inelastic skin; pigmented lesions (on legs); ulcers (especially on feet), loss of hair on toes; acanthosis nigricans
Respiratory
Rapid, deep respirations (Kussmaul's respiration)*
Cardiovascular
Hypotension*; weak, rapid pulse*, peripheral pulses diminished, feet pale and cool to touch
Gastro-Intestinal
Dry mouth, vomiting*, fruity breath*
Neurological
Altered reflexes, restlessness, confusion, stupor, coma, reduced sensation or vibration sense in feet
Musculo-Skeletal
Muscle wasting
Possible Findings
• Glucose level ≥7.0 mmol/L; glucose tolerance test ≥11.1 mmol/L; glycosylated hemoglobin ≥6% • Urinalysis: glycosuria, ketonuria, microalbuminuria, or proteinuria • Other: serum electrolyte abnormalities; acidosis; ↑ creatinine, ↑ total cholesterol, LDL, VLDL, and triglycerides; ↓ HDL; leukocytosis

*Indicates manifestations of ketoacidosis.

HDL, high-density lipoprotein; *LDL*, low-density lipoprotein; *OHA*, oral antihyperglycemic agent; *VLDL*, very-low-density lipoprotein.

Nursing Diagnoses

Nursing diagnoses related to DM may include, but are not limited to, the following.

- *Ineffective health management* related to *insufficient resources* (deficient knowledge of diabetes management)
- *Risk for unstable blood glucose levels* as evidenced by *insufficient diabetes management*
- *Risk for injury* as evidenced by *insufficient knowledge of modifiable factors* (resulting in episodes of hypoglycemia)
- *Risk for peripheral neurovascular dysfunction* (related to vascular effects of diabetes)

Additional information on nursing diagnoses for the patient with diabetes is also presented in Nursing Care Plan (NCP) 52-1, available on the Evolve website.

Planning

The overall goals for the patient with DM include the following: (1) to be an active participant in the management of the DM regimen; (2) to experience few or no episodes of hypoglycemia or acute hyperglycemic emergencies; (3) to maintain blood glucose levels at normal or near-normal levels; (4) to prevent, minimize, or delay the occurrence of chronic complications of DM; and (5) to adjust lifestyle to accommodate DM regimen with a minimum of stress.

Nursing Implementation

Health Promotion.

The role of the nurse in health promotion and maintenance relates to the identification, monitoring, and education of the patient at risk for the development of DM. Obesity is the number one predictor of type 2 DM. The Diabetes Prevention Program (DPP) found that a modest weight loss of 5% to 10% of body weight, from dietary modifications and regular exercise of 30 minutes five times a week, lowered the risk of developing type 2 DM up to 58% (DPP Research Group, 2002).

Diabetes Canada recommends screening every 3 years in individuals 40 years of age or older or in individuals at high risk using a risk calculator. It

is important to screen earlier and more frequently in people with additional risk factors for diabetes or for those at very high risk using a risk calculator. The Canadian Diabetes Risk Assessment Questionnaire (CANRISK) is a statistically valid tool that may be suitable for diabetes risk assessment in the Canadian population and is available at *http://healthycanadians.gc.ca/diseases-conditions-maladies-affections/disease-maladie/diabetes-diabete/canrisk/index-eng.php*.

The FBG, A_{1c}, or both are the preferred methods for screening in clinical settings; however, the 75-g OGTT is indicated in those with IFG or when A_{1c} is 6.0% to 6.4%. Screening should be considered at a younger age or be carried out more frequently in individuals who meet the criteria listed in Table 52-12 (CDA, 2013a).

TABLE 52-12

CRITERIA FOR SCREENING IN ASYMPTOMATIC, UNDIAGNOSED INDIVIDUALS

Type 1 Diabetes Mellitus
Screening presumably healthy individuals for the presence of any immune markers (e.g., HLA), outside of a clinical trial setting, is not recommended.
Type 2 Diabetes Mellitus
In asymptomatic, undiagnosed individuals, or those at high risk using a risk calculator, screening* for diabetes should be considered in all individuals at ≥40 yr and, if normal, should be repeated at 3-yr intervals.
Screening should be considered at a younger age, or be carried out more frequently, in individuals who are at very high risk using a risk calculator or who have the following additional risk factors:
• Are members of a high-risk ethnic population (Indigenous or of Latin American, South Asian, Asian, or African descent) • Are overweight, particularly with abdominal obesity • Have a first-degree relative with type 2 diabetes • Have a history of gestational diabetes mellitus • Have a history of impaired fasting glucose or impaired glucose tolerance • Have acanthosis nigricans • Have complications associated with diabetes • Have delivered a macrosomic infant (>4.4 kg) • Have dyslipidemia • Have hypertension • Have polycystic ovary syndrome • Have schizophrenia • Have vascular disease

*Screening may include fasting blood glucose (FBG), glycated hemoglobin (A_{1c}), or both. A 75-g oral glucose tolerance test (OGTT) is indicated when the FBG is 6.1 mmol/L to 6.9 mmol/L or A_{1c} is 6.0% to 6.4%, or both.

HLA, human lymphocyte antigen.

Acute Intervention.

Acute situations involving the patient with DM include hypoglycemia, DKA, and hyperosmolar hyperglycemic state (HHS). Nursing management for these situations is discussed in more detail later in this chapter. Other areas of acute intervention relate to management during stress, such as during acute illness and surgery.

Stress of Acute Illness and Surgery.

Both emotional and physical stress can increase the blood glucose level and result in hyperglycemia. Because it is impossible to totally avoid stress

in life, certain situations may require more intense management, such as extra insulin, to maintain glycemic goals and prevent hyperglycemia.

Acute illness, injury, and surgery are situations that may evoke a counter-regulatory hormone response resulting in hyperglycemia. Even minor illnesses such as a viral upper respiratory infection or the flu can cause this. When patients with DM are ill, they should continue with the regular meal plan while increasing the intake of noncarbohydrate-containing fluids, such as broth, water, and other decaffeinated beverages. They should also continue taking OHAs and insulin as prescribed and check blood glucose at least every 4 hours around the clock. With type 1 DM, if the glucose is greater than 14 mmol/L, urine should be tested for ketones every 3 to 4 hours. Patients should report moderate to large ketone levels to the health care provider.

When the illness causes the patient to eat less than normal, the patient should continue to take OHAs, noninsulin injectables, and insulin as prescribed, while supplementing food intake with carbohydrate-containing fluids. Examples include soups, juices, and regular decaffeinated soft drinks. The health care provider should be notified promptly if the patient is unable to keep anything down, and the patient should go to the emergency department if vomiting occurs more than twice in 12 hours. The patient should understand that medication for DM, including insulin, should not be withheld during times of illness because counter-regulatory mechanisms often increase the blood glucose level dramatically. Food intake is also important during this time because the body requires extra energy to deal with the stress of the illness. Extra insulin may be necessary to meet this demand and to prevent the onset of DKA in the patient with type 1 DM (CDA, 2013a).

During the perioperative period, adjustments in the DM regimen can be planned to ensure glycemic control. For patients undergoing major surgery who require insulin (type 1 or type 2 DM), IV fluids with dextrose and insulin are administered immediately before, during, and after surgery. For patients undergoing minor or moderate surgery who require insulin (type 1 or type 2 DM), recommendations are provided by the physician to reduce the insulin dosage the night before and the day of surgery. For patients taking OHAs who are undergoing major, moderate, or minor surgery, DM medications may be put on hold for as long as 24 hours before the day of surgery, and IV fluids with dextrose and insulin may be administered. The patient should understand that this is a temporary measure and is not to be interpreted as a worsening of DM. Patients who are undergoing surgery or any radiological procedures that

involve the use of a contrast medium are instructed to hold their metformin (Glucophage) at the time of or before surgery or the procedure. They will also be instructed not to resume the metformin (Glucophage) until 48 hours after the surgery or the procedure and after their serum creatinine has been checked and is normal (Sanofi-Aventis, 2009).

The nurse caring for an unconscious surgical patient receiving insulin must be alert for signs of hypoglycemia, such as sweating, tachycardia, and tremors. Frequent monitoring of blood glucose will prevent episodes of severe hypoglycemia in such a patient (CDA, 2013a).

Ambulatory and Home Care.

Successful management of DM requires ongoing interaction among the patient, the family, and the health care team. It is important that a DM nurse educator be involved in the care of the patient and the family. This person provides expertise in many areas of specialized care needs.

Because DM is a complex, chronic condition, a great deal of patient contact takes place in outpatient and home settings. The major goal of patient care in these settings is to enable the patient or caregiver to reach an optimal level of independence in self-care activities. Unfortunately, many patients with DM face challenges in reaching these goals. DM increases the risk for other chronic conditions that can affect self-care activities. These include visual impairment, lower extremity problems that affect mobility, and other functional limitations related to cardiovascular disease. Therefore, important nursing functions are to assess the ability of patients and caregivers in such activities as meal preparation, SMBG, safe administration of OHAs, and insulin injection techniques. Assistive devices for self-administration of insulin include syringe magnifiers, vial stabilizers, and dose-preparation aids for people who are visually impaired as well as pill organizers for those taking OHAs. In some cases, the nurse will make referrals to others who can help the patient achieve the self-care goals. These may include a community health nurse, pharmacist, dietitian, occupational therapist, or social worker.

A diagnosis of DM affects the patient in many profound ways. Patients with DM must continually contend with lifestyle choices that affect the food they eat, the activities they engage in, and the demands on their time and energy. In addition, they face the prospect of the devastating complications of this disease. Careful assessment of what it means to the patient to have DM should be the starting point of patient teaching. The nurse can help patients make adjustments by displaying an attitude that is

supportive and nonjudgemental. The goals of teaching should be collaboratively determined by the patient and the nurse, based on individual needs as well as therapeutic requirements.

The patient's support system must be identified. The family or other members of the support system need to be involved in teaching so they can care for the patient when self-care is no longer possible. The family and significant others need to be encouraged to provide emotional support and encouragement as the patient deals with the reality of living with a chronic disease.

Insulin Therapy.

Nursing responsibilities for the patient receiving insulin include proper administration, assessment of the patient's response to insulin therapy, and education of the patient regarding administration of, adjustment to, and adverse effects of insulin (RNAO, 2009) (Table 52-13). Table 52-6 lists guidelines for the nurse assessing a patient using OHAs and insulin.

TABLE 52-13

PATIENT & CAREGIVER TEACHING GUIDE
General Guidelines for the Management of Diabetes Mellitus

When teaching patients and caregivers about the management of diabetes mellitus, the nurse should:
Disease Process
• Determine the patient's readiness to learn. • Include an introduction about the pancreas and the islets of Langerhans. • Describe how insulin is made and what affects its production. • Discuss the relationship between insulin and glucose. • Explain the difference between type 1 and type 2 diabetes.
Physical Activity
• Determine patient's readiness to change. • Help the patient identify realistic goals and barriers to physical activity. • Discuss the importance of regular exercise on the management of blood glucose, improvement of cardiovascular function, and general health.
Menu Planning
• Individualize meal plans to accommodate the patient's age, type and duration of diabetes, concurrent medical therapies, treatment goals, values, preferences, needs, culture, lifestyle, economic status, activity level, readiness to change, and abilities. • Educate the patient on the importance of a well-balanced diet as part of a diabetes management plan. • Explain the impact of carbohydrates on the glycemic index and blood glucose levels.
Medication Adherence
• Ensure that the patient is well educated on the proper use of insulin (see Table 52-5) noninsulin injectables, and oral agents. • Account for any limitations or inabilities for self-medication on the patient's part. If necessary, involve the family or caregiver in proper use of medication. • Discuss all adverse effects and safety issues regarding medication.
Monitoring Blood Glucose
• Individualize the frequency of monitoring to the patient's unique circumstances. • Teach how to correctly monitor blood glucose levels. • Include when blood glucose levels should be checked, how to record them, and if appropriate, how to adjust insulin levels accordingly. • Teach how behaviour and actions affect results.
Risk Reduction
• Ensure that the patient understands and appropriately responds to the signs and symptoms of hypoglycemia and hyperglycemia (see Table 52-15). • Stress the importance of proper foot care (see Table 52-20), regular eye examinations, and consistent glucose monitoring. • Inform the patient about the effect that stress can have on blood glucose.
Psychosocial
• Help the patient identify what is important to him or her. • Advise the patient of resources that are available to facilitate the adjustment and answer questions about living with a chronic condition such as diabetes (see Resources at the end of this chapter).

Assessment of the patient who is new to insulin administration must include an evaluation of the patient's ability to manage this therapy safely. This includes the ability to understand the interaction of insulin, diet, and activity and to be able to recognize and treat the symptoms of hypoglycemia appropriately. If the patient does not have the cognitive skills to do these things, another responsible person must be identified and educated. The patient or caregiver must also have the cognitive and the

manual skills needed to prepare and inject the insulin. If the patient or family lacks these, additional resources will be needed to assist the patient.

Many patients are fearful when they first begin using insulin. Some patients find it difficult to self-inject because they are afraid of needles or the pain associated with an injection. Some are afraid they will hurt themselves by giving too much or too little insulin. And in some cases, the patient believes that using insulin is a "last ditch" effort and that he or she is now in the final stages of the disease process. Therefore, it is important to explore the patient's underlying fears before beginning the teaching (Wang & Yeh, 2012; RNAO, 2009).

Follow-up assessment of the patient who has been using insulin therapy includes an inspection of injection sites for signs of lipodystrophy and other reactions; review of insulin preparation, storage, timing, and injection technique; a history of hypoglycemic episodes; and review of the patient's method for handling hypoglycemic episodes. A review of the patient's recorded blood glucose tests is also important in assessing overall glycemic control.

Oral and Noninsulin Injectable Agents.

Nursing responsibilities for the patient taking OHAs and noninsulin injectables are similar to those for the patient taking insulin. Proper administration, assessment of the patient's use of and response to these medications, and education of the patient and the family about OHAs and noninsulin injectables are all part of the nurse's function.

The nurse's assessment can be extremely valuable in determining the most appropriate antihyperglycemic agent for a patient. Factors such as the patient's financial situation, cognitive status, eating habits, home environment, attitude toward DM, and medication history all play a significant role in determining the most appropriate OHA for the individual patient. For example, frail older adults who live alone are at high risk for severe hypoglycemia because low blood glucose is frequently undetected and untreated in this population. This is especially true if the patient has a short-term memory deficit. In these cases, an OHA that does not cause hypoglycemia, or a shorter-acting OHA, would be most appropriate.

Patient education is an essential nursing function when caring for the patient who uses OHAs for blood glucose control. Some patients may assume that their DM is not a serious condition if they are taking "only a pill" for glycemic control. Therefore, the patient should be instructed that these agents will help keep blood glucose controlled and will help prevent

serious long- and short-term complications of DM. Patients should be instructed that OHAs and noninsulin injectables are used in addition to healthy eating and activity as therapy for DM and that they should continue with their meal and activity plans. Patients should not take extra pills if overeating has occurred unless specifically instructed to do so by their health care provider. If the patient uses insulin secretagogues, instructions should be given in regard to prevention, symptom recognition, and management of hypoglycemia.

The patient should also be instructed to contact a health care provider if periods of illness or extreme stress occur. During such a period, insulin therapy may be required to prevent or treat hyperglycemic symptoms and avoid an acute hyperglycemic emergency.

Personal Hygiene.

The potential for microvascular complications and infections necessitates diligent skin and dental hygiene practices on the part of the patient. Because of the susceptibility to periodontal disease, daily tooth brushing and flossing should be encouraged in addition to regular visits to the dentist. When dental work must be done, the dentist should be informed that the patient has DM.

Routine care should include an emphasis on foot care, including daily assessment of feet (RNAO, 2013; CDA, 2013a). Problems associated with the feet and the lower extremities are presented later in this chapter. If cuts, scrapes, or burns occur, they should be treated promptly and monitored carefully. The area should be washed, and a nonabrasive or nonirritating antiseptic ointment may be applied. The area should be covered with a dry, sterile pad. If the injury does not begin to heal within 24 hours, or if signs of infection develop, the health care provider should be notified immediately.

Medical Identification and Travel.

Patients should be instructed to carry medical identification at all times indicating that they have DM (Figure 52-11). Police, paramedics, and many private citizens are aware of the need to look for this identification when working with someone who is sick or unconscious. Every person with DM should wear a medical alert bracelet or necklace. An identification card can supply valuable information, such as the name of the health care provider and the type and dose of insulin, noninsulin injectables, or OHA.

FIGURE 52-11 Medical Alerts. A patient with diabetes should carry a card and wear a bracelet or necklace that indicates diabetes. If the patient with diabetes is unconscious, these measures will ensure prompt and appropriate attention.

Travel for a patient with DM requires advance planning. The patient should have a full set of DM care supplies in the carry-on luggage when travelling by plane, train, or bus. This includes blood glucose monitoring equipment, insulin, and pen needles or syringes. When pen needles, syringes, and lancing devices are carried onto a commercial airliner, a letter from the prescribing health care provider indicating medical necessity may prevent delays at security checkpoints. Screeners should be notified if an insulin pump is used so they can inspect it while it is on the body, rather than remove it.

For patients who use insulin or an OHA that can cause hypoglycemia, snack items and a fast-acting carbohydrate source for treating hypoglycemia should be included in the carry-on luggage and on the person at all times. Extra insulin should be available in case a vial or cartridge breaks or gets lost. In addition, the patient should carry a full day's supply of food to be prepared for possibly cancelled flights, delayed meals, and closed restaurants. If the patient is planning a trip out of the country, it is wise to have a letter from the health care provider explaining that the patient has DM and requires all the materials being transported, particularly pen needles and syringes, for ongoing health care.

Some travel involves significant time changes such as travelling coast to coast or across the International Date Line. The patient should contact the DM health care provider to plan an appropriate meal and insulin schedule. During travel, most patients find it helpful to keep watches set to the time of the city of origin until they reach their destination, and then switch to travel destination time as soon as possible. The key to travel when taking insulin is to know the type of insulin being taken, its onset of action, the anticipated peak time, and mealtimes.

Patient and Caregiver Teaching.

The goals of DM self-management education are to enable the patient to become the most active participant in her or his care, while matching level of self-management to the ability of the individual patient. Patients who actively manage their DM care have better outcomes than those who do not. For this reason, an educational approach that facilitates informed decision making on the part of the patient is widely advocated. Sometimes, this is referred to as the *empowerment approach* to education.

Unfortunately, patients can encounter a variety of physical, psychological, emotional, and socioeconomic barriers when it comes to effectively managing their DM. These barriers may include feelings of inadequacy about one's own abilities, unwillingness to make the necessary behavioural changes, ineffective coping strategies, lack of resources, and cognitive deficits. If the patient is not able to manage the disease, a family member may be able to assume part of this role. If the patient or the family cannot make decisions related to DM management, the nurse may refer the patient to a social worker or other resources within the community. These resources can assist the patient and the family in outlining a feasible treatment program that meets their capabilities. Patient and health care provider resources are listed at the end of this chapter.

An assessment of the patient's knowledge of DM and lifestyle preferences is useful in planning a teaching program. Tables 52-13 and 52-14 present guidelines to use for patient and caregiver teaching (See the "Informatics in Practice" box on using gaming for patient teaching). The nurse should assess the patient's knowledge base frequently so that gaps in knowledge or incorrect or inaccurate ideas can be quickly corrected.

TABLE 52-14

PATIENT & CAREGIVER TEACHING GUIDE
Instructions for Patients With Diabetes Mellitus

Do	Do Not
Blood Glucose	
• Monitor your blood glucose at home and record results in a log. • Take your insulin, OHA, or noninsulin injectable (or any combination) as prescribed. • Rotate injection site areas weekly. • Obtain an A_{1c} blood test every 3–6 mo as an indicator of your long-term blood glucose control. • Know signs and symptoms of hypoglycemia and hyperglycemia. • Carry some form of rapid-acting glucose at all times so you can treat hypoglycemia quickly. • Instruct family members in the use of glucagon administration in the case of emergencies owing to severe hypoglycemia.	• Skip doses of your insulin, especially when you are sick. • Run out of insulin. • Ignore the symptoms of hypoglycemia and hyperglycemia.
Exercise	
• Learn how exercise and food affect your blood glucose levels. • Begin an exercise program after approval from a health care provider.	• Forget that exercise will lower your blood glucose level. • Exercise if your blood glucose levels are very elevated. This may lead to a temporary worsening of your blood glucose levels.
Nutrition	
• Follow a healthy eating plan, and eat regular meals at regular times. • Choose foods low in saturated and trans-fats and high in fibre. • Limit the amount of alcohol you drink. • Know your cholesterol level.	• Drink excessive amounts of alcohol because this may lead to unpredictable low blood glucose reactions and high triglycerides. • Follow a fad diet. • Drink regular pop or lots of fruit juices.
Other Guidelines	
• Obtain an annual eye examination by an ophthalmologist. • Obtain annual urine testing for protein. • Examine your feet at home, daily. • Change socks daily. • Trim nails straight across. • Wear well-fitting shoes to help prevent foot injury. Break in new shoes gradually. • Always carry identification that says you have diabetes. • Have other medical problems treated, especially high blood pressure and high cholesterol. • Quit smoking. • Have an annual influenza vaccination.	• Smoke cigarettes. • Go barefoot. • Put baby oil or lotion between your toes. • Ignore the signs of infection. • Apply hot or cold directly to your feet. • Wear tight socks, garters, or elastics or knee-highs.

OHA, oral antihyperglycemic agent.

Diabetes Canada offers pamphlets, booklets, and a bimonthly magazine called *Diabetes Dialogue*. Chapters of Diabetes Canada are located in all major Canadian cities, and most can be reached by accessing Diabetes Canada online. Diabetes Canada also publishes research and education materials and sponsors conferences for health care providers concerned

with DM education, research, and management of patients. The *2013 Clinical Practice Guidelines for the Prevention and Management of Diabetes in Canada* were released in the spring of 2013 and updated guidelines are released every 5 years (see the Resources at the end of this chapter). Prepared under the leadership of the Clinical and Scientific Section of the Canadian Diabetes Association/Diabetes Canada, the guidelines represent the contributions of more than 99 experts from a broad range of health care disciplines. These experts have evaluated and graded the international literature on the best evidence to guide screening, prevention, diagnosis, care, management, and education for Canadians living with type 1 and type 2 DM and GDM. Diabetes Canada also gives recognition to education programs that meet the international standards of DM education and can provide a list of these programs. Pharmaceutical and diagnostic companies specializing in DM-related products also have promotions and free educational materials for patients and health care providers.

Evaluation

The expected outcomes for the patient with DM are addressed in Nursing Care Plan (NCP) 51-1, available on the Evolve website.

Complementary & Alternative Therapies

Herbs and Supplements That May Affect Glucose Levels

Possible Hypoglycemic Herbs and Supplements*

- Aloe, alpha-lipoic acid, fish oils, goldenseal, bilberry eleuthero, ginseng, milk thistle, Chinese cinnamon (Cinnamomum cassia) chromium, garlic, and sage

Possible Hyperglycemic Herbs and Supplements*

- St. John's wort, celery seed, rosemary, and melatonin

Nursing Implications

- It is very important that patients with diabetes consult with their health care providers before using natural health products such as herbs, probiotics, or nutritional supplements. Patients who use herbs should monitor their blood glucose levels carefully and regularly. The Canadian Diabetes Association (CDA) Clinical Practice Guidelines Expert Committee does not recommend the use of natural health products for the management of diabetes as there is insufficient evidence regarding its safety and efficacy (CDA, 2013a).

*www.naturalstandard.com

Informatics in Practice

Patient Teaching Using Gaming

- Teaching is a critical part of nursing care for patients with diabetes. It is possible to put some fun into patient teaching by using gaming applications.
- Patients can try an application with a quiz-show format. The patient answers questions about diabetes and then compares his or her answers in real time to those of other players. The questions (e.g., How does exercise affect insulin?) are written to help the patient learn to manage diabetes on a daily basis.
- Players in online simulations become either a caregiver to or a patient with type 1 DM. Players earn rewards by properly managing blood glucose levels.

Acute Complications of Diabetes Mellitus

Acute complications of DM arise from events associated with *hyperglycemia* or *hypoglycemia.* Hypoglycemia is also referred to as an *insulin reaction* or *low blood glucose*. It is important for the health care provider to be able to distinguish between hyperglycemia and hypoglycemia because hypoglycemia worsens rapidly and constitutes a serious threat if action is not immediately taken. Table 52-15 compares manifestations, causes, treatment, and prevention of hyperglycemia and hypoglycemia.

TABLE 52-15
COMPARISON OF HYPERGLYCEMIA AND HYPOGLYCEMIA

Hyperglycemia	Hypoglycemia
Manifestations*	
• Abdominal cramps • Blurred vision • Elevated blood glucose† • Glycosuria • Headache • Increase in appetite followed by lack of appetite • Increase in urination • Nausea and vomiting • Progression to DKA or HHS • Weakness, fatigue	• Blood glucose <4.0 mmol/L • Changes in vision • Cold, clammy skin • Emotional changes • Faintness, dizziness • Headache • Hunger • Nervousness, tremors • Numbness of fingers, toes, mouth • Rapid heartbeat • Seizures, coma • Unsteady gait, slurred speech
Causes	
• Corticosteroids • Emotional, physical stress • Illness, infection • Inactivity • Poor absorption or lack of insulin • Too little or no diabetes medication • Too much food	• Alcohol intake without food • Diabetes medication or food taken at wrong time • Loss of weight without change in medication • Too little food—delayed, omitted, inadequate intake • Too much diabetic medication • Too much exercise without compensation • Use of β-adrenergic blockers interfering with recognition of symptoms
Treatment	
• Check blood glucose frequently; check urine for ketones; record results • Continuance of OHA or insulin as ordered; may need increase in dose • Get medical care • Hourly drinking of fluids • IV fluids may be necessary	• Discussion with health care provider about insulin or OHA dosage • Follow-up with snack if regular meal more than 1 hr away, and contact health care provider if no effect • Immediate ingestion of 15–20 g of simple carbohydrates • Ingestion of another 15–20 g of simple carbohydrates in 15 min if no relief obtained
Preventive Measures	
• Accurate administration of insulin, noninsulin injectables, and OHA • Adherence to sick-day rules when ill • Checking of blood for glucose as ordered • Contacting of health care provider regarding ketonuria • Maintenance of diet • Maintenance of good personal hygiene • Taking prescribed dose of medication at proper time • Wearing medical alert bracelet (diabetes)	• Ability to recognize and know symptoms and treat them immediately • Accurate administration of insulin, noninsulin injectables, and OHA • Carrying a snack of simple carbohydrates • Checking blood glucose as ordered • Education of friends, family, fellow employees about symptoms and treatment • Ingestion of all recommended foods at proper time • Provision of compensation for exercise • Taking prescribed dose of medication at proper time • Wearing medical alert bracelet (diabetes)

*There is usually a gradual onset of symptoms in hyperglycemia and a rapid onset in hypoglycemia.

†Specific clinical manifestations related to elevated levels of blood glucose vary according to the patient.

DKA, diabetic ketoacidosis; *HHS,* hyperosmolar hyperglycemic state; *IV,* intravenous; *OHA,* oral antihyperglycemic agent.

Diabetic Ketoacidosis

Etiology and Pathophysiology

Diabetic ketoacidosis (DKA) is an acute metabolic complication of DM occurring when fats are metabolized in the absence of insulin. It is caused by a profound deficiency of insulin and is characterized by hyperglycemia, ketosis, metabolic acidosis, and dehydration (volume depletion). It is most likely to occur in people with type 1 DM but may be seen in type 2 DM in conditions of severe illness or stress, when the pancreas cannot meet the extra demand for insulin. Precipitating factors include illness, infection, inadequate insulin dosage, insulin omission, undiagnosed type 1 DM, and poor self-management.

When the circulating supply of insulin is insufficient, glucose cannot be properly used for energy, so the body breaks down fat stores as a secondary source of fuel (Figure 52-12). Ketones are acidic by-products of fat metabolism that can cause serious problems when they become excessive in the blood. Ketosis alters the pH balance, causing metabolic acidosis to develop. Ketonuria is a process that begins when ketone bodies are excreted in the urine. During this process, electrolytes become depleted as cations (sodium, potassium, and ammonium salts) are eliminated along with the anionic ketones in an attempt to maintain electrical neutrality.

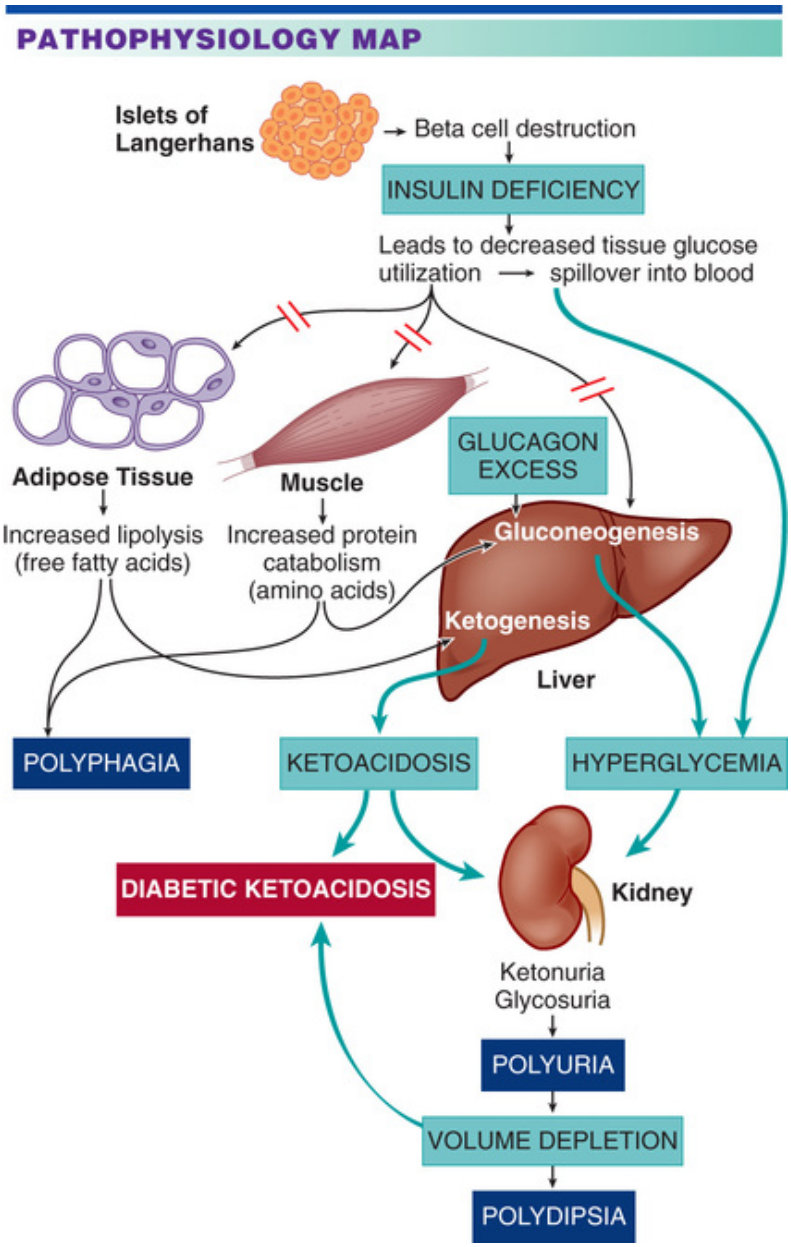

FIGURE 52-12 Metabolic events leading to diabetic ketoacidosis.

Source: Kumar, V., Abbas, A. K., Fausto, N., et al. (2010). *Robbins and Cotran pathologic basis of disease.* (8th ed., p. 1144, Figure 24-39). Philadelphia: Saunders.

Insulin deficiency impairs protein synthesis and causes excessive protein degradation. This condition results in nitrogen losses from the tissues. Insulin deficiency also stimulates the production of glucose from amino acids (from proteins) in the liver and leads to further hyperglycemia. But because there is a deficiency of insulin, the additional glucose cannot be used and the blood glucose level rises further, adding to the osmotic diuresis. Untreated, this condition leads to severe depletion of

sodium, potassium, chloride, magnesium, and phosphate. Potassium is most affected in DKA. Acidosis causes hydrogen ions to move from the extracellular fluid to the intracellular space. Hydrogen movement into the cell promotes potassium movement out of the cell into the extracellular compartment, resulting in severe potassium depletion in the intracellular space. Most of the shifted extracellular potassium is lost in the urine because of osmotic diuresis. The serum potassium can be normal or even high, but this finding is misleading because there is an intracellular and total body loss of potassium (CDA, 2013a).

Vomiting caused by the acidosis results in more fluid and electrolyte losses. Eventually, hypovolemia, followed by shock, ensues.

Renal failure may eventually occur from hypovolemic shock. This result causes the retention of ketones and glucose, and the metabolic acidosis progresses. Untreated, the patient becomes comatose as a result of dehydration, electrolyte imbalance, and acidosis. If the condition is not treated, death is inevitable.

Clinical Manifestations

Signs and symptoms of DKA include polyuria and polydipsia, leading to dehydration. Dehydration is manifested by poor skin turgor, dry mucous membranes, tachycardia, and orthostatic hypotension. Early symptoms may include lethargy and weakness. As the patient becomes severely dehydrated, the skin becomes dry and loose, and the eye sockets become sunken. Nausea and vomiting are common symptoms. Abdominal pain is occasionally seen. This may be owing to dehydration of muscle tissue, delayed gastric emptying, and ileus induced by electrolyte disturbance and metabolic acidosis (Sanuth, Bidlencik, & Volk, 2014). Finally, Kussmaul's respiration (rapid, deep breathing associated with dyspnea) is the body's attempt to reverse metabolic acidosis through the exhalation of excess carbon dioxide. Acetone is noted on the breath as a sweet, fruity odour. (See Chapter 19 for a discussion of respiratory compensation of metabolic acidosis.) Laboratory findings include a blood glucose level above 14 mmol/L, arterial blood pH below 7.35, serum bicarbonate level less than 15 mmol/L, anion gap greater than 12 mmol/L, and ketones in the blood and urine (CDA, 2013a).

Collaborative Care

Before the advent of self-monitoring of blood glucose and β-hydroxybutyrate (capillary blood ketones), all patients with DKA required

hospitalization for treatment. Today, hospitalization may not be required. In instances in which fluid and electrolyte imbalances are not severe and blood glucose levels can be safely monitored at home, early stages of DKA may be managed on an outpatient basis (Table 52-16). However, the decision about where the patient is managed must also take other factors into consideration. These factors include the presence of fever, nausea, vomiting, and diarrhea; altered mental status; nature of the cause of the ketoacidosis; and availability of frequent communication (every few hours) with the health care provider.

TABLE 52-16

COLLABORATIVE CARE
Diabetic Ketoacidosis (DKA) and Hyperosmolar Hyperglycemic State (HHS)

Diagnostic
• History and physical examination • Blood studies, including immediate blood glucose, complete blood count, ketones, pH, electrolytes, blood urea nitrogen, arterial blood gases • Urinalysis, including specific gravity, pH, glucose, ketones
Collaborative Therapy
• Administration of IV fluids • Assessment of blood and urine for ketones • Assessment of blood glucose levels • Assessment of cardiovascular and respiratory status • Assessment of mental status • Central venous pressure monitoring (if indicated) • ECG monitoring • Electrolyte replacement • IV administration of short-acting insulin • Recording of intake and output

ECG, electrocardiogram; *IV*, intravenous.

Regardless of the setting in which it occurs, DKA is a serious condition that proceeds rapidly and must be treated promptly. (Table 52-17 describes the emergency management of a patient with DKA.) Because fluid imbalance is potentially life-threatening, the initial goal of therapy is to establish IV access and begin fluid and electrolyte replacement. Typically, the initial fluid therapy regimen comprises an infusion of 0.45% or 0.9% NaCl IV solution at a rate to restore urine output to 30 to 60 mL/hr and to raise blood pressure. When blood glucose levels approach 14 mmol/L, 5% dextrose is added to the fluid regimen to prevent hypoglycemia (Westerberg, 2013; CDA, 2013a).

TABLE 52-17

EMERGENCY MANAGEMENT
Diabetic Ketoacidosis

Etiology	Assessment Findings	Interventions
• Change in diet, insulin, or exercise regimen • Dehydration owing to illness with vomiting or diarrhea • Inadequate treatment of existing diabetes mellitus • Infection • Insulin not taken as prescribed, or omitted • Undiagnosed diabetes mellitus	• Abdominal pain • Breath odour of acetone • Dry mouth • Eyes that appear sunken • Fever • Flushed, dry skin • Glucosuria and ketonuria • Gradually increasing restlessness, confusion, lethargy • Laboured breathing (Kussmaul's respiration) • Nausea and vomiting • Oral or vaginal *Candida albicans* (yeast infection) • Rapid, weak pulse; orthostatic hypotension • Serum glucose >14 mmol/L • Thirst • Urinary frequency	Initial • Administer IV sodium bicarbonate if severe acidosis (pH <7.0). • Administer oxygen as per physician's order. • Administer potassium IV to correct hypokalemia. • Begin continuous regular insulin drip 0.1 units/kg/hr, as needed. • Begin fluid resuscitation with 0.9% NaCl solution until BP stabilized and urine output 30–60 mL/hr. • Ensure patent airway. • Establish IV access with large-bore catheter. • Identify history of diabetes, time of last food, and time and amount of last insulin injection. Ongoing Monitoring • Assess breath sounds for fluid overload. • Monitor serum glucose, pH, and serum potassium. • Monitor vital signs, level of consciousness, cardiac rhythm, oxygen saturation, and urine output.

BP, blood pressure; *IV*, intravenous.

The aim of fluid and electrolyte therapy is to replace extracellular and intracellular water and to correct deficits of sodium, chloride, bicarbonate, potassium, phosphate, magnesium, and nitrogen. Early potassium replacement is essential because hypokalemia is a significant cause of preventable death during treatment of DKA. Although initial serum potassium may be normal or high, levels can rapidly decrease once therapy starts because insulin drives potassium into the cells, leading to life-threatening hypokalemia.

IV insulin administration is therapy directed toward correcting hyperglycemia and hyperketonemia. Insulin therapy is withheld until fluid resuscitation is under way and serum potassium is greater than 3.3 mmol/L because insulin allows water and potassium to enter the cell along with glucose and can lead to a depletion of vascular volume and hypokalemia. Initially, a bolus of insulin is delivered, followed by a continuous infusion (CDA, 2013a).

Safety Alert

- Too-rapid administration of IV fluid and a rapid lowering of serum glucose can lead to cerebral edema.

Hyperosmolar Hyperglycemic State

Hyperosmolar hyperglycemic state (HHS) is a life-threatening syndrome that can occur in the patient with DM who is able to produce enough insulin to prevent DKA but not enough to prevent severe hyperglycemia, osmotic diuresis, and extracellular fluid depletion (Figure 52-13). HHS is less common than DKA. The main difference between HHS and DKA is that the patient with HHS usually has enough circulating insulin so that ketoacidosis does not occur. Because HHS produces fewer symptoms in the earlier stages, blood glucose levels can climb quite high before the problem is recognized. The higher blood glucose levels increase serum osmolality and produce more-severe neurological manifestations, such as somnolence, coma, seizures, hemiparesis, and aphasia. HHS often occurs in the older-adult patient with type 2 DM and is often related to impaired thirst sensation, a functional inability to replace fluids, or both. There is usually a history of inadequate fluid intake, increasing mental depression, and polyuria. Laboratory values in HHS include blood glucose greater than 34 mmol/L and a marked increase in serum osmolality. Ketone bodies are absent or minimal in both blood and urine.

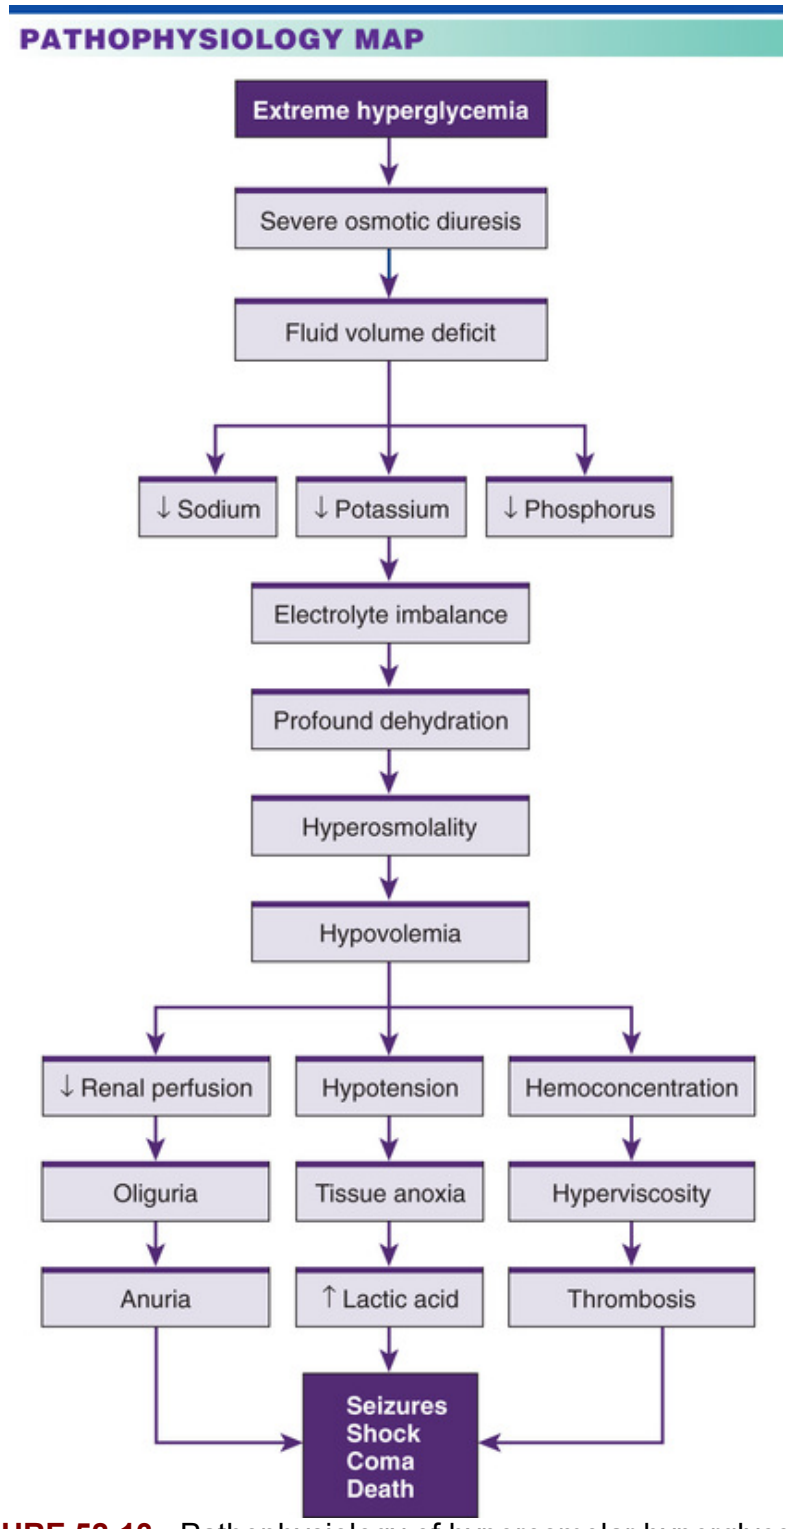

FIGURE 52-13 Pathophysiology of hyperosmolar hyperglycemic state (HHS). Source: Redrawn from Urden, L. D., Stacy, K. M., & Lough, M. E. (2014). *Critical care nursing: Diagnosis and management* (7th ed., p. 828, Figure 33-4). St. Louis: Mosby.

Collaborative Care

HHS constitutes a medical emergency and has a high mortality rate. Therapy is similar to that for the treatment of DKA and includes immediate IV administration of either 0.9% or 0.45% NaCl at a rate that is dependent on cardiac status and the degree of fluid volume deficit. Regular insulin is given by IV bolus, followed by an infusion after fluid replacement therapy is instituted to aid in reducing the hyperglycemia. When blood glucose levels fall to approximately 14 mmol/L, IV fluids containing glucose are administered to prevent hypoglycemia. Electrolytes are monitored and replaced as needed. Hypokalemia is not as significant in HHS as it is in DKA, although fluid losses may result in milder potassium deficits that necessitate replacement. Vital signs, intake and output, tissue turgor, laboratory values, and cardiac monitoring are assessed to monitor the efficacy of fluid and electrolyte replacement. Patients with renal or cardiac compromise require special monitoring to avoid fluid overload during fluid replacement. This includes monitoring of serum osmolality and frequent assessment of cardiac, renal, and neurological status (CDA, 2013a).

The management for both DKA and HHS is similar, except that HHS necessitates greater fluid replacement (see Table 52-16). Once the patient is stabilized, attempts to detect and correct the underlying precipitating cause should be initiated.

Nursing Management Diabetic Ketoacidosis and Hyperosmolar Hyperglycemic State

When hospitalized, the patient is closely monitored with appropriate blood and urine tests. The nurse is responsible for monitoring blood glucose and urine for output and ketones as well as for using laboratory data to support care.

Nursing responsibilities include monitoring the administration of IV fluids to correct dehydration, insulin therapy to reduce blood glucose and serum ketones, and electrolytes to correct electrolyte imbalance; assessment of renal status; assessment of the cardiopulmonary status related to hydration and electrolyte levels; and monitoring of the level of consciousness.

The nurse must also monitor the signs of potassium imbalance resulting from hypoinsulinemia and osmotic diuresis (see Chapter 19). When treatment for hyperglycemia is begun with insulin, serum potassium levels may decrease rapidly because potassium moves into the cells once insulin becomes available. This movement of potassium into and out of extracellular fluid influences cardiac functioning. Cardiac monitoring is a useful aid in detecting hyperkalemia and hypokalemia because characteristic changes indicating potassium excess or deficit are observable on electrocardiogram (ECG) tracings (see Chapter 19, Figure 19-14). Vital signs should be assessed often to determine the presence of fever, hypovolemic shock, tachycardia, and Kussmaul's respiration (Westerberg, 2013).

Hypoglycemia

Hypoglycemia, or low blood glucose, occurs when there is too much insulin in proportion to available glucose in the blood. This causes the blood glucose level to drop to less than 4 mmol/L. Once plasma glucose drops to this level, neuroendocrine hormones are released and the autonomic nervous system is activated. Suppression of insulin secretion and production of glucagon and epinephrine provide defence against hypoglycemia. Epinephrine release causes manifestations that include diaphoresis, tremors, hunger, nervousness, anxiety, pallor, and palpitations. As a primary energy source, the brain requires a constant

supply of glucose in sufficient quantities to function properly; therefore, hypoglycemia can eventually affect cognitive functioning. These manifestations are referred to as *neuroglycopenic signs* and may include irritability, visual disturbances, difficulty speaking, stupor, confusion, and coma. Manifestations of hypoglycemia can mimic alcohol intoxication. Untreated hypoglycemia can progress to loss of consciousness, seizures, coma, and death.

Hypoglycemic unawareness (or *asymptomatic hypoglycemia*) is a condition in which patients do not experience the usual autonomic nervous system warning signs and symptoms of hypoglycemia, increasing their risk for dangerously low blood glucose levels. This condition is often related to autonomic neuropathy of DM that interferes with the secretion of counter-regulatory hormones that produce these symptoms. Older-adult patients and patients who use β-adrenergic blockers are also at risk for hypoglycemic unawareness. For patients with risk factors for hypoglycemic unawareness, it is usually not safe to aim for tight blood glucose control owing to the increased potential of hypoglycemia. They are usually managed with blood glucose goals that are somewhat higher than patients who are able to detect and manage the onset of hypoglycemia.

Hypoglycemic symptoms may occur when a very high blood glucose level falls too rapidly, for example, a blood glucose level of 16 mmol/L falling quickly to 8 mmol/L. Although the blood glucose level is above normal by definition and measurement, the sudden metabolic shift can evoke hypoglycemic symptoms. Too-vigorous management of hyperglycemia with insulin can induce this type of situation.

Causes of hypoglycemia are often related to a mismatch in the timing of food intake and the peak action of insulin or OHAs that increase endogenous insulin secretion. The balance between blood glucose and insulin can be disrupted by the administration of too much insulin or medication, the ingestion of insufficient carbohydrates, delaying the time of eating, and performing unusual amounts of exercise. Insulin reactions can occur at any time, but most occur when the OHA or insulin is at its peak of action. Although hypoglycemia is more common with insulin therapy, it can occur with OHAs and may be severe and persist for an extended time because of the longer duration of action.

Nursing and Collaborative Management Hypoglycemia

Hypoglycemia can usually be quickly reversed with effective and rapid treatment. At the first sign of hypoglycemia, the blood glucose should be checked if possible (Table 52-18). If it is below 4 mmol/L, the patient should begin treatment immediately. If the blood glucose is above 4 mmol/L, other causes of the signs and symptoms should be investigated. If the patient has manifestations of hypoglycemia and monitoring equipment is not available, hypoglycemia should be assumed and treatment should be initiated.

TABLE 52-18

COLLABORATIVE CARE
Hypoglycemia

Diagnostic
• Capillary blood glucose (evaluated and reported on an emergency basis) • History (if possible) and physical examination
Collaborative Therapy
• Determination of cause of hypoglycemia (after correction of condition)
Conscious Patient With Mild to Moderate Hypoglycemia
• Administration of 15–20 g of fast-acting (simple) carbohydrate (e.g., commercial dextrose products [per label instructions]; 175 mL of fruit juice or regular soft drink; 6–8 Life Savers; for patient taking acarbose: 15 mL (1 tbsp) syrup or honey, or 125–150 mL low-fat milk, or dextrose tabs (because the absorption of glucose itself is not affected)* • Recheck of blood glucose in 15 minutes; if no improvement, repetition of treatment of 15–20 g of carbohydrate • Administration of additional food or longer-acting combination such as carbohydrate plus protein or fat (e.g., crackers with peanut butter or cheese) after symptoms subside, if meal is longer than 1 hr away • Immediate notification of health care provider or emergency service (if patient is outside hospital) if symptoms do not subside after two or three administrations of fast-acting carbohydrate
Severe Hypoglycemia or Unconscious Patient
• Intravenous administration of 20–50 mL of dextrose 50% in water (D50W) given over 1–3 min • Subcutaneous or intramuscular injection of 1 mg glucagon

*Canadian Diabetes Association (CDA) Clinical Practice Guidelines Expert Committee. (2013). 2013 Clinical practice guidelines for the prevention and management of diabetes in Canada. *Canadian Journal of Diabetes Care*, *37*(Suppl), S70.

Hypoglycemia is treated by ingesting 15 to 20 g of a simple (fast-acting) carbohydrate, such as three or four glucose tablets, 175 mL of fruit juice or regular soft drink, or six Life Savers candies. Commercial products such as gels or tablets containing specific amounts of glucose are convenient for carrying in a purse or pocket to be used in such situations.

Treatment with sweet foods containing fat, such as chocolate bars, cookies, and ice cream, should be avoided because fat will slow down the absorption of the sugar and delay the response to treatment. Overtreatment with large quantities of simple carbohydrates should be avoided to prevent a rapid fluctuation to hyperglycemia. A prompt but moderate approach is best. Blood glucose should be checked 15 minutes after the initial treatment and repeated if blood glucose remains lower than 4 mmol/L. Once the blood glucose is greater than 4 mmol/L, the patient should eat a snack if the next regularly scheduled meal is more than an hour away in order to prevent hypoglycemia from recurring. Good snacks include one protein and one starch choice such as a peanut butter sandwich, cheese and crackers, or cereal and milk. Blood glucose should also be checked again about 45 minutes after eating the snack to ensure that hypoglycemia is not recurring (CDA, 2013a).

If there is no significant improvement in the patient's condition after two to three doses of 15 to 20 g of simple carbohydrate or if the patient is not alert enough to swallow, 1 mg of glucagon may be administered by intramuscular or subcutaneous injection. Glucagon stimulates a strong hepatic response to convert glycogen to glucose, making glucose rapidly available. Rebound hypoglycemia is a potential adverse effect of glucagon. Having the patient ingest a starch snack after recovery may prevent this from happening. Patients with minimal glycogen stores will not respond to glucagon. These include patients with alcohol-related hepatic disease, starvation, and adrenal insufficiency. In an acute care setting, patients with hypoglycemia are treated with 20 to 50 mL of 50% dextrose by IV push.

Once the hypoglycemic episode has resolved, the nurse should explore with the patient the reasons why the situation developed. This assessment may indicate the need for additional education of the patient and the family to prevent future episodes of hypoglycemia. The danger of hypoglycemic episodes must be stressed; safety concerns include risks such as driving a motorized vehicle or bicycle, operating heavy machinery, and falls; these episodes also have a long-term impact upon memory.

Chronic Complications of Diabetes Mellitus

Chronic complications of DM are primarily those of end-organ disease that result from damage to the large and small blood vessels (angiopathy) secondary to chronic hyperglycemia (Figure 52-14). Angiopathy, or blood vessel disease, is estimated to account for the majority of deaths among patients with DM. These chronic blood vessel dysfunctions are divided into two categories: *macrovascular complications* and *microvascular complications.*

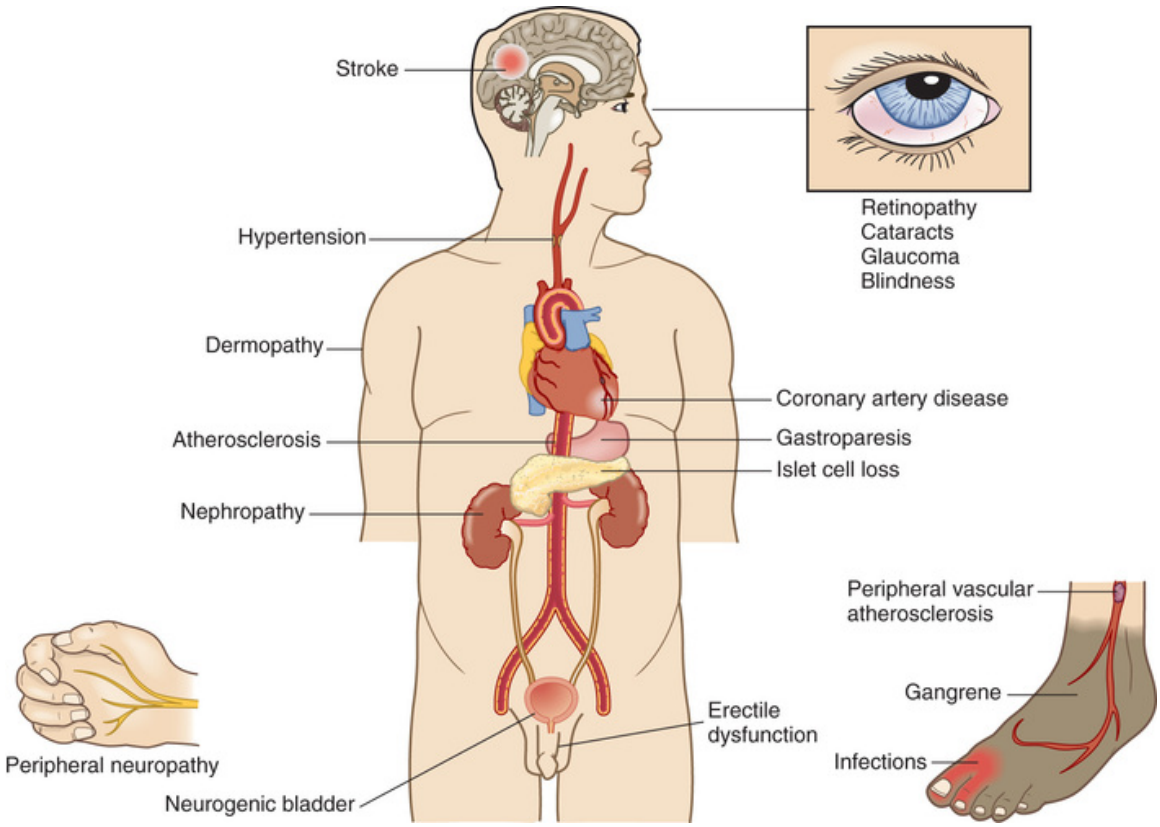

FIGURE 52-14 Long-term complications of diabetes mellitus. Source: Kumar, V., Abbas, A. K., & Aster, J. (2015). *Robbins and Cotran pathologic basis of disease* (9th ed., p. 1116, Figure 24-34). Philadelphia: Saunders.

Several theories exist as to how and why chronic hyperglycemia damages cells and tissues. Possible causes include (1) the accumulation of damaging by-products of glucose metabolism, such as sorbitol, which is

associated with damage to nerve cells; (2) the formation of abnormal glucose molecules in the basement membrane of small blood vessels such as those that circulate to the eye and the kidney; and (3) a derangement called *oxidative stress* in RBC function that leads to a decrease in oxygenation to the tissues.

The Diabetes Control and Complication Trial (DCCT) was a landmark study that has greatly influenced DM management since its results were announced in 1993 (DCCT Research Group, 1993). This study demonstrated that, in patients with type 1 DM, the risk for microvascular complications could be significantly reduced by keeping blood glucose levels as near to normal as possible for as much of the time as possible (intensive insulin therapy). In this study, patients were randomly assigned to one of two groups: intensive or standard treatment. The intensive treatment group took three or more insulin injections a day or used an insulin pump and tested their blood glucose four to five times a day. The patients in the standard treatment group took one to two injections a day and tested their blood glucose once or twice a day. The average A_{1c} in the intensive treatment group was 7.2%; in the standard treatment group, it was 9%. (The normal range for A_{1c} in a person without DM is 4% to 6%.) The results showed that the subjects in the intensive therapy group reduced their risk for the development of retinopathy, nephropathy, and peripheral neuropathy. The adverse effects associated with intensive therapy were an increase in frequency of hypoglycemic episodes and weight gain.

Based on the findings of the DCCT Research Group (1993), the CDA *Clinical Practice Guidelines* (2013a) included recommendations for treatment goals to maintain blood glucose levels as near to normal as possible in most people with diabetes. Specific targets for individual patients must take into account the risk for severe or undetected hypoglycemia as an adverse effect of tight glucose control.

The United Kingdom Prospective Diabetes Study (UKPDS) demonstrated that intensive treatment of type 2 DM with OHAs alone, OHAs in combination with insulin, or insulin alone, can also significantly lower the risk of developing DM-related microvascular complications such as retinopathy, nephropathy, and neuropathy. The findings from this study showed a 25% reduction of microvascular disease in subjects who maintained long-term glycemic control, including a 1% reduction in A_{1c}, regardless of the initial value (UKPDS, 1998).

Because of the devastating effects of long-term complications, patients with DM require scheduled and ongoing monitoring for the detection and

prevention of chronic complications. The recommendations for ongoing evaluation are listed in Table 52-19. It is imperative that patients understand the importance of regular follow-up examinations (CDA, 2013a).

TABLE 52-19

MONITORING FOR LONG-TERM COMPLICATIONS OF DIABETES MELLITUS*

Complication	Type of Examination	Frequency
Retinopathy	Funduscopic–dilated-eye examination by experienced professional	*Type 1:* annually, starting 5 yr after onset of diabetes *Type 2:* at diagnosis; then every 1–2 yr if normal
Nephropathy	Random urinalysis for albumin-to-creatinine ratio (ACR), serum creatinine converted to eGFR	*Type 1:* annually; if no CKD, starting 5 yr after onset of diabetes *Type 2:* at diagnosis and then annually if normal; if CKD present, ACR and eGFR at least every 6 mo
Neuropathy (foot and lower extremities)	Visual examination of foot Comprehensive foot examination: assessment of structural abnormalities, neuropathy (monofilament, tuning fork), vascular disease (peripheral pulses), ulcerations, and evidence of infection	Daily by patient Every visit by health care provider *Type 1:* annually, starting 5 yr after onset of diabetes *Type 2:* at diagnosis and annually
Cardiovascular disease	Blood pressure Lipid panel	Every visit At the time of diagnosis, and then every 1–3 yr
	ECG	Baseline and every 2 yr if >40 yr; >30 yr and duration >15 yr; end organ damage; cardiac risk factors

*Based on the recommendations of the Canadian Diabetes Association (CDA) Clinical Practice Guidelines Expert Committee. (2013). 2013 Clinical practice guidelines for the prevention and management of diabetes in Canada. *Canadian Journal of Diabetes Care, 37*(Suppl 1), S199.

CKD, chronic kidney disease; *ECG,* electrocardiogram; *eGFR*, estimated glomerular filtration rate.

Macrovascular Complications

Macrovascular complications are diseases of the large and medium-sized blood vessels; these complications occur with greater frequency and with an earlier onset in people with DM. Although atherosclerotic plaque formation is believed to have a genetic origin, its development seems to be

promoted by the altered lipid metabolism common to DM. Tight glucose control may help delay the atherosclerotic process (DCCT Research Group, 1993; UKPDS, 1998). Macrovascular diseases include cerebro-vascular, cardiovascular, and peripheral vascular disease. Adults with DM have two to three times the risk for heart and cerebro-vascular disease of those without DM (CDA, 2013a). Although genetic makeup cannot be altered, strategies for vascular protection are recommended and include health behaviour interventions such as healthy eating, weight modification, smoking cessation, and increased physical activity. Smoking is associated with significantly increased risks for total mortality, cardiovascular events, and lower extremity amputation in those with DM. The cessation of smoking reduces cardiovascular risk and the risk for renal disease and improves glycemic control (CDA, 2013a; Pan, Wang, Talaei, et al., 2015). (Smoking is discussed in Chapter 11.) The addition of an angiotensin-converting enzyme (ACE) inhibitor; antiplatelet therapy such as acetylsalicylic acid (ASA; Aspirin); and lipid, blood pressure, and glycemic control are pharmacological interventions that protect the heart and will reduce mortality risk by 50% in patients with type 2 DM (Gaede, Lund-Anderson, Parving, et al., 2008). Optimizing blood pressure control in patients with DM is significant for the prevention of cardiovascular and renal disease. The target blood pressure for people with DM is 130/80 mm Hg.

Insulin resistance seems to play an important role in the development of cardiovascular disease and is implicated in the pathogenesis of essential hypertension and dyslipidemia. The term *metabolic syndrome* is applied to the clinical association of insulin resistance, hypertension, and increased very-low-density lipoprotein (VLDL) and decreased HDL cholesterol concentrations. The role of insulin resistance in the pathogenesis of cardiovascular disease is not well understood, but it seems to combine with dyslipidemia in contributing to greater risk for cardiovascular disease in patients with DM. All patients with DM should be screened for dyslipidemia at the time DM is diagnosed. Most people with DM are considered at high risk for a vascular event (CDA, 2013a).

Lifestyle changes such as healthy eating and exercise are first-line interventions to achieve an optimal lipid profile. If unsuccessful, lipid-lowering therapy such as statins, fibrates, or both may be added to optimize lipid levels, thereby reducing risk for a vascular event.

Microvascular Complications

Microvascular complications result from thickening of the vessel membranes in the capillaries and arterioles in response to conditions of chronic hyperglycemia. They differ from macrovascular complications in that they are specific to DM. Although microangiopathy can be found throughout the body, the areas most noticeably affected are the eyes (retinopathy), the kidneys (nephropathy), the nerves (neuropathy), and the skin (dermopathy). Thickening of the basement membrane has been found in some people with type 2 DM before or at the time of diagnosis or before the onset of symptoms of DM. However, clinical manifestations may not appear until 10 to 20 years after the onset of DM, depending on the glycemic control over that period of time as measured by A_{1c}.

Diabetic Retinopathy

Etiology and Pathophysiology

Diabetic retinopathy refers to the process of microvascular damage to the blood vessels in the retina as a result of chronic hyperglycemia, presence of nephropathy, and hypertension in patients with DM. After 15 years with DM, nearly all patients with type 1 DM and 80% with type 2 DM will have some degree of retinal disease. Diabetic retinopathy is estimated to be the most common cause of new cases of blindness in people of working age (CDA, 2013a; ADA, 2011).

Retinopathy can be classified as nonproliferative or proliferative. In *nonproliferative retinopathy,* the most common form, partial occlusion of the small blood vessels in the retina causes the development of microaneurysms in the capillary walls. The walls of these microaneurysms are so weak that capillary fluid leaks out, causing retinal edema and eventually hard exudates or intraretinal hemorrhages. Vision may be affected if the macula is involved.

Proliferative retinopathy, the most severe form, involves the retina and the vitreous. When retinal capillaries become occluded, the body compensates by forming new blood vessels to supply the retina with blood, a pathological process known as *neovascularization.* These new vessels are extremely fragile and hemorrhage easily, producing vitreous contraction. Eventually, light is prevented from reaching the retina as the vessels become torn and bleed into the vitreous cavity. The patient sees black or red spots or lines. If these new blood vessels pull the retina while the vitreous contracts, causing a tear, partial or complete retinal detachment will occur. If the macula is involved, vision is lost. Without treatment,

more than half of patients with proliferative diabetic retinopathy will be blind.

Collaborative Care

The earliest and most treatable stages of diabetic retinopathy often produce no changes in the vision. Because of this, the patient with DM must have regular dilated-eye examinations by an ophthalmologist or a specially trained optometrist for early detection and treatment. The best approach to the management of diabetic eye disease is to prevent it by maintaining good glycemic and blood pressure control.

The most common forms of treatment for diabetic retinopathy are early laser photocoagulation therapy of the retina, vitrectomy and intraocular injection of pharmacological agents. Photocoagulation by laser destroys the ischemic areas of the retina that produce growth factors that encourage neovascularization, thereby preventing further vision loss, and reduces legal blindness up to 90% in people with severe nonproliferative retinopathy and proliferative retinopathy (CDA, 2013a). (Photocoagulation is discussed in Chapter 24.)

Vitrectomy is the aspiration of blood, membrane, and fibres from the inside of the eye through a small incision just behind the cornea. Vitrectomy is indicated in patients with advanced proliferative retinopathy with vitreous hemorrhage or retinal detachment of the macula. (Vitrectomy is discussed in Chapter 24.)

Recent research has identified the importance of vascular endothelial growth factor (VEFG) in the development of diabetic retinopathy. Three anti-VEFG drugs are now widely used in Canada to treat diabetic retinopathy: aflibercept (Eylea), bevacizumab (Avastin), and ranibizumab (Lucentis) (Canadian Agency for Drugs and Technologies in Health [CADTH], 2016). Bevacizumab (Avastin) is used in an expanded or off-label manner but has not been approved by Health Canada for this purpose (CADTH, 2016).

People with DM are also prone to other visual problems. Glaucoma occurs as a result of the occlusion of the outflow channels, secondary to neovascularization. This type of glaucoma is difficult to treat and often results in blindness. Cataracts develop at an earlier age and progress more rapidly in people with DM.

Nephropathy

Diabetic nephropathy is a microvascular complication associated with damage to the small blood vessels that supply the glomeruli of the kidney. It is the leading cause of end-stage renal disease (ESRD) in Canada. The risk for nephropathy is similar in patients with either type 1 or type 2 DM. Risk factors for the development of diabetic nephropathy include hypertension, genetic predisposition, smoking, and chronic hyperglycemia. Results of the DCCT and UKPDS studies have demonstrated that kidney disease can be significantly reduced when near-normal blood glucose control is achieved and maintained (DCCT Research Group, 1993; UKPDS, 1998).

Hypertension significantly accelerates the progression of diabetic nephropathy and retinopathy and the risk for stroke. Therefore, aggressive blood pressure management is indicated for all patients with DM. ACE-inhibitor drugs (e.g., ramipril [Altace]) and angiotensin II receptor blockers (e.g., losartan [Cozaar]) are commonly prescribed to patients with DM because they are effective blood pressure–lowering agents with few adverse effects. In addition, both these drugs are often prescribed to patients with DM even when they are not hypertensive because drugs in either class have a protective effect on the kidney that prevents the progression of diabetic nephropathy independent of hypertension control (CDA, 2013a). (See Chapter 35 for a discussion of hypertension and Chapter 49 for a discussion of renal failure.)

Standards for the prevention and detection of nephropathy in patients with DM include yearly screening for the presence of microalbuminuria (MAU). This test detects kidney damage at an earlier stage than the standard dipstick test for macroprotein in the urine. Screening for MAU should be performed using a random urine for albumin-to-creatinine ratio (ACR) and serum creatinine for estimated glomerular filtration rate (eGFR). A 24-hour urine collection for determination of creatinine clearance and serum creatinine may be performed when there is doubt about the accuracy of an eGFR (CDA, 2013a).

Neuropathy

Diabetic neuropathy is nerve damage that occurs because of the metabolic derangements associated with DM. About 40% to 50% of patients with DM have some degree of neuropathy, with neurological complications occurring equally in type 1 and type 2 DM (CDA, 2013a). The most common type of neuropathy affecting people with DM is peripheral sensory neuropathy. This condition can lead to the loss of protective

sensation in the lower extremities, and, coupled with other factors, peripheral sensory neuropathy significantly increases the risk for complications that can result in a lower limb amputation. Although, amputation rates for people with diabetes have decreased in the past decade, they remain very high compared with rates for those without diabetes. (CDA, 2013a).

Etiology and Pathophysiology

The pathophysiological processes of diabetic neuropathy are not well understood. Several theories exist, including metabolic, vascular, and autoimmune elements. The prevailing theory suggests that persistent hyperglycemia leads to an accumulation of sorbitol and fructose in the nerves that causes damage by an unknown mechanism. The result is reduced nerve conduction and demyelinization. Ischemia in blood vessels damaged by chronic hyperglycemia that supply the peripheral nerves is also implicated in the development of diabetic neuropathy. Neuropathy can precede, accompany, or follow the diagnosis of DM.

Classification

The two major categories of diabetic neuropathy affect the peripheral nervous system: sensory neuropathy (which affects the somatic division) and autonomic neuropathy (which affects the autonomic division). Each of these types can take on several forms.

Sensory Neuropathy.

The most common form of sensory polyneuropathy is distal symmetrical neuropathy, which affects the hands, the feet, or both, bilaterally. This condition is sometimes referred to as *stocking-glove neuropathy.* Characteristics of distal symmetrical neuropathy include paresthesias, abnormal sensations, pain, and loss of sensation. The paresthesias may be associated with tingling, burning, and itching sensations. The patient may report a feeling of walking on pillows or numb feet. At times, the skin becomes so sensitive (hyperesthesia) that even light pressure from bed sheets cannot be tolerated. Complete or partial loss of sensitivity to touch and temperature is common. The pain, which is often described as burning, cramping, crushing, or tearing, is usually worse at night and may occur only at that time. Foot injury and ulcerations can occur without the patient ever having pain (Figure 52-15). Neuropathy can also cause

atrophy of the small muscles of the hands and feet, causing deformity and limiting fine movement.

FIGURE 52-15 Neuropathy: neurotrophic ulceration. Source: Urden, L. D., Stacy, K. M., & Lough, M. E. (2009). *Thelan's critical care nursing: Diagnosis and management* (6th ed.). St. Louis: Mosby.

Control of blood glucose is the only treatment for diabetic neuropathy. It is effective in many, but not all, cases. Drug therapy may be used to treat neuropathic symptoms, particularly pain. Medications commonly used include topical creams (e.g., capsaicin), tricyclic antidepressants (e.g., amitriptyline [Elavil]), selective serotonin and norepinephrine reuptake inhibitors (e.g., duloxetine [Cymbalta]), and antiseizure medications (e.g., gabapentin [Neurontin]; pregabalin [Lyrica]). Capsaicin is a moderately effective topical cream made from chili peppers. It depletes the accumulation of pain-mediating chemicals in the peripheral sensory neurons. The cream is applied with gloves three to four times a day. There is usually an increase in symptoms at the start of therapy, which is followed by relief of pain in 2 to 3 weeks. Tricyclic antidepressants are also moderately effective in treating the symptoms of diabetic neuropathy. They work by inhibiting the reuptake of norepinephrine and serotonin, which are neurotransmitters that are believed to play a role in the transmission of pain through the spinal cord (Kaur, Hota, Bhansali, et al., 2011). Duloxetine is thought to relieve pain by increasing the levels of serotonin and norepinephrine, which improves the body's ability to regulate pain. Although gabapentin has been found to be effective in

treating the pain of diabetic neuropathy, its mechanism of action is not well understood.

Autonomic Neuropathy.

Autonomic neuropathy can affect nearly all body systems and lead to hypoglycemic unawareness, bowel incontinence and diarrhea, and urinary retention. Delayed gastric emptying (gastro-paresis) is a complication of autonomic neuropathy that can produce anorexia, nausea, vomiting, gastro-esophageal reflux, and persistent feelings of fullness. Gastro-paresis can trigger hypoglycemia by delaying food absorption. Cardiovascular abnormalities associated with autonomic neuropathy are postural hypotension, resting tachycardia, and "silent" or painless myocardial infarction. A patient with postural hypotension should be instructed to change slowly from a lying or sitting position to a standing position.

DM can affect sexual function in men and women. Erectile dysfunction in men with diabetes is well recognized and common, often being the first manifestation of autonomic failure. Erectile dysfunction associated with DM is believed to result from damage to the sacral parasympathetic nerves. Determining whether this problem is of organic or psychological origin is an important part of the assessment. Decreased libido is a problem for some women with DM. Monilial and nonspecific vaginitis are also common. Organic erectile dysfunction or sexual dysfunction in either the male or the female patient requires sensitive therapeutic counselling for both the patient and the patient's partner (Bella, Lee, Carrier, et al., 2015). (See Chapter 57 for a further discussion of erectile dysfunction.)

A neurogenic bladder may develop as sensation in the inner bladder wall decreases, causing urinary retention. A patient with retention has infrequent voiding, difficulty in voiding, and a weak stream of urine. Emptying the bladder every 3 hours in a sitting position helps prevent stasis and subsequent infection. Tightening the abdominal muscles during voiding and using Credé manoeuvre (mild massage downward over the lower abdomen and bladder) may also help with complete bladder emptying. Cholinergic agonist drugs such as bethanechol (Duvoid) may be used. The patient may also have to learn self-catheterization (see Chapter 48).

Complications of the Foot and the Lower Extremity

In Canada, people with diabetes are approximately 20 times more likely to be hospitalized for nontraumatic lower limb amputations than those

without diabetes (Kuhnke, Botros, Elliott, et al., 2013). The development of diabetic foot complications is a multifactorial process (RNAO, 2013). Complications result from a combination of microvascular and macrovascular diseases that place the patient at risk for injury and serious infection that may lead to amputation (Figure 52-16). Sensory neuropathy and peripheral vascular disease (PVD) are risk factors, and clotting abnormalities, impaired immune function, and autonomic neuropathy also play important roles. Smoking is deleterious to the health of lower extremity blood vessels and increases the risk for amputation.

FIGURE 52-16 The necrotic toe developed as a complication of diabetes. **A,** Before amputation. **B,** After amputation. Source: Chew, S. L., & Leslie, D. (2006). *Clinical endocrinology and diabetes: An illustrated colour text.* Edinburgh: Churchill Livingstone.

Sensory neuropathy is a major risk factor for lower extremity amputation in the person with DM. Loss of protective sensation (LOPS) often prevents the patient from becoming aware that a foot injury has occurred. Improper footwear and injury from stepping on foreign objects while barefoot are common causes of undetected foot injury in the person with LOPS (Alexiadou & Doupis, 2012). Because the primary risk factor for

lower extremity amputation is LOPS, annual screening using a *monofilament* is an extremely important preventive measure. This is done by applying a thin, flexible filament to several spots on the plantar surface of the foot and toes and asking the patient to report if it is felt. Insensitivity to a 10-g Semmes-Weinstein monofilament has been shown to greatly increase the risk for diabetic foot ulcers that can lead to amputation. If the patient has LOPS, aggressive measures must be taken to teach the patient how to prevent foot ulceration. These measures include the selection of proper footwear, including prescription shoes. Other measures are to carefully avoid injury to the foot, practise diligent skin and nail care, inspect the foot thoroughly each day, and treat small problems promptly (CDA, 2013a; RNAO, 2013).

PVD increases the risk for amputation by causing a reduction in blood flow to the lower extremities. When blood flow is decreased, oxygen, white blood cells, and vital nutrients are not available to the tissues. Therefore, wounds take longer to heal and the risk for infection increases. Signs of PVD include intermittent claudication, pain at rest, cold feet, loss of hair, delayed capillary filling, and dependent rubor (redness of the skin that occurs when the extremity is in a dependent position). The disease is diagnosed by history, ankle–brachial index (ABI), and angiography. Management includes control or reduction of risk factors, particularly smoking, high saturated fat intake, and hypertension. Femoral bypass or graft surgery is indicated in some patients. Proper care of the feet is essential for patients with PVD. Guidelines for patient teaching are listed in Table 52-20.

TABLE 52-20

PATIENT & CAREGIVER TEACHING GUIDE
Foot Care

The following instructions should be included when teaching the patient and caregiver about foot care

1. Wash feet daily with a mild soap and warm water. Test water temperature with a thermometer or hands first.
2. Pat feet dry gently, especially between toes.
3. Examine feet daily for cuts; blisters; swelling; and red, tender areas. Do not depend on feeling sores. If eyesight is poor, have others inspect feet.
4. Use lanolin on feet to prevent skin from drying and cracking. Do not apply between toes.
5. Do not use commercial remedies or sharp blades to remove calluses or corns.
6. Cleanse cuts with warm water and mild soap, covering with clean dressing. Do not use iodine, rubbing alcohol, or strong adhesives.
7. Report skin infections or nonhealing sores to health care provider immediately.
8. Cut and file toenails even, with the rounded contour of the toes. Do not cut down corners. The best time to trim nails is after a shower or bath. See a foot care specialist if advice or treatment is needed.
9. Separate overlapping toes with cotton or lamb's wool.
10. Avoid open-toe, open-heel, and high-heel shoes. Leather shoes are preferred to synthetic ones. Wear slippers at home and shoes on the beach. Do not go barefoot. Shake out shoes before putting on.
11. Wear clean, absorbent (cotton or wool) socks or stockings that have not been mended. Coloured socks must be colourfast.
12. Do not wear socks or stockings that leave impressions, hindering circulation.
13. Do not use hot water bottles or heating pads to warm feet. Wear socks for warmth.
14. Guard against frostbite.
15. Exercise feet daily either by walking or by flexing and extending feet in suspended position. Avoid prolonged sitting, standing, and crossing of legs.

Source: Canadian Diabetes Association (CDA) Clinical Practice Guidelines Expert Committee. (2013). 2013 Clinical practice guidelines for the prevention and management of diabetes in Canada. *Canadian Journal of Diabetes*, *37*(Suppl.1), S1–S227.

The Doppler instrument is used to perform the ABI to diagnose the presence or degree of PVD. Similar to an electronic stethoscope, this device amplifies sound. The procedure is noninvasive and can measure blood pressure and blood flow velocity in the lower extremities. It can indicate areas of stenosis or occlusion and is useful as an indicator of the need for additional vascular tests. To determine location and extent of PVD, an angiography can be completed. Angiography is an invasive procedure and it provides information on the actual blood vessel condition.

Proper care of a diabetic foot ulcer is critical to prevention of infections. Management requires an interdisciplinary approach that addresses glycemic control, infection, lower extremity vascular status, and local wound care (CDA, 2013a). The fundamentals of good wound care involve an optimal wound environment, off-loading of the ulcer site, and in nonischemic wounds, regular debridement of nonviable tissue.

Neuropathic arthropathy, or *Charcot foot*, results in ligament softening and bony deformities that ultimately lead to joint dysfunction and foot drop. The pathogenesis of Charcot foot is not clear, but it is likely owing to a combination of mechanical and vascular factors resulting from

peripheral neuropathy and is mediated through an uncontrolled inflammation in the foot (Hordon, 2011; Rogers, Frykberg, Armstrong, et al., 2011; CDA, 2013a). Changes that occur with Charcot foot happen gradually and create an abnormal distribution of weight over the foot, further increasing the chances of developing an ulcer on the plantar aspect of the foot as new pressure points emerge. Neuropathic ulcers resemble a "BB-shot" or "punched-out" wound and are usually painless. This high-risk foot complication requires immediate attention such as foot radiographic studies and referral to a high-risk foot team of chiropody, orthopedic surgery, and plastic surgery specialists. Infection and subsequent amputation is a danger and necessitates the long-term use of antibiotics and weeks of avoidance of weight bearing on the affected limb (CDA, 2013a). Foot deformity should be recognized early and proper footwear fitted before ulceration occurs.

Integumentary Complications

The skin is often affected in patients with DM. *Acanthosis nigricans* is a dark, coarse, thickened skin predominantly seen in flexures and on the neck. Acanthosis nigricans is a risk factor for type 2 DM and is associated with hyperinsulinemia and insulin resistance (CDA, 2013a; Atwa et al., 2014). Skin disorders such as diabetic dermopathy and necrobiosis lipoidica diabeticorum are attributed to microangiopathy. Shin spots are brown spots located on the anterior surfaces of the lower extremities. They are harmless and painless and initially measure less than 1 cm in diameter. *Necrobiosis lipoidica diabeticorum* (Figure 52-17) is believed to be the result of the breakdown of collagen in the skin. It usually appears as red-yellow lesions, with atrophic skin that becomes shiny and transparent, revealing tiny blood vessels under the surface. Because the thin skin is prone to injury, special care must be taken to protect affected areas from injury and ulceration. This condition is not common, but it may appear before other clinical signs or symptoms of DM. It is more frequently seen in young women. *Granuloma annulare,* associated mainly with type 1 DM, is probably autoimmune in nature and forms partial rings of papules, often on the dorsal surface of hands and feet.

FIGURE 52-17 Necrobiosis lipoidica diabeticorum. Source: Chew, S. L., & Leslie, D. (2006). *Clinical endocrinology and diabetes: An illustrated colour text.* Edinburgh: Churchill Livingstone.

Infection

A patient with DM is more susceptible to infections than other patients are. The mechanisms for this phenomenon include a defect in the mobilization of inflammatory cells and an impairment of phagocytosis by neutrophils and monocytes. Organisms such as yeast thrive in a high–blood glucose environment. Thus, recurring or persistent infections such as *Candida albicans,* as well as boils and furuncles, in the undiagnosed patient often lead the health care provider to suspect DM. Loss of sensation (peripheral neuropathy) may delay the detection of an infection in the feet.

Persistent glycosuria may predispose to bladder infections, especially in patients with a neurogenic bladder. Decreased circulation resulting from angiopathy can prevent or delay the immune response. Antibiotic therapy has prevented infection from being a major cause of death in patients with DM. The treatment of infections must be prompt and vigorous.

Age-Related Considerations

Diabetes Mellitus

The prevalence of DM increases with age. A major reason for this is that the process of aging is associated with a reduction in beta-cell function, decreased insulin sensitivity, altered carbohydrate metabolism, and a progressive increase in A_{1c} (CDA, 2013a). Aging is also associated with a number of conditions that are more likely to be treated with medications that impair insulin action (e.g., corticosteroids, antihypertensives, phenothiazines). Undiagnosed and untreated DM is more common in the older adult, partly because many of the normal physiological changes of aging, such as visual changes and decreased glomerular filtration, resemble those of DM.

Although good glycemic control is important to people of all ages with DM, several factors are taken into account when determining glycemic goals for an older adult. One is that hypoglycemic unawareness is more common in this age group, making these patients more likely to suffer adverse consequences from blood glucose–lowering therapy. They may also have delayed psychomotor function that could interfere with the ability to treat hypoglycemia. Other factors to consider in establishing glycemic goals for the older-adult patient include the patient's own desire for treatment and other coexisting medical problems such as cognitive impairment. Compounding the challenge is that DM has been found to contribute to a greater rate of decline of cognitive function. Although it is generally agreed that treatment aiming for the same glycemic targets is indicated for otherwise healthy older adults as well as younger persons with DM to prevent acute complications and avoid unpleasant symptoms, strict glycemic control should be based on the degree of frailty (CDA, 2013a). Patients with moderate or advanced frailty have a reduced life expectancy and thus should have a less stringent glycemic target A_{1c} of <8.5%, as recommended by CDA 2013 clinical practice guidelines.

As for any group, healthy eating and exercise are recommended as therapy for older-adult patients with DM. This plan should take into account functional limitations that may interfere with physical activity and the ability to prepare meals. Because of the physiological changes that occur with aging, the therapeutic outcome for the older adult with DM who receives OHAs may be altered. The short-acting insulin secretagogues (e.g., repaglinide [GlucoNorm]) are usually well tolerated and appear to

have fewer adverse effects and fewer drug interaction problems than longer-acting insulin secretagogues (glyburide [Diabeta]). Other OHAs described earlier in this chapter may also be used in older-adult patients with DM. Insulin therapy may be instituted if OHAs are not effective. However, it is important to recognize that older-adult patients are more likely to have limitations in manual dexterity and visual acuity, both of which are necessary for accurate insulin administration (CDA, 2013a).

Patient teaching should be based on the individual's needs, using a slower pace with simple printed materials. It is important to include family or a support person in the teaching. The patient education issues for the older-adult patient include those related to vision, mobility, cognitive status, memory, functional ability, financial and social situation, the effect of multiple medications, eating habits, the potential for undetected hypoglycemia, and quality-of-life issues.

Case Study

Diabetic Ketoacidosis

Source: KreativeKolors/Shutterstock.com.

Patient Profile

Hector DeSouza, a 34-year-old male, was admitted to the emergency department after he was found unconscious in his apartment by his wife.

Subjective Data (Provided by Wife)

- Was diagnosed with type 1 DM 12 months ago
- Has had difficulty coping with the diagnosis and missed his last 2 follow-up appointments with his diabetes team.

- Was taking 50 units of insulin daily: 5 units of insulin lispro (Humalog) with breakfast, 5 units with lunch, and 10 units with dinner, plus 30 units of insulin glargine (Lantus) at bedtime
- Has history of gastro-enteritis for 1 week, with vomiting and anorexia
- Stopped taking insulin 2 days ago when he was unable to eat

Objective Data

Physical Examination

- Breathing is deep and rapid
- Acetone smell on breath
- Skin flushed and dry

Diagnostic Studies

- Blood glucose level of 40.5 mmol/L
- Blood pH of 7.26

Discussion Questions

1. Briefly explain the pathophysiology of the development of diabetic ketoacidosis (DKA) in this patient.
2. What clinical manifestations of DKA does Mr. DeSouza exhibit?
3. What factors precipitated Mr. DeSouza's DKA?
4. ***Priority decision:*** What is the priority nursing intervention for Mr. DeSouza?
5. What distinguishes this case history from one of hyperosmolar hyperglycemic state (HHS) or hypoglycemia?
6. ***Priority decision:*** What is the priority teaching that should be done with Mr. DeSouza and his family?
7. What role should Mr. DeSouza's wife have in the management of his diabetes?
8. ***Priority decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
9. ***Evidence-informed practice:*** Mr. DeSouza's wife asks if she should have given her husband insulin when he got sick. How should the

nurse respond?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Polydipsia and polyuria related to diabetes mellitus are primarily caused by which of the following?
   a. The release of ketones from cells during fat metabolism
   b. Fluid shifts resulting from the osmotic effect of hyperglycemia
   c. Damage to the kidneys from exposure to high levels of glucose
   d. Changes in red blood cells resulting from attachment of excessive glucose to hemoglobin
2. Which statement would be correct for a client with type 2 diabetes mellitus who is admitted to the hospital with pneumonia?
   a. The client must receive insulin therapy to prevent the development of ketoacidosis.
   b. The client has islet-cell antibodies that have destroyed the ability of the pancreas to produce insulin.
   c. The client has minimal or absent endogenous insulin secretion and requires daily insulin injections.
   d. The client may have sufficient endogenous insulin to prevent ketosis but is at risk for development of hyperosmolar hyperglycemic state.
3. Analyze the following diagnostic findings for a client with type 2 diabetes. Which of the following results will need further assessment?
   a. A_{1c} 9.0%
   b. FBG 7.2 mmol/L
   c. BP 126/80
   d. LDL cholesterol of 2.1 mmol/L
4. Which statement by the client with type 2 diabetes is accurate?
   a. “I am supposed to have a meal or snack if I drink alcohol.”
   b. “I am not allowed to eat any sweets because of my diabetes.”
   c. “I do not need to watch what I eat because my diabetes is not the bad kind.”
   d. “The amount of fat in my diet is not important. Only carbohydrates raise my blood sugar.”

5. The nurse is caring for a client with newly diagnosed type 1 diabetes. What information is essential to include in the client teaching before discharge from the hospital? *(Select all that apply)*
   a. Insulin administration
   b. Elimination of sugar from diet
   c. Need to reduce physical activity
   d. Use of a portable blood glucose monitor
   e. Hypoglycemia prevention, symptoms, and treatment
6. What is the priority action for the nurse to take if the client with type 2 diabetes complains of blurred vision and irritability?
   a. Call the physician.
   b. Administer insulin as ordered.
   c. Check the client's blood glucose level.
   d. Assess for other neurological symptoms.
7. A client with diabetes has a serum glucose level of 36 mmol/L and is unresponsive. Following assessment of the client, the nurse suspects diabetic ketoacidosis (DKA) rather than hyperosmolar hyperglycemic state (HHS), based on which finding?
   a. Polyuria
   b. Severe dehydration
   c. Rapid, deep respirations
   d. Decreased serum potassium
8. Which of the following are appropriate therapies for clients with diabetes mellitus? *(Select all that apply)*
   a. Use of diuretics to treat nephropathy
   b. Use of angiotensin-converting enzyme inhibitors to treat nephropathy
   c. Use of serotonin agonists to decrease appetite
   d. Use of laser photocoagulation to treat retinopathy
   e. Use of statins to treat dyslipidemia

1. b; 2. d; 3. a; 4. a; 5. a, d, e; 6. c; 7. c; 8. b, d, e.

CHAPTER 53

Nursing Assessment

Reproductive System

Written by, Kim K. Choma

Adapted by, Maureen A. Barry

LEARNING OBJECTIVES

1. Describe the structures and functions of the male and female reproductive systems.
2. Summarize the functions of the major hormones essential for functioning of the male and female reproductive systems.
3. Explain the physiological changes during the stages of sexual response for both a man and a woman.
4. Link the age-related changes of the male and female reproductive systems to the differences in assessment findings.
5. Identify significant subjective and objective data related to the male and female reproductive systems and information about sexual function that should be obtained from a patient.
6. Select the appropriate techniques to use in the physical assessment of the male and female reproductive systems.
7. Differentiate normal from common abnormal findings of a physical assessment of the male and female reproductive systems.
8. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the male and female reproductive systems.

menopause, p. 1333
menstrual cycle, p. 1332
mons pubis, p. 1330
nulliparous, p. 1329
spermatogenesis, p. 1326

Structures and Functions of the Male and Female Reproductive Systems

Both the male and female reproductive systems consist of primary (or essential) organs and secondary (or accessory) organs. The primary reproductive organs are referred to as gonads**.** The female gonads are the ovaries; the male gonads are the testes. The primary responsibility of the gonads is secretion of hormones and production of gametes (ova and sperm). Secondary or accessory organs are responsible for (a) transporting and nourishing the ova and sperm and (b) preserving and protecting the fertilized eggs.

Male Reproductive System

The three primary roles of the male reproductive system are (a) production and transportation of sperm, (b) deposit of sperm in the female reproductive tract, and (c) secretion of hormones. The primary reproductive organs in boys and men are the testes. Secondary reproductive organs include ducts (epididymis, ductus deferens, ejaculatory duct, and urethra), sex glands (prostate gland, Cowper's glands, and seminal vesicles), and the external genitalia (scrotum and penis) (Figure 53-1).

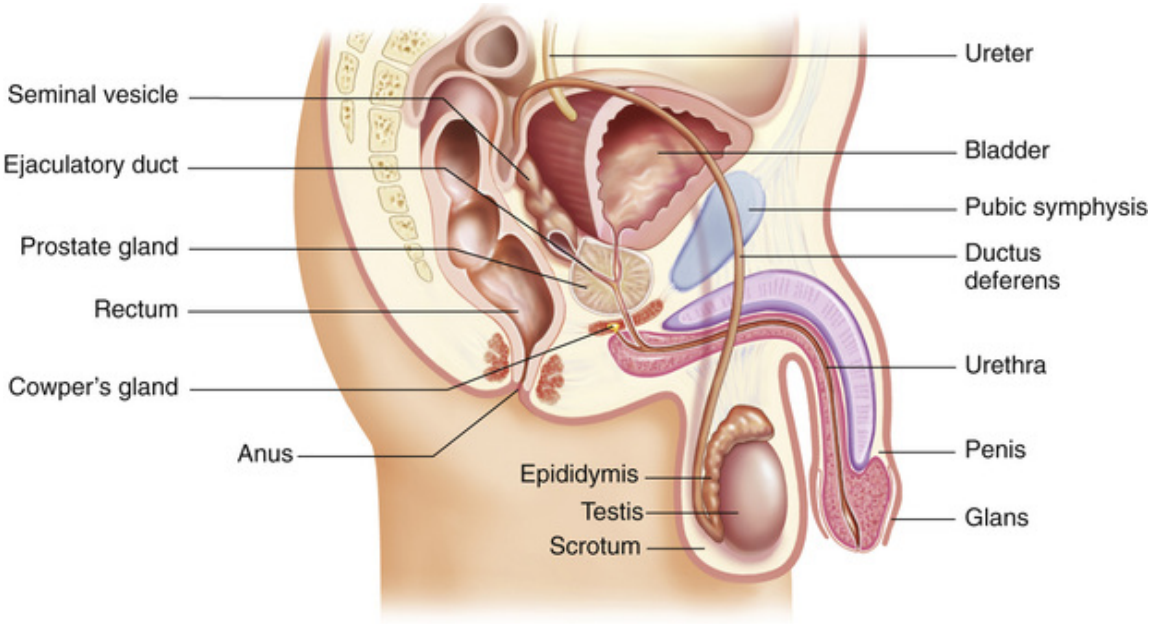

FIGURE 53-1 External and internal male sex organs. Source: Patton, K. T., & Thibodeau, G. A. (2013). *Anatomy and physiology* (8th ed., p. 1045, Figure 34-1). St. Louis: Mosby.

Testes.

The paired testes are ovoid, smooth, firm organs measuring 3.5 to 5.5 cm long and 2 to 3 cm wide. They are within the scrotum, which is a loose protective sac composed of a thin, loose outer layer of skin over a tough connective tissue layer. Within the testes, coiled structures known as seminiferous tubules form *spermatozoa* (immature sperm). The process of sperm production is called spermatogenesis**.** Interstitial cells of the testes lie between the seminiferous tubules and produce the male sex hormone testosterone.

Ducts.

Sperm formed in the seminiferous tubules move through a series of ducts. These ducts transport the sperm from the testes to the outside of the body. As sperm exit the testes, they enter and pass through the epididymis, the ductus deferens, the ejaculatory duct, and the urethra.

The epididymis is a comma-shaped structure located on the posterior-superior aspect of each testis within the scrotum; it transports the sperm as they mature (Figure 53-2; see also Figure 53-1). It is a very long, tightly coiled tubular structure that measures about 6 m in length (Patton &

Thibodeau, 2015). The epididymis transports the sperm as they mature. Sperm exit the epididymis through a long, thick tube known as the ductus deferens (or vas deferens).

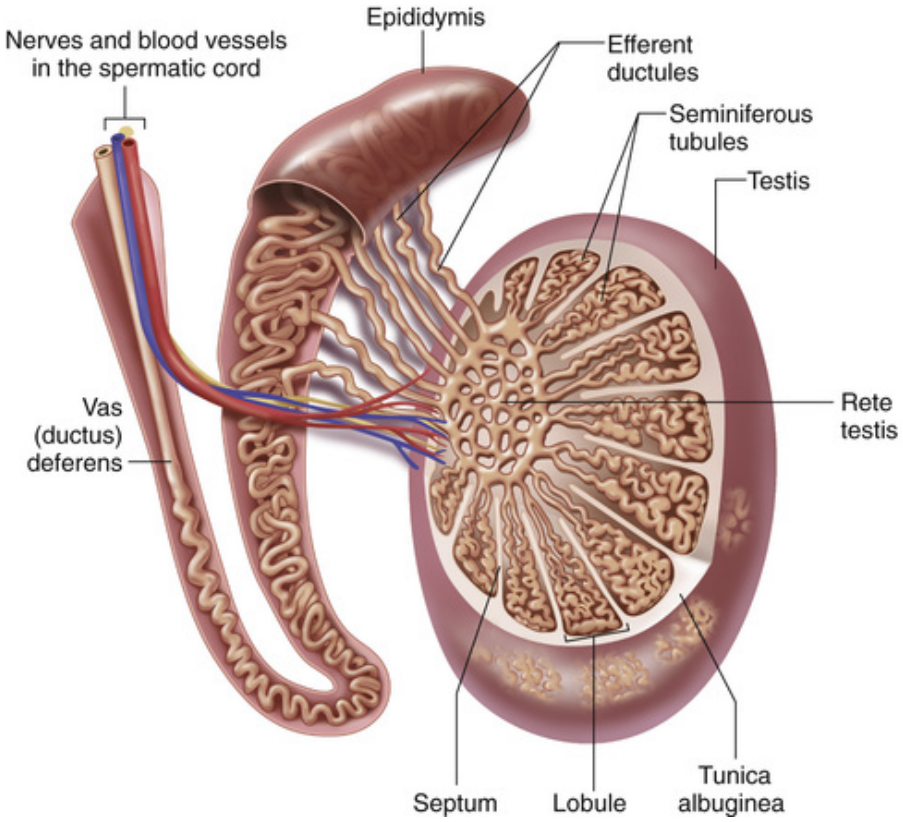

FIGURE 53-2 Seminiferous tubules, testis, epididymis, and ductus (vas) deferens in the male reproductive system. Source: Patton, K. T., & Thibodeau, G. A. (2013). *Anatomy and physiology* (8th ed., p. 1046, Figure 34-3B). St. Louis: Mosby.

The ductus deferens is continuous with the epididymis within the scrotal sac. It travels upward through the scrotum and continues through the inguinal ring into the abdominal cavity. The spermatic cord is a connective tissue sheath that encloses the ductus deferens, arteries, veins, nerves, and lymph vessels as it ascends up through the inguinal canal (see Figure 53-2). In the abdominal cavity, the ductus deferens travels up, over, and behind the bladder. Posterior to the bladder, the ductus deferens joins the seminal vesicle to form the ejaculatory duct (see Figure 53-1).

The ejaculatory duct passes downward through the prostate gland, connecting with the urethra. The urethra extends from the bladder, through the prostate, and ends in a slitlike opening (the meatus) on the

ventral side of the *glans,* the tip of the penis. During the process of ejaculation, sperm travels through the urethra and out of the penis.

Glands.

The seminal vesicles, prostate gland, and Cowper's (bulbourethral) glands are the accessory glands of the male reproductive system. These glands produce and secrete seminal fluid (semen), which surrounds the sperm and forms the *ejaculate.*

The seminal vesicles lie posterior to the bladder and between the rectum and the bladder. The ducts of the seminal vesicles fuse with the ductus deferens to form the ejaculatory ducts that enter the prostate gland. The prostate gland lies beneath the bladder. Its posterior surface is in contact with the rectal wall. The prostate normally measures 2 cm wide and 3 cm long and is divided into right and left lateral lobes and an anteroposterior median lobe. Cowper's glands lie on each side of the urethra and slightly posterior to it, just below the prostate. The ducts of these glands enter directly into the urethra.

Secretions from the seminal vesicles, prostate, and Cowper's glands make up most of the fluid in the ejaculate. These various secretions serve as a medium for the transport of sperm and create an alkaline, nutritious environment that promotes sperm motility and survival.

External Genitalia.

The external genitalia consist of the penis and the scrotum. The penis consists of a shaft, and the tip is known as the *glans.* The glans is covered by a fold of skin, the prepuce (or foreskin), that forms at the junction of the glans and the shaft of the penis. In circumcision, the prepuce has been removed. The shaft of the penis consists of erectile tissue composed of the corpus cavernosum, the corpus spongiosum, the fibrous sheath that encases the erectile tissue, and the urethra. The skin covering the penis is thin, loose, and hairless.

Female Reproductive System

The three primary roles of the female reproductive system are (a) production of ova (eggs), (b) secretion of hormones, and (c) protection and facilitation of the development of the fetus during gestation. Like males, females have primary and secondary reproductive organs. The primary reproductive organs in females are the paired ovaries. Secondary

reproductive organs include ducts (Fallopian tubes), the uterus, the vagina, sex glands (Bartholin's glands and breasts), and the external genitalia (vulva).

Pelvic Organs

Ovaries.

The ovaries are usually located on either side of the uterus, just behind and below the Fallopian (uterine) tubes (Figures 53-3 and 53-4). The almond-shaped ovaries are firm and solid, approximately 1.5 cm wide and 3 cm long. Their functions include *ovulation* and secretion of the two major reproductive hormones, estrogen and progesterone. The outer zone of the ovary contains follicles with germ cells, or *oocytes.* Each follicle contains a primordial (immature) oocyte surrounded by granulosa and theca cells. These two layers protect and nourish the oocyte until the follicle reaches maturity and ovulation occurs. However, not all follicles reach maturity. In a process termed *atresia,* most of the primordial follicles become smaller and are reabsorbed by the body. Thus the number of follicles declines from 2 to 4 million at birth to approximately 300,000 to 400,000 at menarche. This number continues to decrease throughout a woman's reproductive years. Fewer than 500 oocytes are actually released by ovulation during the reproductive years of a normal healthy woman.

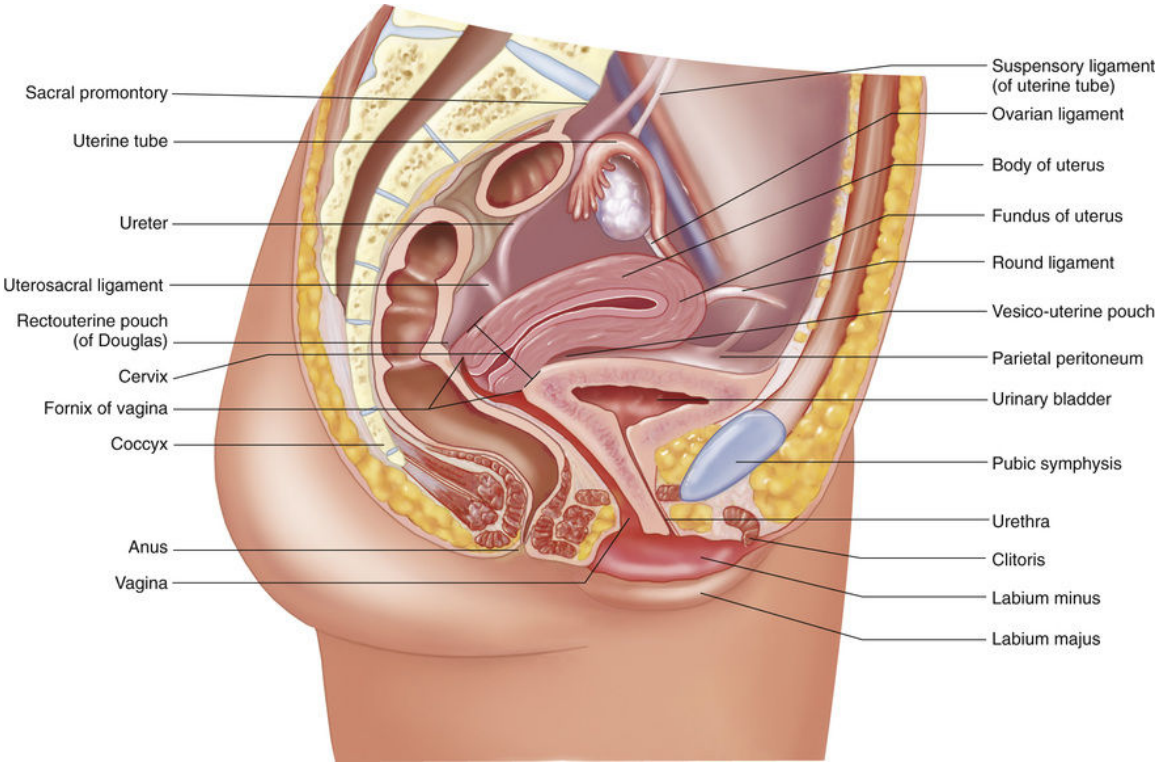

FIGURE 53-3 Female reproductive tract and related organs. Source: Patton, K. T., & Thibodeau, G. A. (2013). *Anatomy and physiology* (8th ed., p. 1065, Figure 35-1A). St. Louis: Mosby.

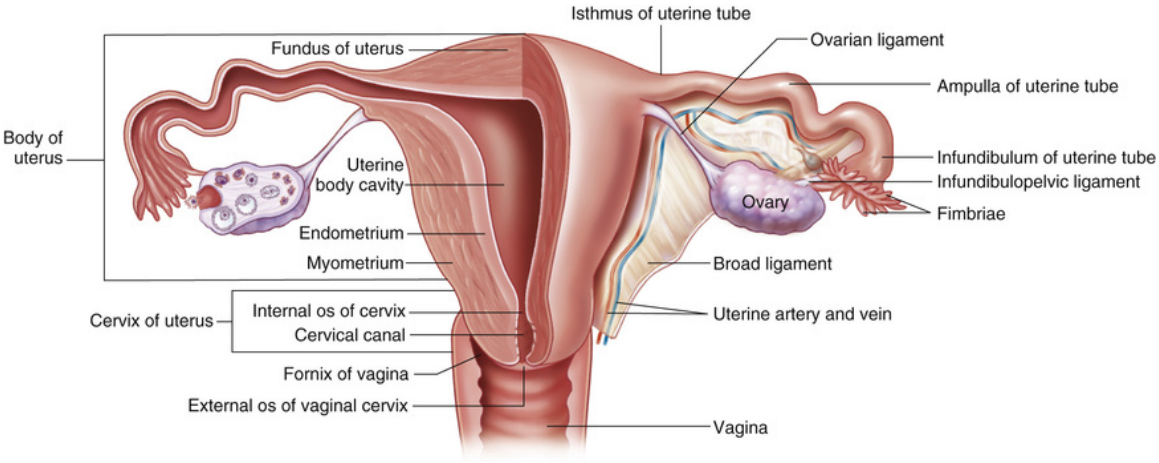

FIGURE 53-4 Female reproductive tract. Source: Modified from Patton, K. T., & Thibodeau, G. A. (2013). *Anatomy and physiology* (8th ed., p. 1066, Figure 35-3A). St. Louis: Mosby.

Fallopian Tubes.

Normally, each month during a woman's reproductive years, one ovarian follicle reaches maturity, and the ovum is ovulated, or expelled, from the ovary through the stimulus of the gonadotropic hormones: follicle-stimulating hormone (FSH) and luteinizing hormone (LH). The ovum then travels up a Fallopian tube, where fertilization by sperm may occur. An ovum can be fertilized up to 72 hours after its release from the ovary.

The distal ends of the Fallopian tubes consist of finger-like projections called *fimbriae* that "massage" the ovaries at ovulation to help extract the mature ovum. The tubes, which average 12 cm in length, extend from the fimbriae to the superior lateral borders of the uterus. Fertilization usually takes place within the outer third of the Fallopian tubes.

Uterus.

The uterus is a pear-shaped, hollow, muscular organ (see Figures 53-3 and 53-4). It is located between the bladder and the rectum. In the mature nulliparous (never pregnant) woman, the uterus is approximately 6 to 8 cm long and 4 cm wide. The uterine walls consist of an outer serosal layer, the perimetrium; a middle muscular layer, the myometrium; and an inner mucosal layer, the endometrium.

The uterus consists of the fundus, the body (or corpus), and the cervix (see Figures 53-3 and 53-4). The body makes up about 80% of the uterus and connects with the cervix at the isthmus (or neck). The cervix is the lower portion of the uterus that projects into the anterior wall of the vaginal canal. It makes up about 15% to 20% of the uterus in the nulliparous female. The cervix consists of the *ectocervix,* the outer portion that protrudes into the vagina, and the *endocervix,* the canal in the opening of the cervix. The opening of the cervix is referred to as the *cervical os* (Figure 53-5).

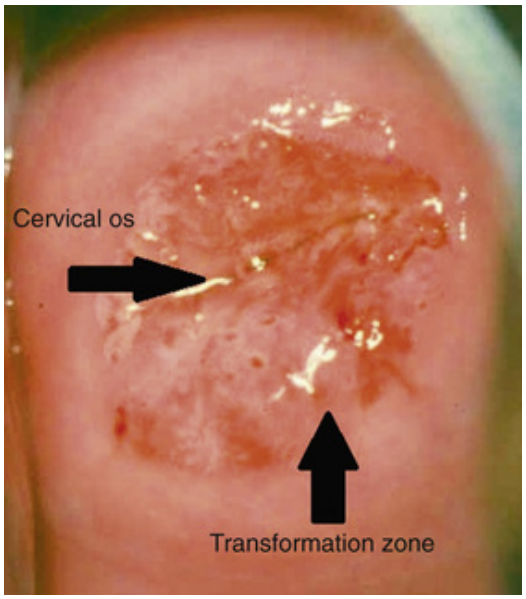

FIGURE 53-5 Cervical os and squamocolumnar junction (transformation zone). Courtesy Candy Tedschi, NP, Great Neck, NY.

The ectocervix is covered with squamous epithelial cells, which give it a smooth, pinkish appearance. The endocervix contains a lining of columnar epithelial cells, which give it a rough, reddened appearance. The junction at which the two types of epithelial cells meet is termed the *squamocolumnar junction* and contains the optimal types of cells needed for an accurate Papanicolaou (Pap) smear to screen for cervical cancer.

The cervical canal is 2 to 4 cm long and is relatively tightly closed. The cervix, however, allows sperm to enter the uterus and also allows menstruation to occur. The columnar epithelium, under hormonal influence, provides elasticity; thus the cervix can stretch to allow passage of a fetus during labour and the birth process. The entrance of sperm into the uterus is facilitated by mucus produced by the cervix under the influence of estrogen. Under normal conditions, the cervical mucus becomes watery, stretchy, and more abundant at ovulation. This mucus facilitates the passage of sperm into the uterus. The postovulatory cervical mucus, under the influence of progesterone, is thick and inhibits sperm passage.

Vagina.

The vagina is a tubular structure 8 to 10 cm long that is lined with squamous epithelium. The secretions of the vagina consist of cervical mucus, desquamated epithelium, and during sexual stimulation, a watery secretion. These fluids protect against vaginal infection. The muscular and

erectile tissue of the vaginal walls allows enough dilation and contraction to accommodate the passage of the fetus during labour, as well as penetration of the penis during intercourse. The anterior vaginal wall lies along the urethra and the bladder. The posterior vaginal wall is adjacent to the rectum.

Pelvis.

The female pelvis consists of four bones (two pelvic bones, sacrum, and coccyx) held together by several strong ligaments. The sections of these bones that lie below the iliopectineal line play a very important role during birth: their ability to separate is often a factor in determining the ability of a woman to deliver a child vaginally.

External Genitalia.

The external portion of the female reproductive system (Figure 53-6), commonly called the *vulva,* consists of the mons pubis, labia majora, labia minora, clitoris, urethral meatus, Skene's glands, vaginal introitus (opening), and Bartholin's glands.

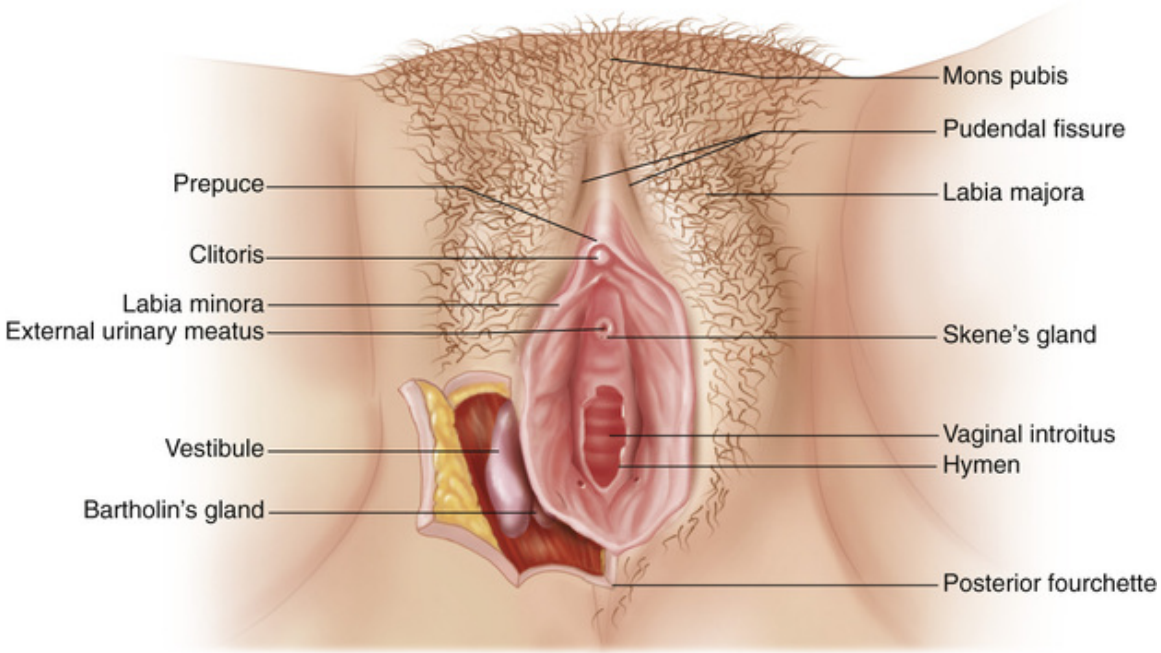

FIGURE 53-6 External female genitalia. Source: Modified from Thibodeau, G. A., & Patton, K. T. (2013). *Anatomy and physiology* (8th ed., p. 1065, Figure 35-2). St. Louis: Mosby.

The mons pubis is a fatty layer lying over the pubic bone. In female adults, it is covered by coarse hair that lies in a triangular pattern. (The pubic hair pattern in male adults is diamond-shaped.) The labia majora are folds of adipose tissue that form the outer borders of the vulva. The hairless labia minora form the borders of the vaginal orifice and extend anteriorly to enclose the clitoris (Hurt, Guile, Bienstock, et al., 2011).

The *vestibule* is a boat-shaped fossa between the labia minora, extending from the clitoris at the anterior end to the vaginal opening at the posterior end. The perineum is the area between the vagina and the anus. The vaginal introitus is surrounded by thin membranous tissue called the *hymen.* In female adults, the hymen usually appears as folds or hymenal tags and separates the external genitalia from the vagina. At the posterior aspect of the vagina, a tense band of mucous membrane connecting the posterior ends of the labia minora is referred to as the *posterior fourchette.*

The clitoris is erectile tissue that lies anterior to the urethral meatus and the vaginal orifice and becomes engorged during sexual excitation. It lies anterior to the urethral meatus and the vaginal orifice and is usually covered by the prepuce (McCance, Huether, Brashers, et al., 2014). Clitoral stimulation is an important part of sexual activity for many women.

Ducts of the Skene's glands lie alongside the urinary meatus and are thought to help lubricate the urinary meatus (McCance, Huether, Brashers, et al., 2014). Bartholin's glands, located at the posterior and lateral aspects of the vaginal orifice, secrete a thin, mucoid material believed to contribute slightly to lubrication during sexual intercourse. These glands are not usually palpable unless sebaceous-like cysts form or an infection is present, such as a sexually transmitted infection (STI).

Breasts.

The breasts are a secondary sex characteristic; they develop during puberty in response to estrogen and progesterone. Cyclical hormonal changes lead to regular changes in breast tissue to prepare it for lactation when fertilization and pregnancy occur.

The breasts extend from the second to the sixth ribs, with an area called the *tail of Spence* reaching the axilla. The fully mature breast is dome-shaped and contains a pigmented centre termed the *areola.* The areolar region contains Montgomery's tubercles, which are similar to sebaceous glands and assist in lubricating the nipple. During lactation, the alveoli secrete milk (Figure 53-7). The milk then flows into a ductal system and is transported to the lactiferous sinuses. The nipple contains 15 to 20 tiny

openings through which the milk flows during breastfeeding. The fibrous and fatty tissue that supports and separates the channels of the mammary duct system primarily accounts for the varying sizes and shapes of the breasts in different individuals.

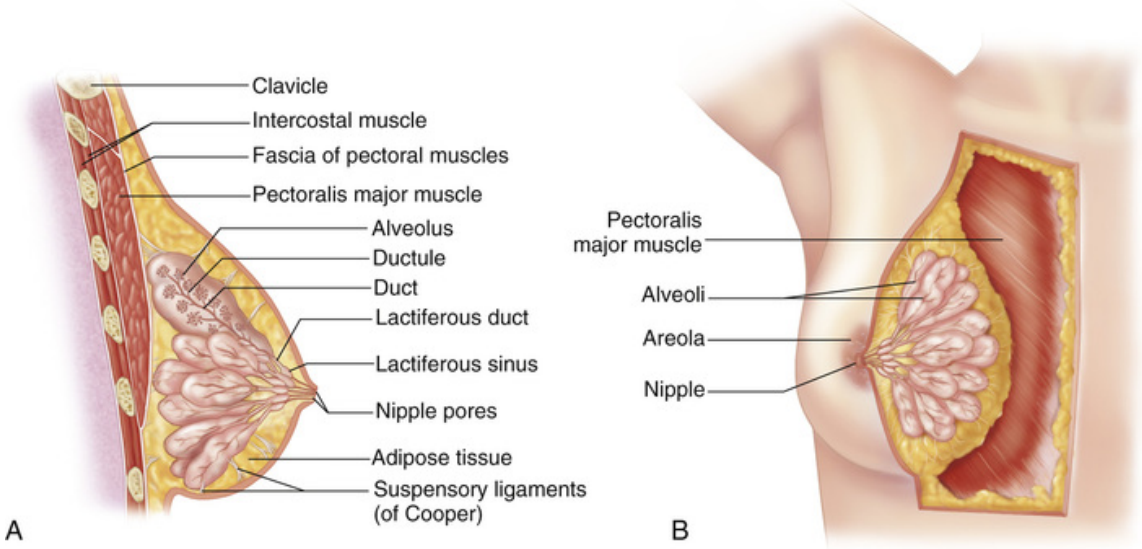

FIGURE 53-7 The lactating female breast. **A,** Illustration of a sagittal section of a lactating breast. Glandular structures are anchored to the overlying skin and to the pectoral muscle by suspensory ligaments of Cooper. Each lobule of glandular tissues is drained by a lactiferous duct that eventually opens through the nipple. **B,** Illustration of the anterior view of a lactating breast. In nonlactating breasts, the glandular tissue is much less evident; adipose tissue makes up most of each breast. Source: Thibodeau, G. A., & Patton, K. T. (2013). *Anatomy and physiology* (8th ed., p. 1083, Figure 36-16). St. Louis: Mosby.

The breast has a rich lymphatic network that drains into the axillary and clavicular channels (see Chapter 54, Figure 54-7). Superficial lymph nodes are located in the axilla and are accessible to examination. This system is often responsible for the metastasis of a malignant tumour from the breast to other parts of the body.

Case Study

Patient Introduction

Source: Dubova/Shutterstock.com.

Anna Kaluza is a 68-year-old woman who comes to the breast centre because she found a large lump in her right breast while showering. She is somewhat anxious, stating, "My breasts are typically lumpy, but this feels different!"

Discussion Questions

Throughout this chapter, think about Mrs. Kaluza's concerns with the following questions in mind:

1. What are the possible causes for a lump in Mrs. Kaluza's breast?
2. What would be the priority assessment of Mrs. Kaluza?
3. What questions would the nurse ask Mrs. Kaluza?
4. What should be included in the physical assessment? What would the nurse be looking for?
5. What diagnostic studies would the nurse expect to be ordered?

Mrs. Kaluza and her condition will be followed throughout this assessment chapter. See pp. 1336, 1340, and 1347 for more information on Mrs. Kaluza.

Neuroendocrine Regulation of the Reproductive System

The hypothalamus, the pituitary gland, and the gonads secrete numerous hormones (Figure 53-8). (Endocrine hormones are discussed in Chapter 50.) These hormones regulate the processes of ovulation, spermatogenesis (process of sperm production), and fertilization and the formation and function of the secondary sex characteristics. In women, the hormones secreted by the anterior pituitary gland cause cyclical changes in the ovaries. The hypothalamus secretes gonadotropin-releasing hormone (GnRH), which stimulates the pituitary gland to secrete its hormones, including FSH and LH. LH in males is sometimes called *interstitial cell–*

stimulating hormone (ICSH). The gonadal hormones are estrogen, progesterone, and testosterone.

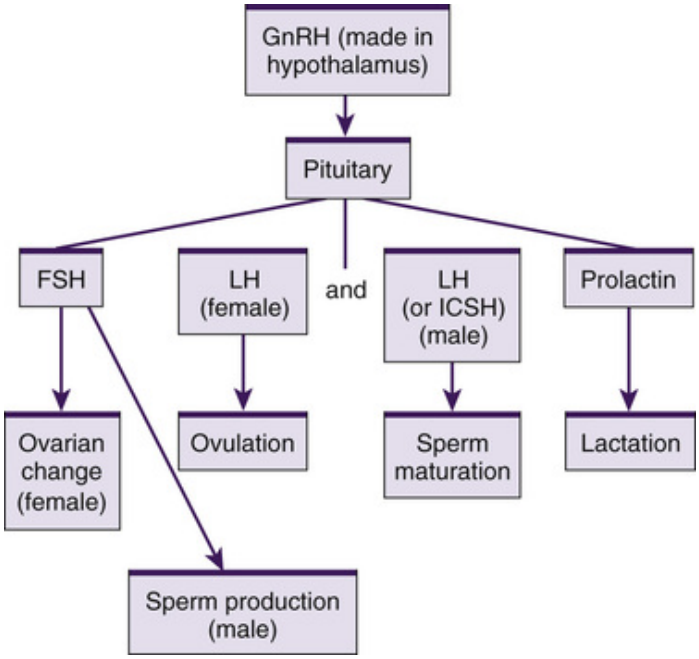

FIGURE 53-8 Hypothalamic–pituitary–gonadal axis. Only the major pituitary hormone actions are depicted. *FSH,* follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *ICSH,* interstitial cell–stimulating hormone; *LH,* luteinizing hormone.

In women, FSH production by the anterior pituitary gland stimulates the growth and maturity of the ovarian follicles necessary for ovulation (Bulun, 2011). The mature follicle produces estrogen, which in turn suppresses the release of FSH. Another hormone, inhibin, is also secreted by the ovarian follicles and inhibits both GnRH and FSH secretion. In men, FSH stimulates the seminiferous tubules to produce sperm.

LH contributes to the ovulatory process because it causes follicles to complete maturation and undergo ovulation. It also causes the ruptured follicle (area where the ovum exited during ovulation) to turn into a corpus luteum from which progesterone is secreted. Progesterone maintains the rich vascular state of the uterus (secretory phase) in preparation for fertilization and implantation. In men, LH (ICSH) triggers testosterone production by the interstitial cells of the testes and thus is essential for the full maturation of sperm. Prolactin has no known function in men. In women, prolactin stimulates the development and growth of

the mammary glands. During lactation, it initiates and maintains milk production.

The gonadal hormones, estrogen and progesterone, are produced by the ovaries in women. Small amounts of an estrogen precursor are also produced in the adrenal cortices. Estrogen is essential to the development and maintenance of the secondary sex characteristics, the proliferative phase of the menstrual cycle immediately after menstruation, and the uterine changes essential to pregnancy. The role and importance of estrogen in men are not well understood. In men, estrogen is produced predominantly in the adrenal cortex.

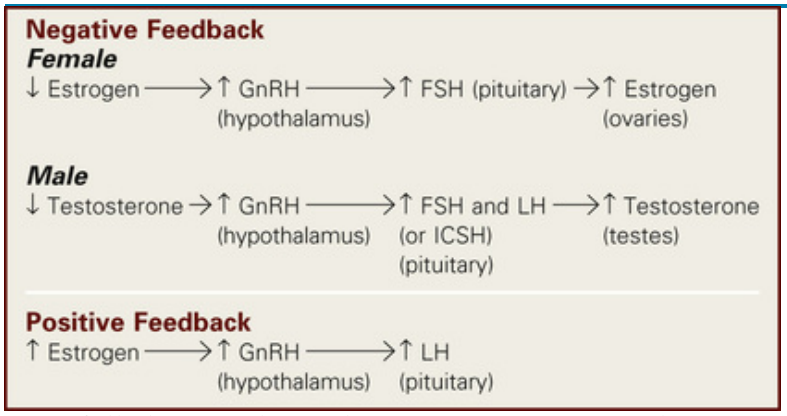
Progesterone plays a major role in the menstrual cycle but most specifically in the secretory phase. Like estrogen, progesterone is involved in the bodily changes associated with pregnancy. Adequate progesterone is necessary to maintain an implanted egg.

In men, the major gonadal hormone is testosterone, which is produced by the testes. Testosterone is responsible for the development and maintenance of secondary sex characteristics, as well as for adequate spermatogenesis. In women, androgens are produced in small amounts by the adrenal glands and ovaries.

The circulating levels of gonadal hormones are controlled primarily by a *negative feedback process.* Receptors within the hypothalamus and the pituitary are sensitive to the circulating blood levels of the hormones (Table 53-1). Increased levels of hormones stimulate a hypothalamic response that decreases the high circulating levels. Likewise, low circulating levels provoke a hypothalamic response that increases the low circulating levels. For example, if the circulating level of testosterone in men is low, the hypothalamus is stimulated to secrete GnRH. This triggers the anterior pituitary gland to secrete greater amounts of FSH and LH, which in turn set off an increase in the production of testosterone. The high levels of testosterone then stimulate a decrease in the production of GnRH and thus of FSH and LH.

TABLE 53-1

Gonadal Feedback Mechanisms



FSH, follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *ICSH,* interstitial cell–stimulating hormone; *LH,* luteinizing hormone.

In women, however, this process is slightly different. The circulating levels are controlled through a combination of both a negative and a positive feedback system. The negative feedback control mechanism is similar to that described previously in men. When circulating estrogen levels are low, the hypothalamus is stimulated to increase its production of GnRH. GnRH stimulates the pituitary to secrete greater amounts of FSH and LH, which results in higher levels of estrogen production by the ovaries. Reciprocally, higher levels of circulating estrogen result in a decreasing secretion of GnRH and thus bring about a decrease in the secretion of FSH by the pituitary gland.

A positive feedback control mechanism also exists in women: With the increased levels of circulating estrogen, GnRH is produced at a higher level, which results in an increased level of LH from the pituitary, which instigates ovulation. Likewise, lowered levels of estrogen result in a lowered level of LH.

Menarche

Menarche is the first episode of menstrual bleeding and indicates that a girl has reached puberty. Menarche usually occurs at approximately 12 to 13 years of age (Jameson, De Groot, de Kretser, et al., 2016). Menstrual cycles are often irregular for the first 1 to 2 years after menarche because of *anovulatory* cycles (cycles without ovulation).

Menstrual Cycle

The major functions of the ovaries are ovulation and the secretion of hormones. These functions are accomplished during the normal menstrual cycle, a monthly process mediated by the hormonal activity of the hypothalamus, the pituitary gland, and the ovaries. Menstruation occurs during each month in which an egg is not fertilized (Figure 53-9). The endometrial cycle is divided into three phases labelled in relation to uterine and ovarian changes: (a) the *proliferative* or *follicular phase,* (b) the *secretory* or *luteal phase,* and (c) the *menstrual* or *ischemic phase.* The length of the menstrual cycle ranges from 20 to 40 days, the average being 28 days.

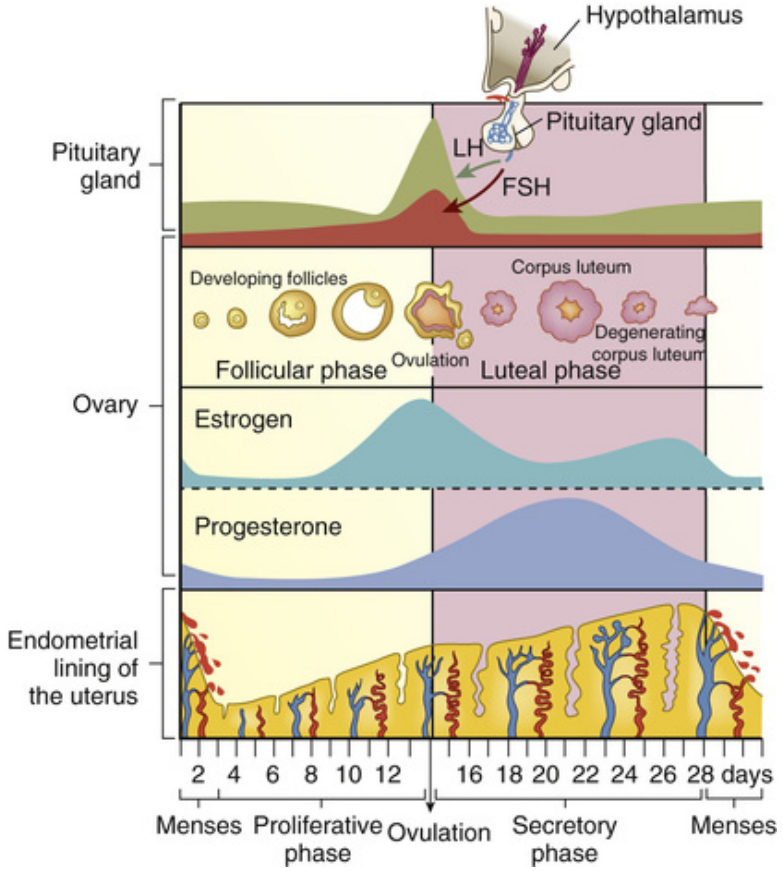


FIGURE 53-9 Events of the menstrual cycle. The various *lines* depict the changes in blood hormone levels, the development of the follicles, and the changes in the endometrium during the cycle. *FSH,* follicle-stimulating hormone; *LH,* luteinizing hormone. Source: Adapted from Thibodeau, G. A., & Patton, K. T. (2013). *Anatomy and physiology* (8th ed., p. 1079, Figure 35-14). St. Louis: Mosby.

The menstrual cycle begins on the first day of one menstrual period (menses), which usually lasts 4 to 6 days, and ends the day before the first

day of the next. Table 53-2 includes characteristics of the menstrual cycle and related patient teaching. During this time, estrogen and progesterone levels are low, but FSH levels begin to increase. During the follicular phase, usually a single follicle matures fully under the stimulation of FSH. (The mechanism that ensures that usually only one follicle reaches maturity is not known.) The mature follicle stimulates estrogen production, causing the negative feedback that results in decreased FSH secretion.

TABLE 53-2

PATIENT & CAREGIVER TEACHING GUIDE
Characteristics of Menstruation

The following information should be included when teaching the patient and her family about menstruation.	
Characteristic	**Teaching**
Menarche	
Occurs between ages 10 and 16 yr; average age at onset is 12 or 13 yr.	See health care provider regarding possible endocrine or developmental abnormality when menarche is delayed.
Interval	
Usually is 21–35 days, but regular cycles as short as 17 or as long as 45 days are considered normal if pattern is consistent for individual.	Keep written record to identify own pattern of menstrual cycle. Expect some irregularity in perimenopausal period. Be aware that drugs (phenothiazines, opioids, contraceptives) and stressful life events can result in missed periods.
Duration	
Menstrual flow generally lasts 2–8 days.	Realize that pattern is fairly constant but that wide variations do exist.
Amount	
Menstrual flow varies from 20 to 80 mL per menses; average is 30 mL. Amount varies among women and in the same woman at different times. It is usually heaviest first 2 days.	Count number of pads or tampons used per day. The average tampon or pad, when completely saturated, absorbs 20-–30 mL. Very heavy flow is indicated by complete soaking of two pads in 1-–2 hr. IUD or drugs such as anticoagulants and thiazides can produce heavy menses.
Composition	
Menstrual discharge is a mixture of endometrium, blood, mucus, and vaginal cells. It is dark red and less viscous than blood and usually does not clot.	Clots indicate heavy flow or vaginal pooling.

IUD, intrauterine device.

Although the initial stage of follicular maturation is stimulated by FSH, complete maturation and ovulation occur only when LH is present. When estrogen levels peak on about the twelfth day of the cycle, there is a surge of LH, which triggers ovulation a day or two later. After ovulation (maturation and release of an ovum), LH promotes the development of the corpus luteum.

The fully developed corpus luteum continues to secrete estrogen and initiates progesterone secretion. If fertilization occurs, high levels of estrogen and progesterone continue to be secreted owing to the continued

activity of the corpus luteum from stimulation by human chorionic gonadotropin (hCG). If fertilization does not take place, estrogen production decreases, and progesterone secretion stops, and, accordingly, menses occurs.

During the *follicular phase,* the endometrial lining of the uterus also undergoes change. As larger amounts of estrogen are produced, the endometrial lining undergoes proliferative changes, and cellular growth, including the length of blood vessels and glandular tissue, increases.

With ovulation and the resulting increased levels of progesterone, the *luteal* (or *secretory*) phase begins. If the corpus luteum regresses (i.e., fertilization does not occur) and estrogen and progesterone levels fall, the endometrial lining can no longer be supported. As a result, the blood vessels contract, and tissue begins to slough (fall away). This sloughing results in the menses and the start of the menstrual cycle (Rebar & Erickson, 2011).

Menopause

Menopause is the physiological cessation of menses associated with declining ovarian function. It is usually considered complete after 1 year of amenorrhea (absence of menstruation; Hurt, Guile, Bienstock, et al., 2011). (Menopause is discussed in Chapter 56.)

Phases of the Sexual Response

The sexual response is a complex interplay of psychological and physiological phenomena and is influenced by a number of variables, including daily stress, illness, and crisis. The changes that occur during sexual excitement are similar for men and women. Masters and Johnson (1966) described the sexual response in terms of excitement, plateau, orgasmic, and resolution phases.

Male Sexual Response.

The penis and the urethra are essential for the transport of sperm into the vagina and the cervix during intercourse. This transport is facilitated by penile erection in response to sexual stimulation during the *excitement phase.* Erection results from the filling of the large venous sinuses within the erectile tissue of the penis. In the flaccid state, these sinuses hold only a small amount of blood, but during the erection stage, they are congested with blood. Because the penis is richly endowed with sympathetic,

parasympathetic, and pudendal nerve endings, it is readily stimulated to erection. The loose skin of the penis becomes taut as a result of the intense venous congestion. This erectile tautness allows for easy insertion during intercourse.

As the man reaches the *plateau phase,* the erection is maintained, and the penis increases in diameter as a result of a slight increase in vasocongestion. Testicle size also increases. Sometimes the glans penis becomes more reddish-purple.

The subsequent contraction of the penile and urethral musculature during the *orgasmic phase* propels the sperm outward through the meatus. In this process, termed *ejaculation,* sperm are released into the ductus deferens during contractions. Sperm advance through the urethra, where fluids from the prostate and the seminal vesicles are added to the sperm, forming the ejaculate. The sperm continue their path through the urethra, receiving a small amount of fluid from Cowper's glands, and are finally ejaculated through the urinary meatus. *Orgasm* is characterized by the rapid release of the vasocongestion and muscular tension (myotonia) that have developed. The rapid release of muscular tension (through rhythmic contractions) occurs primarily in the penis, prostate gland, and seminal vesicles. After ejaculation, a man enters the *resolution phase.* During this phase, the penis undergoes involution, gradually returning to its unstimulated, flaccid state.

Female Sexual Response.

The changes that occur in a woman during sexual excitation are similar to those in a man. In response to stimulation, the clitoris becomes congested and vaginal lubrication increases as a result of secretions from the cervix, Bartholin's glands, and vaginal walls. This initial response is the *excitation phase.*

As excitation is maintained in the *plateau phase,* the vagina expands and the uterus is elevated. In the *orgasmic phase,* contractions occur in the uterus from the fundus to the lower uterine segment. The cervical os relaxes slightly, which helps the sperm enter, and the vagina undergoes rhythmic contractions. Muscular tension is rapidly released through rhythmic contractions in the clitoris, the vagina, and the uterus. This phase is followed by a *resolution phase* in which these organs return to their pre-excitation state. However, women do not have to go through the resolution (refractory) recovery state before they can be orgasmic again. They can be multiorgasmic without resolution between orgasms.

Age-Related Considerations

The Reproductive System and Sexual Response

With advancing age, changes occur in the male and female reproductive systems. In women, many of these changes are related to the altered estrogen production that is associated with menopause. A reduction in circulating estrogen along with an increase in androgens in postmenopausal women is associated with breast and genital atrophy, reduction in bone mass, and increased rate of atherosclerosis. Vaginal dryness may occur, which can lead to urogenital atrophy and changes in the quantity and composition of vaginal secretions (Kaunitz & Manson, 2015).

A gradual hormonal decline also occurs in elderly men. Manifestations of hormonal decline in men can be physical, psychological, or sexual. Some of the changes include an increase in prostate size and a decrease in testosterone level, sperm production, muscle tone of the scrotum, and size and firmness of the testicles (Laborde & Brannigan, 2011). Erectile dysfunction and sexual dysfunction occur in some men as a result of these changes. Age-related changes in the reproductive systems and differences in assessment findings are presented in Table 53-3.

TABLE 53-3

AGE-RELATED DIFFERENCES IN ASSESSMENT Reproductive System

Changes		Differences In Assessment Findings
Male		
Penis	Decreased subcutaneous fat, decreased skin turgor	Easily retractable foreskin (if uncircumcised); decrease in size; fewer sustained erections
Testes	Decreased testosterone production	Decrease in size; change in position (lower)
Prostate	Benign hyperplasia	Enlargement
Breasts	Enlargement	Gynecomastia (abnormal enlargement)
Female		
Breasts	Decreased subcutaneous fat, increased fibrous tissue, decreased skin turgor	Less resilient, looser, more pendulous tissue; decreased size; duct around nipple may feel like stringy strand
Vulva	Decreased skin turgor	Atrophy; decreased amount of pubic hair; decreased size of clitoris and labia
Vagina	Atrophy of tissue, decreased muscle tone, alkaline pH	Pale and dry mucosa; relaxation of outlet; mucosa thinning; narrowing and shortening of vagina; increased potential for infection
Urethra	Decreased muscle tone	Cystocele (protrusion of bladder through vaginal wall)
Uterus:	Decreased thickness of myometrium	Decrease in size, uterine prolapse
Ovaries	Decreased ovarian function	Nonpalpable ovaries; decreased size

Gradual changes resulting from advancing age occur in the sexual responses of men and women (Table 53-4). The cumulative effects of these changes, as well as the negative social attitude toward sexuality in older adults, can affect the sexual practices of older adults. Nurses have an important role in providing accurate and unbiased information about sexuality and age. Nurses should emphasize the normality of sexual activity in older adults.

TABLE 53-4

AGE-RELATED CHANGES IN SEXUAL FUNCTIONING

Men
• Increased stimulation necessary for erection • Decreased force of ejaculation • Decreased ability to attain or sustain erection • Decreased size and rigidity of the penis at full erection • Decreased libido and interest in sex
Women
• Decreased vaginal lubrication • Decreased sensitivity with labia shrinking and more clitoris exposed • Difficulty in maintaining arousal • Difficulty in achieving orgasm after stimulation • Decreased libido and interest in sex

Assessment of the Male and Female Reproductive Systems

Subjective Data

Important Health Information.

In addition to general health information, the nurse must elicit information specifically relating to the reproductive system. Reproduction and sexual issues are often considered extremely personal and private. The nurse must develop trust to elicit such information. A professional demeanour is important when the nurse obtains a reproductive or sexual history. The nurse must be sensitive, ask gender-neutral questions when asking about partners, and maintain an awareness of a patient's culture and beliefs. It is helpful if the nurse begins with the least sensitive information (e.g., menstrual history) before asking questions about more sensitive issues, such as sexual practices or STIs.

Past Health History.

The past health history should include information about major illnesses, hospitalizations, and surgeries. The nurse should inquire about any infections involving the reproductive system, including STIs. For women, a complete obstetrical and gynecological history should be documented.

Common pediatric illnesses that affect reproductive function are mumps and rubella. The occurrence of mumps in young men has been associated with an increase in sterility. Bilateral testicular atrophy can occur secondary to mumps-related orchitis. In the health history, the nurse should ask male patients whether they have had mumps, have been immunized with mumps vaccine, or have any indications of sterility.

Rubella is of primary concern to women of child-bearing age. If rubella occurs during the first 3 months of pregnancy, the fetus is at increased risk for congenital anomalies. For this reason, nurses should encourage immunization for all women of child-bearing age who have not yet been immunized for rubella or have not already had the disease. (Rubella immunity can be determined by antibody titres.) However, women should not be immunized if they are already pregnant (Centers for Disease Control and Prevention, 2014). Women are also advised not to conceive for at least 1 month after being immunized with the combination measles-mumps-rubella vaccine (Centers for Disease Control and Prevention, 2014).

The nurse should also ask about the patient's current health status and the presence of any acute or chronic health problems. Problems in other body systems are often related to problems with the reproductive system. The nurse must ask about possible endocrine disorders, particularly diabetes mellitus, hypothyroidism, and hyperthyroidism, because these disorders directly interfere with women's menstrual cycles and with sexual performance. Men who have diabetes mellitus may experience erectile dysfunction and retrograde ejaculation. In women with uncontrolled diabetes mellitus, pregnancy may incur significant health risks. Many other chronic illnesses such as cardiovascular disease, respiratory disorders, anemia, cancer, and kidney and urinary tract disorders may affect the reproductive system and sexual functioning.

A history of stroke should be determined. In men, strokes may cause physiological or psychological erectile dysfunction. Men who have suffered a myocardial infarction may experience erectile dysfunction because of the fear that sexual activity will precipitate another heart attack. Women share this concern, both as partners of someone who has had a myocardial infarction and as patients recovering from a myocardial infarction. Although most patients have concerns about sexual activity after a myocardial infarction, many are not comfortable expressing these concerns to the nurse. The nurse must be sensitive to this concern. In women, a history of cardiovascular disease (e.g., hypertension, thrombophlebitis, angina) causes a higher incidence of morbidity and mortality with pregnancy or the use of oral contraceptives.

Family History.

The nurse should inquire about a history of cancer, particularly cancer of the reproductive organs. Having a first-degree relative who has cancer of the breast, the ovaries, the uterus, or the prostate significantly increases the risk of cancer for the patient. It is also important to determine if the patient has a familial tendency for diabetes mellitus, hypothyroidism, hyperthyroidism, hypertension, stroke, angina, myocardial infarction, endocrine disorders, or anemia.

Medications.

The nurse should document all prescription and over-the-counter medications that the patient is taking, as well as the reasons for using the medications, the dosages, and the lengths of time that the medications have been taken. All drugs taken by female patients of child-bearing age

should be evaluated for possible teratogenic effects. The patient should also be asked about the use of herbal products and dietary supplements.

Particularly relevant in the assessment of the reproductive system is the use of diuretics (sometimes prescribed for premenstrual edema), psychotropic agents (which may interfere with sexual performance), and antihypertensives (some of which may cause erectile dysfunction). Patients who use certain cardiovascular and antihypertensive medications such as thiazide diuretics (e.g., hydrochlorthiazide), aldosterone receptor blockers (e.g., spironolactone [Aldactone]) or β-adrenergic receptor blockers (e.g., propranolol [Inderal]) must be closely assessed for problems that interfere with sexual performance (Chrysant, 2015). The nurse must also note the use of drugs such as alcohol, marijuana, barbiturates, amphetamines, and phencyclidine (PCP [also called "angel dust"]), which can have serious behavioural and physiological effects on the functioning of the reproductive system.

In women, the use of oral contraceptives or other hormone therapy should be noted. The long-term use of both estrogen and progesterone in hormone therapy appears to increase the risk of blood clots, cardiovascular disease, stroke, gallbladder disease, and breast and uterine cancer in postmenopausal women (American College of Obstetricians and Gynecologists, 2015). The short-term use of hormone therapy appears to be appropriate for certain women, depending on their risk factors. (Hormone therapy is discussed in Chapter 56.) Women who use tobacco have a much higher risk of clotting disorders than do women who do not use tobacco.

A history of cholecystitis and hepatitis is important information because these conditions may be contraindications to oral contraceptive use. Cholecystitis is often aggravated by oral contraceptives, and chronic active inflammation of the liver generally precludes the use of estrogen products because they are metabolized by the liver. Chronic obstructive pulmonary disease may be a contraindication to oral contraceptive use because progesterone thickens respiratory secretions.

Case Study

Subjective Data

Source: Dubova/Shutterstock.com.

A focused assessment of Anna Kaluza revealed the following information.

Past Medical History: Type 2 diabetes for 5 yr, hypertension, stress incontinence, osteoarthritis. No surgical history. No personal history of breast cancer.

Family History: Her mother received a diagnosis of breast cancer at age 60, and her sister, at age 40.

Medications: Metformin (Glucophage), 500 mg PO bid for the past 4 yr; estradiol/norethisterone acetate (Activelle), 1 mg/0.5 mg/day PO for the past 14 yr; lisinopril (Prinivil), 10 mg/day PO for the past 3 yr.

Overall Health Management: Had onset of menarche at age 11, menopause at age 53. Has two daughters (aged 34 and 32) and a son (30). Mrs. Kaluza denies any breast pain. She is afraid that she may now have breast cancer because of her family history.

Functional Assessment

Activity and Mobility: Mrs. Kaluza does not exercise routinely. Occasionally takes a walk around the block with her husband. Otherwise, her life is fairly sedentary.

Nutrition and Metabolic History: Mrs. Kaluza is 158 cm tall and weighs 75 kg. She reports gaining most of her weight after menopause. She tries to eat a well-balanced meal and watch her carbohydrate intake because of her diabetes.

Elimination: Denies any changes or difficulty with urination or bowel movements except for stress incontinence when she coughs or laughs. States she always wears a panty liner "just in case."

Self-Care and Health Promotion Activities: Her last mammogram was obtained 2 years ago. She does not smoke but does enjoy one to two glasses of wine with her dinner every evening.

See pp. 1331, 1340, and 1347 for more information on Mrs. Kaluza.

Surgery or Other Treatments.

Any surgical procedures should be noted in the health history. Surgical procedures involving the reproductive system are listed in Table 53-5. Therapeutic or spontaneous abortions should also be documented.

TABLE 53-5
SURGICAL PROCEDURES INVOLVING THE REPRODUCTIVE SYSTEMS

Surgery	Description
Male	
Herniorrhaphy	Repair of hernia
Orchiectomy	Removal of one or both testes
Prostatectomy	Removal of prostate gland
Repair of testicular torsion	Correction of axial rotation of spermatic cord, which cuts off blood supply to the testicle, epididymis, and other structures
Transurethral resection of prostate (TURP)	Removal of prostate tissue via the urethra (e.g., obstructive benign prostatic hyperplasia)
Varicocelectomy	Repair of varicose vein of scrotum
Vasectomy	Removal of part of ductus (vas) deferens; can be an elective procedure for sterilization or contraception
Female	
Cryosurgery	Use of subfreezing temperature to destroy tissue, especially for treatment of abnormal cells in the cervix
Dilation and curettage (D&C)	Dilation of cervix and scraping of endometrium, performed to diagnose disease of uterus, to correct heavy or prolonged vaginal bleeding, or to empty uterus of products of conception; also used in the treatment of infertility to correlate state of endometrium and time of cycle
Hysterectomy	Removal of uterus
Mastectomy	Removal of one or both breasts
Oophorectomy	Removal of one or both ovaries
Repair of cystocele	Correction of protrusion of urinary bladder into vagina
Repair of rectocele	Correction of protrusion of rectum into vagina
Salpingectomy	Removal of one or both Fallopian tubes
Tubal ligation or sterilization	Ligation of Fallopian tubes

Documenting a Health History Related to a Reproductive Problem.

When collecting information related to reproductive health, the nurse should start with questions of lesser sensitivity, proceeding to more sensitive issues after rapport has been established. The nurse is also in a

unique position to discuss general health issues related to women or men and to emphasize health promotion and self-care activities. The key questions to ask a patient with a reproductive problem are presented in Table 53-6 and discussed in more detail in the paragraphs below.

TABLE 53-6

HEALTH HISTORY
Reproductive System: Questions for Obtaining Subjective Data

Past History
• Are you having any problems in the area of your genitals?*
• Have you had treatment for such problems in the past, and how were those treated?
• Have you had any surgery on your uterus, ovaries, vagina, or prostate?*
• Any history of kidney disease, kidney stones, prostate problems?*
• Have you had bladder infections? If so, when? How often?
Family History
• Describe the health of your family members. Any history of breast, uterine, ovarian, or prostate cancer?
Review of Systems
Overall Health Status
• How do you feel in general? Have you had any changes recently in your health? • What is your weight and height? Have there been any changes in your appetite or weight?* Gastro-Intestinal System • Describe your usual bowel pattern. Have you noted any bowel changes?*
Genito-Urinary System
• Do you experience problems with urination (e.g., pain; burning; dribbling; inability to control urine; frequency; small amounts; urinating at night; blood in the urine; urine that is dark, cloudy, or foul smelling)? Do you urinate when you sneeze or laugh or cough? • Do you have any discharge from your vagina or penis?* • Have you had bladder infections? If so, when? How often? Sexual and Reproductive History†
Women
• *Menstrual history:* When did you start to menstruate? Was this earlier or later than other women in your family? Do you have scant, heavy, or irregular menstrual flows? On what date did your most recent menstrual period begin? • *Obstetrical history:* How many children have you had? How many times were you pregnant? How many living children, miscarriages, or abortions? Could you be pregnant now? Are you trying to become pregnant? • *Menopausal history:* Have your periods changed or stopped? Are you experiencing any of the symptoms of menopause—hot flashes, headaches, heavy sweats, vaginal dryness? Are you taking or have you taken HT? How are you feeling about menopause? • Are you postmenopausal? If so, do you have any bleeding from your uterus?
Men
• Have you noticed any changes in your ability to have an erection?* • Are you trying to have children but cannot?*
Functional Assessment (Including Activities of Daily Living)
Activity and Mobility
• Do you have a planned exercise program? If yes, what is it, and have you had to make any changes in this routine lately? If so, why and what kinds of changes?
Sleep and Rest
• How many hours do you sleep at night? Do you feel rested on awakening? • Are you ever awakened by sweating during the night?*
Nutrition
• *Women:* Have you had any problems with anemia?* Have you had problems with eating disorders?*
Interpersonal Relationships
• Are you in a relationship? Are you able to take care of your significant others and your home? If not, why not?
Self-Care and Health Promotion Activities
• *Women:* Have you noticed anything different about your breasts? Have you had a Pap test or mammography recently? If so, what were the results and dates of these tests? How often do you have these checks? • *Men:* Have you noticed anything different about your testes? Have you had a prostate examination recently? If so, what were the results and dates of these tests?

*If yes, describe.

†See Table 53-7 for sexual history questions.

HT, hormone therapy; *Pap,* Papanicolaou.

Adapted from Jarvis, C., Browne, A. J., MacDonald-Jenkins, J. & Luctkar-Flude, M. (Eds.). (2014). *Physical examination and health assessment*. (2nd Canadian ed.). (pp. 66–73). Toronto: Elsevier Canada.

Menstrual History.

The menstrual history includes the date of the beginning of the most recent menstrual period, description of menstrual flow, age at menarche, and, if applicable, age at menopause. Menstrual history data are used in the detection of pregnancy, infertility, and numerous other gynecological concerns. Changes in the usual menstrual pattern must be explicitly described to determine whether the change is transient and unimportant or connected with a more serious gynecological problem. *Metrorrhagia* (spotting or bleeding between menstruations), *menorrhagia* (excessive menstrual bleeding), *amenorrhea* (absence of menstruation), and *postcoital bleeding* are examples of such problems. Changes in menstrual patterns associated with the use of contraceptive pills, intrauterine devices (IUDs), birth control patches, or medroxyprogesterone (Depo-Provera) injections must be identified. Contraceptive pills usually decrease the amount and duration of flow, whereas some IUDs may cause an increase in the amount and duration. Some IUDs also increase the severity of dysmenorrhea. However, newer IUDs contain progestin and may be therapeutic.

Obstetrical History.

The obstetrical history includes the number of pregnancies, full-term births, preterm births, and live births. Other obstetrical information should include information about any ectopic pregnancies or abortions, either spontaneous or therapeutic, and any problems that occurred with pregnancy.

Menopause.

Obtaining a menopause history includes asking the date of the beginning of the most recent menstrual period and asking about any other symptoms of menopause such as hot flashes, heavy sweats, vaginal dryness, headaches, sleeping problems, mood changes, decreased libido, and urinary problems. Women should be asked whether they are using or have ever used hormone therapy. It is also important to explore how the woman feels about menopause because the drop in estrogen levels during perimenopause and menopause can lead to depression. Women are also

more prone to osteoporosis and heart disease after menopause owing to the lower levels of estrogen, and the nurse must discuss ways to prevent and reduce the risk of these diseases.

Nutritional History.

Anemia is a common problem in women in their reproductive years, particularly during pregnancy and the postpartum period. The adequacy of the diet should be evaluated with this condition in mind.

A thorough nutritional and psychological history should be taken to assess for the presence of an eating disorder. Anorexia can cause amenorrhea and the subsequent problems, such as osteoporosis, that are related to estrogen deficiency. From early adolescence, women can be counselled regarding adequate calcium intake and the role of calcium in the prevention of osteoporosis. The patient's daily calcium intake should be estimated to determine whether the patient needs supplementation. Folic acid intake for women in their reproductive years should be evaluated because a deficiency can result in spina bifida and other neural tube defects in the fetus (Cordero, Crider, Rogers, et al., 2015).

Self-Care History.

It is important to establish the patient's perception of his or her own health and measures that the patient takes to maintain health. Specifically, it is important to ask about self-examination practices and screenings. Regular breast self-examination is no longer recommended but women are encouraged to become familiar with their own breasts because they are often the ones who notice changes possibly indicative of breast cancer (Canadian Cancer Society, 2016a). Screening mammography according to age-specific guidelines (see Chapter 54), and Papanicolaou (Pap) tests are integral to a woman's health. Sexually active women older than 21 are also advised to have regular Pap tests every 1 to 3 years, depending on provincial/territorial screening guidelines and previous test results (Canadian Cancer Society, 2016b). There is not enough evidence to support regular testicular self-examinations for men but it is important that they know what is normal for them because most testicular cancers are discovered first by men themselves (Canadian Cancer Society, 2016c). Men older than 50 years are advised to talk to their physician about their personal risk for prostate cancer and the advisability of them having screening tests for early detection of prostate cancer such as a digital rectal examination and a prostate-specific antigen test (Canadian Cancer Society, 2016d). Men at high risk for prostate cancer (i.e., Black men, men with

first-degree relatives who have prostate cancer) should begin these discussions before age 50 with their health care provider (Canadian Cancer Society, 2016d).

Assessment of the reproductive system is incomplete without information about the patient's lifestyle choices. The nurse should know whether a woman uses cigarettes, alcohol, caffeine, or other drugs because these substances can be detrimental to both mother and fetus. Cigarette smoking may delay conception and can also increase the risk of morbidity in women using oral contraceptives. Early menopause is also associated with smoking in women. These substances may also adversely affect the sperm count in men and cause erectile dysfunction or decreased libido.

The nurse should also document whether the patient is allergic to sulfonamides, penicillin, rubber, or latex. Sulfonamides and penicillin are used frequently in the treatment of reproductive and genito-urinary problems such as vaginitis and gonorrhea. Rubber and latex are commonly used in diaphragms and condoms. An allergy to these substances precludes their use as contraceptive methods.

Elimination.

Many gynecological problems can result in genito-urinary problems. Stress incontinence and urge incontinence are common in older women because the pelvic musculature relaxes as a result of multiple births or advancing age. Vaginal infections predispose patients to chronic or recurrent urinary tract infections. Metastasis of malignant tumours of the reproductive system to the genito-urinary system is possible because of their proximity. Benign prostatic hyperplasia is a common problem of older men. It can alter normal urination, causing retention and difficulty in initiating the urinary stream.

Sexual Health History.

The extent and the depth of the interview about a patient's sexuality depend primarily on the expertise of the interviewer and on the needs and the willingness of the patient. Before obtaining a sexual history, interviewers should assess their comfort with their own sexuality because any discomfort in questioning becomes obvious to the patient. Interviews must be carried out in an environment that provides reassurance, confidentiality, and a nonjudgmental attitude. The nurse needs to explain that a sexual health history is a routine part of history taking for all patients and ask permission to ask questions related to sexual health.

There is evidence that older adults avoid seeking help for sexual concerns because of sexual stigma, including lack of knowledge about sexual problems, discomfort talking about sex, and beliefs that sexual activity in older persons is inappropriate (Syme & Cohn, 2016). Sexual history taking should be a routine part of periodic health examinations. According to Ports, Barnack-Tavlaris, Syme, and associates (2014), health care providers underestimate the prevalence of patients' sexual concerns and would benefit from more training in comprehensive sexual history taking, especially with older adults.

Table 53-7 outlines specific questions for a sexual history. A sexual history should include information regarding sexual activity, beliefs, and practices. Sexual preference (heterosexual, homosexual, bisexual), the frequency and type of sexual activity (e.g., penile–vaginal, penile–rectal, oral, etc), and the number of partners and protective measures against STIs and pregnancy should be explored. The patient's knowledge of safe sexual practices should be determined. A history of multiple sex partners and unprotected sex increases the risk of contracting an STI. For a woman, this can increase the risk of pelvic inflammatory disease, which can compromise her ability to become pregnant.

TABLE 53-7
SEXUAL HEALTH HISTORY FORMAT

- Are you currently in a sexual relationship? If yes, do you prefer relationships with men, women, or both? In which type of sex do you engage (e.g., penile–vaginal, penile–rectal, oral)?
- How frequently do you engage in sexual activities? Are you and your partner(s) satisfied with the sexual relationship? Do you communicate comfortably about sexual activity?
- Do you have a significant other? If yes, is this relationship satisfying? If no, explain.
- Do you or your partner(s) have multiple partners? How many sexual partners have you had in the past 3 months?
- Do you prefer relationships with men, women, or both? (If the patient is gay or lesbian, inquire whether he or she is in a significant relationship.)
- Has your sex life changed during the past year? If yes, how?
- What kind of sex do you engage in (e.g., oral, vaginal, rectal)?
- Are you experiencing any problems that are affecting your sexuality? If yes, describe.
- Have you ever had a sexually transmitted infection? If yes, what?
- How do you protect yourself from sexually transmitted infections? If protection is used, what type? Do you use protection every time you have intercourse?
- Are you currently using any birth control measures? If yes, what type(s)? How long have you been using this method? How effective do you feel this has been?
- How old were you when you first had intercourse? Was it by choice? Have you ever been forced into sexual acts as a child or an adult? If so, how has this affected you or your partner?
- How often have you experienced erectile dysfunction (male) or difficulty with vaginal lubrication (female) or pain with intercourse?
- Do you or your partner(s) frequently use drugs or alcohol before you engage in sexual activity?

Source: Adapted from Wilson, S. F., & Giddens, J. F. (2013). *Health assessment for nursing practice* (5th ed.). St. Louis: Mosby.

Individuals should be asked about their general satisfaction with sexuality. The patient should be questioned about sexual beliefs and practices and whether orgasm is achieved. Any unexplained change in sexual practices or performance should be explored. Problems of the reproductive system can cause physiological or psychological problems that can lead to dyspareunia (painful intercourse), erectile dysfunction, sexual dysfunction, or infertility. Both the cause and the effect of such problems should be determined.

Inclusive and Appropriate Health Care for Sexual and Gender Minority Communities.

People who identify themselves as lesbian, gay, bisexual, transgender, or queer (LGBTQ) account for approximately 5% to 10% of the population in the United States (Grant, Koskovich, Frazer, et al., 2010). In the Community Health Survey (Statistics Canada, 2014), 1.7% of Canadians aged 18 to 59 identified themselves as homosexual (gay or lesbian) and 1.3% as bisexual. Members of sexual and gender minority communities experience barriers to inclusive and appropriate health care (Rapid Response Service, 2014). Because prevailing attitudes in society discourage self-disclosure, members of the LGBTQ community often seek help later in the disease process. They underutilize the health care system because they often encounter insensitivity or homophobic attitudes, as well as discrimination, in some health care settings (Rainbow Health Ontario, 2014). A growing body of international research indicates that sexual- and gender-minority communities experience higher rates of cervical, breast, and anal cancer; eating disorders; depression and other mental health issues; and a higher incidence of smoking- and alcoholism-related health problems (Rainbow Health Ontario, 2014; Rapid Response Service, 2014).

Nurses must understand the unique needs of LGBTQ community members and provide inclusive and appropriate health care. Members of sexual- and gender-minority communities need to know that they are welcome, have rights, and are safe. The physical environment must acknowledge that LGBTQ people exist and are welcome (e.g., signage, posters, brochures, agency literature).

In language and agency forms and assessment tools, heterosexuality should not be assumed as the norm but should allow individuals to disclose their sexual identity, same-sex partnerships and sexual behaviour without fear of discrimination. Some examples of inclusive care are the use of the following language and concepts: *partner* or *spouse* instead of

husband or *wife, significant relationships* instead of *next of kin,* and a broad definition of family that goes beyond traditional concepts to recognize as family whomever the patient considers that family to be.

Members of the LGBTQ community and their families also need affirmation that their identity is acknowledged and respected. In addition, the behaviour of the health care provider must demonstrate understanding of each person's unique needs.

Objective Data

Physical Examination: Male.

The examination of the male external genitalia includes inspection and palpation. An examination may be performed with the patient lying or standing. The standing position is generally preferred. The examiner should be seated in front of the standing patient and should wear gloves during examination of the male genitalia.

Pubis.

The nurse observes the distribution and general characteristics of the pubic hair and the skin. Normally, the hair is in a diamond-shaped pattern and is coarser than scalp hair. The absence of hair is not a normal finding unless the man is shaving or waxing the pubic hair.

Penis.

The nurse notes the size and the skin texture of the penis and any lesions, scars, or swelling. In addition, the location of the urethral meatus, as well as the presence or absence of a foreskin, should be documented. The foreskin, if present, should be retracted to note any redness, discharge, irritation, or swelling and then replaced over the glans after observation. The glans is compressed to note any discharge and, if present, its amount, colour, and odour. The examiner palpates the penile shaft for tenderness or masses and observes the ventral and dorsal aspects.

Scrotum and Testes.

This part of the examination is performed by a nurse with advanced skills. The nurse would start by performing a complete skin examination by lifting each testis to inspect all sides of the scrotal sac. The scrotum is palpated in order to note changes in consistency or the presence of masses. It is important to note whether the testes are descended. The left testis usually hangs lower than the right. An undescended testis is a major risk

factor for testicular cancer, as well as a potential cause of male infertility (Zoltick, 2011).

Inguinal Region and Spermatic Cord.

This part of the examination is performed by a nurse with advanced skills. The nurse first inspects the skin overlying the inguinal regions for rashes or lesions. The patient should be asked to bear down or cough. While he is straining, the inguinal area should be inspected for the presence of a bulge. No bulging should be seen.

Examination of the inguinal area continues with palpation. Using the index or the middle finger, the nurse palpates the right and left inguinal rings. The finger should be inserted into the lower aspect of the scrotum and should follow the spermatic cord upward through the triangular, slitlike opening of the inguinal ring. At this point, the patient should be asked to bear down and cough. The nurse determines whether the strain produces a bulging of the intestines through the ring, indicating the presence of a hernia, a condition that necessitates follow-up. The inguinal lymph nodes should also be palpated. Enlargement of the lymph nodes (termed *lymphadenopathy*) could suggest a pelvic organ infection or malignancy.

Anus and Prostate.

The nurse inspects the anal sphincter and the perineal region for lesions, masses, and hemorrhoids. A digital rectal examination is required for all men who have symptoms of prostate trouble, such as difficulty in initiating the flow and the urge to void frequently. This examination should be performed annually for all men 50 years of age or older. This part of the examination is performed by a nurse with advanced skills.

Physical Examination: Female.

Physical examination of female genitalia often begins with inspection and palpation of the breasts and then proceeds to the abdomen and the genitalia. Examination of the abdomen provides an opportunity to detect pain or any masses that may involve the genito-urinary system. (Abdominal examination is discussed in more detail in Chapter 41.) The nurse needs to assess the patient's comfort level and obtain consent before beginning an assessment of the reproductive system. It is also important to be sensitive to the patient's questions and needs during the procedure.

Breasts.

A clinical breast examination is a thorough breast assessment performed by a trained health care provider. Clinical breast examination is not considered an effective screening procedure for breast cancer, and so it is not done routinely. It is performed if there is a lump or change in a woman's breasts or axillae area (Canadian Cancer Society, 2016a).

When performing a clinical breast examination, the nurse first examines the breasts by visual inspection. With the patient seated, the breasts are observed for symmetry, size, shape, skin colour and texture, vascular patterns, dimpling, and unusual lesions. The patient is asked to put her arms at her sides and then overhead, to lean forward, and to press hands on hips. The nurse observes for any abnormalities during these manoeuvres. The axillae and the clavicular areas are palpated for enlarged lymph nodes.

After the patient assumes a supine position, a pillow is placed under her back on the side to be examined. The nurse should asks the patient to put her arm above and behind her head. These manoeuvres flatten breast tissue and make palpation easier. Then the nurse palpates the breast in a systematic manner, using the distal finger pads for palpation. The area palpated includes the tail of Spence (the upper outer tail of breast tissue that extends into the axilla) because this region and the upper outer quadrant are the areas where most breast malignancies develop. Finally, the nurse palpates the area around the areolae for masses. The nipple is compressed to determine the presence of discharge or any masses. The colour, consistency, and odour of any discharge are documented.

Case Study

Objective Data: Physical Examination

Source: Dubova/Shutterstock.com.

Focused assessment of Anna Kaluza reveals the following:

> A palpable, firm, fixed, 1.5-cm mass in upper, outer quadrant of right breast. No dimpling, redness, or swelling noted. No masses palpated in left breast. No lymphadenopathy noted.

Throughout this chapter, consider which diagnostic studies would be performed for Mrs. Kaluza. See pp. 1331, 1336, and 1347 for more information on Mrs. Kaluza.

External Genitalia.

Gloves are used for examination of the female external genitalia. The nurse inspects the mons pubis, labia majora, labia minora, posterior fourchette, perineum, and anal region for characteristics of skin, hair distribution, and contour. Any lesions, inflammation, swelling, and discharge are documented. The nurse separates the labia to fully inspect the clitoris, the urethral meatus, and the vaginal orifice.

Internal Pelvic Examination.

This part of the examination is performed by a nurse with advanced skills. During the speculum examination, the nurse observes the walls of the vagina and the cervix for inflammation, discharge, polyps, and suspicious growths. During this examination, it is possible to obtain a Pap test and collect secretions for culture and microscopic examination. After the speculum examination, the nurse performs a bimanual examination to assess the size, the shape, and the consistency of the uterus, the ovaries, and the tubes. The tubes are not normally palpable.

Parts of the pelvic and bimanual examinations are not included in this text because they are considered advanced skills and are not usually within the scope of the nurse generalist.

Table 53-8 provides an example of a recording format for the physical assessment findings for the male and female reproductive systems. Tables

53-9 through 53-11 summarize common assessment abnormalities of the breasts, the female reproductive system, and the male reproductive system, respectively.

TABLE 53-8

PHYSICAL ASSESSMENT OF THE REPRODUCTIVE SYSTEM: NORMAL FINDINGS

Male	Female
Breasts	
Symmetrical. No masses or tenderness behind nipple. No drainage, retraction, or lesions noted. No lymphadenopathy.	Symmetrical without dimpling. No masses or tenderness behind nipple. Nipples soft; no drainage, retraction, or lesions noted. No lymphadenopathy.
External Genitalia	
Diamond-shaped hair distribution. No lesions or discharge noted. Scrotum symmetrical, testes descended; no masses. No inguinal hernia.	Triangular hair distribution. Genitalia dark pink; no lesions, redness, swelling, or inflammation in perineal region. No vaginal discharge noted. No tenderness with palpation of Skene's ducts and Bartholin's glands.
Anus	
No hemorrhoids, fissures, or lesions noted.	No hemorrhoids, fissures, or lesions noted.

TABLE 53-9

ASSESSMENT ABNORMALITIES
Breast

Finding	Description	Possible Etiology and Significance
Nipple inversion or retraction	Recent onset, erythematous, pain, unilateral.	Abscess, inflammation, cancer.
	Recent onset (usually within past year), unilateral, lack of tenderness.	Neoplasm.
Nipple secretions		
• Galactorrhea (female)	Milky, no relationship to lactation, unilateral or bilateral or intermittent or consistent presentation.	Drug therapy, particularly phenothiazines, tricyclic antidepressants, methyldopa. Hypofunction or hyperfunction of thyroid or adrenal glands. Tumours of hypothalamus or pituitary gland. Excessive estrogen. Prolonged suckling or breast foreplay.
• Galactorrhea (male)	Milky, bilateral presentation.	Chorioepithelioma of testes, manifestation of pituitary tumour.
• Purulent	Grey-green or yellow. Frequent unilateral presentation. Association with pain, erythema, induration, nipple inversion.	Puerperal (after birth) mastitis (inflammatory condition of breast) or abscess.
	Same description as mastitis or abscess but usually without nipple inversion.	Infected sebaceous cyst.
• Serous discharge	Clear appearance, unilateral or bilateral or intermittent or consistent presentation.	Intraductal papilloma.
• Dark green or multicoloured discharge	Thick, sticky, and frequently bilateral.	Ductal ectasia (dilation of mammary ducts).
• Serosanguineous or bloody drainage	Unilateral presentation.	Papillomatosis (widespread development of nipple-like growths), intraductal papilloma, carcinoma (male and female).
Scaling or irritation of nipple	Unilateral or bilateral presentation, crusting, possible ulceration.	Paget's disease, eczema, infection.
Nodules, lumps, or masses (male and female)	Multiple, bilateral, well-delineated, soft or firm, mobile cysts. Pain. Premenstrual occurrence.	Fibrocystic changes.
	Rubbery consistency, fluid-filled interior. Pain.	Ductal ectasia.
	Soft, mobile, well-delineated cyst. Absence of pain.	Lipoma, fibroadenoma.
	Erythema, tenderness, induration.	Infected sebaceous cysts, abscesses.
	Usually singular, hard, irregularly shaped, poorly delineated, nonmobile.	Neoplasm.
Dimpling of breast	Unilateral, recent onset, no pain.	Neoplasm.

TABLE 53-10

ASSESSMENT ABNORMALITIES
Female Reproductive System

Finding/Description	Possible Etiology and Significance
Vulvar Discharge	
White, thick, curdy, frequent itching and inflammation, yeast-like smell or lack of odour	Candidiasis (candidal or yeast infection), vaginitis
Thin grey or white, copious flow; malodorous or "fishy" smell; vulvar irritation	Bacterial vaginosis infection
Frothy green or yellow; malodorous	*Trichomonas vaginalis* infection
Bloody discharge	*Chlamydia trachomatis* or *Neisseria gonorrhoeae* infection, menstruation, trauma, cancer
Vulvar Erythema	
Bright or beefy red colour, itching	*Candida albicans,* allergy, chemical vaginitis
Reddened base, painful vesicles or ulcerations	Genital herpes
Macules or papules, itching	Chancroid (STI), contact dermatitis, scabies, pediculosis
Vulvar Growths	
Soft, fleshy growth; nontender	Condyloma acuminatum
Flat and warty appearance, nontender	Condyloma latum
Same as either of preceding descriptions, possible pain	Neoplasm
Reddened base, vesicles, and small erosions; pain	Lymphogranuloma venereum, genital herpes, chancroid
Indurated, firm ulcers; lack of pain	Chancre (syphilis), granuloma inguinale
Abdominal Pain or Tenderness	
Intermittent or consistent tenderness in right or left lower quadrant	Salpingitis (infection of Fallopian tube), ectopic pregnancy, ruptured ovarian cyst, PID, tubal or ovarian abscess
Periumbilical location, consistent occurrence	Cystitis, endometritis (inflammation of endometrium), ectopic pregnancy
Abnormal Vaginal Bleeding	
Unusual and inappropriate uterine bleeding	Dysfunctional uterine bleeding, usually anovulatory bleeding, menorrhagia (heavy menstrual bleeding), metrorrhagia (irregular, frequent bleeding), postmenopausal bleeding

PID, pelvic inflammatory disease; *STI*, sexually transmitted infection.

TABLE 53-11

ASSESSMENT ABNORMALITIES
Male Reproductive System

Finding	Description	Possible Etiology and Significance
Penile growths or masses	Indurated, smooth, disclike appearance; absence of pain; singular presentation	Chancre
	Papular to irregularly shaped ulceration with pus, lack of induration	Chancroid
	Ulceration with induration and nodularity	Cancer
	Flat, wartlike nodule	Condyloma latum
	Elevated, fleshy, moist, elongated projections with single or multiple projections	Condyloma acuminatum
	Localized swelling with retracted, tight foreskin	Paraphimosis (inability to replace foreskin to its normal position after retraction), trauma
Vesicles, erosions, or ulcers	Painful, erythematous base; vesicular or small erosions	Genital herpes, balanitis (inflammation of glans penis), chancroid
	Painless, singular, small erosion with eventual lymphadenopathy	Lymphogranuloma venereum, cancer
Scrotal masses	Localized swelling with tenderness, unilateral or bilateral presentation	Epididymitis (inflammation of epididymis), testicular torsion, orchitis (mumps)
	Swelling, tenderness	Incarcerated hernia
	Unilateral or bilateral presentation; swelling without pain; translucent, cordlike or wormlike appearance	Hydrocele (accumulation of fluid in outer covering of testes), spermatocele (firm, sperm-containing cyst of epididymis), varicocele (dilation of veins that drain testes), hematocele (accumulation of blood within scrotum)
	Firm, nodular testes or epididymis; frequent unilateral presentation	Tuberculosis, cancer
Penile discharge	Clear to purulent colour, minimal to copious flow	Urethritis or gonorrhea, *Chlamydia trachomatis* infection, trauma
Penile or scrotal erythema	Macules and papules	Scabies, pediculosis
Inguinal masses	Bulging, unilateral presentation during straining	Inguinal hernia
	1- to 3-cm nodules	Lymphadenopathy

A *focused assessment* is used to evaluate the status of previously identified reproductive problems and to monitor for signs of new problems (see Table 3-6). This evaluation is described in the "Focused Assessment" box.

Focused Assessment

Reproductive System

Use this checklist to ensure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses

Vaginal discharge/itching, unusual bleeding	Y	N
Penile pain, lesions, discharge	Y	N
Medications: oral contraceptives, antihypertensives, psychotropics, hormones	Y	N
Clinical examinations of reproductive systems (breast, pelvis, testicles, prostate) and results	Y	N
Pain in the abdomen, pelvis, or genitalia	Y	N

Objective: Diagnostic

Check the following for results and critical values

Serum hCG	✓
Serum PSA	✓
Culture and sensitivity test results	✓
Hormone levels (testosterone, progesterone, estrogen) if done	✓
Screen for STIs (e.g., *Chlamydia,* gonorrhea)	✓
Laboratory reports: wet mounts, dark-field microscopy	✓
Radiograph of pelvis or breasts	✓
Ultrasound study of prostate	✓

Objective: Physical Examination

Inspect

External genitalia for redness, swelling, drainage	✓
Breasts for swelling, dimpling, retraction, drainage	✓

Diagnostic Studies of Reproductive Systems

The most commonly used diagnostic studies in the assessment of the reproductive systems are summarized in Table 53-12, and select studies (Figure 53-10) are described in more detail below.

TABLE 53-12

DIAGNOSTIC STUDIES
Male and Female Reproductive Systems

Study	Description and Purpose	Nursing Responsibility
Urine Studies		
Human chorionic gonadotropin (hCG)	Reveals pregnancy Also reveals hydatidiform mole and chorioepithelioma (in men and women) *Males and nonpregnant females*: negative	Obtain menstrual history from patient, including birth control methods. Determine presence or absence of presumptive signs of pregnancy (e.g., breast changes, increased whitish vaginal discharge).
Testosterone	Reveals tumours and developmental anomalies of the testes *Female:* 6.9–41.6 nmol/24 hr *Male:* 139–469 nmol/24 hr	Instruct patient to collect 24-hr urine specimen and to keep it refrigerated.
Follicle-stimulating hormone (FSH)	Indicates gonadal failure because of pituitary dysfunction *Female:* Follicular phase: 2–5 U/24 hr Midcycle: 8–60 U/24 hr Luteal phase: 2–10 U/24 hr Postmenopause: 35–100 U/24 hr *Male:* 3–11 U/24 hr	Instruct patient to collect 24-hr urine specimen; to indicate phase of menstrual cycle or if menopausal; and to indicate whether taking oral contraceptives or hormones.
Blood Studies		
Prolactin	Reveals pituitary dysfunction that can cause amenorrhea *Female:* <25 mcg/L *Male:* <20 mcg/L	Observe venipuncture site for bleeding or hematoma.
Prostate-specific antigen (PSA)	Reveals prostate cancer Also a sensitive test for monitoring response to therapy Reference interval: <2.5 mcg/L	Inform patient that there are no food or fluid restrictions. Collect 5 mL of blood. Observe venipuncture site for bleeding.
hCG	Reveals pregnancy Can be used as a tumour marker for testicular malignancy Also used to detect hydatidiform mole *Males and nonpregnant females:* <5 IU/mL	Ask patient at point what she is in her menstrual cycle, whether she has missed menses, and, if so, how late menses are.
Testosterone	Indicates whether androgen levels are elevated because of testicular, adrenal, or ovarian dysfunction or pituitary tumours Serum levels also measured to assess male infertility and tumours of testicle or ovary *Male:* 9.75–38 nmol/L *Female:* <0.52–2.43 nmol/L	Collect health history to rule out potential sources of interference with accuracy of results (e.g., use of corticosteroids or barbiturates, presence of hypothyroidism or hyperthyroidism).

Study	Description and Purpose	Nursing Responsibility
Progesterone	Indicates cause of infertility Used to monitor success of drugs for infertility or the effect of treatment with progesterone Indicates whether ovulation is occurring Helps diagnose problems with the adrenal glands and some types of cancer *Female:* Follicular phase: <1.6 nmol/L Luteal phase: 9.54–79.5 nmol/L After menopause: <1.27 nmol/L *Male:* 0.32–1.6 nmol/L	Include measurements during most recent menstrual period and trimester of pregnancy because progesterone levels vary with gestation.
Estradiol	Indicates ovarian function Useful in assessing estrogen-secreting tumours and states of precocious female puberty May be used to confirm perimenopausal status Increased serum estradiol levels in men may be indicative of testicular tumours *Female:* Follicular phase: 73.4–1284.9 pmol/L Luteal phase: 110–1652 pmol/L After menopause: ≤73.4 pmol/L *Male:* 37–183.5 pmol/L	Observe venipuncture site for bleeding or hematoma.
FSH	Indicates gonadal failure owing to pituitary dysfunction Used to validate menopausal status *Female:* Follicular phase: 1.37–9.9 IU/L Ovulatory peak: 6.7–17.2 IU/L Luteal phase: 1.09–9.2 IU/L Postmenopause: 19.3–100.6 IU/L *Male:* 1.42–15.4 IU/L	Inform patient that no food or fluid restrictions are required. Ask patient which phase of menstrual cycle she is in, whether she is menopausal, and whether she is taking oral contraceptive or hormone therapy.
Venereal Disease Research Laboratory (VDRL) test (flocculation)	Nonspecific antibody tests used to screen for syphilis Readings can be positive within 1–2 wk after appearance of primary lesion (chancre) or 4–15 wk after initial infection *Reference interval:* negative or nonreactive	
Rapid plasma reagin (RPR) assay (agglutination)	Nonspecific antibody tests used to screen for syphilis *Reference interval:* negative or nonreactive	Obtain data to identify conditions such as hepatitis, pregnancy, and autoimmune diseases that may interfere with accuracy of results.
Fluorescent treponemal antibody absorption (FTA-Abs) test	Reveals syphilis antibodies Also reveals early syphilis with great accuracy Usually performed if results of aforementioned nonspecific tests are equivocal *Reference interval:* negative or nonreactive	
Cultures and Smears		

Study	Description and Purpose	Nursing Responsibility
Dark-field microscopy	Direct examination of specimen obtained from potential syphilitic lesion (chancre) to detect *Treponema pallidum*	Avoid direct skin contact with open lesion.
Wet mounts	Direct microscopic examination of specimen of vaginal discharge, performed immediately after collection Indicates presence or absence and number of *Trichomonas* organisms, bacteria, white and red blood cells, and candidal buds or hyphae May reveal other clues to or causes of inflammation or infection	Explain procedure and purpose to patient. Instruct patient not to use douche before examination. Prepare for collection of specimens (glass slide, 10%–20% potassium hydroxide [KOH] solution, sodium chloride [NaCl] solution, and cotton-tipped applicators).
Cultures	Specimens of vaginal, urethral, or cervical discharge that are cultured to assess presence of gonorrhea or *Chlamydia* Rectal and throat cultures may also be obtained, depending on data in sexual history	Obtain specific contact and sexual history inclusive of oral and rectal intercourse. Instruct patient against using douche before examination. Obtain urethral specimen from men before they void. Instruct women who are sexually active with multiple partners to have at least a yearly culture for gonorrhea and *Chlamydia.* Instruct sexually active men to have any discharge evaluated immediately to rule out gonorrhea strains that do not cause classic symptoms of dysuria.
Gram stain	Used for rapid detection of gonorrhea Presence of gram-negative intracellular diplococci generally warrants initiation of treatment Not highly accurate for women Also a valid alternative for *Chlamydia* testing	Same as for cultures
Cytological Studies		
Papanicolaou (Pap) smear	Microscopic study of exfoliated cells via special staining and fixation technique to detect abnormal cells Most commonly studies of cells obtained directly from the endocervix and ectocervix	Instruct women who are sexually active and who are between the ages of 21 and 69 to have Pap smears according to Canadian Cancer Society guidelines (every 1–3 yr, depending on provincial and territorial screening guidelines).* Instruct patients not to use douche for at least 24 hr before examination. Carefully document menstrual and gynecological history.
Nipple discharge test	Cytological study of nipple discharge	Ask whether patient is taking hormonal preparations or other drugs, is breastfeeding, or has a history of amenorrhea.
Radiological Studies		
Mammography	X-ray image of breast tissue on radiographic film, used to assess breast tissue	Instruct patient about advantages of the examination. Explain that the Canadian Cancer Society recommends screening with mammography every 2 yr for women who are 50–69 yr of age (see Chapter 54 for more information).†
• Screening	Reveals benign and malignant masses	

Study	Description and Purpose	Nursing Responsibility
• Diagnostic	Performed when patient has suspect clinical symptoms or when an abnormality is found on screening mammogram Additional views of affected breast are taken	
Ultrasonography (abdominal and transvaginal)	Used to measure and record high-frequency sound waves as they pass through tissues of variable density In women, useful in detecting masses >3 cm, such as ectopic pregnancy, IUD, ovarian cyst, and hydatidiform mole In men, used to detect testicular torsion or masses	Instruct patient that a full bladder may be required, depending on the reason for the study.
Ultrasound-guided biopsy	Use of ultrasound guidance during a biopsy, usually done as an outpatient procedure Used to direct the biopsy needle into the region of interest and obtain a sample of tissue Small tissue sample is removed to diagnose infection, inflammation, or mass	Inform patient of purpose of this procedure. It is usually done as an outpatient procedure.
Computed tomography (CT) of pelvis	Reveals tumours within the pelvis	Explain procedure to patient. Instruct patient to lie still during the procedure. If IV contrast medium is used, check for iodine allergy.
Magnetic resonance imaging (MRI)	Use of radio waves and magnetic field to view soft tissue Useful if mammogram is abnormal or in presence of breast dysplasia Also used to diagnose abnormalities in the female and male reproductive systems	Screen patient for metal parts and pacemaker. Inform patient that the procedure is painless. Instruct patient to lie still during the procedure.
Invasive Procedures		
Breast biopsy	Histological examination of breast tissue excised either by needle aspiration or excisional biopsy	*Before biopsy:* Instruct patient about operative procedures and sedation. *After biopsy:* Perform wound care and instruct patient about breast self-examination.
Hysteroscopy	Visualization of uterine lining through hysteroscope inserted through cervix Used mainly to diagnose and treat abnormal bleeding such as that caused by fibroids or polyps Biopsy sample may be taken during the procedure	Explain purpose and method of procedure and that it might be done in the physician's office. Inform patient that mild cramping and slight bloody discharge after procedure is normal.
Hysterosalpingography	Fluoroscopy with a contrast material injected into the uterine cavity via the cervix Used to check for blocked Fallopian tubes, adhesions near ovary, or abnormalities of the uterus	Inform patient about procedure and that it may be fairly uncomfortable. Check patient for iodine allergy.

Study	Description and Purpose	Nursing Responsibility
Colposcopy	Direct visualization of cervix with binocular microscope that allows magnification and study of cellular dysplasia and cervix abnormalities Used as follow-up study for abnormal Pap test results and for examination of women exposed to DES in utero Biopsy sample from cervix may be taken during examination Valuable in decreasing number of false-negative results of cervical biopsies	Describe this outpatient procedure to patient. Inform patient that this examination is similar to speculum examination.
Conization	Removal of cone-shaped sample of squamocolumnar tissue of cervix for direct study	Explain purpose and method of procedure and that it requires use of surgical facilities and anaesthesia. Instruct patient to avoid sexual intercourse and tampons for about 3–4 wk. Also discuss necessity for 3-wk follow-up.
Loop electrosurgical excision procedure (LEEP)	Excision of cervical tissue via an electrosurgical instrument Helps diagnose and treat cervical dysplasia Minimizes amount of tissue removed and preserves child-bearing ability	Explain purpose and method of procedure and that it may be done in the physician's office. Inform patient that she may feel slight tingling or abdominal cramping during procedure. Inform patient that discharge, bleeding, and cramping may occur for 1–3 days after procedure.
Culdotomy, culdoscopy, and culdocentesis	*Culdotomy:* incision made through posterior fornix of cul-de-sac that allows visualization of peritoneal cavity (i.e., uterus, tubes, and ovaries) *Culdoscopy:* used after culdotomy to closely study these structures; valuable in fertility evaluations. *Culdocentesis:* withdrawal of fluid for examination	Explain purpose and method of procedure. Prepare patient for vaginal operation with preoperative instruction and sedation. Perform assessment of bleeding and discomfort after surgery.
Laparoscopy (peritoneoscopy)	Visualization of pelvic structures via fibre-optic endoscopes inserted through small abdominal incisions Instillation of CO_2 into cavity to improve visualization Used in diagnostic assessment of uterus, tubes, and ovaries (see Figure 53-10) Can be performed in conjunction with tubal sterilization	Before surgery, instruct patient about procedure, prepare patient's abdomen, and reassure patient about sedation. Inform patient of probability of shoulder pain owing to air in the abdomen.
Dilatation and curettage (D&C)	Operative procedure dilates cervix and allows curetting of endometrial lining Used in assessment of abnormal bleeding and cytological evaluation of lining.	Before surgery, instruct patient about procedure and sedation. Perform postoperative assessment of degree of bleeding (frequent perineal pad check during first 24 hr).
Fertility Studies		

Study	Description and Purpose	Nursing Responsibility
Semen analysis	Assessment of semen for volume (2–5 mL), viscosity, sperm count (>20 million/mL), sperm motility (60% motile), and percentage of abnormal sperm (60% with normal structure).	Instruct patient to bring in fresh specimen within 2 hr of ejaculation.
Basal body temperature assessment	Indirectly indication of whether ovulation has occurred (temperature rises at ovulation and remains elevated during secretory phase of normal menstrual cycle)	Instruct woman to take her temperature with special basal temperature thermometer (calibrated in tenths of degrees) every morning before getting out of bed. Instruct woman to record temperature on graph.
Huhner, Sims-Huhner test	Examination of mucus sample of cervix within 2–8 hr after intercourse Assessment of total number of sperm in relation to number of live sperm Used to determine whether cervical mucus is "hostile" to passage of sperm from vagina into uterus	Instruct couples to have intercourse at estimated time of ovulation and be present for test within 2–8 hr after intercourse.
Endometrial biopsy	Use of small curette to obtain piece of endometrial lining to assess endometrial changes common to progesterone secretion after ovulation Also used to assess abnormal menstrual or postmenopausal uterine bleeding	Tell patient that test must be performed after ovulation. Explain that procedure should cause only short period of uterine cramping and light, bloody vaginal discharge for about 24 hr.
Hysterosalpingography	See earlier section in table related to hysterosalpingography, under "Invasive Procedures."	See earlier section in table related to hysterosalpingography, under "Invasive Procedures."
Serum progesterone measurement	Same those of as blood studies.	Same as those of blood studies.
Genetic Studies		
DNA testing for *BRCA1* and *BRCA2* gene mutations (blood or saliva sample)	Testing for inherited mutations in breast cancer *(BRCA)* genes, which increase a female's susceptibility for the development of breast or ovarian cancer Recommended in cases of family history associated with an increased risk of a harmful mutation in either gene	Inform patient that results may take up to 1 month to be available. Advise genetic counselling before and after testing.

Urine Studies

Pregnancy Testing.

Pregnancy is generally validated by measuring human chorionic gonadotropin (hCG) in the urine (Office on Women's Health, 2014). A solution containing monoclonal antibodies specific for hCG is mixed with a small amount of urine. The presence of hCG causes a change in colour of the tested urine.

In home pregnancy test kits, the same assay principle is used. Positive results are based on the presence of hCG in urine. Some tests can detect pregnancy as early as the first day after a missed menstrual period. These tests are 99% accurate if the test is performed exactly per instructions (Office on Women's Health, 2014). A second test is recommended within a week if the first test result is negative (assuming menses have not yet occurred).

Hormone Studies.

Although estrogen studies are performed on urine, the results are frequently inaccurate because estrogen levels vary during the normal cycle and it is difficult to estimate the day of the cycle in women with irregular menses. Adrenal androgens are precursors of estrogens and can be measured in the urine of both men and women. For more information regarding hormone studies, see Chapter 50.

Blood Studies

Hormone Studies.

Serum assays for hCG can detect pregnancy before a woman misses her menstrual period, as early as 10 days after conception (Pagana & Pagana, 2013). The prolactin assay is used primarily in the workup of a patient with amenorrhea. High levels of prolactin are normally associated with low levels of estrogen, such as those that occur during lactation. However, the same finding can occur with pituitary adenomas, especially with otherwise unexplained *galactorrhea* (excessive secretion of breast milk). Serum progesterone and estradiol are sometimes measured in ovarian function assessment, particularly for amenorrhea. In addition, hormonal blood studies are essential components of a thorough fertility workup.

Tumour Markers.

Biological tumour markers are used to assess for malignant disease and to monitor therapy (marker levels rise as disease progresses and fall with disease regression). Alpha-fetoprotein, hCG, and cancer antigen 125 (CA-125) are sometimes used as tumour markers for reproductive system malignancies. A specific tumour antigen such as prostate-specific antigen is another type of tumour marker, frequently measured to determine the presence of prostate cancer.

Serological Tests for Syphilis.

The Venereal Disease Research Laboratory (VDRL) test and the rapid plasma reagin (RPR) test are used to detect the presence of antibodies in the serum of patients thought to be infected with syphilis. These tests are inexpensive and reliable but yield high levels of false-positive results in patients with inflammatory disorders. The fluorescent treponemal

antibody absorption test is a more specific treponemal assay and should be used after a positive finding on the VDRL or RPR test.

Cultures and Smears

Cultures and smears are most frequently employed in the diagnosis of STIs. Specimens for cultures and smears are most commonly taken from the vagina, endocervix, and rectum for females and the urethra and rectum for males. For a culture, the specimen is placed on a special culture medium. A smear involves rubbing the specimen on a slide for direct examination. Gram stain smears have been shown to be effective in the diagnosis of *Chlamydia* infection. A nucleic acid amplification test is used to screen for both gonorrhea and *Chlamydia* from a wide variety of samples, including vaginal, endocervical, urine, and urethral specimens. Dark-field microscopy involves the direct examination of a specimen obtained from a syphilitic chancre for the diagnosis of syphilis.

Cytological Studies

Cytology is the study of cells under microscopic examination. The Pap smear is a screening test to detect abnormal cells obtained from the cervix or vagina. It involves obtaining cells from the cervical canal, preferably the endocervix, as well as from the vagina. The cells are placed in a fixative for examination by a cytologist for cellular abnormalities. Screening guidelines for the Pap test (also called a *smear*) are discussed in Chapter 56.

Cytological study is also indicated for nipple discharge. Cytological examination can detect the presence of malignant cells and distinguish the discharge with such cells from one associated with infection.

Radiological Studies

Mammography.

Mammography, one of the most frequently used diagnostic tools to assess the reproductive system, is used to detect breast masses. Mammography and screening guidelines for mammography are discussed in Chapter 54.

Case Study

Objective Data: Diagnostic Studies

Source: Dubova/Shutterstock.com.

The breast specialist orders the following for Mrs. Kaluza:

- Digital mammography
- Ultrasonography of breasts
- Magnetic resonance imaging (MRI) of breasts

The mammography reveals an increased density in the right breast. The ultrasound study identifies the mass as solid and not fluid filled. The MRI confirms the presence of a suspicious mass in the right breast.

The health care provider schedules Mrs. Kaluza for a fine-needle aspiration (FNA) biopsy. The results of the ultrasonography-guided FNA biopsy reveal an adenocarcinoma. See pp. 1331, 1336, and 1340 for more information on Mrs. Kaluza.

Ultrasonography.

Ultrasonography has many applications for diagnostic study. Pelvic ultrasonography is used to obtain images of the pelvic organs. Transvaginal ultrasonography can be used to aid in diagnosing abnormalities of the ovaries or the uterus. These types of ultrasound studies are also used to detect pregnancy in the uterus, ectopic pregnancy, ovarian cysts, and other pelvic masses. Breast ultrasonography is useful in the detection of fluid-filled masses. In men, ultrasonography is used to detect testicular masses and testicular torsion. Transrectal ultrasonography is useful in locating prostate tumours.

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Which of the following is a normal reproductive function that may be altered in a client who undergoes a prostatectomy?
   a. Sperm production
   b. Production of testosterone
   c. Production of seminal fluid
   d. Release of sperm from the epididymis
2. What does estrogen production by the mature ovarian follicle cause?
   a. Decreased secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH)
   b. Increased production of gonadotropin-releasing hormone (GnRH) and FSH
   c. Release of GnRH and increased secretion of LH
   d. Decreased release of FSH and decreased progesterone production
3. Female orgasm is the result of which of the following? *(Select all that apply)*
   a. Constriction of the cervical os
   b. Uterine and vaginal contractions
   c. Vaginal enlargement and uterine elevation
   d. Clitoral swelling and increased vaginal lubrication
   e. Rapid release of muscular tension in the reproductive structures
4. Which of the following is an age-related finding noted by the nurse during assessment of an older woman's reproductive system?
   a. Dyspareunia
   b. Vaginal dryness
   c. Nipple retraction
   d. Increased sensitivity of labia
5. Which of the following should be included as significant information about a client's past medical history in relation to the reproductive system?
   a. Extent of sexual activity

b. General satisfaction with sexuality

c. Previous sexually transmitted infections

d. Self-image and relationships with others

6. Which of the following examination techniques is used to evaluate a client's breasts? *(Select all that apply)*

a. Palpation

b. Percussion

c. Inspection

d. Auscultation

7. Which of the following would be considered an abnormal finding during physical assessment of the male reproductive system?

a. Slight clear urethral discharge

b. The glans covered with prepuce

c. Symmetrical scrotum

d. Descended testes

8. The nurse is caring for a client scheduled for an endometrial biopsy who is having difficulty becoming pregnant. What will the nurse explain to the woman?

a. That the outpatient procedure is usually performed before ovulation

b. That bleeding and discharge are common 2 to 4 days after the procedure

c. That a small sample of tissue is obtained to diagnose and treat cervical dysplasia

d. That common changes in endometrial cells in relation to progesterone levels will be assessed

1. c; 2. c; 3. b, c, d, e; 4. b; 5. c; 6. a, c; 7. c; 8. d.

CHAPTER 54

Nursing Management

Breast Disorders

Written by, Darcy Burbage

Adapted by, Jackie Hartigan-Rogers

LEARNING OBJECTIVES

1. Summarize screening guidelines for the early detection of breast cancer.
2. Describe the technique of breast self-awareness, including rationale and reasons for referral.
3. Explain the types, causes, clinical manifestations, collaborative care, and nursing management of common benign breast disorders.
4. Assess the risk factors for breast cancer.
5. Describe the pathophysiology and clinical manifestations of breast cancer.
6. Describe the collaborative care and the nursing management of breast cancer.
7. Specify the physical and psychological preoperative and postoperative aspects of nursing management for patients undergoing a mastectomy.
8. Explain the indications for reconstructive breast surgery; types, potential risks, and complications of reconstructive breast surgery; and nursing management after reconstructive breast surgery.

mastalgia, p. 1351

mastectomy, p. 1353

mastitis, p. 1351

Paget's disease, p. 1356

Breast disorders are a significant health concern for women. Most breast pain is of a benign nature, with the most frequently encountered breast disorders in women being nipple discharge, intraductal papilloma, duct ectasia, breast pain, and fibrocystic changes such as cysts and fibroadenomas (Onstad & Stuckey, 2013; "Managing Fibrocystic", 2015; Women's College Hospital, 2015). In men, gynecomastia is the most common breast disorder.

In Canada, there is a one in eight chance that a woman will receive a diagnosis of breast cancer in her lifetime (Canadian Cancer Society, 2017a). Whether the actual diagnosis is one of a benign condition or a malignancy, the initial discovery of a lump or change in the breast often triggers intense feelings of anxiety, fear, and denial. These feelings can be associated with both the fear of death and the possible loss of a breast. The potential loss of a breast, or part of a breast, may be devastating because of the significant psychological, social, sexual, and body image implications associated with it.

Assessment of Breast Disorders

It is critical that breast disorders be detected early, diagnosed accurately, and treated promptly. The frequency of breast examinations is determined by a woman's age, the presence of significant risk factors, and her medical history. Guidelines established in Canada regarding breast surveillance practices include the following:

- Women of all ages should be familiar with their breasts and report any changes to their health care providers.
- Women ages 40 to 49 should discuss with a health care provider their individual risk for breast cancer, along with the risks and benefits of mammography.
- Women aged 50 to 69 should undergo mammography every 2 years.
- Women aged 70 or older should talk to a health care provider about an individualized screening program.
- A health care provider may also perform a physical examination of the breasts (clinical breast examination).
- Women who are at high risk for developing breast cancer should talk to their health care providers about a personal plan of testing (Canadian Cancer Society, 2017b).

It is recommended that all women discuss the risks and benefits of mammography with their health care providers (Canadian Cancer Society, 2017b). The benefits of early detection of breast cancer are well established. The use of screening mammography has significantly improved early and accurate detection of breast malignancies. Mammography can identify breast abnormalities that may be cancer before physical symptoms appear. Canada's national guidelines have been established on the basis of

research that women aged 50 to 69 benefit most from regular breast screening (Canadian Cancer Society, 2017b).

There has been some confusion with regard to the value of breast self-examination (BSE) and screening mammography for younger women and its role in reducing rates of mortality from breast cancer (Canadian Task Force on Preventive Health Care, 2011; Silversides, 2012). The emphasis now is to assist women to become aware of how their breasts normally look and feel and to understand that there is no right or wrong way for them to check their breasts (Figure 54-1). Nurses should teach women that it is important to get to know the whole area of breast tissue including up to the collarbone and under armpits and nipples (Canadian Cancer Society, 2017b). Women should be encouraged to report any new breast changes (e.g., nipple discharge, presence of a lump) to their health care providers (Canadian Cancer Society, 2017b).

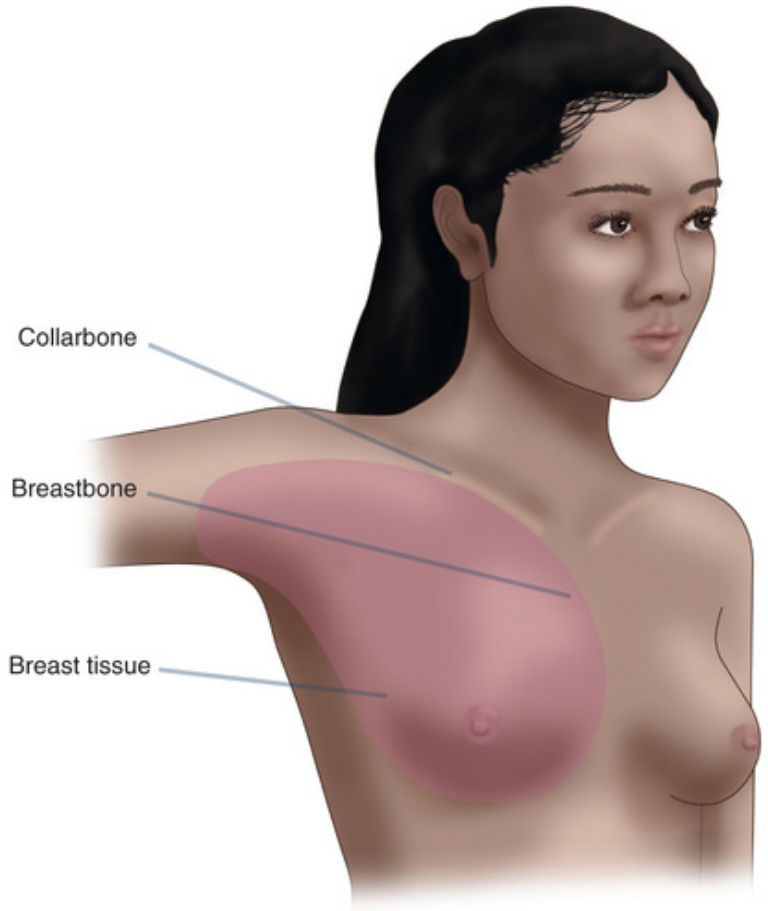

FIGURE 54-1 Every woman should know her breasts. She should be aware of what is normal by looking at and feeling her breasts any way that works best for her. She should get to know the whole area of her breast tissue: up to the collarbone, under the armpits, and including the nipples. Every woman should get to know her breasts well enough to notice changes. Source: Monica Schroeder/Science Source.

If a woman decides she wants to practise BSE and undergo mammography screening, health care providers must ensure that the benefits and risks, as well as the woman's values and preferences, are discussed fully (Canadian Task Force on Preventive Health Care, 2011).

It is also important that nurses ensure patients' awareness of Canada's clinical practice guidelines for the care and treatment of breast cancer. All patients who have completed primary treatment for breast cancer should have regular follow-up surveillance that comprises a medical history, physical examination, and annual mammography. The frequency of visits must be adjusted according to the individual patient's needs. Special topics of concern that have to be addressed with patients who have breast cancer include cognitive functioning, fatigue, weight management, osteoporosis,

sexual functioning, and pregnancy (Canadian Task Force on Preventive Health Care, 2011).

Diagnostic Studies

Radiological Studies

Several techniques can be used to screen for breast disorders or provide a diagnosis of a suspect physical finding. *Mammography* is a method used to visualize the internal structure of the breast with the use of radiography (Figure 54-2). This generally well-tolerated procedure can detect suspect findings that cannot be felt by palpation. Mammography has significantly improved the early and accurate detection of breast malignancies. Improved imaging technology has also reduced the amount of radiation used in mammography. Digital mammography, in which radiographic images are digitally coded into a computer, is an addition to screening programs (Canadian Partnership Against Cancer, 2013; Figure 54-2).

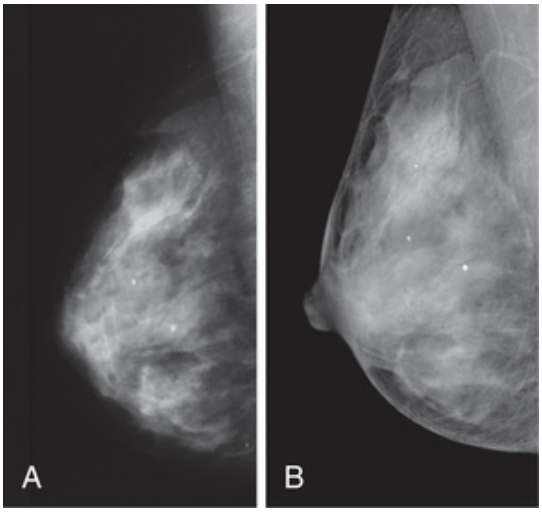

FIGURE 54-2 Screening mammograms showing dense breast tissue and benign, scattered microcalcifications of a 57-year-old. **A,** Image obtained with conventional radiography. **B,** Image obtained with digital radiography. Source: Adam, A. (2008). *Grainger and Allison's diagnostic radiology* (5th ed.). St. Louis: Churchill Livingstone.

Three-dimensional (3-D) mammography is a new type of mammography; it provides a clearer 3-D view of overlapping breast tissue structures, which helps to accurately detect and diagnose breast cancer (Canadian Agency for Drugs and Technologies in Health [CADTH], 2015).

Calcifications are the abnormality most easily recognized on mammograms (see Figure 54-2). These deposits of calcium crystals form in the breast for many reasons, such as inflammation, trauma, and aging. Although most calcifications are benign, they also may be associated with preinvasive cancer.

A comparison of current and prior mammograms may reveal early cancerous tissue changes. Because some tumours metastasize late, early detection by mammography allows for earlier treatment and the prevention of metastasis of lesions that are smaller or less aggressive. In younger women, mammography is less sensitive because of the greater density of breast tissue and because developing breast tissue is radiosensitive, resulting in more false-negative results (CADTH, 2015). About 10% to 15% of all breast cancers cannot be seen on mammograms and are detected only by palpation. If the clinical findings are suspect, ultrasound or magnetic resonance imaging (MRI) may be used, and biopsy may be recommended based on the findings.

Ultrasonography is used in conjunction with mammography to differentiate a solid mass from a cystic mass, to evaluate a mass in a pregnant or lactating woman, or to locate and guide biopsy for a suspect lesion on breast MRI. Palpable masses should be investigated with both mammography and ultrasonography (CADTH, 2015).

MRI is recommended as a sensitive screening tool for women at high risk for breast cancer, for women whose findings on mammography or ultrasonography are suspect for malignancy, and for women in whom breast cancer was previously detected by mammography. Limitations of MRI include its high cost, which may result in less frequent use of this method of screening (CADTH, 2015).

Biopsies

A definitive diagnosis of a suspect area is made by means of histological examination of a biopsy sample of tissue. Biopsy techniques include fine-needle aspiration (FNA), core needle, stereotactic core needle, wire localization, and surgical biopsy (also called *open biopsy*).

In *FNA biopsy,* a thin, fine needle is inserted into the lesion and cellular fluid aspirated into a syringe. Three or four passes are usually made. FNA and cytological evaluation may be helpful in making a diagnosis and planning treatment. If the results are negative but the lesion is suspect, an additional biopsy may be necessary. Biopsy results are usually available within 24 to 48 hours.

A *core needle biopsy* is commonly used as a preferred method for obtaining and diagnosing a breast tissue specimen (Onstad & Stuckey, 2013). It involves removing samples of breast tissue using a hollow needle, which takes small cylinder-shaped (core) samples.

Stereotactic core needle biopsy is a reliable diagnostic technique for obtaining a biopsy sample of an abnormality seen on a mammogram. The use of 3-D images assists in pinpointing the exact location of a lump or suspect lesion in order to guide the needle to obtain a sample of breast tissue. Patients should be informed that the procedure is uncomfortable. The patient is positioned lying face down on a table that has an opening for the breast. The skin is anaesthetized, and a small incision is made to allow the entrance of a biopsy needle that has a special cutting device. This process is repeated several times, and the core samples are sent for pathological analysis. Larger samples of tissue can be removed using a special *vacuum-assisted device* (VAD), which uses suction to collect the tissue sample. An advantage of VAD is that the needle is inserted only once into the breast and then can be rotated, which allows for multiple samples through a single needle insertion.

These outpatient techniques have advantages over a surgical biopsy, including minimal scarring, local anaesthesia, reduced cost, and shorter recovery time. A *surgical biopsy* involves removal of part or all of a suspect lesion through an incision into the breast. If the lesion is small, deep, and difficult to locate, a *wire localization biopsy* may be used during surgery. A special fine wire is placed into the lesion under radiographic guidance, and then the surgeon follows this wire to help locate the lesion.

Benign Breast Disorders

Mastalgia

Mastalgia (breast pain) is the most common breast-related complaint in women. The most common form is *cyclic mastalgia*, which coincides with the menstrual cycle (Onstad & Stuckey, 2013). It is described as diffuse breast tenderness or heaviness. Breast pain may last 2 to 3 days or most of the month. The pain is related to hormonal sensitivity. The symptoms often decrease with menopause. *Noncyclic mastalgia* has no relationship to the menstrual cycle and can continue into menopause. It may be constant or intermittent throughout the month and last for several years. Symptoms include a burning sensation, aching, or soreness in the breast. The cause of the pain of noncyclic mastalgia is not known (Canadian Cancer Society, 2017c).

Mammography and targeted ultrasound are often performed to exclude cancer and provide etiology of mastalgia. Cyclic pain may be relieved somewhat by reductions in caffeine and dietary fat intake; by vitamins E, A, and B complex and gamma-linolenic acid (evening primrose oil); and by continual wearing of a support bra. Massage with ice or heat, analgesics, and anti-inflammatory medications may also help. Medications that might be recommended include oral contraceptives and danazol (Cyclomen). Because of the androgenic adverse effects of danazol (acne, edema, hirsutism), this therapy is unacceptable for many women.

Breast Infections

Mastitis.

Mastitis is an inflammatory condition of the breast that occurs most frequently in lactating women (Table 54-1). *Lactational mastitis* manifests as a localized area that is erythematous, painful, and tender on palpation. Fever is often present. The infection develops when organisms, usually staphylococci, gain access to the breast through a cracked nipple. In its early stages, mastitis can be cured with antibiotics. Breastfeeding should continue unless an abscess is forming or a purulent drainage is noted. The mother may wish to use a nipple shield or to hand-express milk from the involved breast until the pain subsides. She should see her health care provider promptly to begin a course of antibiotic therapy. Any breast that remains red, tender, and not responsive to antibiotics necessitates follow-

up care and evaluation for inflammatory breast cancer (Onstad & Stuckey, 2013).

TABLE 54-1

SELECT BENIGN BREAST DISORDERS

Disorder	Incidence	Clinical Manifestations
Lactational mastitis	Occurs in up to 10% of postpartum lactating mothers (both primipara and multipara), usually 2–4 wk after parturition	Warm to touch, indurated, painful, often unilateral; most commonly caused by *Staphylococcus aureus*
Fibrocystic changes	Most common between ages 35 and 50	Not usually discrete masses but nodularity instead (movable, soft); usually accompanied by cyclic pain and tenderness; mass(es) often cyclic in occurrence
Cyst	Most common after age 35, incidence decreases after menopause; develop in 1 per 14 women	Palpable fluid-filled mass (movable, soft); multiple cysts can occur and recur; rarely associated with breast cancer
Fibroadenoma	Occurs in 10% of all women aged 15–40	Palpable mass (movable, firm), usually 2–3 cm in size; rarely associated with breast cancer
Fat necrosis	Many women report previous history of trauma to breast	Usually a hard, very tender, mobile, indurated mass with irregular borders
Duct ectasia	Perimenopausal woman: most common in women in their 50s; previous lactation; inverted nipples	Fixation of nipple, usually accompanied by nipple discharge of thick, grey material; often associated with breast pain

Lactational Breast Abscess.

If lactational mastitis persists after several days of antibiotic therapy, a lactational breast abscess may have developed. In this condition, the skin may become red and edematous over the involved breast, often with a corresponding palpable mass, and the patient may have a fever. Antibiotics alone constitute insufficient treatment for a breast abscess. Ultrasonography-guided drainage of the abscess or surgical incision and drainage are necessary (Onstad & Stuckey, 2013). The drainage is cultured, sensitivities are measured, and therapy with an appropriate antibiotic is begun. Breastfeeding can continue in most cases with ongoing treatment of the abscess (Irusen, Rohwer, Steyn, et al., 2015).

Fibrocystic Changes

Fibrocystic changes in the breast constitute a benign condition characterized by changes in breast tissue (Figure 54-3). The changes include the development of excess fibrous tissue, hyperplasia of the epithelial lining of the mammary ducts, proliferation of mammary ducts, and cyst formation. Pain is caused by nerve irritation from edema in the connective tissue and by fibrosis from pinching of the nerve. Fibrocystic

changes are not associated with increased risk for breast cancer. Masses or nodularities can appear in both breasts. They are often found in the upper, outer quadrants and usually occur bilaterally.

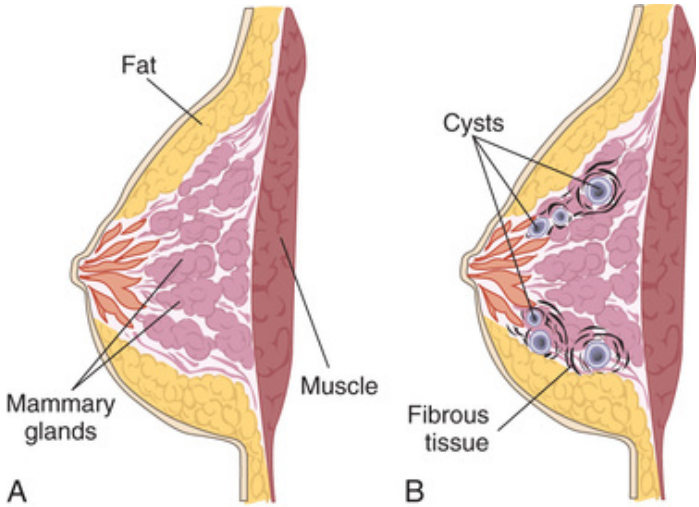

FIGURE 54-3 **A,** Normal breast tissue. **B,** Fibrocystic breast tissue.

Fibrocystic changes are the most frequently occurring breast disorder. They occur most frequently in women between 35 and 50 years of age but often begin as early as 20 years of age. Pain and nodularity often increase over time but tend to subside after menopause unless high doses of estrogen replacement are used. Fibrocystic changes are thought to result from a heightened responsiveness of breast tissue to circulating estrogen and progesterone (Canadian Cancer Society, 2017d).

Fibrocystic changes most commonly occur in women with premenstrual abnormalities, nulliparous women, women with a history of spontaneous abortion, nonusers of oral contraceptives, and women with early menarche and late menopause. Symptoms related to fibrocystic changes often worsen in the premenstrual phase and subside after menstruation.

Manifestations of fibrocystic breast changes include one or more palpable lumps that are often round, well delineated, and freely movable within the breast (see Table 54-1). Discomfort ranging from tenderness to pain may also occur. The lump is usually observed to increase in size and perhaps in tenderness before menstruation. Cysts may enlarge or shrink rapidly, becoming larger before menstruation and shrinking afterward. Nipple discharge associated with fibrocystic breasts is often milky, watery-milky, yellow, or green.

Mammography may be helpful in distinguishing fibrocystic changes from breast cancer. However, in some women, the breast tissue is so dense that it is difficult to obtain a mammographic study. In these situations, ultrasonography may be more useful in differentiating a cystic mass from a solid mass.

Nursing and Collaborative Management Fibrocystic Changes

With the initial discovery of a discrete mass in the breast by a woman or her health care provider, aspiration or surgical biopsy may be indicated. If the nodularity is recurrent, a wait of 7 to 10 days may be planned in order to note any changes that may be related to the menstrual cycle. For large or frequent cysts, surgical removal may be favoured over repeated aspiration. An excisional biopsy would be recommended if (a) no fluid is found on aspiration, (b) the fluid that is found is hemorrhagic, or (c) a residual mass remains after fluid aspiration. Excisional biopsy is performed in an outpatient surgery unit.

Biopsy may be indicated for women with fibrocystic disorders who are at increased risk for breast cancer. Atypical hyperplasia, which is discovered on breast biopsy, increases a woman's risk for developing breast cancer later in life.

Women with cystic changes should be encouraged to return regularly for follow-up examinations throughout life. They may also be taught BSE to self-monitor changes. Severe fibrocystic changes may make palpation of the breast more difficult. Any changes in symptoms or changes found during the BSE should be reported and evaluated.

Treatment for a fibrocystic condition is similar to that described earlier for mastalgia. The nurse's role in the care of patients with fibrocystic breast changes is primarily one of teaching. Patients should be taught that the cysts may recur in one or both breasts until menopause and that the cysts may enlarge or become painful just before menstruation. In addition, patients should be reassured that the cysts do not “turn into” cancer. Patients should be advised that any new lump that does not respond in a cyclic manner over 1 to 2 weeks should be examined by a health care provider promptly.

Fibroadenoma

Fibroadenoma is a common cause of discrete benign breast lumps in young women, generally between 15 and 40 years of age. It is the most frequent cause of breast masses in women younger than 25 years. The possible cause of fibroadenoma may be increased estrogen sensitivity in a localized area of the breast. Fibroadenomas are usually small but can be

large (2 to 3 cm) and are typically painless, round, well delineated, and very mobile. They may be soft but are usually solid, firm, and rubbery in consistency. There is no accompanying retraction or nipple discharge, and they are often painless. Fibroadenomas may appear as a single, unilateral mass, although multiple, bilateral fibroadenomas have been reported. Growth is slow and often ceases when the size reaches 2 to 3 cm. Size is not affected by menstruation. However, pregnancy can stimulate dramatic growth.

Nursing and Collaborative Management Fibroadenoma

Fibroadenomas are easily detected on physical examination and may be visible on mammography and ultrasonography. Definitive diagnosis, however, requires an image-guided core needle biopsy or excisional biopsy and tissue examination by a pathologist. Treatment of fibroadenomas can include observation with regular monitoring, after a malignancy has been ruled out, or surgical excision. In women older than 35 years, all new lesions should be evaluated with breast ultrasonography and, possibly, biopsy.

In some clinical settings, as an alternative to surgery, cryoablation can be used to remove tumours after an established diagnosis of a fibroadenoma. In *cryoablation,* a cryoprobe is inserted into the tumour under ultrasound guidance. Extremely cold gas is piped into the tumour. The frozen tumour dies and is either reduced in size or completely eliminated. Benefits include minimal scarring and quick recovery time.

The nurse needs to emphasize to patients with a fibroadenoma the benign nature of the lesion and encourage them to have follow-up examinations.

Nipple Discharge

Nipple discharge may occur spontaneously or as a result of nipple manipulation. A milky secretion constitutes inappropriate lactation **(galactorrhea)** and may be a result of drug therapy, endocrine problems, or a neurological disorder, or it may be idiopathic.

Secretions can also be serous, grossly bloody, or brown to green (Onstad & Stuckey, 2013). These secretions may be caused by either benign or malignant disease. Cytological study of the secretion may help determine the specific disease. Diseases associated with nipple discharge include intraductal papilloma, duct ectasia, cystic disease, and malignancies. Treatment depends on identification of the cause (Onstad & Stuckey, 2013). In most cases, nipple discharge is not related to malignancy.

Intraductal Papilloma.

An *intraductal papilloma* is a benign, soft, wartlike growth found in the mammary ducts. It is usually unilateral. It is typically accompanied by a

bloody discharge from the nipple that can be intermittent or spontaneous. Most intraductal papillomas are beneath the areola and cannot be palpated. They are usually found in women aged 40 to 60 years. A single duct or several ducts may be involved. Treatment includes excision of the papilloma and the involved duct or duct system. Papillomas may be associated with an increased risk for cancer.

Duct Ectasia.

Duct ectasia (duct dilation) is a benign breast disorder of perimenopausal and postmenopausal women that involves the ducts in the subareolar area. Several bilateral ducts are usually involved. Multicoloured, sticky discharge is the primary symptom. Duct ectasia is initially painless but may progress to causing a burning sensation, itching, and pain around the nipple, as well as swelling in the areolar area. Inflammatory signs are often present, the nipple may retract, and the discharge may become bloody in more advanced disease. Duct ectasia is not associated with malignancy. If an abscess develops, warm compresses and antibiotics are usually effective treatments. Therapy consists of close follow-up examinations or surgical excision of the involved ducts.

Gynecomastia

Gynecomastia, a transient, noninflammatory enlargement of one or both breasts, is a common noncancerous breast problem in men (Canadian Cancer Society, 2017e). Gynecomastia by itself is not an established risk factor for breast cancer. Mammography may be completed to screen for malignancy. The most common cause of gynecomastia is a disturbance of the normal ratio of active androgen to estrogen in plasma or within the breast itself.

Gynecomastia may also be a manifestation of other problems. It may accompany developmental abnormalities of the male reproductive organs. Gynecomastia may occur as an adverse effect of drug therapy, particularly with administration of estrogens and androgens, digitalis, ranitidine (Zantac), and spironolactone (Aldactone). Use of heroin and marihuana can also cause gynecomastia.

Senescent Gynecomastia.

Senescent gynecomastia occurs in up to 70% of older men (Deepinder & Braunstein, 2011). A probable cause is the elevation in plasma estrogen in

older-adult men as the result of increased conversion of androgens to estrogens in peripheral circulation. Although initially unilateral, the tender, firm, centrally located enlargement may become bilateral. When gynecomastia is characterized by a discrete, circumscribed mass, it must be biopsied to differentiate it from the rarer breast cancer in men. Senescent gynecomastia necessitates no treatment and generally regresses within 6 to 12 months.

Age-Related Considerations

Breast Changes

The loss of subcutaneous fat and structural support and the atrophy of mammary glands often cause breasts to become pendulous in postmenopausal women. The nurse should encourage older women to wear a well-fitting bra. Adequate support can improve physical appearance and reduce pain in the back, shoulders, and neck. It can also prevent *intertrigo* (dermatitis caused by friction between opposing surfaces of skin). Surgical lifting of sagging breasts is possible and may be desirable when reconstruction is performed after a **mastectomy** (surgical removal of all or a portion of a breast).

The decrease in glandular tissue in older women makes a breast mass easier to palpate. This decreased density is probably age related and occurs to a lesser degree with women receiving hormone therapy. Rib margins may be palpable in older women and can be confused with a mass. As a woman becomes more familiar with her own breasts and is reassured about her findings, the anxiety about this finding should decrease. The nurse should encourage older women to continue examining their breasts and to talk to their health care providers about an individualized screening program, because the incidence of breast cancer increases with age.

Breast Cancer

Breast cancer is the most common cancer in Canadian women, excluding nonmelanoma skin cancer. It is second only to lung cancer as the leading cause of death from cancer in women. It can occur in men, although less commonly (Canadian Cancer Society, 2017a). It was estimated that, in 2017, 26 300 new cases of breast cancer would be diagnosed in women in Canada, and approximately 230 new cases in men. Each year in Canada, approximately 5 060 deaths (5 000 women and 60 men) occur in relation to breast cancer (Canadian Cancer Society, 2017a). The number of deaths of women from breast cancer in every age group has declined, partly as a result of increased mammography screening and decreased use of hormone therapy (Canadian Cancer Society, 2017f). The five-year survival rate for women with breast cancer is 87% and 79% for men (Canadian Cancer Society, 2017a).

Etiology and Risk Factors

Although the etiology is not completely understood, a number of factors are thought to contribute to breast cancer (Table 54-2). Risk factors appear to be cumulative and interacting. Therefore, the presence of other risk factors may greatly increase the overall risk, especially for people with a positive family history. Identification of risk factors increases the need for careful clinical surveillance of a patient and for participation in cancer screening measures.

TABLE 54-2

RISK FACTORS FOR BREAST CANCER

Increased Risk	Comments
Female	Women account for 99% of breast cancer cases.
Age 50 or older	The majority of breast cancers are found in postmenopausal women. After age 60, the incidence is greatly elevated.
Family history	Breast cancer in a first-degree relative—particularly when the person is premenopausal or the tumour is bilateral—increases risk. Gene mutations (*BRCA1* or *BRCA2*) play a role in 5%–10% of breast cancer cases.
Hormone use	The use of estrogen, progesterone, or both as hormone therapy, especially in postmenopausal women, increases risk.
Personal history of breast cancer, colon cancer, endometrial cancer, ovarian cancer	Personal history significantly increases risk of breast cancer, risk of cancer in the other breast, and recurrence.
Early menarche (<age 12); late menopause (>age 55)	A long menstrual history increases the risk for breast cancer.
First full-term pregnancy after age 30; nulliparity	Prolonged exposure to unopposed estrogen increases risk for breast cancer.
Benign breast disorder with atypical epithelial hyperplasia, LCIS	Atypical changes in breast biopsy increase the risk for breast cancer.
Dense breast tissue	Mammograms are harder to read and interpret. Dense tissue may be associated with more aggressive tumours.
Weight gain and obesity after menopause	Fat cells store estrogen, which increases the likelihood of developing breast cancer.
Exposure to ionizing radiation	Radiation (e.g., prior treatment for Hodgkin's lymphoma) damages DNA.
Alcohol consumption	Women who drink ≥1 alcoholic beverage per day have an increased risk for breast cancer.
Physical inactivity	Breast cancer risk is decreased by 33% in physically active women in comparison with sedentary women.

DNA, deoxyribonucleic acid; *LCIS*, lobular carcinoma in situ.

Risk Factors for Women.

The identifiable risk factors most associated with breast cancer include female gender and advancing age. Women are at far greater risk than men because 99% of breast cancers occur in women. The incidence of breast cancer in women is very low before 25 years of age and increases gradually until age 60. After age 60, the incidence increases dramatically.

Hormonal regulation of the breast is related to the development of breast cancer, but the mechanisms are poorly understood. The hormones estrogen and progesterone may act as tumour promoters to stimulate breast cancer growth if malignant changes in the cells have already occurred. Data from the Women's Health Initiative study have shown that the use of combined hormone therapy (estrogen plus progesterone) increases breast cancer risk by 25% (Canadian Cancer Society, 2017g). The use of estrogen replacement therapy alone (for women who have had a

prior hysterectomy) does not currently appear to increase breast cancer risk. Oral contraceptives that contain both estrogen and progesterone cause a slight increase in the risk of breast cancer, particularly for women who have used them for 10 years or longer (Canadian Cancer Society, 2017f). Modifiable risk factors include weight gain during adulthood, sedentary lifestyle, dietary fat intake, obesity, and alcohol intake (Canadian Cancer Society, 2017f). Environmental factors such as radiation exposure may also play a role.

Genetic Factors.

Family history is an important risk factor, especially if the involved family member also had ovarian cancer, was premenopausal, had bilateral breast cancer, and is a first-degree relative (i.e., mother, sister, daughter). Having any first-degree relative with breast cancer increases a woman's risk for breast cancer 1.5 to 3 times, depending on age. (The Determinants of Health box discusses other factors contributing to breast cancer.)

Determinants of Health

Breast Cancer

Personal Health Practices and Coping Skills

- Women with a higher body mass index (BMI) (>31.1) are at an increased risk for developing breast cancer.*
- Physical inactivity is a probable risk factor for breast cancer.*

Gender

- Breast cancer is more common in women; it can occur in men, although it is rare.†

Income

- Women with higher incomes have a slightly higher incidence of breast cancer, which may be related to having children later in life or

having fewer children.*

Lifestyle

- Working at night may increase the risk of developing breast cancer.*

References

Canadian Cancer Society. *Risk factors for breast cancer*. [Retrieved from] http://www.cancer.ca/en/cancer-information/cancer-type/breast/risks/?region=on; 2017.

Canadian Cancer Society. *Know your risk: Gender and age*. [Retrieved from] http://www.cbcf.org/central/AboutBreastHealth/KnowYourRisk/Pages/Gender-Age.aspx; 2017.

As many as 5% to 10% of all patients with breast cancer may have inherited a specific genetic abnormality contributing to the development of their breast cancer (Canadian Cancer Society, 2017f). The *BRCA1* gene, located on chromosome 17, and the *BRCA2* gene, located on chromosome 11, are tumour suppressor genes that, when functioning normally, inhibit tumour development. Women with inherited *BRCA1* or *BRCA2* mutations have up to an 85% lifetime chance of developing breast cancer (Canadian Cancer Society, 2017f). These women are also at high risk for developing ovarian cancer (Canadian Cancer Society, 2017f). Routine screening for genetic abnormalities in women without evidence of a strong family history of breast cancer is not warranted (see the "Genetics in Clinical Practice: Breast Cancer" box). Research investigating the role of genes in the development of breast cancer continues.

Risk Factors for Men.

Predisposing risk factors for breast cancer in men include hyperestrogenism, a family history of breast cancer, and radiation exposure. A thorough examination of the male breast should be a routine part of a physical examination for all men. Men in *BRCA*-positive families may consider genetic testing. Men with an abnormal *BRCA* gene also have an increased risk of developing prostate cancer.

Genetics in Clinical Practice

Breast Cancer

Genetic Basis

- Mutations in genes *BRCA1* and *BRCA2*
- Autosomal dominant transmission

Incidence

- Approximately 5% to 10% of breast cancers are related to *BRCA1* and *BRCA2* gene mutations.
- Women with *BRCA1* and *BRCA2* gene mutations have a 40% to 80% lifetime risk of developing breast cancer.
- *BRCA1* and *BRCA2* gene mutations are associated with early-onset breast cancer.
- Men with *BRCA1* and *BRCA2* gene mutations have an increased risk for breast and prostate cancer.
- Family history of both breast and ovarian cancer increases the risk of having a *BRCA1* mutation.

Genetic Testing

- DNA testing is available for *BRCA1* and *BRCA2* gene mutations.

Clinical Implications

- Most breast cancers (about 90%–95%) are not inherited. They are associated with genetic changes that occur after a person is born (somatic mutations).
- Bilateral oophorectomy, bilateral mastectomy, or both reduce the risk for breast cancer in women with *BRCA1* and *BRCA2* mutations.
- Mutations in the *BRCA1* and *BRCA2* genes increase the risk for ovarian cancer.
- Genetic counselling and testing for *BRCA* mutations should be considered for women whose personal or family history puts them at high risk for a genetic predisposition to breast cancer.

Prophylactic Oophorectomy and Mastectomy.

In women with *BRCA1* or *BRCA2* mutations, prophylactic bilateral oophorectomy can decrease the risk for breast cancer and ovarian cancer (Canadian Cancer Society, 2017h). In deciding whether and when to undergo this surgical procedure, women should receive counselling about the risks and benefits of prophylactic oophorectomy, including those related to fertility.

Women who have a high risk of developing breast cancer (i.e., related to factors such as family history and prior tissue biopsy findings) may, in consultation with their health care provider, choose to undergo prophylactic bilateral mastectomy. Research has shown that contralateral prophylactic mastectomy (mastectomy of the unaffected breast) can decrease the risk for contralateral breast cancer, but survival rates have not been determined (Chagpar, 2014).

Women with hereditary (non-*BRCA*) breast cancer have a higher risk of developing a secondary primary breast cancer in the unaffected (contralateral) breast. These women may also choose to have the unaffected breast removed prophylactically at the time of initial surgery for breast cancer or at a later time. The rate of contralateral prophylactic mastectomies in women has been steadily increasing (Chagpar, 2014).

Pathophysiology

Various types of breast cancer have been identified on the basis of their histological characteristics and growth patterns (Table 54-3). The main components of the breast are lobules (milk-producing glands) and ducts (milk passages that connect the lobules and the nipple). In general, breast cancer arises from the epithelial lining of the ducts *(ductal carcinoma)* or from the epithelium of the lobules *(lobular carcinoma).* Breast cancers may be in situ (within the duct or lobule) or invasive (arising from the duct or lobule and invading through the wall of the duct or lobule).

TABLE 54-3
TYPES OF BREAST CANCER

Type	Frequency of Occurrence
Invasive/Infiltrating ductal carcinoma • Colloid (mucinous) • Inflammatory • Paget's disease • Medullary • Tubular	70%–75%
Invasive/Infiltrating lobular carcinoma	5%–10%
Noninvasive carcinoma • Ductal carcinoma in situ	20%

Metastatic breast cancer is breast cancer that has spread to bone, the liver, the lungs, or the brain. Cancer growth rate can range from slow to rapid. Factors that affect cancer prognosis are tumour size, axillary node involvement (the more nodes involved, the worse the prognosis), tumour differentiation, estrogen and progesterone receptor status, and *human epidermal growth factor receptor 2* (HER2) status. HER2 is a transmembrane receptor that helps regulate cell growth. In many patients with breast cancer, it is overexpressed (Yeo, Turner, & Jones, 2014).

Types of Breast Cancer

Breast cancer can be classified as noninvasive or invasive, and as ductal or lobular (see Table 54-3).

Noninvasive Breast Cancer.

An estimated 20% of all breast cancers are noninvasive. These intraductal cancers include *ductal carcinoma in situ* (DCIS) and *lobular carcinoma in situ* (LCIS). DCIS tends to be unilateral and may progress to invasive breast cancer if left untreated.

Although the management of DCIS can be controversial, patients should discuss all treatment options with their physician, including local excision, mastectomy with breast reconstruction, breast-conserving surgery (lumpectomy), radiation therapy, and tamoxifen (Nolvadex-D) therapy.

The term *lobular carcinoma in situ* is somewhat misleading. Although LCIS is a risk factor for developing breast cancer, it is not known to be a premalignant lesion. Although no treatment is necessary, patients with LCIS should increase their surveillance for breast cancer. Tamoxifen may be given to some patients as a chemopreventive drug.

Invasive (Infiltrating) Ductal Carcinoma.

Invasive (infiltrating) ductal carcinoma is the most common type of breast cancer. It starts in the milk duct and then breaks through the wall of the duct, invading the surrounding tissue. From there it may metastasize to other parts of the body.

Types of invasive (infiltrating) ductal carcinoma include *medullary carcinoma*, which accounts for 15% of all breast cancers and most frequently occurs in women in their late 40s and 50s. *Tubular carcinoma* accounts for about 2% of all breast cancers, is usually found in women over 50 years of age, and has an excellent prognosis. *Colloid (mucinous) carcinoma* accounts for about 1% to 2% of all breast cancers and usually has a favourable prognosis.

Inflammatory Breast Cancer.

Inflammatory breast cancer, the most malignant form of all breast cancers, is rare. It is an aggressive and fast-growing cancer with a high risk for metastasis. The skin of the breast looks red, feels warm, and has a

thickened appearance that is often described as resembling an orange peel *(peau d'orange).* The inflammatory changes, often mistaken for an infection, are caused by blockage of lymph channels by cancer cells. Chemotherapy given before surgery is usually the first course of treatment, often followed by radiation. Hormonal therapy may also be indicated.

Paget's Disease.

Paget's disease is a rare breast malignancy characterized by a persistent lesion of the nipple and areola with or without a palpable mass. (This is different from Paget's disease of the bone, which is discussed in Chapter 66.) Most women with Paget's disease have underlying ductal carcinoma. Only in rare cases is the cancer confined to the nipple itself. Itching, a burning sensation, bloody nipple discharge with superficial erosion, and ulceration may be present. Diagnosis of Paget's disease is confirmed by pathological examination of the erosion. Nipple changes are often diagnosed as an infection or dermatitis, which can lead to delays in proper treatment. The treatment of Paget's disease may include lumpectomy and radiation therapy or a simple or modified radical mastectomy. The prognosis is good when the cancer is confined to the nipple. The nursing care for patients with Paget's disease is the same as the care for patients with breast cancer.

Invasive (Infiltrating) Lobular Carcinoma.

Invasive (infiltrating) lobular carcinoma usually appears as a subtle thickening in the upper outer quadrant of the breast. Often positive for estrogen and progesterone receptors, these tumours respond well to hormone therapy.

Clinical Manifestations

Breast cancer is detected as a lump or mammographic abnormality in the breast. It occurs most often in the upper outer quadrant of the breast because this is the location of most of the glandular tissue (Figure 54-4). Breast cancers vary in growth rate. If palpable, breast cancer is characteristically hard and may be irregularly shaped, poorly delineated, nonmobile, and nontender.

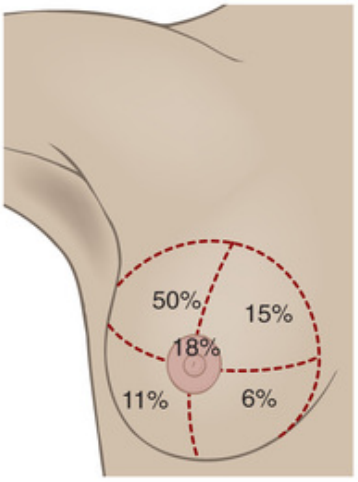

FIGURE 54-4 Distribution of where breast cancer occurs.

A small percentage of breast cancers cause nipple discharge. The discharge is usually unilateral and may be clear or bloody. Nipple retraction may occur. *Peau d'orange* may result from the plugging of the dermal lymphatic vessels. With large cancers, infiltration, induration, and dimpling (pulling in) of the overlying skin may also be noted.

Complications

The main complication of breast cancer is recurrence (Table 54-4). Recurrence may be local or regional (skin or soft tissue near the mastectomy site, axillary or internal mammary lymph nodes) or distant (most commonly involving bone, the lung, the brain, or the liver). However, metastatic disease can be found in any distant site.

TABLE 54-4

COMMON SITES OF BREAST CANCER RECURRENCE AND METASTASIS

Site	Clinical Manifestations
Local Recurrence	
Skin, chest wall	Firm, discrete nodules; occasionally pruritic, usually painless; commonly in or near a scar
Regional Recurrence	
Lymph nodes	Enlarged nodes in axilla or supraclavicular area, usually nontender
Distant Metastases	
Skeletal	Localized pain of gradually increasing intensity; percussion tenderness at involved sites; pathological fracture caused by involvement of bone cortex
Spinal cord	Progressive back pain, localized and radiating; change in bladder or bowel function; loss of sensation in lower extremities
Brain	Headache described as "different"; unilateral sensory loss; focal muscular weakness, hemiparesis, incoordination (ataxia); nausea or vomiting unrelated to medication; cognitive changes
Pulmonary (including lung nodules and pleural effusions)	Shortness of breath, tachypnea, nonproductive cough (not present in all patients)
Liver	Abdominal distension; right lower quadrant abdominal pain, sometimes with radiation to scapular area; nausea and vomiting, anorexia, weight loss; weakness and fatigue; hepatomegaly, ascites, jaundice; peripheral edema; elevated liver enzyme levels
Bone marrow	Anemia; infection; increased bleeding, bruising, petechiae; weakness and fatigue; mild confusion, light-headedness; dyspnea

Metastatic disease involves the growth of colonies of cancerous breast cells in parts of the body distant from the breast. Metastases primarily occur through the lymphatic vessels, principally those of the axilla (see Figure 54-7, later in the chapter). However, the cancer can spread to other parts of the body without invading the axillary nodes even when the primary breast tumour is small. Even with node-negative breast cancer, there is a possibility of distant metastasis.

Diagnostic Studies

In addition to studies used to diagnose breast cancer (see discussion earlier in this chapter), other tests are useful in predicting the risk for local or systemic recurrence. These tests include axillary lymph node status, tumour size, estrogen and progesterone receptor status, and cell-proliferative indices. Results of many of these diagnostic studies are useful prognostic indicators of the disease.

Axillary lymph node involvement is one of the most important prognostic factors in breast cancer. An *axillary lymph node dissection (ALND)* is often performed to determine whether cancer has spread to the axilla on the side of the breast cancer (Canadian Cancer Society, 2017i).

The more nodes involved, the higher the risk for recurrence. Patients with four or more positive nodes have the highest risk for recurrence.

Lymphatic mapping and *sentinel lymph node biopsy (SLNB)* helps the surgeon identify the lymph node or nodes that drain first from the tumour site *(sentinel node).* SLNB is less invasive than ALND (Canadian Cancer Society, 2017j). A radioisotope or blue dye is injected into the tumour site, and intraoperatively, it is determined in which sentinel lymph nodes the radioisotope or blue dye is located (Figure 54-5). A local incision is made in the axilla, and the surgeon dissects the blue-stained sentinel node or the radioactive lymph node. In general, in SLNB, one to four axillary lymph nodes are removed. The nodes are then sent for a frozen-section pathological analysis. If the results are negative, no further axillary surgery is required. If the results are positive, the surgeon may choose to remove additional lymph nodes during the same procedure or during a follow-up surgical procedure in consultation with the patient. SLNB has been associated with lower rates of lymphedema and other arm symptoms (Canadian Cancer Society, 2017j).

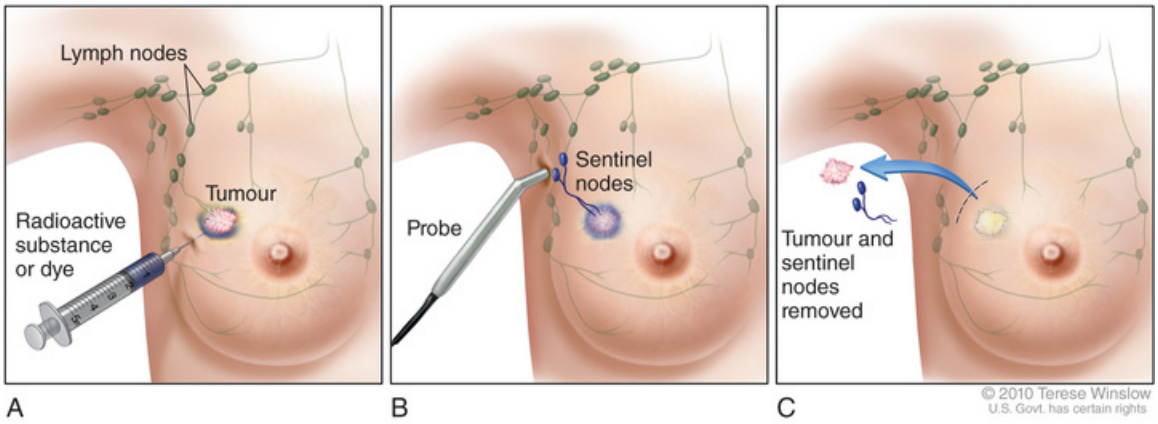

FIGURE 54-5 Sentinel lymph node biopsy of the breast. **A,** A radioactive dye or blue dye is injected near the tumour. **B,** The injected material is detected visually or with a probe that detects radioactivity. **C,** The sentinel nodes (the first lymph nodes to take up the material) are removed and checked for cancer cells. Source: Ignatavicius, D., & Workman, M. L. (2016). *Medical-surgical nursing: Patient-centered collaborative care*. (8th ed., p. 1472, Figure 70-5). St. Louis: Saunders.

Tumour size is a valuable prognostic variable: the larger the tumour, the poorer the prognosis. The wide variety of histological types of breast cancer explains the heterogeneity of the disease. In general, the more well

differentiated the tumour is, the less aggressive it is. Poorly differentiated tumours appear morphologically disorganized and are more aggressive.

Another diagnostic test useful for both treatment decisions and prediction of prognosis is measurement of estrogen and progesterone receptor status. Receptor-positive tumours (a) commonly show histological evidence of being well differentiated, (b) frequently have a diploid (more normal) deoxyribonucleic acid (DNA) content and low proliferative indices, (c) have a lower chance for recurrence, and (d) are frequently hormone dependent and responsive to hormone therapy. Receptor-negative tumours (a) are often poorly differentiated histologically, (b) have a high incidence of aneuploidy (abnormally high or low DNA content) and higher proliferative indices, (c) frequently recur, and (d) are usually unresponsive to hormonal therapy.

Ploidy status correlates with tumour aggressiveness. Diploid tumours have been shown to have a significantly lower risk for recurrence than aneuploid tumours.

Cell-proliferative indices indirectly measure the rate of tumour cell proliferation. The percentage of tumour cells in the synthesis (S) phase of the cell cycle (see Chapter 18, Figure 18-1) is another important prognostic indicator.

Another prognostic indicator is the marker HER2, which is a protein that can be measured in breast tissue. Overexpression of this receptor has been associated with a greater risk for recurrence and a poorer prognosis in breast cancer. Between 20% and 30% of metastatic breast cancers produce excessive HER2. High numbers of HER2 receptors are associated with unusually aggressive tumour growth. The presence of this marker assists in the selection and sequence of chemotherapy and the prediction of a patient's response to treatment (Canadian Cancer Society, 2017k).

Collaborative Care

Currently, a wide range of treatment options is available to patients and health care providers making critical decisions about how to treat breast cancer (Tables 54-5 and 54-6). Prognostic factors are considered when treatment decisions are made about a specific breast cancer. Some of these factors also enter into the staging of breast cancer. The most widely accepted staging method for breast cancer is the American Joint Committee on Cancer's TNM system (Canadian Cancer Society, 2017l). In this system, tumour size (T), nodal involvement (N), and presence of metastasis (M) are used to determine the stage of disease. The stage of a

breast cancer describes its size and the extent to which it has spread (Table 54-7).

TABLE 54-5
COLLABORATIVE CARE
Breast Cancer

Diagnostic
Prediagnosis
• Health history, including risk factors • Biopsy • Breast MRI (if indicated) • Mammography • Physical examination, including breast and lymph nodes • Ultrasonography
Postdiagnosis
• Cell-proliferative indices • Estrogen and progesterone receptor status • Genetic assays • HER2 marker • Lymphatic mapping and SNLD
Staging Workup
• Bone scan (if indicated) • Calcium and phosphate levels • Chest radiograph • Complete blood cell count, platelet count • CT scan of chest, abdomen, pelvis (if indicated) • Liver function tests • MRI (if indicated) • PET (if indicated)
Collaborative Therapy

• Surgery
  • Breast-conserving (lumpectomy) with SNLD, ALND, or both
  • Modified radical mastectomy (may include reconstruction)
• Radiation therapy
  • Primary radiotherapy
  • Adjuvant radiotherapy
  • High-dose brachytherapy
  • Palliative radiotherapy
• Drug therapy (see Table 54-6)
  • Biological and targeted therapy
  • Chemotherapy
  • Chemotherapy for recurrent or metastatic disease
  • Hormonal therapy
  • Neoadjuvant or adjuvant chemotherapy

ALND, axillary lymph node dissection; *CT,* computed tomography; *HER2,* human epidermal growth factor receptor 2; *MRI,* magnetic resonance imaging; *PET,* positron emission tomography; *SNLD,* sentinel lymph node dissection.

TABLE 54-6

DRUG THERAPY
Breast Cancer

Drug Class	Mechanism of Action	Indications
Hormone Therapy		
Estrogen Receptor Blockers		
Tamoxifen (Nolvadex-D)	Blocks estrogen receptors (ERs)	ER-positive breast cancer in premenopausal and postmenopausal women Used as a preventive measure in high-risk premenopausal and postmenopausal women
Fulvestrant (Faslodex)	Blocks ERs	ER-positive breast cancer in postmenopausal women only
Aromatase Inhibitors		
Anastrozole (Arimidex) Letrozole (Femara) Exemestane (Aromasin)	Prevents production of estrogen by inhibiting aromatase	ER-positive breast cancer in postmenopausal women only
Estrogen Receptor Modulator		
Raloxifene (Evista)	In breast, blocks the effect of estrogen In bone, promotes the effect of estrogen and prevents bone loss	Postmenopausal women
Biological and Targeted Therapy		
Trastuzumab (Herceptin) Pertuzumab (Perjeta)	Blocks HER2 receptor	ER-positive breast cancer in postmenopausal women only
Lapatinib (Tykerb)	Inhibits HER2 tyrosine kinase and EGFR tyrosine kinase	ER-positive breast cancer in postmenopausal women only

EGFR, epidermal growth factor receptor; *HER2,* human epidermal growth factor receptor 2.

TABLE 54-7
STAGING OF BREAST CANCER

Stage	Tumour Size	Lymph Node Involvement	Metastasis
0	TIS*	No	No
I	<2 cm	No	No
II			
A	No evidence of tumour ranging to 5 cm	No, or 1–3 axillary nodes or internal mammary nodes or both	No
B	Ranging from 2 to >5 cm	No, or 1–3 axillary nodes or internal mammary nodes or both	No
III			
A	No evidence of tumour ranging to >5 cm	Yes, 4–9 axillary nodes or internal mammary nodes or both	No
B	Any size with extension to chest wall or skin	Yes, 4–9 axillary nodes or internal mammary nodes or both	No
C	Any size	Yes, ≥10 axillary nodes, internal mammary nodes, infraclavicular nodes, or a combination of these	No
IV	Any size	Any type of nodal involvement	Yes

**TIS*, tumour in situ.

Source: Adapted from Canadian Cancer Society. (2015). Stages of breast cancer. Retrieved from *http://www.cancer.ca/en/cancer-information/cancer-type/breast/staging/?region=on*; and American Joint Committee on Cancer. (2010). AJCC cancer staging manual (7th ed.). Retrieved from *https://cancerstaging.org/references-tools/deskreferences/Pages/AJCC-7th-Ed-Cancer-Staging-Manual.aspx*.

The stages range from I to IV, with stage I being very small tumours (<2 cm) with no lymph node involvement and no metastasis. Further classification within these stages depends on the size of the tumour and the number of lymph nodes involved. Stage IV indicates the presence of metastatic spread, regardless of tumour size or lymph node involvement.

The therapeutic regimen is often dictated by the clinical stage and biology of the cancer. (Adverse drug effects and appropriate nursing management of general treatment modalities for cancer are discussed in Chapter 18 and in Nursing Care Plan [NCP] 18-1, available on the Evolve website.)

In spite of the advent of new prognostic indicators such as determination of DNA content and analysis of cell-cycle phases, the presence or absence of malignant cells in lymph nodes remains a powerful prognostic factor related to local recurrence or metastasis after primary therapy.

Surgical Therapy.

Surgery is considered the primary treatment for breast cancer. Table 54-8 describes the most common surgical procedures used to treat breast

cancer. Breast-conserving surgery with radiation therapy and modified radical mastectomy with or without reconstruction are currently the most common options for resectable breast cancer (Figure 54-6). Most women with a diagnosis of early-stage breast cancer (≤4 to 5 cm in size) are candidates for either treatment choice. The overall survival rate with lumpectomy and radiation is about the same as that with modified radical mastectomy (Hwang, Lichtensztajn, Gomez, et al., 2013).

TABLE 54-8
SURGICAL PROCEDURES FOR BREAST CANCER

Procedure	Description	Adverse Effects	Complications	Patient Issues
Breast-conserving surgery (lumpectomy) with radiation therapy	Wide excision of tumour, SLNB or ALND, radiation therapy	Breast soreness Breast edema Skin reactions Arm swelling Sensory changes in breast and arm	Short-term: moist desquamation,* hematoma, seroma, infection Long-term: fibrosis, lymphedema,† myositis, pneumonitis,* rib fractures*	Prolonged treatment* Impaired arm mobility† Change in texture and sensitivity of breast
Modified radical mastectomy	Removal of breast, preservation of pectoralis muscle, SLNB or ALND	Tightening of chest wall, scarring Phantom breast sensations Lymphedema Sensory changes Impaired range of motion	Short-term: skin flap necrosis, seroma, hematoma, infection Long-term: sensory loss, muscle weakness, lymphedema	Loss of breast Incision Body image Need for prosthesis Impaired arm mobility
Tissue expansion and breast implants	Expander used to slowly stretch tissue; saline gradually injected into reservoir over weeks to months Insertion of implant under musculo-fascial layer of chest wall	Discomfort Sensation of chest wall tightness	Short-term: skin flap necrosis, wound separation, seroma, hematoma, infection Long-term: capsular contractions, displacement of implant	Body image Prolonged physician visits to expand implants Potential additional surgical procedures for nipple construction, symmetry
Breast reconstruction tissue flap procedures	TRAM flap procedure‡: a musculo-cutaneous flap (muscle, skin, fat, blood supply) is transposed from abdomen to the mastectomy site	Pain related to two surgical sites and extensive surgery	Short-term: delayed wound healing, infection, skin flap necrosis, abdominal hernia, hematoma	Prolonged postoperative recovery
	DIEP flap procedure: a free flap that transfers skin and fat from the abdomen to the chest; differs from TRAM flap because no muscle is moved	Requires more time in surgery than TRAM flap Pain related to two surgical sites	If procedure fails, tissue flap may die and have to be completely removed If tissue dies, new reconstruction may not be done for 6–12 months	Patients may experience less pain and restriction of movement than with a TRAM flap

*Specific to radiation therapy.

†If ALND is performed (less likely with SLNB).

‡May be performed concurrently with mastectomy.

ALND, axillary lymph node dissection; *DIEP,* deep inferior epigastric artery perforator; *SLNB,* sentinel lymph node biopsy; *TRAM,* transverse rectus abdominis musculocutaneous.

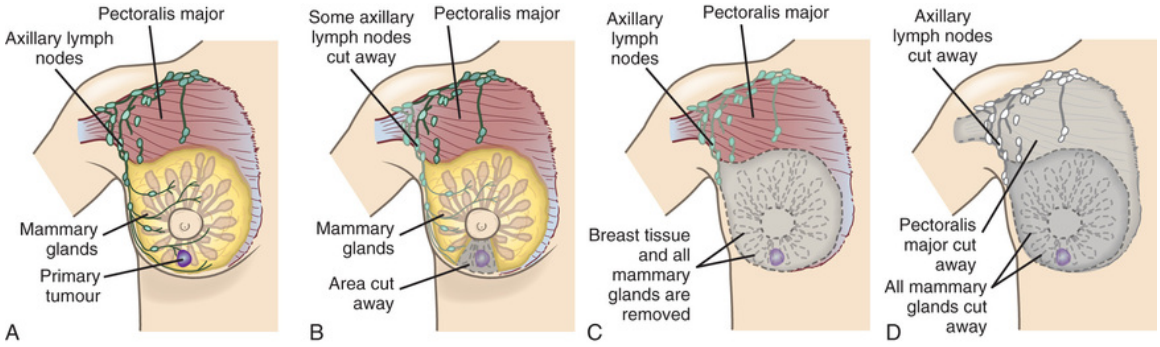

FIGURE 54-6 Breast cancer surgery. **A,** Preoperative. **B,** Lumpectomy. **C,** Simple mastectomy. **D,** Modified radical mastectomy.

Breast-Conserving Surgery.

Breast-conserving surgery (also called **lumpectomy**) involves the removal of the entire tumour along with a margin of normal surrounding tissue (Figure 54-6, *A*). After surgery, radiation therapy is delivered to the entire breast, ending with a boost to the tumour bed. Depending on the staging of the disease, chemotherapy may be administered before radiation therapy. Contraindications to breast-conserving surgery include the following: breast size too small in relation to the tumour size to yield an acceptable cosmetic result, masses and calcifications that are multifocal (within the same breast quadrant), masses that are multicentric (in more than one quadrant), diffuse calcifications in more than one quadrant, or central location of tumour near the nipple. Contraindications to radiation therapy (e.g., active lupus or prior radiation therapy in the radiation field) may make mastectomy a better surgical option.

One of the main advantages of breast-conserving surgery and radiation therapy is that the breast, including the nipple, is preserved. The goal of the combined surgery and radiation is to both maximize the benefits of the cancer treatment and the cosmetic outcome and minimize the risks.

Disadvantages of this approach include the increased cost of the surgery plus radiation therapy over surgery alone and the possible adverse effects of irradiation.

Axillary Node Dissection.

ALND on the same side as the breast cancer is often performed and, until the early 2000s, was the standard of care for invasive breast cancer. In general, ALND typically involves the removal of 12 to 20 nodes. SLNB has replaced ALND for patients in whom malignant cells are not identified in the sentinel nodes (see Figure 54-5). Recent guidelines suggest that women with one or two positive sentinel lymph nodes who are having breast-conserving surgery followed by radiotherapy may not need ALND (Yeo, Turner, & Jones, 2014). Examination of the lymph nodes provides prognostic information and helps determine further treatment (chemotherapy, hormone therapy, or both).

Lymphedema (accumulation of lymph in soft tissue) can occur as a result of the excision or irradiation of lymph nodes (Nicholson, 2015) (Figure 54-7). When the axillary nodes cannot return lymph fluid to the central circulation, the fluid accumulates in the arm, causing obstructive pressure on the veins and impeding venous return (Figure 54-8). Patients may experience heaviness, pain, impaired motor function in the arm, and numbness and paraesthesia in the fingers as a result of lymphedema. Cellulitis and progressive fibrosis can result from lymphedema. Although lymphedema is not always preventable, it can be controlled somewhat after surgery or radiation therapy (see discussion later in this chapter).

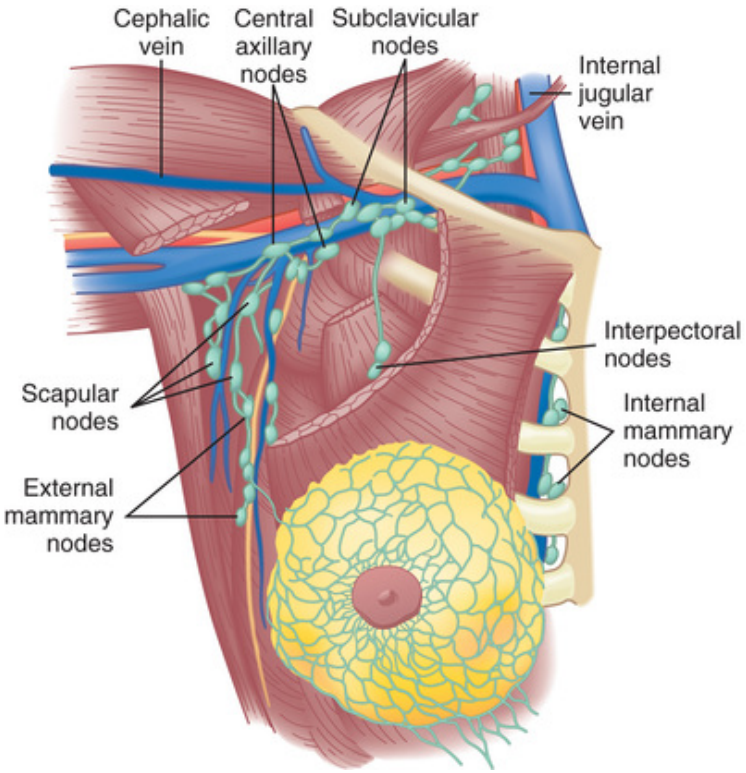

FIGURE 54-7 Illustration of lymph nodes and drainage in the axilla. The sentinel lymph node is usually found in the external mammary nodes. In a complete axillary dissection, all nodes would be removed. Source: Townsend, C. M., Beauchamp, R. D., Evers, B. M., et al. (2009). *Sabiston textbook of surgery* (18th ed.). St. Louis: Mosby.

FIGURE 54-8 Lymphedema. Accumulation of fluid in the tissue after excision of lymph nodes. Source: Swartz, M. H. (2010). *Textbook of physical diagnosis: History and examination* (6th ed., p. 443, Figure 15-3). Philadelphia: W. B. Saunders.

Modified Radical Mastectomy.

A modified radical mastectomy includes removal of the breast and the axillary lymph nodes, but it spares the pectoralis major muscle. This surgery is preferred over breast-conserving surgery if the tumour is too large to excise with adequate margins, or if it is so large that excision would produce a poor cosmetic result. Some patients may select this surgical procedure over lumpectomy when presented with a choice.

When a modified radical mastectomy is performed, patients have the option of breast reconstruction. If a patient chooses to have reconstructive surgery, it can be performed immediately after the mastectomy, or it can be delayed until postoperative recovery is complete (Canadian Cancer Society, 2017m).

Postmastectomy Pain Syndrome.

Postmastectomy pain syndrome can occur after a mastectomy or an axillary node dissection. Common symptoms include chest and upper arm pain, tingling sensations down the arm, numbness, shooting or pricking pain,

and unbearable itching that persist beyond the normal 3-month healing time. The cause most commonly theorized about the onset of this syndrome is injury to intercosto-brachial nerves, which are sensory nerves that exit chest wall muscles and provide sensation to the shoulder and the upper arm.

Treatments include nonsteroidal anti-inflammatory drugs, antidepressants, topical lidocaine patches, eutectic mixture of local anaesthetics (lidocaine and prilocaine), and anticonvulsant drugs (e.g., gabapentin [Neurontin]). Other possible treatment modalities include imagery, biofeedback, physical therapy to prevent "frozen shoulder" syndrome as a result of inadequate movement, and psychological counselling with a person trained in the management of chronic pain syndromes.

Adjuvant Therapy.

The decision to recommend adjuvant (additional) therapy after surgery depends on the stage of the disease (number of involved nodes and tumour size); the menstrual status, health, and age of the patient; cancer cell characteristics; and presence or absence of estrogen, progesterone, and HER2. Adjuvant therapies include local radiation therapy and systemic therapies such as chemotherapy and hormone therapy (Canadian Cancer Society, 2017n).

Radiation Therapy.

Radiation therapy may be used as (a) primary treatment to prevent local breast recurrences after breast-conserving surgery (see the Evidence-Informed Practice: Translating Research Into Practice box), (b) adjuvant treatment after mastectomy to prevent local and nodal recurrences, and (c) palliative treatment for pain caused by local, regional, or distant recurrence.

Evidence-Informed Practice

Translating Research Into Practice

Maia Samsa is a 53-year-old woman who was diagnosed with breast cancer 2 weeks ago. She is recovering from a lumpectomy with negative

lymph nodes. Her physician has recommended adjuvant therapy with radiation.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
The addition of radiation therapy to lumpectomy reduces the risk for local cancer recurrence.	Radiation is recommended even with negative lymph nodes after a lumpectomy. Many patients have minimal or no adverse effects from radiation therapy. The most common ones are fatigue, malaise, skin reactions, and ulcers or irritation of the skin.	She tells the nurse that she is not sure if she wants to have radiation treatment because she is afraid of the adverse effects.

Decision and Action

The nurse should review the possible adverse effects and how they can be managed and then explain to Ms. Samsa the risks of not taking the radiation treatment, which can include recurrence. Ms. Samsa tells the nurse that she will discuss it with her husband and possibly reconsider. The nurse understands the patient's concerns and informs the physician of her indecisiveness.

Reference for Evidence

Berrang TS, Olivotto I, Kim DH, et al. Three-year outcomes of a Canadian multicenter study of accelerated partial breast irradiation using conformal radiation therapy. *International Journal of Radiation Oncology, Biology, Physical*. 2011;81(5):1220–1227; 10.1016/j.ijrobp.2010.07.2003.

Primary Radiation Therapy.

When radiation therapy is the primary treatment, it is usually performed after local excision of the breast mass. The breast (and, in some cases, the regional lymph nodes) is irradiated 5 days per week over the course of approximately 4 to 6 weeks. An external beam of radiation is used to deliver an approximate total dose of 4 500 to 5 000 cGy (4 500 to 5 000 rd). During the final week or so, the patient receives a supplemental dose of radiation targeted directly to the area where the tumour was located. This dose is called a "boost" and is usually delivered in a method similar to the patient's regular radiation but to a smaller area. Fatigue, skin changes, and breast edema may be temporary adverse effects of external beam radiation therapy. To decrease the risk for axillary recurrence, irradiation of the axilla or supraclavicular nodes or both may be indicated when lymph nodes are involved. Chemotherapy may be used systemically before radiation therapy to enhance the local effects of radiation. (Nursing management of patients receiving radiation therapy is discussed in Chapter 18, and in NCP 18-1.)

The decision to use radiation therapy after mastectomy is based on the probability that local residual cancer cells are present (related to tumour size and biology and number of involved lymph nodes). Irradiating the area does not prevent the appearance of distant metastasis at a later date. The site of the radiation therapy field (lymph nodes, chest wall, or both) depends on the risk for recurrence.

High-Dose Brachytherapy.

Brachytherapy (internal radiation) is an alternative to traditional radiation treatment for early-stage breast cancer. For many years, internal radiation therapy has been delivered primarily through a multicatheter implant method that requires many catheters to be placed in the breast. After

placement, a radioactive seed is delivered into each catheter to treat the target area.

Currently, the most widely practised method is balloon brachytherapy. Traditional radiation treatments can take 5 to 6 weeks; in contrast, high-dose brachytherapy with the balloon catheter may require only 5 days.

The MammoSite Radiation Therapy System (MammoSite RTS) is a minimally invasive method of delivering internal radiation therapy. In this technique, a balloon catheter is used to insert radioactive seeds into the breast after the tumour is removed (Figure 54-9). Radiation is emitted by a tiny radioactive seed attached by a wire on the way to an afterloader, a computer-controlled machine. The seed travels through the MammoSite RTS applicator into the inflated balloon. The radiation dose is focused on the area of the breast at highest risk for tumour recurrence.

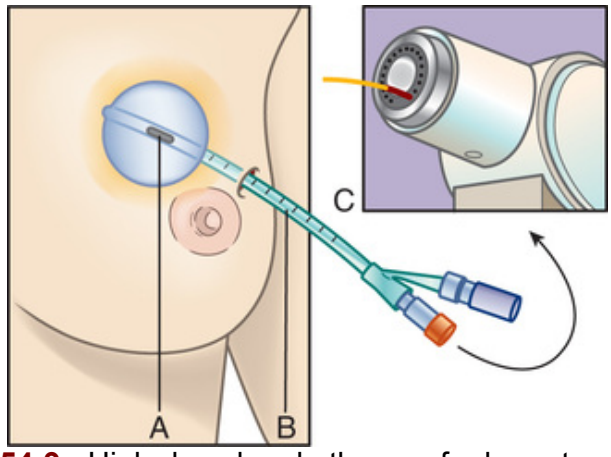

FIGURE 54-9 High-dose brachytherapy for breast cancer. The MammoSite Radiation Therapy System involves the insertion of a single small balloon catheter *(B)* at the time of the lumpectomy or shortly thereafter into the tumour resection cavity (the space that is left after the surgeon removes the tumour). A tiny radioactive seed *(A)* is inserted into the balloon, connected to a machine called an *afterloader (C)*, and delivers the radiation therapy.

Radiation therapy with the MammoSite RTS is performed over a 1- to 5-day period on an outpatient basis. Patients typically receive treatments twice a day for 5 days.

The MammoSite RTS may also be used as boost therapy in conjunction with external irradiation.

The source of radiation does not remain in the body between treatments or after the final treatment is over. The tiny radioactive seed is inserted

only during treatment and then removed. Once the final session is completed, the balloon is deflated, and the system is removed.

Palliative Radiation Therapy.

In addition to reducing the primary tumour mass with a resultant decrease in pain, radiation therapy is used to stabilize symptomatic metastatic lesions in such sites as bone, soft tissue organs, the brain, and the chest and is successful in controlling recurrent or metastatic disease.

Systemic Therapy.

The goal of systemic therapy is to destroy tumour cells that may have spread to distant sites. Systemic therapy as an adjuvant to primary local treatment (in the absence of demonstrable metastases) can decrease the rate of recurrence and increase the length of survival. Because of the high risk for recurrent disease, nearly all women with evidence of node involvement, particularly those whose hormone receptor status is negative, have some type of systemic therapy. Some women, particularly those with a larger tumour or a more aggressive type of tumour, are at higher risk for recurrent or metastatic disease. Systemic therapy is often recommended for such women even when no evidence of node involvement is found. Weighing the risks and benefits of adjuvant therapy is a complex process.

Chemotherapy.

Chemotherapy is the use of cytotoxic drugs to destroy cancer cells. Many breast cancers are responsive to chemotherapy. In some patients, chemotherapy is administered preoperatively. Preoperative (neoadjuvant) chemotherapy can decrease the size of the primary tumour, possibly enabling surgery to be less extensive. Breast cancer survival rates with preoperative chemotherapy are no different from those with postoperative chemotherapy (Kong, Moran, Zhang, et al., 2011).

Combinations of drugs yield results superior to those of a single drug. The benefits of combination treatment result from the use of drugs that have different mechanisms of action and work at different parts of the cell cycle. The more common combination-therapy protocols are as follows:

- Cyclophosphamide (Procytox), methotrexate, and 5-fluorouracil (5-FU), referred to as *CMF*

- Doxorubicin and cyclophosphamide, with or without the addition of a taxane such as paclitaxel (Abraxane) or docetaxel (Taxotere)
- Cyclophosphamide, doxorubicin or epirubicin (Pharmorubicin PFS), and 5-FU, referred to as *CAF* or *CEF*

Drug Alert

Doxorubicin

- Patient should be monitored for signs of cardiotoxicity and heart failure (e.g., new onset of shortness of breath, pedal edema, decreased activity tolerance, dysrhythmias, ECG changes).
- Patient should not have immunizations without physician's approval.
- Patient must avoid contact with those who recently received live virus vaccine.

Certain drugs may be used alone to treat metastatic breast cancer. A medication used alone results in fewer adverse effects than do combinations. Docetaxel (Taxotere), capecitabine (Xeloda), and an albumin-bound form of paclitaxel (Abraxane) are used when metastatic breast cancer has not responded to standard chemotherapy (Canadian Cancer Society, 2017o). Vinorelbine (Navelbine), used to treat metastatic breast cancer, is better tolerated because it produces fewer and milder adverse effects than do other chemotherapeutic drugs.

Because healthy cells are also affected by chemotherapy, various adverse effects accompany this treatment modality. The incidence and severity of predictable and commonly observed adverse effects are influenced by the specific drug combination, drug schedule, and drug doses. Usually, body organs with rapidly dividing cells are the most strongly affected. The most common adverse effects involve the gastro-intestinal tract, bone marrow, and hair follicles, resulting in nausea, anorexia, weight gain, bone marrow suppression and subsequent fatigue, and alopecia (hair loss) (Canadian Cancer Society, 2017p).

Cognitive changes during and after treatment, especially with chemotherapy ("chemo brain"), have been reported in 30% to 60% of women with breast cancer. These changes include difficulties in concentration, memory, and maintaining focus and attention. Ongoing research is focusing on why the cognitive impairment occurs (Player, Mackenzie, Willis, et al., 2014).

Hormonal Therapy.

Estrogen can promote the growth of breast cancer cells if the cells are estrogen receptor–positive. Hormonal therapy blocks the source of estrogen, thus promoting tumour regression (Canadian Cancer Society, 2017q). Hormonal therapy may be used as an adjuvant to primary treatment or in patients with recurrent or metastatic cancer. Two advances have increased the use of hormone therapy in breast cancer. First, hormone receptor assays, which are reliable diagnostic tests, identify women who are likely to respond to hormone therapy. Both the estrogen and progesterone receptor status of the tumour can be determined. The importance of these assays is their ability to predict whether hormonal therapy is a treatment option for women with breast cancer, either at the time of initial therapy or if the cancer recurs. Second, drugs have been developed that can inactivate the hormone-secreting glands as effectively as surgery or radiation. Chances of tumour regression are significantly greater in women whose tumours contain estrogen and progesterone receptors (Canadian Cancer Society, 2017q).

Estrogen deprivation can occur when ovarian function is damaged by surgery, radiation therapy, or drug therapy (see Table 54-6). Hormonal therapy can (a) block or destroy the estrogen receptors or (b) suppress estrogen synthesis through inhibiting aromatase, an enzyme needed for endogenous estrogen synthesis.

Estrogen Receptor Blockers.

Tamoxifen (Nolvadex) has for many years been the hormonal agent of choice in estrogen receptor–positive women with breast cancer of all stages (Canadian Cancer Society, 2017q). Tamoxifen, an antiestrogen drug, blocks the estrogen receptor sites of malignant cells and thus inhibits the growth-stimulating effects of estrogen. It is commonly used in early-stage and advanced breast cancer and to treat recurrent disease. Tamoxifen may also be used to prevent breast cancer in individuals at high risk for its development. Adverse effects of tamoxifen may include hot flashes, mood swings, vaginal discharge and dryness, and other effects commonly

associated with decreased estrogen levels. It also increases the risk for blood clots, cataracts, stroke, and endometrial cancer in postmenopausal women. Treatment with tamoxifen generally lasts 5 years (Canadian Cancer Society, 2017q).

Drug Alert

Tamoxifen (Nolvadex)

- Irregular vaginal bleeding or spotting may occur.
- Decreased visual acuity, corneal opacity, and retinopathy can occur in women receiving high doses (240–320 mg/day for >17 months). These problems may be irreversible.
- Patient should be instructed to report decreased visual acuity immediately.
- Patient should be monitored for signs of deep-vein thrombosis, pulmonary embolism, and stroke, including shortness of breath, leg cramps, and weakness.

Fulvestrant (Faslodex) may be administered when advanced breast cancer no longer responds to tamoxifen. This drug slows cancer progression by destroying estrogen receptors in the breast cancer cells. Fulvestrant is given intramuscularly on a monthly basis. Common adverse effects include fatigue, hot flashes, and nausea.

Aromatase Inhibitors.

Aromatase inhibitor drugs interfere with the enzyme that synthesizes endogenous estrogen and are used in the treatment of breast cancer in postmenopausal women. These drugs include anastrozole (Arimidex), letrozole (Femara), and exemestane (Aromasin). Aromatase inhibitors do not block the production of estrogen by the ovaries; thus they are of little benefit and may be harmful in premenopausal women.

Clinical trials have demonstrated improved disease-free survival when these drugs are given after tamoxifen treatment has ended (Canadian Cancer Society, 2017q). They also appear to be more effective than tamoxifen in preventing breast cancer recurrence and possibly more effective in preventing contralateral disease. The adverse effects of

aromatase inhibitors are different from those of tamoxifen. Aromatase inhibitors only rarely cause blood clots, and they do not cause endometrial cancer. Because they block the production of estrogen in postmenopausal women, osteoporosis and bone fractures may occur. These drugs have also been associated with night sweats, nausea, arthralgias, and myalgias.

Raloxifene (Evista), a drug used to prevent bone loss, is now being used to reduce the risk for breast cancer in postmenopausal women without stimulating endometrial growth. Raloxifene may act by blocking estrogen receptors in the breast, similar to its action in the bone. (Raloxifene is discussed in the section on osteoporosis in Chapter 66.)

Less common hormone-deprivation strategies include bilateral oophorectomy, adrenalectomy, and hypophysectomy.

Biological and Targeted Therapy.

Some breast cancers make excessive amounts of the HER2 protein. For patients who are HER2 positive, trastuzumab (Herceptin) is a monoclonal antibody to HER2. After the antibody attaches to the antigen, it is taken into the cancer cells and eventually kills them. It can be used alone or in combination with other chemotherapy such as docetaxel (Taxotere) or paclitaxel (Abraxane) to treat patients whose tumours overexpress the *HER2* gene. Additional genetic testing may offer information on which patients are good candidates for treatment with trastuzumab.

Drug Alert

Trastuzumab (Herceptin)

- Drug should be used with caution in women with pre-existing heart disease.
- Patient should be monitored for signs of ventricular dysfunction and heart failure.

A new kind of targeted anticancer drug, trastuzumab emtansine (Kadcyla), is made up of the drugs trastuzumab and emtansine, which is an antibody-drug combination. Pertuzumab (Perjeta) is another new anti-HER2 therapy that is used for patients who have not received prior

treatment for metastatic breast cancer with an anti-HER2 agent or chemotherapy.

Lapatinib (Tykerb) may be used in combination with capecitabine (Xeloda) for patients with advanced, metastatic disease whose tumours produce excessive HER2. The combination treatment is indicated for women in whom disease has become resistant to other cancer drugs (Canadian Cancer Society, 2017r). Lapatinib works inside the cell by blocking the function of the HER2 protein. Adverse effects can include diarrhea, nausea, vomiting, rash, and a syndrome of numbness, tingling, swelling, and pain in the hands and feet. Cardiotoxicity has also been reported.

Advanced breast cancer in postmenopausal women who are estrogen and progesterone receptor–positive and HER2 positive may be treated with lapatinib in combination with capecitabine (Xeloda) and letrozole (Femara). Denosumab (Prolia, Xgeva), a monoclonal antibody, may be used to increase bone mass in patients with metastasis to the bone and at high risk for fracture from aromatase inhibitor therapy. (The use of biological and targeted therapies is discussed further in Chapter 18.)

Follow-Up and Survivorship Care.

After surgery, patients must be monitored for the rest of their life at regular intervals. Most have professional examinations every 6 months for 2 years and then annually thereafter. In addition, it is recommended that these patients perform monthly examinations on both breasts or on the remaining breast and the surgical site. The most common site of local recurrence of breast cancer is at the surgical site. These patients should also undergo appropriate breast imaging at regular intervals (usually 6 months to 1 year), as determined by their risk for recurrence and breast cancer history.

Evidence-Informed Practice

Research Highlight

What Is the Effect of Physical Activity in Cancer Survivors?

Clinical Question

For cancer survivors (P) does physical activity (I) improve physical and psychological outcomes (O) after primary treatment completion (T)?

Best Available Evidence

Systematic review of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence

- Thirty-four RCTs of cancer survivors: 22 studies were of breast cancer survivors. Intervention was mostly aerobic exercise. Duration of physical activity ranged from 3 to 60 wk (median of 13 wk). Control groups mainly were sedentary or assigned no exercise.
- Breast cancer survivors who did physical activity had an increased ability to bench and leg press, improved quality of life, and decreased fatigue and depression.
- Overall, cancer survivors who exercised showed improved BMI, body weight, peak oxygen consumption, distance walked in 6 min, handgrip strength, and quality of life.

Conclusion

- Physical activity has positive effects on physical and psychological outcomes and quality of life.

Implications for Nursing

- To help patients get interested in physical activity, nurses should discuss with them their favourite forms of exercise, hobbies, and activities.
- Nurses should help patients identify physical activity resources (e.g., walking paths, swimming pool, gym).
    - The patient's barriers to active participation in exercise should be assessed.
    - When possible, patients should be assisted in adhering to recommended activities.

BMI, body mass index; *P,* patient population of interest; *I,* intervention or area of interest; *O,* outcome(s) of interest; *T,* timing (see Chapter 1).

Culturally Competent Care

Breast Cancer

Among diverse ethnic groups, differences exist in the incidence, mortality rates, and relevant care issues related to breast cancer. In addition, cultural differences may involve gender roles, health beliefs, religion, and family structure. Other differences may relate to dietary factors and disparities in the access to and use of clinical breast examinations and screening mammography. Inequities in cancer care and outcomes exist among Canada's various ethnic and social groups despite universal health care (Ahmed & Shahid, 2012). Cultural values strongly influence how women respond to and cope with breast cancer and treatment. Nurses need to consider how health behaviours are influenced by cultural norms and, in particular, the cultural value of breasts and the cultural factors related to the disease of breast cancer. Immigrants to Canada often underutilize screening and prevention services. Women may delay screening or treatment for varying reasons, including an acceptance of disease as inevitable fate or "God's will," a mistrust of Western medicine, language barriers, lack of health care access, or the stigma of a cancer diagnosis. Among Indigenous populations, survival rates for preventable cancers are poorer than in the general population. Action strategies that eliminate cultural barriers to quality cancer care are essential, including integration of person-centred care and cultural competency as core values, to meet the needs of racially and ethnically diverse patients with breast cancer (Ahmed & Shahid, 2012).

Nursing Management Breast Cancer

Nursing Assessment

Many factors need to be considered when a nurse is assessing a patient with a breast problem. The history of the breast disorder assists in establishing the diagnosis. The presence of nipple discharge, pain, rate of growth of the lump, breast asymmetry, and correlation with the menstrual cycle should all be investigated.

The size and location of the lump or lumps should be carefully documented. The physical characteristics of the lesion, such as consistency, mobility, and shape, should be assessed. If nipple discharge is present, the colour and consistency should be noted, as well as whether it occurs from one or both breasts.

Subjective and objective data that should be obtained from an individual with suspected or diagnosed breast cancer are presented in Table 54-9.

TABLE 54-9

NURSING ASSESSMENT
Breast Cancer

Subjective Data
Important Health Information
Past health history: • Family history of breast cancer (especially mother or sister, young age at diagnosis) • History of abnormal mammogram findings or atypical findings in prior biopsy • Benign breast disorders with atypical changes • Previous unilateral breast cancer • Menstrual history (early menarche with late menopause) • Pregnancy history (nulliparity or first full-term pregnancy after age 30) • Previous endometrial, ovarian, or colon cancer • Hyperestrogenism and testicular atrophy (in men) • Dietary habits and history of alcohol use • Level of usual physical activity, weight, and BMI
Medications: Use of hormones, especially as postmenopausal hormone therapy and in oral contraceptives; infertility treatments
Surgeries or other treatments: Exposure to therapeutic radiation (e.g., for Hodgkin's lymphoma or thyroid cancer)
Symptoms
• Palpable change found on self-examination • Obesity; unexplained severe weight loss (possible indicator of metastasis) • Changes in cognition; headache; bone pain (possible indicators of metastasis) • Unilateral nipple discharge (clear, milky, or bloody) • Change in breast contour, size, or symmetry • Psychological stress • Anxiety regarding threat to self-esteem
Objective Data
General
Axillary and supraclavicular lymphadenopathy
Integumentary
Firm, discrete nodules at mastectomy site (possible indicator of local recurrence); peripheral edema (possible indicator of metastasis)
Respiratory
Pleural effusions (possible indicator of metastasis)
Gastro-Intestinal
Hepatomegaly, jaundice; ascites (possible indicators of liver metastasis)
Reproductive
Hard, irregular, nonmobile breast lump, most often in upper outer sector, possibly fixated to fascia or chest wall; nipple inversion or retraction, erosion; edema (*peau d'orange* appearance), erythema, induration, infiltration, or dimpling (in later stages)
Possible Diagnostic Findings
Finding of mass or change in tissue on breast examination; abnormal findings on mammography, ultrasonography, or breast MRI; positive results of FNA or surgical biopsy or similar results with needle biopsy

BMI, body mass index; *FNA*, fine-needle aspiration; *MRI*, magnetic resonance imaging.

Nursing Diagnoses

Nursing diagnoses related to the care of a patient with diagnosed breast cancer vary. After diagnosis and before a treatment plan has been selected, the following diagnoses apply:

- *Decisional conflict* related to *insufficient information* (treatment options and their effects)
- *Anxiety* related to *threat to current status, threat of death* (diagnosis of cancer)
- *Disturbed body image* related to *alteration in self-perception*

If a mastectomy or lumpectomy is planned, the nursing diagnoses may include but are not limited to those presented in NCP 54-1, available on the Evolve website.

Planning

The overall goals are that patients with breast cancer will (a) actively participate in the decision-making process related to treatment options, (b) adhere to the therapeutic plan, (c) manage the adverse effects of adjuvant therapy, and (d) access and benefit from the support provided by significant others and health care providers.

Nursing Implementation

Acute Intervention.

The time between the diagnosis of breast cancer and the selection of a treatment plan can be a difficult period for a woman and her family. Although the primary care provider has discussed treatment options, patients often rely on a nurse to clarify and expand on these options. During this often stressful time, patients may not be coping effectively. Appropriate nursing interventions are to explore the patient's usual decision-making patterns, to help her accurately evaluate the advantages and disadvantages of the options, to provide information relevant to the decision, and to support the patient and family once the decision is made.

During this period, patients may exhibit signs of distress or tension—such as tachycardia, increased muscle tension, sleep disturbances, and restlessness—whenever they focus on the decision to be made. Nurses should assess the body language, motor activity, and affect of their patients during periods of high stress and indecision so that appropriate interventions can be used.

Regardless of the surgery planned, patients must be provided with sufficient information to ensure informed consent. Some patients seek extensive, detailed information, whereas others avoid information. Sensitivity to the individual's need for and type of information is essential. The information includes (a) preoperative instructions on pain control, turning, coughing, and deep breathing; (b) a review of postoperative exercises; and (c) explanation of the recovery period from the time of surgery until discharge.

Many women who undergo breast-conserving surgery have an uncomplicated postoperative course with variable pain intensity. Pain is most affected by the extent of the lymph node dissection performed. If an ALND or a mastectomy has been performed, drains are generally left in place, and patients are discharged home with them. Patients and their families need to be taught, with a return demonstration, how to manage the drains at home.

Restoring arm function on the affected side after mastectomy and ALND is a key nursing goal. The patient should be placed in a semi-Fowler's position with the arm on the affected side elevated on a pillow. Flexing and extending the fingers should begin in the recovery room, with progressive increases in activity encouraged.

Postoperative arm and shoulder exercises are instituted gradually with a surgeon's direction (Figure 54-10). These exercises are designed to prevent contractures and muscle shortening, maintain muscle tone, and improve lymph and blood circulation. The difficulty and pain encountered by the patient in performing the previously simple tasks included in the exercise program may cause frustration and depression. The goal of all exercise is a gradual return to full range of motion within 4 to 6 weeks.

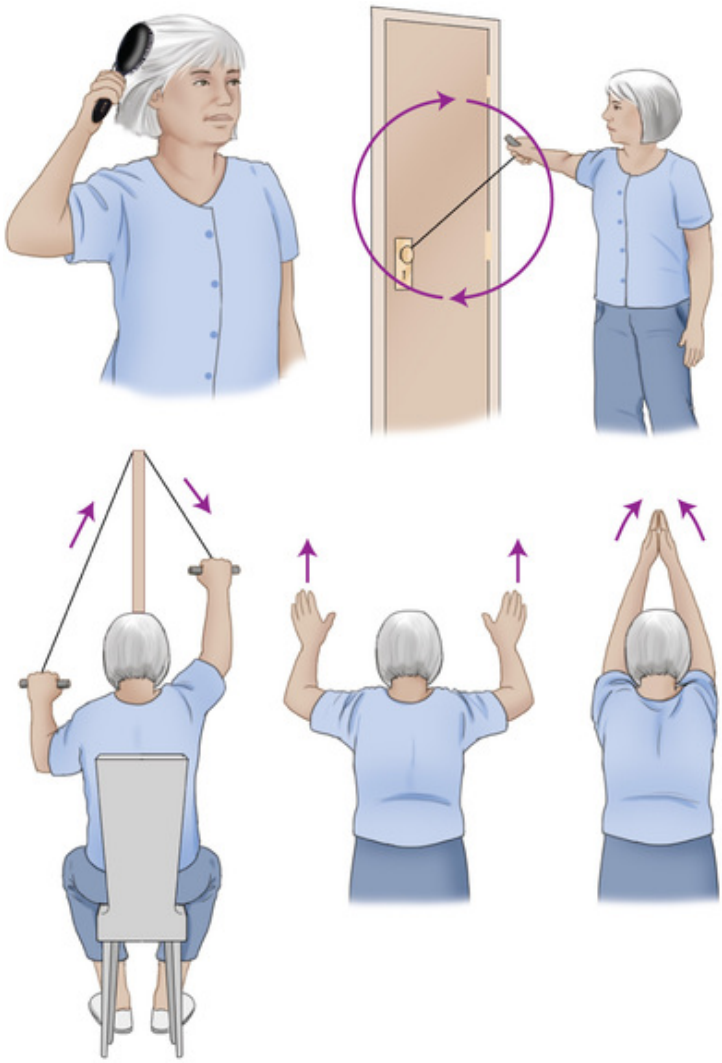

FIGURE 54-10 Postoperative exercises for patient with a mastectomy or lumpectomy with axillary lymph node dissection.

The nurse can minimize postoperative discomfort by administering analgesics about 30 minutes before the patient initiates exercises. When the patient is able to shower, the warm water on the involved shoulder often has a muscle-relaxing effect and reduces joint stiffness.

The nurse must use measures to prevent or reduce lymphedema after ALND and must teach these to the patient. The affected arm should not be dependent, even during sleep. Elastic bandages should not be used in the early postoperative period because they inhibit collateral lymph drainage. Patients must be instructed to protect the arm on the operative side from even minor trauma such as a pinprick or sunburn. If trauma to the arm occurs, the area should be washed thoroughly with soap and water, and a topical antibiotic ointment and a bandage or other sterile dressing should

be applied. Patients must be taught to advise their surgeon of the trauma, and the site of injury must be observed closely for evidence of inflammation. Patients must understand that for the rest of their life, they are at risk of developing lymphedema.

Safety Alert

- Blood pressure readings, venipunctures, and injections should not be performed on the affected arm so as to prevent lymphedema.

When lymphedema is acute (see Figure 54-8), complete decongestive therapy may be recommended (Canadian Cancer Society, 2017s). This therapy consists of a massage-like technique to mobilize the subcutaneous accumulation of fluid. This is then followed by compression bandaging and the wearing of a pneumatic compression sleeve. This sleeve intermittently applies mechanical massage to the arm and facilitates lymph drainage up toward the heart. Diuretics, isometric exercises, and elevation of the arm so that it is level with the heart may be recommended to reduce the fluid volume in the arm. The patient may need to wear a fitted elastic pressure-gradient sleeve (a) during waking hours to maintain maximum volume reduction and (b) preventively during air travel.

Psychological Care.

Effective care includes sensitivity to the woman's efforts to cope with a life-threatening disease. A relationship in which the woman can express her authentic feelings is therapeutic. The nurse can help to meet the woman's psychological needs in the following ways:

- Providing a safe environment for the expression of the full range of feelings
- Helping her identify sources of support and strength, such as her partner, family, and spiritual or religious practices
- Encouraging her to identify and learn individual coping strengths

- Promoting communication between the patient and her family, friends, or both
- Providing accurate and complete answers to her questions about the disease, treatment options, and reproductive, fertility, or lactation issues (if appropriate)
- Offering information about community resources, such as CancerConnection through the Canadian Cancer Society, CanSurmount, Look Good Feel Better, and local support organizations and groups
- Offering information about available resources for mental health counselling if needed

Nurses can promote a woman's recovery by referring her to peer support resources. The Reach to Recovery program of the Canadian Cancer Society is a rehabilitation program for women who have undergone breast surgery. It is designed to help them meet their psychological, physical, and cosmetic needs. The volunteers, who have had breast cancer, can answer questions about expectations, surgery, and recovery. The Canadian Cancer Society and the Canadian Cancer Society Research Institute can provide excellent materials to assist nurses in meeting the special needs of women with breast cancer.

It is important for health care providers to remain sensitive to the complex psychological effect that a diagnosis of cancer and subsequent breast surgery can have on a woman and her family (Astin, Shapiro, & Shapiro, 2013). Diverse emotional responses are common. The nurse's accepting attitude and the offering of resources can greatly alleviate the common feelings of fear, anger, anxiety, and depression experienced by many patients.

Ambulatory and Home Care.

The nurse should explain the specific follow-up routine to patients and emphasize the importance of ongoing monitoring and breast self-awareness. To address needs for individual and family support in addition to coping needs, referral to a mental health care provider may be indicated. Immediately after surgery, symptoms that should be reported to

the clinician include fever, inflammation at the surgical site, erythema, postoperative constipation, and unusual swelling. Changes to report beyond the immediate postsurgical period are new back pain, weakness, shortness of breath, and confusion.

For women who have undergone mastectomy without breast reconstruction, a variety of products are available to meet specific individual needs. These include garments ranging from camisoles with soft breast prosthetic inserts to a fitted prosthesis with bra. For women who choose a breast prosthesis, a certified fitter can help them select a comfortable, more permanent weighted prosthesis and bra, generally at 4 to 8 weeks postoperatively. The role of the nurse is to present the choices and resources without judgement.

The loss of a breast can have varying implications for women's sexual identity and relationships. The nurse can initiate a discussion of sexuality by inviting questions about relationships or intimacy concerns within the recovery framework (Dow & Kennedy Sheldon, 2015). To be effective sources of support for the patient, the spouse, sexual partner, or family members often need help in dealing with their emotional reactions to the diagnosis and surgery. There are no physical reasons for a mastectomy to prevent sexual satisfaction. Women taking hormonal therapy, however, may have a decreased sexual drive or vaginal dryness. They may need to use lubrication to prevent discomfort during intercourse. Concerns about sexuality are not well addressed by many health care providers (Dow & Kennedy Sheldon, 2015). If difficulty in adjustment or other problems develop, counselling may be necessary to deal with the emotional component of a mastectomy and the diagnosis of cancer.

Depression and anxiety may occur with the continued stress and uncertainty of a cancer diagnosis. Patients' self-esteem and identity may also be threatened. The support of family and friends and participation in a cancer support group are important aspects of care that are often helpful in improving quality of life.

Evaluation

The expected outcomes for patients after a mastectomy or lumpectomy are presented in NCP 54-1, available on the Evolve website.

Mammoplasty

Mammoplasty is the surgical change in the size or shape of the breast. It may be performed electively for cosmetic purposes to either enlarge or reduce the size of the breasts. It may also be performed to reconstruct the breast after a mastectomy.

A professional, nonjudgemental attitude and clear information about surgical breast options are most useful for women engaged in decision making about mammoplasty. It is important that patients set realistic expectations about what mammoplasty can accomplish and about possible complications, such as hematoma formation, hemorrhage, and infection. If an implant is involved, the woman must understand that capsular contracture (complication of internal scar tissue forming a constricting capsule around a breast implant) and the resultant loss of the implant are possible (Health Canada, 2012).

Breast Reconstruction

Breast reconstructive surgery may be performed simultaneously with a mastectomy or some time afterward to achieve symmetry and to restore or preserve body image. The timing of reconstruction surgery should be based on the psychological needs of individual patients. Immediate breast reconstruction after mastectomy is commonly performed. The advantages of immediate reconstruction are the need for only one surgical procedure, only one anaesthesia induction, and only one recovery period; also, reconstructive surgery takes place before the development of scar tissue or adhesions. Early reconstruction does not delay or influence further treatment or adversely affect predicted survival.

Indications.

The main indication for breast reconstruction is to improve a woman's self-image and help her regain a sense of normality and assist her in coping with the loss of the breast. Current techniques cannot restore lactation, nipple sensation, or nipple erectility. Therefore, the erotic functions of the breast are not present. Although the breast will not fully resemble its premastectomy appearance, the reconstructed appearance usually represents an improvement over the mastectomy scar (Figure 54-11). The contour of the breast is restored without the use of an external prosthesis.

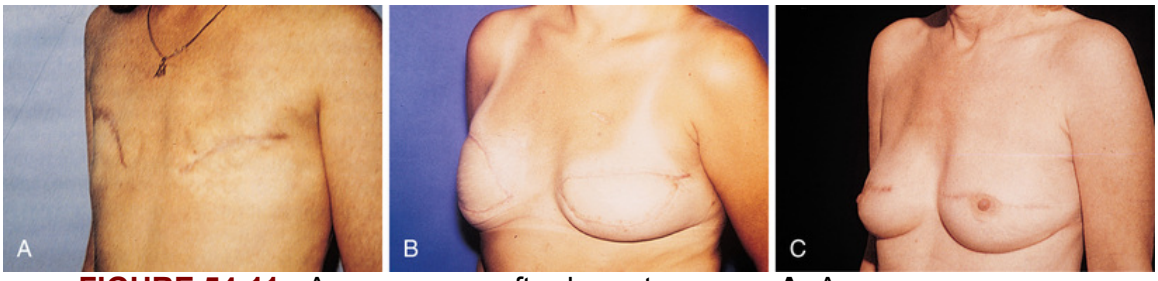

FIGURE 54-11 Appearances after breast surgery. **A,** Appearance of chest after bilateral mastectomy. **B,** Postoperative breast reconstruction before nipple–areolar reconstruction. **C,** Postoperative breast reconstruction after nipple–areolar reconstruction. Types of Reconstruction

Breast Implants and Tissue Expansion.

Breast implants are placed in a pocket under the pectoralis muscle, which protects the implant and provides soft tissue coverage over it. Implants can be placed either at the time of mastectomy or later. A small magnet is embedded in most expanders to help locate the port where the fluid is injected. Therefore, a woman with a magnet in place should not undergo MRI. Because many patients who have undergone mastectomy have insufficient tissue, simple placement of an implant may lead to small breast reconstruction that is tight or firm. Autologous (one's own) tissue reconstruction may then be recommended.

A tissue expander can be used to stretch the skin and muscle at the mastectomy site before implants are inserted (Figure 54-12). The use of tissue expanders and breast implants is the most common breast reconstruction technique currently used. Placement of the expander can be performed at the time of mastectomy or at a later date. The tissue expander, which is minimally inflated at the time of surgery, is gradually filled by weekly injections of sterile water or saline solution, which stretch the skin and muscle. Once the tissue is adequately stretched and the anticipated breast size is reached, the expander is surgically removed and a permanent implant is inserted. Some expanders are designed to remain in place and become the implant, eliminating the need for a second surgical procedure. Tissue expansion does not work well in individuals with extensive scar tissue from surgery or radiation therapy.

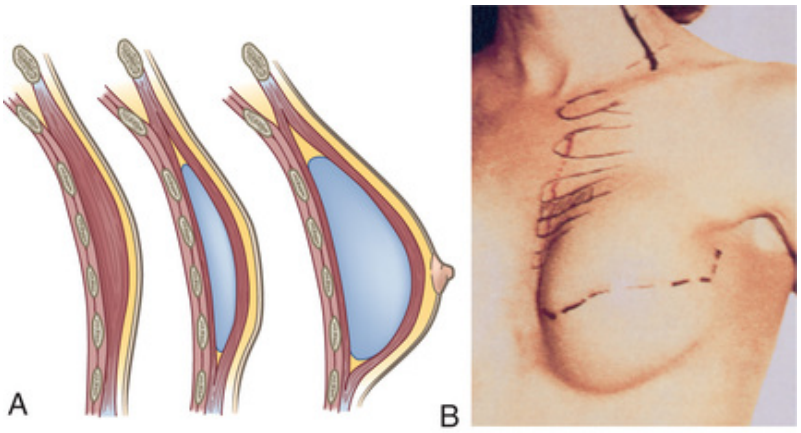

FIGURE 54-12 Tissue expansion. **A,** Diagram of tissue expander with gradual expansion. **B,** Tissue expander in place after mastectomy. Sources: **A,** Cameron, J. (1995). *Current surgical therapy* (5th ed.). St. Louis: Mosby. **B,** Fortunato, N., & McCullough, S. M. (1998). *Plastic and reconstructive surgery*. St. Louis: Mosby. Courtesy Brian Davies, MD.

The body's natural response to the presence of a foreign substance is the formation of a fibrous capsule around the implant (Health Canada, 2012). If excessive capsular formation occurs as a result of infection, hematoma, trauma, or reaction to a foreign body, a contracture can develop, resulting in deformation of the breast. Surgeons differ in their approaches to the prevention of contracture formation, although gentle manual massage around the implant is routine. Prevention of the problems that cause excessive capsule formation is critical. Other postoperative complications include skin ulceration, hypertrophic scar formation, intercostal neuralgia, and wound infection.

Tissue Flap Procedures.

An additional choice for breast reconstruction is the use of autologous tissue to re-create a breast mound. If insufficient muscle is left after mastectomy or if the chest wall has been irradiated, the person's own tissue may be used to repair the soft tissue defects. Musculo-cutaneous flaps are most often taken from the back (latissimus dorsi muscle) or the abdomen (transverse rectus abdominis muscle). In the latissimus dorsi musculo-cutaneous flap, a block of skin and muscle from the patient's back is used to replace tissue removed during mastectomy. A small implant may be needed beneath the flap to obtain reasonable breast shape and size. A disadvantage of this technique is an additional scar on the back.

The *transverse rectus abdominis musculo-cutaneous (TRAM) flap* is the most frequently used flap operation (Canadian Cancer Society, 2017t). The

rectus abdominis muscles are paired flat muscles running from the rib cage down to the pubic bone. Arteries running inside the muscles provide branches at many levels, and these branches supply the fat and skin across a large expanse of the abdomen. In this technique, the surgeon elevates a large block of tissue from the lower abdominal area but leaves it attached to the rectus muscle (Figure 54-13). This tissue is then tunnelled or placed as "free flaps" under the skin up to the area where the breast will be reconstructed. Then it is moulded and fashioned to form a breast. The abdominal incision is closed, which results in an appearance similar to that of an abdominoplasty. This surgical procedure can last 2 to 8 hours, and recovery can take at least 6 to 8 weeks. Some patients have reported persistent fatigue and reduced quality of life following surgery (Stagl, Antoni, Lechner, et al., 2014; Amaya, Hosokawa, Okamoto, et al., 2015). Complications include bleeding, seroma, hernia, infection, and low back pain. An implant may be used in addition to the flap if the flap does not provide the desired cosmetic result alone. Patients who smoke, who are too thin, or who are overweight are not good candidates for this type of procedure.

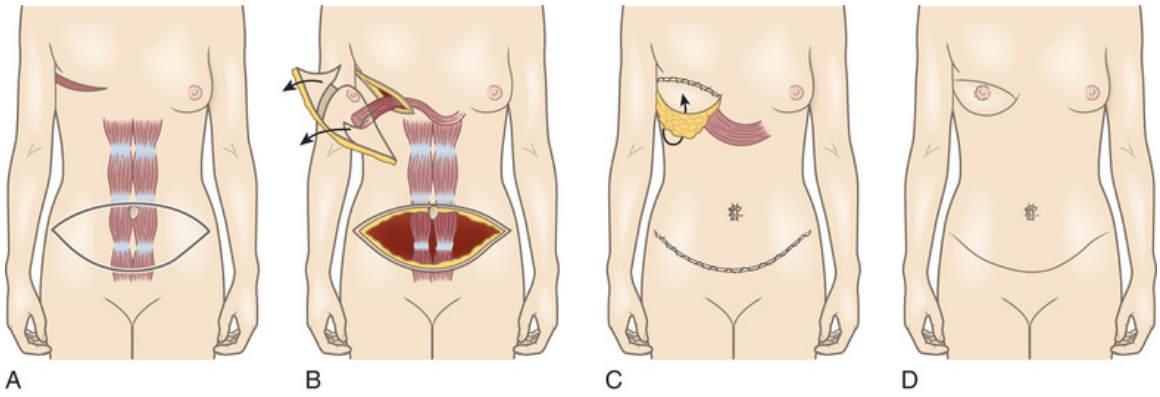

FIGURE 54-13 Diagrams of the transverse rectus abdominis musculo-cutaneous (TRAM) flap procedure. **A,** TRAM flap is planned. **B,** The abdominal tissue, while attached to the rectus muscle, nerve, and blood supply, is tunnelled through the abdomen to the chest. **C,** The flap is trimmed to shape the breast. The lower abdominal incision is closed. **D,** Nipple and areola are reconstructed after the breast is healed.

A *deep inferior epigastric artery perforator (DIEP) flap* is a version of the free flap that does not use muscle tissue. With the DIEP flap, only the skin and fat are taken from the same lower abdominal area as the TRAM flap.

Patients may experience less pain and restriction of movement with this procedure.

Total skin-sparing mastectomy is the preservation of the skin of the nipple and areola with the removal of underlying breast tissue. It can be done at the same time as immediate breast reconstructive surgery.

Nipple–Areolar Reconstruction.

The majority of patients who undergo breast reconstruction also receive nipple–areolar reconstruction. Nipple reconstruction gives the reconstructed breast a much more natural appearance. Nipple–areolar reconstruction is usually done a few months after breast reconstruction. Tissue to construct a nipple may be taken from the opposite breast or from a small flap of tissue on the reconstructed breast mound. The areola may be grafted from the labia, skin in the area of the groin, or lower abdominal skin, or it may be tattooed with a permanent pigmented dye. In some patients, a small implant may be placed under the completed nipple–areolar reconstruction to add additional projection.

Breast Augmentation

In augmentation mammoplasty (the procedure to enlarge the breasts), an implant is placed in a surgically created pocket between the capsule of the breast and the pectoral fascia or, ideally, under the pectoral muscle. Most implants are silicone envelopes filled with a fluid such as dextran, saline, or silicone. Because of their resemblance to the human breast, implants filled with silicone were the most widely used until 1992, when Health Canada asked manufacturers to stop the sale of silicone implants in Canada in response to potential health hazards related to silicone leakage. Currently in Canada, two types of breast implants (saline-filled and silicone gel–filled) have the required licensing from Health Canada. All implants contain an insert that identifies all potential risks related to breast implant surgery (Health Canada, 2012).

Breast Reduction

For some women, large breasts can be a source of physical and psychological discomfort. They can interfere with normal daily activities such as walking, typing, and driving a car. The weight of large breasts can lead to back, shoulder, and neck problems, including degenerative nerve changes. Overly large breasts can interfere with self-esteem and self-image, and the comfort in wearing some clothing may be affected.

Reduction in the size of the breasts can have positive effects on both the psychological and physical health of the patient. Reduction mammoplasty is performed by resecting wedges of tissue from the upper and lower quadrants of the breast. The excess skin is removed, and the areola and nipple are relocated on the breast. Lactation can usually be accomplished if massive amounts of tissue are not removed and the nipples are left connected during surgery.

Nursing Management Breast Augmentation and Reduction

Breast augmentation and breast reduction may be performed in the outpatient surgical area, or they may involve overnight hospitalization. General anaesthesia is used. Drains are generally placed in the surgical site to prevent hematoma formation and then removed 2 to 3 days after surgery or when drainage is less than 20 to 30 mL per day. The drainage must be examined for colour and odour to detect postoperative infection or hemorrhage. The woman's temperature should also be monitored. Dressings should be changed as necessary, with sterile technique. After surgery, the woman should be assured that the appearance of the breast will improve once healing is complete. Depending on physician instructions, patients may be instructed to wear a bra that provides good support continuously for 2 to 3 days after breast reduction or augmentation. Depending on the extent of the operation, most women can resume normal activities within 2 to 3 weeks. Strenuous exercise may not be appropriate until several weeks later.

Case Study

Breast Cancer

Source: Dubova/Shutterstock.com

Patient Profile

Anna Kaluza, a 68-year-old married woman, has been diagnosed with breast cancer (see the case study in Chapter 53). She is scheduled for

surgery in the morning for a lumpectomy and sentinel lymph node biopsy (SLNB) with possible axillary dissection.

Collaborative Care

Preoperative

- When she is seen in the preoperative clinic 1 week before surgery, Mrs. Kaluza is crying uncontrollably and says, "My husband does not want to look at me anymore. He is afraid of what I am going to look like with a flat chest."
- She says, "I cannot sleep, so I just pace the floor at night."
- She expresses concern that her two daughters (34 and 32) and their daughters are going to get "this horrible disease."

Operative Procedure

- A lumpectomy and SLNB are performed.
- Mrs. Kaluza has cancer cells in her sentinel lymph node.
- Axillary node dissection is then done involving the removal of 12 to 20 nodes.

Postoperative

- She does not want to leave hospital; she wants to stay in bed.
- She has fever with swelling and restricted range of motion in right arm.
- Pain is not controlled well with pain medication.

Follow-Up Findings and Treatment

- Two positive lymph nodes are found.
- She is scheduled for outpatient chemotherapy followed by external beam radiation.

Discussion Questions

1. What in Mrs. Kaluza's breast cancer experience with her family members (see the assessment case study in Chapter 53) might influence her coping response?
2. What information would the nurse provide to Mrs. Kaluza about her surgery?
3. What complication did she develop after her surgery?
4. Which common postoperative exercises will Mrs. Kaluza need to practise after her surgery?
5. What community resources are available to help Mrs. Kaluza and her family adjust to the change in her body and to cope with the diagnosis of cancer? How can the nurse access these resources?
6. What information about breast cancer risks is important to provide to Mrs. Kaluza about her radiation treatment and chemotherapy?
7. ***Priority decision:*** On the basis of the assessment data, what are the priority nursing diagnoses? Are there any collaborative problems?
8. What information is it important for the nurse to provide to Mrs. Kaluza and her daughters? What early-detection measures are important for them to know?
9. ***Evidence-informed practice:*** Mrs. Kaluza wants to know what the psychological benefit may be for her daughters if they decide on a breast cancer genetic risk assessment.

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. An occupational health nurse is planning a program on breast screening practices for women in the company. Which method should the nurse use to promote learning and adherence among participants? (*Select all that apply)*
   a. An audiotape that describes the procedure of breast self-awareness
   b. Distribution of a packet of articles from the medical literature
   c. A discussion of the value of early detection of breast cancer
   d. Written guidelines for mammography and breast self-awareness
   e. Community resources where they can obtain an ultrasound and MRI
2. Which of the following techniques is the most appropriate way to teach a client how to know her breasts?
   a. Teach her palpation of cervical lymph nodes.
   b. Teach her to practise hard squeezing of the breast tissue.
   c. Teach her the importance of a mammogram to evaluate breast tissue.
   d. Teach her inspection of the whole area of breast tissue for any changes.
3. What explanation should the nurse provide when teaching a client with painful fibrocystic breast changes about the condition?
   a. All discrete breast lumps must be subjected to biopsy to rule out malignant changes.
   b. The symptoms will probably subside after menopause unless hormone replacement is used.
   c. The lumps will become progressively larger and more painful, eventually necessitating surgical removal.
   d. Restriction of coffee and chocolate and supplements of vitamin E can relieve the discomfort for many patients.
4. When discussing risk factors for breast cancer with a group of women, which of the following should the nurse stress as the greatest known risk factor for breast cancer?
   a. Being a woman older than 60 years
   b. Experiencing menstruation for 40 years or more

c. Using estrogen replacement therapy during menopause

d. Having a paternal grandmother with postmenopausal breast cancer

5. A client has a lumpectomy with sentinel lymph node biopsy that yields results positive for cancer. Which of the following results supports the most favourable prognosis? *(Select all that apply)*

   a. Well-differentiated tumour

   b. Estrogen receptor–positive tumour

   c. Involvement of two to four axillary nodes

   d. Overexpression of *HER2* cell marker

   e. Aneuploidy status from cell proliferation studies

6. A client with breast cancer has been scheduled for a modified radical mastectomy with an axillary node dissection. Which of the following should the nurse perform postoperatively to restore arm function on the affected side?

   a. Apply heating pads or blankets to increase circulation.

   b. Place daily ice packs to minimize the risk for lymphedema.

   c. Teach passive exercises with the affected arm in a dependent position.

   d. Emphasize regular exercises for the affected shoulder to increase range of motion.

7. Which of the following should the nurse implement preoperatively to meet the psychological needs of a woman scheduled for a modified radical mastectomy?

   a. Discuss the limitations of breast reconstruction.

   b. Include her significant other in all conversations.

   c. Promote an environment for expression of feelings.

   d. Explain the importance of regular follow-up screening.

8. Which of the following statements is suitable to make when teaching clients how to prevent capsular formation after breast reconstruction with implants?

   a. Gently massage the area around the implant.

   b. Bind the breasts tightly with elastic bandages.

   c. Exercise the arm on the affected side to promote drainage.

   d. Avoid strenuous exercise until implant healing has occurred.

1. c, d; 2. d; 3. d; 4. a; 5. a, b; 6. d; 7. c; 8. a.

CHAPTER 55

Nursing Management

Sexually Transmitted Infections

Written by, Adena Bargad

Adapted by, Shelley L. Cobbett

LEARNING OBJECTIVES

1. Assess the factors contributing to the high incidence of sexually transmitted infections (STIs).
2. Explain the etiology, clinical manifestations, complications, and diagnostic abnormalities of gonorrhea, syphilis, chlamydial infections, genital herpes, and genital warts.
3. Compare and contrast primary genital herpes with recurrent genital herpes.
4. Explain the collaborative care and the drug therapy for gonorrhea, syphilis, chlamydial infections, genital herpes, and genital warts.
5. Identify the nursing assessment and the nursing diagnoses for patients who have a sexually transmitted infection.
6. Describe the nursing role in the prevention and control of sexually transmitted infections.
7. Describe the nursing management of patients with sexually transmitted infections.

KEY TERMS

chancre, p. 1378, Table 55-3

Sexually Transmitted Infections

Sexually transmitted infections (STIs) are infectious diseases that are commonly acquired through sexual contact (Table 55-1) but may also be contracted by other routes, such as through blood, blood products, perinatal transmission, and autoinoculation. STIs can be bacterial (gonorrhea, chlamydial infection, syphilis), viral (genital herpes, genital warts), or both. Most infections start as lesions on the genitalia and other sexually exposed mucous membranes.

TABLE 55-1
CAUSES OF SEXUALLY TRANSMITTED INFECTIONS

Cause	Infection or Condition
Bacterial	
Chlamydia trachomatis	Nongonococcal urethritis; cervicitis; lymphogranuloma venereum
Neisseria gonorrhoeae	Gonorrhea
Treponema pallidum	Syphilis
Viral	
Cytomegalovirus	Encephalitis, esophagitis, retinitis, pneumonitis in immuno-compromised patients
Hepatitis B & C viruses	Hepatitis B and C (see Chapter 46)
Herpes simplex virus (HSV)	Genital herpes
Human immunodeficiency virus (HIV) (See Chapter 17)	HIV infection, acquired immune deficiency syndrome (AIDS)
Human papilloma virus (HPV)	Genital warts; cervical, vulvar, vaginal, penile, anal, and oropharyngeal cancers
Poxvirus*	Molluscum contagiosum
Other	
Trichomonas vaginalis	Trichomoniasis
Phthirus pubis (crab louse)*	Ectoparasitic infestation (pubic lice) See Chapter 26
Sarcoptes scabiei*	Ectoparasitic infestation (scabies) See Chapter 26

*Transmission through both intimate sexual and nonsexual contact

Wide dissemination to other areas of the body can then occur. A latent or subclinical phase is present with all STIs. This can lead to a long-term persistent infection and the transmission of disease from an asymptomatic (but infected) person to another person. Having one STI increases the risk of acquiring another. A person can have different STIs at the same time.

In Canada, three nationally reportable STIs—gonorrhea, syphilis, and chlamydial infection—must be reported to the Communicable Disease Division in each province and territory (Public Health Agency of Canada [PHAC], 2013a). Since 1997, there has been a steady increase in the rates of all three of these infections (PHAC, 2013a) but it is not clear if this is an

actual increase or just a result of changes in the diagnosing and reporting of STIs (PHAC, 2013b). Young Canadians have the highest reported rates of sexually transmitted infections, although the numbers of cases being reported among middle-aged and older adults is increasing (PHAC, 2013b). There are also some noteworthy trends related to populations at high risk for STIs, such as injection-drug users, sex workers, individuals who are homeless, and anonymous sexual partners (e.g., a person met online or at a bathhouse or rave party) (PHAC, 2013a).

The more commonly diagnosed STIs are discussed in this chapter. Human immunodeficiency virus (HIV) infection and related problems are discussed in Chapter 17. Hepatitis B & C infection and related problems are discussed in Chapter 46.

Factors Affecting Incidence of Sexually Transmitted Infection

Many factors contribute to the current STI rates. Earlier reproductive maturity and increased longevity have resulted in a longer sexual lifespan. The increase in the total population has resulted in an increase in the number of susceptible hosts. Other factors include greater sexual freedom, failure to use barrier methods (e.g., condom, dental dam) during sexual activity, and the media's increased emphasis on sexuality. Substance use contributes to unsafe sexual practices. In addition, increased leisure time, more national and international travel, and urbanization have brought together people with varying social behaviours and value systems.

Changes in the methods of contraception that are typically used are also reflected in the incidence of STIs. The condom is considered to be the best form of protection (other than abstinence) against STIs. However, among the 1.8 million sexually active Canadians aged 15 to 49 years who had two or more sexual partners, only 57.5% used a condom the last time they had sex (Statistics Canada, 2015). Males are more likely than females to use a condom, and condom use decreases with age (Statistics Canada, 2015). Commonly used oral contraceptives cause the secretions of the cervix and the vagina to become more alkaline. This change produces a more favourable environment for the growth of organisms that cause STIs at these sites. Women who take oral contraceptives have a lower risk for pelvic inflammatory disease (PID) as a result of the ability of the cervical mucus to act as a barrier against bacteria. However, the proliferation of *Chlamydia* organisms, the leading cause of nongonococcal PID, may be enhanced by oral contraceptive use. Whether users of intrauterine devices

(IUDs) are at increased risk for PID is controversial, but IUDs do not confer protection from STIs. Long-acting contraceptives such as levonorgestrel (Jaydess) and medroxyprogesterone (Depo-Provera) also confer no protection against STIs. Although these methods do not prevent transmission from partner to partner, they do prevent pregnancy and, therefore, transmission of the infection to a fetus.

Nurses need to strive to attend to the physiological and psychological needs of the large number of people living with incurable STIs in Canada. Chronic viral STIs can have longstanding negative effects on a patient's psychosocial well-being, highlighting the need for strengthened prevention efforts.

Bacterial Infections

Gonorrhea

Gonorrhea is the second-most frequently occurring STI. Between 2003 and 2012, the rate of reported cases of gonorrhea increased by 38.9%, from 26.0 to 36.2 per 100 000 (PHAC, 2012). Although rates of gonorrhea increased in both sexes and across all age groups (12 561 cases reported in 2012), a greater relative rate increase was observed in females (PHAC, 2012). Continued monitoring for antimicrobial resistance is important to prevent the spread of drug-resistant gonorrhea and to ensure successful cure rates for this treatable infection. Most provinces and territories have enacted laws that permit examination and treatment of minors without parental consent.

Etiology and Pathophysiology

Gonorrhea is caused by *Neisseria gonorrhoeae,* a gram-negative diplococcus bacterium. The infection is spread by direct physical contact with an infected host, usually during sexual activity (vaginal, oral, or anal). Mucosal tissues in the genitalia (urethra in men, cervix in women), rectum, and oropharynx are especially sensitive to gonococcal infection. Neonates can develop gonorrhea during delivery from an infected mother. The delicate gonococcus is easily killed by drying, heating, or washing with an antiseptic solution. As a consequence, indirect transmission by instruments or linens is rare.

The incubation period is 3 to 8 days. The disease confers no immunity to subsequent reinfection. Gonorrhea elicits an inflammatory response that, if left untreated, leads to the formation of fibrous tissue and adhesions, which increase a woman's risk of experiencing an ectopic pregnancy (PHAC, 2013a).

Clinical Manifestations

Men.

The initial site of infection in men is usually the urethra. Symptoms of urethritis consist of dysuria and profuse, purulent urethral discharge that develops 2 to 5 days after infection (Figure 55-1). The testicles may also become painful or swollen. Men generally seek medical evaluation early in

the infection because their symptoms are usually obvious and distressing. It is unusual for men with gonorrhea to be asymptomatic (PHAC, 2013a).

FIGURE 55-1 Profuse, purulent drainage in a patient with gonorrhea. Source: Marx, K., Walls, R., & Hockberger, R. (2010). *Rosen's emergency medicine: Concepts and clinical practice* (7th ed.). St Louis: Mosby.

Women.

Most women who contract gonorrhea are asymptomatic or have minor symptoms that are often overlooked, which makes it possible for them to remain a source of infection. A few affected women may complain of vaginal discharge, dysuria, or frequency of urination. Changes in menstruation may be a symptom, but many affected women disregard these changes. After the incubation period, redness and swelling occur at the site of contact, which is usually the cervix or the urethra (Figure 55-2). A greenish-yellow purulent exudate often develops, with a potential for abscess formation. The infection may remain local or can spread by direct tissue extension to the uterus, fallopian tubes, and ovaries. Although the vulva and the vagina are uncommon sites for a gonorrheal infection, they may become involved when little or no estrogen is present, as is the case in prepubertal girls and postmenopausal women. Because the vagina acts as a natural reservoir for infectious secretions, transmission is often more efficient from men to women than it is from women to men.

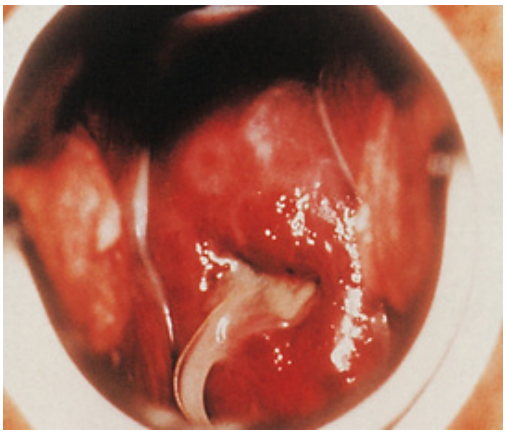

FIGURE 55-2 Endocervical gonorrhea. Cervical redness and edema with discharge. Source: Morse, S., Moreland, A., & Holmes, K. (Eds.). (1996). *Atlas of sexually transmitted diseases and AIDS.* London: Mosby-Wolfe.

General.

Anorectal gonorrhea may be present and is usually caused by anal intercourse. Symptoms may include soreness, itching, and mucopurulent anal discharge. In a small percentage of individuals, gonococcal pharyngitis results from orogenital sexual contact. Most patients with rectal infections and infections in the throat have few symptoms. When the gonococcus can be demonstrated by a laboratory culture, individuals of either sex can transmit the infection to their sexual partners.

Complications

Because men often seek treatment early in the course of the disease, they are less likely to develop complications. The complications that do occur in men are prostatitis, urethral strictures, and sterility from orchitis or epididymitis. Because women without symptoms seldom seek treatment, complications are more common and usually constitute the reason for seeking medical attention. PID, Bartholin abscess, ectopic pregnancy, chronic pelvic pain, and infertility are the main complications of gonorrhea in women. A small percentage of infected people may develop disseminated gonococcal infection (DGI). In DGI, the appearance of skin lesions, fever, arthralgia, arthritis, or endocarditis usually causes the patient to seek medical help (Figure 55-3).

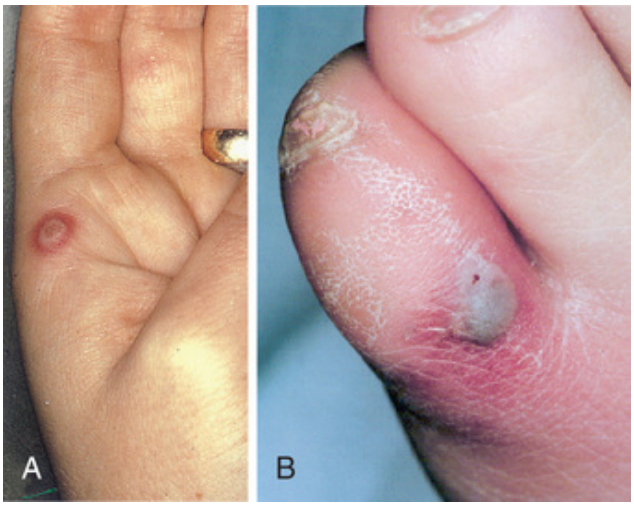

FIGURE 55-3 Skin lesions from disseminated gonococcal infection. **A,** On hand. **B,** On the fifth toe. Sources: **A,** Cohen, J., & Powderly, W. G. (2004). *Infectious diseases* (2nd ed.). St. Louis: Mosby. **B,** Mandell, G. L., Bennett, J. E., & Dolin, R. (2010). *Mandell, Douglas, and Bennett's principles and practice of infectious diseases* (7th ed.). Philadelphia: Churchill Livingstone.

Eye Infections in Newborns.

Infants with untreated gonorrheal infection develop permanent blindness. Most provinces and territories require the instillation of a prophylactic drug such as erythromycin or tetracycline into the eyes of all newborns as a precaution (Perry, Hockenberry, Lowdermilk, et al., 2017). Gonococcal eye infections in newborns (ophthalmia neonatorum) are therefore relatively rare today.

Diagnostic Studies

For men, a presumptive diagnosis of gonorrhea is made if the man has a history of sexual contact with a new or infected partner followed within a few days by a urethral discharge. Typical clinical manifestations, combined with a positive finding in a Gram-stained smear of the purulent discharge from the penis, give an almost certain diagnosis. A culture of the discharge is indicated for men whose smears are negative in the presence of strong clinical evidence. The nucleic acid amplification test (NAAT) (using ligase or polymerase chain reaction) is a nonculture test with sensitivity similar to culture tests for *N. gonorrhoeae* and can be done on a wide variety of samples, including vaginal, endocervical, urethral, and urine specimens (Borhart & Birnbaumer, 2011).

Diagnosing gonorrhea in women on the basis of symptoms is difficult because most infected women are symptom-free or have complaints that may be confused with other conditions. Smears and purulent discharge do not establish a diagnosis of gonorrhea because the female genito-urinary tract normally harbours a large number of organisms that resemble *N. gonorrhoeae.* A culture must be performed to confirm the diagnosis. Although the cervix is the most common site of sampling, specimens for culture may also be taken from the urethra, anus, or oropharynx. A urine specimen can reveal gonorrhea if it is present in the cervix or urethra.

Collaborative Care

Collaborative care for the patient with a gonorrheal infection is presented in Table 55-2.

TABLE 55-2
COLLABORATIVE CARE
Gonorrhea

Diagnostic
• History and physical examination • Gram-stained smears of urethral or endocervical exudate • Cultures for *Neisseria gonorrhoeae* • NAAT to detect *N. gonorrhoeae* • Testing for other STIs (syphilis, HIV, chlamydial infection)
Collaborative Therapy
Drug Therapy

• Uncomplicated gonorrheal infections:
  • Cefixime (Suprax) 800 mg PO in a single dose (preferred) plus azithromycin (Zithromax) 1 g PO in a single dose OR
  • Ceftriaxone 250 mg IM in a single dose plus azithromycin (Zithromax) 1 g PO in a single dose
  • Alternate treatment with azithromycin (Zithromax) 2 g PO in a single dose
• Also treated for chlamydial infection, unless a *Chlamydia* test result is available and negative
• Gonococcal infections reportable to the public health department in all provinces and territories
• Treatment of sexual contacts
• Instruction on abstinence from sexual intercourse and alcohol during treatment
• Re-examination if symptoms persist or recur after completion of treatment

HIV, human immunodeficiency virus; *IM,* intramuscularly; *PO,* by mouth (per os); *NAAT,* nucleic acid amplification test; *STI,* sexually transmitted infection.

Drug Therapy.

Because of a short incubation period and high infectivity, treatment is generally instituted before culture results are available, even in the absence of any signs or symptoms (PHAC, 2013a). Quinolones such as ciprofloxacin and ofloxacin are no longer preferred drugs for the treatment of gonorrhea in Canada because of the rapid increase in quinolone-resistant strains of *N. gonorrhoeae* (PHAC, 2013a). Patients with coexisting syphilis are likely to be treated with the same drugs used for gonorrhea.

All sexual contacts of patients with gonorrhea must be examined and treated to prevent reinfection after resumption of sexual relations. The "ping-pong" effect of re-exposure, treatment, and reinfection can cease only when infected partners are treated simultaneously. In addition, the patient should be counselled to abstain from sexual intercourse and alcohol during treatment. Sexual intercourse allows the infection to spread and can delay complete healing, and alcohol has an irritant effect on the healing urethral walls. Caution men against squeezing the penis to look for further discharge. Reinfection, rather than treatment failure, is the main cause for infections identified after treatment has ended.

Syphilis

The incidence of syphilis has steadily increased in Canada by 101.0% between 2003 and 2012, from 2.9 to 5.8 per 100 000 (PHAC, 2012). During this same time frame, rates increased among males by 128.3% and decreased among females by 40.9%, and the rate of reported cases of infectious syphilis in males was markedly higher than that in females (11 as compared to 0.5 per 100 000) (PHAC, 2012). In males, rates of infectious syphilis were highest among those aged 25 to 29; in females, rates were highest among those aged 20 to 24. In 2012, infectious syphilis rates varied geographically, and the highest rates occurred in Quebec (PHAC, 2012). Syphilis remains an important health problem.

Etiology and Pathophysiology

Syphilis is caused by *Treponema pallidum,* a spirochete. This bacterium is thought to enter the body through very small breaks in the skin or mucous membranes. Its entry is facilitated by the minor abrasions that often occur during sexual intercourse. Syphilis is a complex disease in which many organs and tissues of the body can become infected with *T. pallidum.* The infection causes the production of antibodies that also react with normal tissues. Not all people who are exposed to syphilis acquire the disease. In

about one-third of cases, infection is acquired after intercourse with an infected person; in addition to sexual contact, syphilis may be spread through contact with infectious lesions and sharing of needles among people who use intravenous (IV) drugs.

T. pallidum is extremely fragile and easily destroyed by drying, heating, or washing. The incubation period for syphilis ranges from 3 to 90 days (average, 21 days) (PHAC, 2013a). In congenital syphilis, the infection is transmitted from an infected mother to the fetus in utero after the tenth week of gestation. An infected pregnant woman has a high risk for a stillbirth or a baby dying shortly after birth (Hawkes, Matin, Broutet, et al., 2011). Universal screening of pregnant women has remained the standard of care in Canada (PHAC, 2013a).

People at high risk for acquiring syphilis are also at an increased risk for acquiring HIV infection. The presence of syphilitic lesions on the genitalia enhances HIV transmission. HIV-infected patients with syphilis appear to be at greatest risk for clinically significant central nervous system (CNS) involvement and may require more intensive treatment with penicillin than other patients with syphilis do. The treatment failure rate is higher in HIV-positive patients with syphilis than in HIV-negative patients who acquire syphilis (Lin, Zheng, Tong, et al., 2011). Therefore, the assessment of all patients with syphilis should also include testing for HIV (with the patient's consent). Conversely, patients with HIV should be tested at least annually for syphilis.

Clinical Manifestations

Syphilis has a variety of signs and symptoms that can mimic those of a number of other diseases (Da Silva Carneiro, Pirmez, de Hollanda, et al., 2013) (Figures 55-4, 55-5, and 55-6); thus in comparison with other STIs, it is more difficult to recognize syphilis. If it is not treated, specific clinical stages are characteristic of the progression of the disease (Table 55-3).

TABLE 55-3
STAGES OF SYPHILIS

Manifestations	Communicability
Primary	
Chancre (painless indurated lesion of penis, vulva, lips, mouth, vagina, and rectum) (Figure 55-4) occurs 3 to 90 days after inoculation Regional lymphadenopathy (draining of the microorganisms into the lymph nodes) Genital ulcers *Duration of stage:* 3–8 wk	Exudate from chancre highly infectious; blood is infectious Most infectious stage, but transmission can occur at any stage if there are moist lesions
Secondary	
Occurs a few weeks after chancre appears Systemic manifestations: flulike symptoms (e.g., malaise, fever, sore throat, headaches, fatigue, arthralgia, headache, generalized adenopathy) Cutaneous lesions bilateral; symmetric rash that begins on the trunk and involves the palms and soles (Figure 55-5); mucous patches in the mouth, tongue, or cervix; *Condylomata lata* (moist, weeping papules) in the anal and genital area Weight loss, alopecia *Duration of stage:* 1–2 yr	Exudate from skin and mucous membrane lesions highly infectious
Latent	
Absence of signs or symptoms Diagnosis based on positive specific treponemal antibody test together with normal CSF and absence of clinical manifestations *Duration of stage:* Throughout life or progression to late stage	Noninfectious after 4 yr; possible placental transmission Almost 25% of persons with latent syphilis develop late syphilis, in some cases many years later
Late (Tertiary)*	
Appearance 3–20 yr after initial infection **Gummas** (chronic, destructive lesions affecting any organ of body, especially skin, bone, liver, mucous membranes) (Figure 55-6) *Cardiovascular:* Aneurysms, aortic valve insufficiency, aortitis *Neuro-syphilis:* General paresis (personality changes from minor to extreme [psychosis], tremors, physical and mental deterioration), tabes dorsalis (ataxia, areflexia, paresthesias, lightning pains, damaged joints [Charcot's joints]), speech disturbances. *Duration of stage:* Chronic (without treatment), possibly fatal	Noninfectious Spinal fluid possibly containing organism

*Several forms such as cardiovascular syphilis and neuro-syphilis occur together in approximately 25% of untreated cases.

CSF, cerebro-spinal fluid.

Complications

Complications of the disease occur mostly in the late stage of syphilis. The gummas of benign late syphilis may produce irreparable damage to bone, liver, or skin but seldom result in death. In cardiovascular syphilis, the resulting aneurysm may press on structures such as the intercostal nerves, causing pain. The possibility of a rupture rises as the aneurysm increases

in size. Scarring of the aortic valve results in aortic valve insufficiency and, eventually, heart failure.

Neuro-syphilis causes degeneration of the brain with mental deterioration (Mehrabian, Raycheva, Traykova, et al., 2012). Problems related to sensory nerve involvement are a result of tabes dorsalis (progressive locomotor ataxia). There may be sudden attacks of pain anywhere in the body, which can confuse the diagnosis with other conditions. Loss of vision and sense of position in the feet and legs can also occur. Walking may become even more difficult as joint stability is lost. (Neuro-syphilis is also discussed in Chapter 63.)

Diagnostic Studies

The first step in the diagnosis of syphilis is to obtain a detailed and accurate sexual history. Chapter 53 provides some guidelines for taking a sexual health history as well as examples of sexual health history questions in Chapter 53, Table 53-7.

When taking a sexual history, it is important to know the sexual orientation and gender identity of the patient, but is also important not to assume that the patient is heterosexual or clearly gendered. What is more helpful is to consider sexuality and gender as existing along a continuum rather than the limitations of terms such as *heterosexual* or *homosexual* and *male* or *female.* Questions such as, "Do you have sex with men or women or both?" are more inclusive and provide more useful information when questioning patients about their sexual practices. In addition, inquire about vaginal, oral, or anal sex. A physical examination should be done to identify any suspicious lesions or other significant signs and symptoms. Since syphilis is "the great imitator" of other conditions, it is easily missed. Oral sex is an important transmission route that is sometimes overlooked.

The presence of spirochetes on dark-field microscopic examination and direct fluorescent antibody (DFA) tests of lesion exudate or tissue can confirm a clinical diagnosis of syphilis. However, syphilis is more commonly diagnosed through a serological test. Tests for syphilis may be classified as those performed for screening and those performed for confirmation of a positive screening result. Nonspecific antitreponemal antibodies can be detected by tests such as the Venereal Disease Research Laboratory (VDRL) test and the rapid plasma reagin (RPR) test. These nontreponemal tests are suitable for screening purposes and usually yield positive results 10 to 14 days after the appearance of a chancre. The fluorescent treponemal antibody absorption (FTA-ABS) test and the *T.*

pallidum particle agglutination (TP-PA) test detect specific antitreponemal antibodies and are suitable for confirming the diagnosis.

False-negative and false-positive results do occur with the nontreponemal tests (VDRL, RPR). A false-negative result may be obtained during primary syphilis if the test is performed before the individual has had time to produce antibodies. A false-positive finding may occur after smallpox vaccination or with other diseases or conditions such as hepatitis, infectious mononucleosis, collagen diseases (e.g., systemic lupus erythematosus), pregnancy, or aging. Positive nontreponemal test results should be confirmed by more specific treponemal tests to rule out other causes. In the cerebro-spinal fluid (CSF), changes such as increased white blood cell count, increased total protein levels, and a positive result of the treponemal antibody test are diagnostic of asymptomatic neuro-syphilis.

If a patient is treated with antibiotics early in the course of the disease on the basis of the history and the symptoms, the serological test may not indicate the presence of syphilis. Once a patient has positive serological findings for syphilis, indicating the presence of antibodies, these findings may remain positive for an indefinite period in spite of successful treatment.

Collaborative Care

Drug Therapy.

Management of syphilis is aimed at eradication of all syphilitic organisms (Table 55-4). However, treatment cannot reverse damage that is already present in the late stage of the disease. Benzathine penicillin G remains the treatment of choice for all stages of syphilis (PHAC, 2013a). Therapy for the various stages of syphilis that is in accordance with national STI guidelines provided by the PHAC (2013a) is described in Table 55-5. All stages of syphilis should be treated. When symptoms are chronic or recur after drug therapy has ended, the patient should undergo repeated treatment. All patients with neuro-syphilis must be carefully monitored, with periodic serological testing, clinical evaluation at 6-month intervals, and repeat CSF examinations for at least 3 years. Specific management is based on the symptoms. It is also very important that all sexual contacts in the previous 90 days be treated.

TABLE 55-4

COLLABORATIVE CARE
Syphilis

Diagnostic
• History and physical examination • Dark-field microscopy • Nontreponemal or treponemal (or both) serological testing • Testing for other STIs (HIV infection, gonorrhea, chlamydial infection)
Collaborative Therapy

• Appropriate drug therapy (see Table 55-5)
• Confidential counselling and testing for HIV infection
• Case finding
• Surveillance
  • Repeat of quantitative nontreponemal tests at 6 and 12 months
  • Examination of cerebro-spinal fluid at 1 year if treatment involves alternative antibiotics or treatment failure has occurred

HIV, human immunodeficiency virus; *STI,* sexually transmitted infections.

TABLE 55-5

DRUG THERAPY
Syphilis

Stage	Preferred Treatment	Alternative Treatment*
All nonpregnant adults: • Primary syphilis • Secondary syphilis • Early latent syphilis (<1 year duration)	Benzathine penicillin G (Bicillin L-A) 2.4 million units IM in a single dose	• Doxycycline (Vibramycin) 100 mg PO BID for 14 days • Alternate agent (to be used in exceptional circumstances)—ceftriaxone 1 g IV or IM daily for 10 days
All nonpregnant adults • Late latent syphilis • Latent syphilis of unknown duration • Cardiovascular syphilis and other tertiary syphilis not involving central nervous system	Benzathine penicillin G (Bicillin L-A) three doses of 2.4 million units each, IM, at 1-wk intervals (total dose, 7.2 million units)	• Consider penicillin desensitization • Doxycycline (Vibramycin) 100 mg PO BID for 28 days • Alternate agent (to be used in exceptional circumstances)—ceftriaxone 1 g IV or IM daily for 10 days
All adults • Neuro-syphilis	Penicillin G 3-4 million units every 4 hr IV for 10–14 days (total dose, 16–24 million units)	• Strongly consider penicillin desensitization followed by treatment with penicillin • Ceftriaxone 2 g IV or IM daily for 10–14 days

*Given when penicillin is contraindicated.

IM, intramuscularly; *IV,* intravenously; *PO,* by mouth (per os).

Drug Alert

Benzathine penicillin G (Bicillin L-A)

- Reports from some jurisdictions have indicated inappropriate use of short-acting benzylpenicillin (penicillin G) intramuscularly for the treatment of infectious syphilis rather than long-acting benzathine penicillin G (Bicillin L-A) (PHAC, 2013a).
- Nurses need to be aware of the similar names of these two products to prevent and avoid inappropriate and inadequate treatment.

There are approximately 1.36 million pregnant women globally that have probable active syphilis (Newman, Kamb, Hawkes, et al., 2013). In pregnant women with syphilis, benzathine penicillin G, 2.4 million units IM weekly for one to three doses, is administered, depending on the stage of syphilis. Treatment administered in the second half of pregnancy may pose a risk for premature labour and fetal distress. Pregnant women receiving treatment should be advised to seek medical care if fetal movements decrease.

Chlamydial Infections

Chlamydial infections are the most prevalent bacterial STI in Canada today, with 103 716 cases reported in 2012 and with approximately 1 of every 2 cases reported in women (PHAC, 2012). In both sexes, rates of chlamydial infections were highest in those aged 20 to 24 years (PHAC, 2012). Under-reporting is substantial because most infected people have no symptoms and therefore do not seek testing. Chlamydial infections are a major contributor to PID, ectopic pregnancy, and infertility among women and to nongonococcal urethritis in men (Bender, Hermann, Anderson, et al., 2011).

Etiology and Pathophysiology

Chlamydial infections are caused by *Chlamydia trachomatis,* a Gram-negative bacterium, and can be transmitted during vaginal, anal, or oral sex. Numerous different serotypes, or strains, of *C. trachomatis* cause urogenital infections (e.g., nongonococcal urethritis [NGU] in men and

cervicitis in women), ocular trachoma, and lymphogranuloma venereum. Table 55-6 lists the risk factors for chlamydial infection. Because of the high prevalence of asymptomatic infections, screening of populations at high risk is needed to identify those infected (see the "Evidence-Informed Practice" box).

TABLE 55-6

RISK FACTORS FOR CHLAMYDIAL INFECTION

- Early age at first sexual intercourse
- History of STIs, coexisting and cervical ectopy
- Inconsistent or incorrect use of barrier contraception (condoms, dental dams)
- New or multiple sex partners
- Use of alcohol and drugs (indirect risk factors)
- Vulnerable populations (people who use injection drugs, incarcerated individuals, sex trade workers, street youth)
- Women and adolescents

STIs, sexually transmitted infections.

Evidence-Informed Practice

Research Highlight

What Strategies Improve Screening Rates for Repeat Chlamydial Infections?

Clinical Question

In patients with repeat chlamydial infections (P), what is the effect of reminders and mailed screening kits (I) versus no intervention (C) on rescreening rates (O)?

Best Available Evidence

Systematic review of randomized controlled trials (RCTs) and observational studies

Critical Appraisal and Synthesis of Evidence

- Eight trials (N = 25 to 5 863/trial) compared patient rescreening rates for repeat chlamydial infections.
- Interventions were mailed screening kits, motivational interviewing, financial incentives, and reminders.
- Rescreening occurred 3 weeks to 12 months after the initial chlamydial infection.
- Mailed screening kits for sample self-collection and phone call, postcard, and email reminders significantly increased rescreening rates.

Conclusion

- Mailed screening kits, reminders, and a combination of both methods increased rescreening rates.

Implications for Nursing Practice

- Repeat chlamydial infections are common and increase the risk for complications.
- Remind patient of importance of rescreening.
- To increase rescreening rates, tailor interventions to meet patient needs and preferences.
- Text message and automated phone call reminders may also be effective.

P, Patient population of interest; *I,* intervention or area of interest; *C,* comparison of interest or comparison group; *O,* outcomes of interest (see Chapter 1).

Clinical Manifestations and Complications

Chlamydial infection is known as a silent disease because symptoms may be absent or minor in most infected women and in many men (Champion & Collins, 2012). Signs and symptoms in men include urethritis (dysuria, urethral discharge), epididymitis (unilateral scrotal pain, swelling, tenderness, fever), and proctitis (rectal discharge and pain during defecation). In women, signs and symptoms include cervicitis (mucopurulent discharge, hypertrophic ectopy [area that is edematous and bleeds easily]), urethritis (dysuria, frequent urination, pyuria), bartholinitis (purulent exudate), dyspareunia (pain with intercourse), and menstrual abnormalities.

Complications often develop when chlamydial infections are poorly managed, inaccurately diagnosed, or undiagnosed. Because chlamydial infections are closely associated with gonococcal infections, clinical differentiation may be difficult. In men, urethritis, epididymitis, and proctitis may occur with both infections. In women, bartholinitis, cervicitis, and salpingitis (inflammation of the fallopian tube) can occur in both chlamydial and gonococcal infections. Therefore both infections are usually treated concurrently, even without diagnostic proof. The incubation period of 1 to 3 weeks for chlamydial infection is longer than that for gonorrhea, and the symptoms are often milder. If a pregnant woman has chlamydia, her baby may be born prematurely, have eye infections, or develop pneumonia (Government of Canada, 2013).

In men, epididymitis can lead to rare complications, including abscess, sepsis, and infertility. In women, chlamydial infections can cause fallopian tube damage, a leading cause of ectopic pregnancy and infertility. Complications from chlamydial infections in women may result in PID and scarring of the fallopian tubes, which can result in infertility and a higher risk for ectopic or tubal pregnancies (Government of Canada, 2013). Although it is rare, both sexes are at risk for a type of arthritis known as Reiter's syndrome, which causes inflammation and swelling of the joints (Government of Canada, 2013).

Diagnostic Studies and Collaborative Care

Chlamydial infections in men can be diagnosed by ruling out gonorrhea. The discharge in chlamydial infections (cervical in women; urethral in men and women) appears to be less purulent, less watery, and less painful than in gonorrhea. Culture is the preferred method of diagnosis for medicolegal purposes, and culture is recommended for throat specimens (PHAC, 2013a). NAATs are more sensitive and more specific than culture, enzyme immunoassay, and direct fluorescent antibody assay. For nonmedicolegal purposes, NAATs should be used whenever possible for urine and for urethral or cervical specimens.

Drug Therapy.

When diagnosed, chlamydial infection can be easily treated and cured. Chlamydial infections respond to treatment with doxycycline or azithromycin, with erythromycin or ofloxacin used as an alternative treatment regimen (PHAC, 2013a). Follow-up care should include advising the patient to return if the symptoms persist or recur, treatment of sex partners, and encouraging the use of condoms during all sexual contacts. The high incidence of recurrence may be due to failure to treat the sexual partners of infected people. Because of the high prevalence of asymptomatic infections, screening of high-risk populations is needed to identify those who are infected.

Drug Alert

Doxycycline

- Patients on this drug should avoid unnecessary exposure to sunlight.
- Patients should not take this drug with antacids, iron products, or dairy products.

Viral Infections

Genital Herpes

Genital herpes is not a reportable infection in most provinces and territories, except the Atlantic provinces. The annual incidence of genital herpes in Canada is, therefore, not known. In the United States, approximately 15.5% of people aged 14 to 49 have genital herpes (Centers for Disease Control and Prevention, 2015).

Etiology and Pathophysiology

Genital herpes is a sexually transmitted infection caused by the herpes simplex virus (HSV), usually type 2. The virus enters through the mucous membranes or breaks in the skin during contact with an infected person (Figure 55-7). HSV then reproduces inside the cell and spreads to the surrounding cells. The virus next enters the peripheral or autonomic nerve endings and ascends to the sensory or autonomic nerve ganglion, where it often becomes dormant. Viral reactivation (recurrence) may occur when the virus descends to the initial site of infection, either the mucous membranes or the skin. When a person is infected with HSV, the infection is usually chronic within the individual for life. Transmission occurs through direct contact with skin or mucous membrane or through asymptomatic viral shedding (PHAC, 2013a).

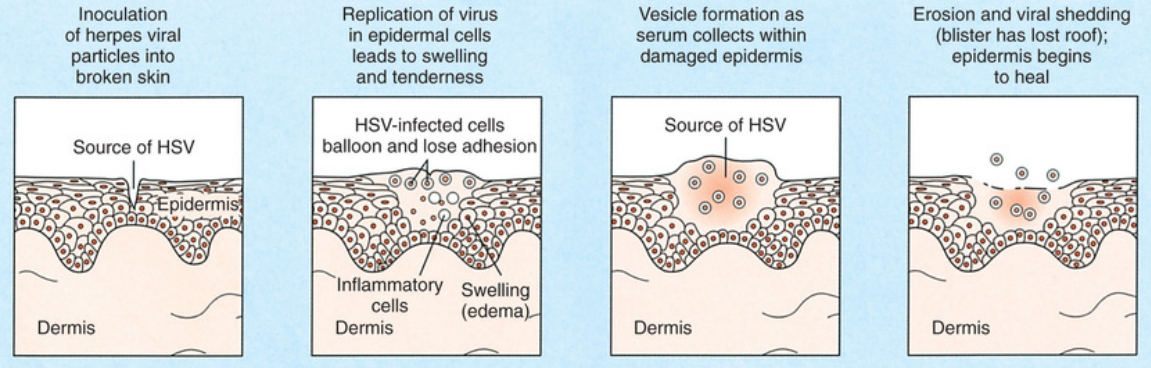

FIGURE 55-7 Stages of infection with herpes simplex virus (HSV).

Source: Morse, S., Moreland, A., & Holmes, K. (Eds.). (1996). *Atlas of sexually transmitted diseases and AIDS.* London: Mosby-Wolfe.

Two different strains of HSV cause infection. In general, HSV type 1 (HSV-1) causes infection above the waist, involving the gingivae, the dermis, the upper respiratory tract, and the CNS. HSV-2 most frequently infects the genital tract and the perineum (i.e., locations below the waist). However, either strain can cause disease on the mouth or the genitals. The incidence and prevalence of HSV-1 genital infection are increasing globally, particularly among college students. The majority of genital herpes cases, however, are caused by HSV-2 infection (PHAC, 2013a).

Clinical Manifestations

In the primary (initial) episode of genital herpes, the patient may complain of burning, itching, or tingling at the site of inoculation. Multiple small, vesicular, and sometimes painless lesions may appear on the inner thigh, penis, scrotum, vulva, perineum, perianal region, vagina, or cervix (Roett, Mayor, & Uduhiri, 2012) and contain large quantities of infectious viral particles (Figure 55-8). The lesions rupture and form shallow, moist ulcerations. Finally, crusting and epithelialization of the erosions occur. Primary infections tend to be associated with local inflammation and pain, accompanied by systemic manifestations such as fever, headache, malaise, myalgia, and regional lymphadenopathy.

FIGURE 55-8 Unruptured vesicles of herpes simplex virus type 2 (HSV-2). **A,** Vulvar area. **B,** Perianal area. **C,** Penile herpes simplex, ulcerative stage. Sources: **A** and **C,** From the Centers for Disease Control and Prevention; courtesy Susan Lindsley. **B,** From Morse, S., Moreland, A., & Holmes, K. (Eds.). (1996). *Atlas of sexually transmitted diseases and AIDS,* London: Mosby-Wolfe.

Urination may be painful from the urine touching active lesions. Urinary retention may occur as a result of HSV urethritis or cystitis. A purulent vaginal discharge may develop with HSV cervicitis. The duration of symptoms is longer and the frequency of complications is greater in women. Primary lesions are generally present for 17 to 20 days, but new lesions sometimes continue to develop for 6 weeks. The lesions heal spontaneously unless secondary infection occurs.

Recurrent genital herpes occurs in about 50% to 80% of individuals during the year after the primary episode. Stress, fatigue, sunburn, general illness, immuno-suppression, and menses are commonly noted triggers. Many patients can predict a recurrence by noticing the early prodrome symptoms of tingling, burning, and itching at the site where the lesions will eventually appear (Roett et al., 2012). The symptoms of recurrent

episodes are less severe, and the lesions usually heal within 8 to 12 days. With time, the lesions generally recur less frequently.

Complications

Although most infections are of a relatively benign nature, complications of genital herpes may involve the CNS, causing aseptic meningitis and lower motor neuron damage. Neuron damage may result in atonic bladder, erectile dysfunction, and constipation. Another complication is *autoinoculation* of the virus to extragenital sites such as the lips (Figure 55-9), the breasts, and, most commonly, the fingers (herpetic whitlow).

FIGURE 55-9 Autoinoculation of herpes simplex virus (HSV) to the lips. Source: Centers for Disease Control and Prevention public image library. Retrieved from *http://phil.cdc.gov/phil/quicksearch.asp* (image #5434).

Herpes Simplex Virus Infection During Pregnancy.

Pregnant women with a primary episode of HSV near the time of delivery have the highest risk of transmitting genital herpes to the neonate (Stephenson-Famy & Gardella, 2014). The risk for transmission is lowest for women who acquire HSV early in the pregnancy or have a history of recurrent HSV. An active genital lesion at the time of delivery is usually an indication for Caesarean section delivery because most infections in neonates occur during birth (Su & McKay, 2012).

Diagnostic Studies and Collaborative Care

A diagnosis of genital herpes is usually based on the patient's symptoms and history. The diagnosis can be confirmed through isolation of the virus from active lesions by means of tissue culture, and this is the most

common method currently used in Canada (PHAC, 2013a). Polymerase chain reaction assay is four times more sensitive than HSV culture and is 100% specific; however, it has not yet replaced the culture for routine screening in Canada (PHAC, 2013a). Other techniques to detect HSV include direct immuno-fluorescence, enzyme immunoassay, and DNA amplification. These tests enable more rapid identification of HSV than a culture does. Highly accurate serological methods for detecting the HSV type are available. The Tzanck smear, with a low sensitivity, is no longer considered a reliable test to confirm diagnosis (PHAC, 2013a).

It is important to encourage symptomatic treatment, such as using good genital hygiene and wearing loose-fitting cotton undergarments. The lesions should be kept clean and dry. To ensure complete drying of the perineal area, women may use a hair dryer set on a cool setting. Frequent sitz baths may soothe the area and reduce inflammation. Drying agents such as colloidal oatmeal (Aveeno) and aluminum salts (Burow solution) may provide some relief from the burning and itching. Techniques to reduce pain on urination include pouring a pitcher of water onto the perineal area while voiding to dilute the urine, and voiding in a warm tub of water or shower. Pain may require a local anesthetic such as lidocaine (Xylocaine) or systemic analgesics such as codeine and acetylsalicylic acid (ASA; Aspirin).

Sexual transmission of HSV can occur during asymptomatic periods so the use of barrier methods, especially condoms, should be encouraged. When lesions are present, the patient should avoid sexual activity altogether because even barrier protection is not satisfactory in eliminating infection transmission.

Drug Therapy.

Three antiviral agents are available for the treatment of HSV: acyclovir (Zovirax), valacyclovir (Valtrex), and famciclovir (Famvir). These drugs inhibit herpetic viral replication and are prescribed for primary and recurrent infections (Table 55-7). Acyclovir, valacyclovir, and famciclovir are also used to suppress frequent recurrences (more than six episodes per year). Although not a cure, these drugs shorten the duration of viral shedding and the healing time of genital lesions and reduce outbreaks by 62% (Barnabas, Baeten, Lingappa, et al., 2015). Continued use of oral acyclovir as suppressive therapy for up to 6 years is safe and effective. Adverse reactions are mild and include headache, occasional nausea and vomiting, and diarrhea. The safety of these drugs for treatment of pregnant women has not been established. Acyclovir ointment appears to

have no clinical benefit in the treatment of recurrent lesions, either in speed of healing or in resolution of pain, and is not commonly recommended. IV acyclovir is reserved for severe or life-threatening infections in which hospitalization is required for the treatment of disseminated infections, CNS infections (meningitis), or pneumonitis. Nephrotoxicity has been observed with high-dose IV administration. Clinical trials are examining the effectiveness of a vaccine for HSV-2 (Johnston, Koelle, & Wald, 2011).

TABLE 55-7

COLLABORATIVE CARE
Genital Herpes

Diagnostic
• History and physical examination • Antibody assay for specific HSV viral type • Viral isolation by tissue culture
Collaborative Therapy
Treatment for First Episode
• For severe primary disease, IV acyclovir 5 mg/per kg over 60 min every 8 hours with later conversion to oral drug therapy • Acyclovir (Zovirax) 200 mg PO five times daily for 5–10 days; or famciclovir (Famvir) 250 mg PO three times daily for 5 days; or valacyclovir (Valtrex) 1 000 mg PO twice daily for 10 days; or acyclovir 400 mg PO three times daily for 7–10 days (recommended by Centers for Disease Control and Prevention).
Treatment for Recurrent Episodes
• Acyclovir (Zovirax) 200 mg PO five times daily for 5 days or 800 mg PO three times daily for 2 days • Valacyclovir (Valtrex) 500 mg PO twice daily or 1 g daily for 3 days; or famciclovir (Famvir) 125 mg PO twice daily for 5 days
Suppressive Therapy for Frequent Recurrence in Nonpregnant Patients
Any of the treatments listed below: • Acyclovir (Zovirax) 200 mg PO 3–5 times daily or 400 mg PO twice daily • Famciclovir (Famvir) 250 mg PO twice daily • Valacyclovir (Valtrex) 500 mg PO daily (patients with ≤9 recurrences per year) or 1 000 mg PO daily (patients with >9 recurrences per year)
Other Considerations
• Abstinence from sexual contact while lesions are present; however, virus may be shed without lesions • Annual Pap smear • Confidential counselling and testing for HIV • Identify trigger mechanisms • Symptomatic care

HIV, human immunodeficiency virus; *HSV,* herpes simplex virus; *IV,* intravenously; *Pap,* Papanicolaou; *PO,* by mouth (per os).

Genital Human Papilloma Virus Infections

Human papilloma virus (HPV) causes skin and mucosal infections and has a strong affinity for the moist mucosa of the anal, genital, and aerodigestive tracts. There are more than 130 types of the virus, many of which are sexually transmitted. Most types do not cause any symptoms and go away on their own. The most common low-risk genotypes are 6 and 11, which cause condylomata acuminata (genital warts), and the most common high-risk genotypes are 16 and 18, predisposing to precancerous or cancerous lesions (PHAC, 2014). HPV infection is a highly contagious STI and is the most common viral STI; it is frequently observed in young, sexually active adults. Risk factors include young age, lower level of education, lower consumption of vegetables, more sexual partners, young age at first sexual experience, more pregnancies, and high alcohol consumption (Bell, Schmidt-Grimminger, Jacobsen, et al., 2011). Of the adult population in Canada, 75% have at least one genital HPV infection over their lifetime (PHAC, 2014).

Minor trauma during intercourse can cause abrasions that allow HPV to enter the body. The incubation period of the virus is generally 3 to 4 months but may be longer. Prevention is hampered by a high proportion of asymptomatic infections and lack of curative treatment. In Canada, the reporting of HPV infection is not required.

Clinical Manifestations and Complications

The discussion of clinical manifestations, complications, and care focuses on the low-risk HPV genotypes resulting in genital warts; cervical cancer is discussed in Chapter 56. Genital warts are discrete single or multiple papillary growths that are white to grey and flesh-pink. They may grow and coalesce to form large, cauliflower-like masses. Most affected patients have from 1 to 10 genital warts. In men, the warts may occur on the penis and the scrotum, around the anus, or in the urethra. In women, the warts may be located on the vulva, in the vagina or the cervix, and in the perianal area (Figure 55-10). There are usually no other signs or symptoms. Itching may occur with anogenital warts. Bleeding on defecation may occur with anal warts.

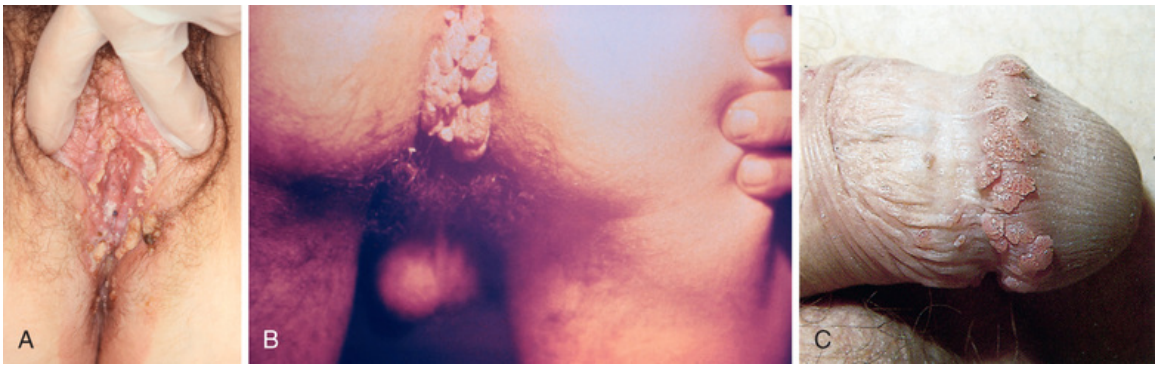

FIGURE 55-10 Genital warts. **A,** Severe vulvar warts. **B,** Perineal wart. **C,** Multiple genital warts of the glans penis. Source: **A,** From the Centers for Disease Control and Prevention, courtesy Joe Millar. **B,** From the Centers for Disease Control and Prevention, courtesy Dr. Wiesner. **C,** From the Centers for Disease Control and Prevention, courtesy Susan Lindsley.

During pregnancy, genital warts tend to grow rapidly and there is recent evidence that mild local hyperthermia may be a promising method for treating genital warts in pregnant women (Huo, Di, Xiao, et al., 2014). An infected mother may transmit the condition to her newborn (Nigam & Mishra, 2011). Caesarean delivery is not routinely indicated unless the birth canal becomes blocked by massive warts.

Diagnostic Studies and Collaborative Care

Up to two-thirds of the early lesions caused by HPV are undetectable by visual examination. Genital warts can be diagnosed on the basis of the gross appearance of the lesions. However, the warts may be confused with condylomata lata of secondary syphilis, carcinoma, or benign neoplasms. The HPV DNA test is recommended with women who have abnormal Papanicolaou (Pap) test results (PHAC, 2014). The HPV DNA test can identify women who are infected with the high-risk HPV strains (types 16 and 18), associated with cervical cancer. At present, access to HPV DNA tests in Canada is limited to a small number of jurisdictions, and HPV cannot be confirmed by culture (PHAC, 2014).

The primary goal in treating visible genital warts is the removal of symptomatic warts. The removal may or may not decrease infectivity. Genital warts are difficult to treat and often necessitate multiple office visits with a variety of treatment modalities. The therapy should be modified if a patient has not experienced improvement after three treatments or if after six treatments the warts have not completely disappeared. Treatment consists of chemical or ablative (removal with

laser or electrocautery) methods. One common treatment is the use of 50% to 80% trichloroacetic acid (TCA) or bichloroacetic acid (BCA) solutions in 70% alcohol, applied directly to the wart surface. Petroleum jelly is applied to the surrounding normal skin to minimize irritation before a small amount of TCA is applied to the wart with a cotton swab. A sharp stinging pain is often felt with initial acid contact, but this quickly subsides. TCA is not washed off after treatment and is safe for use during pregnancy.

Topical treatments include imiquimod, podofilox/podophyllotoxin, podophyllin, sinecatechins, and trichloroacetic acid (TCA) (PHAC, 2014). With topical treatments it is important to avoid contact with mucosal tissue, eyes, tongue, lips, broken skin, and surrounding healthy skin, and patients should be instructed to refrain from sexual activity while undergoing treatment (PHAC, 2014). Treatment may cause skin reactions such as itching, tenderness, erythema, and ulceration. TCA is the only treatment that is to be used with pregnant, and lactating women (PHAC, 2014). If topical treatments are not effective, over-the-counter, self-applied cryotherapy kits are available (PHAC, 2014). Because treatment does not destroy the virus, merely the infected tissue, recurrences and reinfection are possible, and careful long-term follow-up is advised.

Human Papilloma Virus Immunization

HPV infection has been linked to cervical and anogenital cancers, as well as certain cancers of the head and neck (PHAC, 2013c). HPV vaccines include Gardasil (HPV4) and Cervarix (HPV2). HPV2 or HPV4 vaccine is recommended for women 9 to 26 years of age and HPV4 vaccine is recommended for men aged 9 to 26 years (PHAC, 2013c). The most commonly reported adverse events following HPV vaccination are injection site pain, swelling or redness, and syncope (PHAC, 2013c). These vaccines do not treat active HPV infections. Ideally, they should be administered before the start of sexual activity, but people who are sexually active, as well as those infected, would still obtain protection from the HPV types not already acquired.

Evidence-Informed Practice

Translating Research Into Practice

Francis Ceres is a 19-yr-old man who is being seen in the health care centre for signs and symptoms of a urinary tract infection. When asked, he shares with the nurse that he is sexually active. After reviewing his health history, the nurse learns that he has not received the human papilloma virus (HPV) vaccine. The nurse discusses the risks and benefits of the vaccine and suggests that he consider getting it.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
Males ages 9–26 years, including males who have sex with males, are advised to be vaccinated with one of the HPV vaccines available to reduce the incidence of penile, anal, and oropharyngeal cancers as well as genital warts. The majority of all HPV–associated cancers are caused by HPV 16 or 18. Approximately 64% of invasive HPV-associated cancers are attributable to HPV 16 or 18.	Approximately 90% of anal cancers have been linked to HPV infection. Males may be unaware of the expanded recommendations for HPV vaccines, which were originally approved to prevent cervical, vulvar, and vaginal cancer caused by HPV types 6, 11, 16, and 18 in females ages 9 through 26.	Mr. Ceres states that he never has unprotected sex and does not like injections.

Decision and Action

After listening carefully, Mr. Ceres decides to talk to a few of his friends before making a decision about the vaccine. He tells the nurse that he had no idea that he could get HPV infections. If he decides to get the vaccine, he will be back. The nurse documents the discussion in his chart.

Nursing Management Sexually Transmitted Infections

Nursing Assessment

Subjective and objective data that should be obtained from a person with an STI are presented in Table 55-8.

TABLE 55-8

NURSING ASSESSMENT
Sexually Transmitted Infections

Subjective Data
Important Health Information
Past health history: Contact with individuals with STIs, multiple sexual partners, pregnancy, shared needles during IV drug use, previous vaccination against HPV
Medications: Oral contraceptives; allergy to any antibiotics, especially penicillin
Symptoms
• Alopecia • Arthralgia, headache • Dyspareunia; vaginal discharge, menstrual abnormalities; presence of painful, burning genital or perianal lesions • Dysuria, urinary frequency, retention; urethral discharge; tenesmus, proctitis • Itching at infected site; lesions that cause pain or burning sensation • Malaise; chills • Nausea, vomiting, anorexia, pharyngitis, oral lesions
Objective Data
General
Fever, lymphadenopathy (generalized or inguinal)
Integumentary
Syphilis: • *Primary:* painless, indurated genital, oral, or perianal lesions • *Secondary:* bilateral, symmetrical rash on palms, soles, or entire body; mucous patches on mouth or tongue; alopecia Genital herpes: Painful genital or anal vesicular lesions Genital warts: Single or multiple grey or white genital or anal warts (possibly becoming massive)
Gastro-Intestinal
Purulent rectal discharge (indicator of gonorrhea), rectal lesions, proctitis
Urinary
Urethral discharge, erythema
Reproductive
Cervical discharge, lesions, inflamed Bartholin glands
Possible Diagnostic Findings
• *Chlamydial infection:* Positive culture or DNA amplification for *Chlamydia* • *Genital herpes:* Positive tissue culture for HSV-1 or HSV-2; positive HSV-1 or HSV-2 antibody titre • *Gonorrhea:* Positive Gram stain, smears, cultures, and DNA amplification for *Neisseria gonorrhoeae* • *Syphilis:* Positive findings on VDRL and RPR tests, spirochetes on dark-field microscopy

HPV, human papilloma virus; *HSV-2*, herpes simplex virus type 2; *IV*, intravenous; *RPR*, rapid plasma reagin; *STI*, sexually transmitted infection; *VDRL*, Venereal Disease Research Laboratory.

Nursing Diagnoses

Nursing diagnoses for the patient with an STI include, but are not limited to, the following:

- *Risk for infection* as evidenced by *insufficient knowledge to avoid exposure to pathogens* (STI

transmission, engaging in high-risk behaviours)
- *Anxiety* related to *stressors, threat to current status* (impact of condition on relationships, long-term effects of infection)
- *Ineffective health maintenance* related to *insufficient resources* (lack of knowledge about disease process and transmission)

Planning

The overall goals are that the patient with an STI will (a) demonstrate understanding of the mode of transmission of STIs and the risk posed by STIs, (b) complete treatment and return for appropriate follow-up, (c) notify or assist in notification of sexual contacts about their need for testing and treatment, (d) abstain from intercourse until the infection is resolved, and (e) demonstrate knowledge of safer sex practices.

Nursing Implementation

Health Promotion.

Many approaches to curtailing the spread of STIs have been advocated and have met with varying degrees of success. Nurses should be prepared to discuss "safe" sex practices with all patients, not only those who are perceived to be at risk. These practices include abstinence, monogamy with an uninfected partner, avoidance of certain high-risk sexual practices, and use of barriers (e.g., dental dams, condoms) to limit contact with potentially infectious body fluids or lesions. Limiting sexual intimacies outside of a well-established monogamous relationship can reduce the risk of contracting an STI. A patient and caregiver teaching guide related to the patient with an STI is presented in Table 55-9.

TABLE 55-9

PATIENT & CAREGIVER TEACHING GUIDE
Sexually Transmitted Infections

When teaching the patient with sexually transmitted infections, the nurse should carry out the following steps:

1. Instruct patient in hygienic measures, such as washing and urinating after intercourse to flush out some of the causative organisms.
2. Explain the importance of taking all antibiotics or antiviral agents (or both) as prescribed. Symptoms improve after 1 to 2 days of therapy but organisms may still be present.
3. Teach patient about the need for treatment of sexual partners to prevent transmission of disease.
4. Instruct patient to abstain from sexual intercourse during treatment and to use condoms when sexual activity is resumed to prevent spread of infection and prevent reinfection.
5. Explain the importance of follow-up examination and repeated culture at least once after treatment if appropriate, to confirm complete cure and prevent relapse.
6. Allow patient and partner to verbalize concerns to clarify areas that need explanation.
7. Instruct patient about symptoms of complications and need to report problems to ensure proper follow-up and early treatment of reinfection.
8. Explain precautions to take, such as being monogamous; asking potential partners about sexual history; avoiding sex with partners who use intravenous drugs or who have visible oral, inguinal, genital, perineal, or anal lesions; using male or female condoms or dental dams; and voiding and washing genitalia after intercourse to reduce the occurrence of reinfection.
9. Inform patient regarding state of infectivity to prevent a false sense of security, which might result in careless sexual practices and poor personal hygiene.
10. Provide information related to HPV vaccination.

HPV, human papilloma virus.

All sexually active women should be screened for cervical cancer using a Pap test. Women with a history of STIs are at greater risk for cervical cancer than women without this history are. Anal Pap tests should also be done for all individuals who are recipients of anal sex. (Pap smears are discussed in Chapter 56.)

Measures to Prevent Infection.

An inspection of the sexual partner's genitalia before coitus is recommended. Discharge, sores, blisters, or rash should be viewed with concern. A person who is aware of specific signs and symptoms of infection can intelligently make the decision to continue the sexual interaction with modifications or elect not to have sexual relations. The person should remember that, when engaging in sex, there is exposure to the infections of everyone with whom the partner has ever had sex. Men should be told that some protection is provided if they void immediately after intercourse and wash their genitalia and the adjacent areas with soap and water. Women may also benefit from postcoital voiding and washing. However, it is important to emphasize that this does not provide adequate protection against STIs after exposure to infection.

Vaginal microbicides, topical gels, or creams that contain tenofovir may reduce HIV and HSV-2 acquisition in heterosexual women, but there is no

evidence that other kinds of vaginal microbicides have an effect in reducing acquisition of HIV, HSV-2, or any other STI (Obiero, Mwethera, & Wiysonge, 2012). These gels or creams can serve as supplementary lubrication, thereby decreasing irritation and friction and chances for development of a minor laceration that could serve as an entry point for the organism. Proper use of a condom is a highly effective mechanical barrier to infection—the condom should be undamaged and correctly in place throughout all phases of sexual activity. A deterrent to condom usage is alcohol and drug use (Davis, Jacques-Tiura, Stappenbeck, et al., 2015). Use of barrier contraceptives requires planning and motivation, both of which are impaired with alcohol or drug ingestion. The patient should be given specific verbal and written instructions on the proper use of condoms (see Chapter 17, Table 17-19). The objections to condom usage, such as interference with spontaneity and the presence of a barrier, should be discussed by the partners. Information about the mechanics of sexual arousal and incorporating the use of a condom into lovemaking can help in overcoming resistance to its use. Female condoms are lubricated polyurethane sheaths with a ring at each end designed for vaginal use but are considerably more expensive than male condoms (see Chapter 17, Table 17-20).

Among couples with one infected partner, consistent and scrupulous barrier use can reduce transmission to the uninfected partner. Unprotected anal intercourse and other high-risk behaviours should be eliminated, and condoms should be used if sexual contact continues.

The nurse should initiate a discussion to assess the patient's risk of contracting an STI. Questions to ask include number of partners, type of birth control used, use of condoms and dental dams, use of intravenous drugs, history of STIs, and sexual preference. Although the majority of STIs are transmitted between men having sex with men and heterosexual contact, it is possible to transmit an STI between women (Ripley, 2011). The nurse should plan patient education based on the response to these questions. Interpersonal skills necessary for this interview include respect, compassion, and a nonjudgemental attitude. Counselling should be tailored to the individual patient. The nurse should not assume that older people are not at risk; an increasing number of older people are acquiring STIs.

Screening Programs.

Screening programs can help prevent certain STIs. For many years, there have been various screening programs to identify cases of syphilis. With

the increase of infection rates across Canada, more stringent screening and follow-up treatment are required. Many institutions offer voluntary prenatal HIV and syphilis testing and counselling for pregnant women.

Screening programs have also been developed and implemented for detection of gonorrhea and chlamydial infection. These programs are targeted to women because women are more likely to have asymptomatic gonorrhea and thereby serve as sources of infection. Gonorrheal and chlamydial testing during pelvic examinations and prenatal visits is becoming a major routine part of these programs. Mass application of screening programs for genital chlamydial infections, genital herpes, and HPV infections may also be possible with the advent of rapid, cost-effective tests.

Case Finding.

Interviewing and case finding are other processes used to control STIs. These activities are directed toward locating and examining all contacts of each known patient with an STI as soon after sexual exposure as possible so that effective treatment can be initiated. Trained interviewers may often find cases even if they are supplied with only limited information. The caseworkers, who are often nurses, are aware of the social implications of these diseases and the need for discretion. Often, sexual contacts are not informed about the origin of the information naming them as a contact, so that greater cooperation and privacy is ensured. (See the "Ethical Dilemmas" box on confidentiality.) Although still controversial, *expedited partner therapy (EPT)* allows a health care provider to provide prescriptions to a patient to take to his or her partner, without examining the partner; this method may be beneficial in high-risk and hard-to-reach populations (PHAC, 2013a).

Ethical Dilemmas

Confidentiality

Situation

A nurse in a clinic gives the positive results of a test for *Chlamydia* infection to a patient and advises her to tell her sexual partners that she has this infection. The patient refuses to tell her boyfriend because he will

then know that she has had sex with another partner. Should the nurse contact the boyfriend?

Important Points for Consideration

- Nurses and other health care providers have both a legal and an ethical obligation to maintain confidentiality of patient information. If confidentiality is violated, trust is eroded and patients may not share privileged information that is essential to plan effective care.
- Nurses have a legal responsibility to report three STIs in Canada: chlamydia, syphilis, and gonorrhea.
- The nurse must assess if giving the patient the option to tell his or her partner is responsible, accountable, ethical nursing practice, as this may put the patient at risk for intimate partner violence.
- Health care providers have an obligation to maintain confidentiality unless there is a risk to the health or life of innocent third parties.
- The nurse's primary obligation is to the patient seeking care. However, there are long-term health consequences for this patient, as well as for the public in general.
- Patient teaching is one way to establish a partnership with this woman. Information should be shared about the effects of the infection being untreated, the risks for and consequences of re-infection, and the results that the infection may have on others who may not know they are infected. The patient can then be encouraged to inform her partners of the diagnosis for the good of everyone.

Clinical Decision-Making Questions

1. What are the provincial or territorial requirements for reportable conditions?
2. What information should the nurse share with this patient regarding the transmission of chlamydial infection so that she may be more willing to discuss the results with her boyfriend?
3. What is the best way to balance the needs of an individual patient with those of the general public?

Educational and Research Programs.

Nurses should actively encourage those in their community to provide better education about STIs for its citizens. Teenagers, who are known to have a high incidence of infection, should be a prime target for such educational programs. STI rates are on the rise among older adults (Jeffers & DiBartolo, 2011); they are less likely to use condoms and in general have a harder time initiating discussion of sexual health issues. Hotline services, reliable Internet sites, school nurses, nurse practitioners, nurse midwives, and outreach programs sponsored by Canada's Health Protection Branch are effective means of providing educational programs.

Knowledge and understanding can decrease the STI epidemic. The HPV vaccine that protects against genital warts and cervical cancer should be encouraged before the start of sexual activity. Accurate and current information may help reduce parental fears related to the vaccine. Nurses should consider stressing the prevention of cancer as a reason for the vaccine, which may be more productive and less controversial, thus making the parent and adolescent more receptive. Efforts are being made to develop vaccines for syphilis, gonorrhea, genital herpes, and HIV. The development of effective vaccines is viewed by many clinicians as a prerequisite for eradication of STIs.

Harm Reduction.

Behavioural interventions to promote condom use, to modify HIV sexual risk behaviours, or both include individual counselling, skills training, coping strategies, peer education, and social and educational support (Carvalho, Goncalves, Faria, et al., 2011) and should be integrated in harm-reduction programs and health care settings to prevent STIs and reduce HIV transmission. For individuals identified as being at ongoing risk for STIs, screening is recommended at 3-month intervals for HIV, gonorrhea, syphilis, and chlamydial infection. Ongoing contact with a health care provider is an opportunity for reinforcement of safer sex practices. Canada has an annual Sexual and Reproductive Health week, which occurs in February. (Harm reduction is discussed in Chapter 11.)

Acute Intervention

Psychological Support.

The diagnosis of an STI may be met with a variety of emotions, such as shame, guilt, anger, and a desire for vengeance. Nurses should provide counselling and encourage the patient to verbalize feelings. Couples in marital or committed relationships are confronted with an added problem

when an STI is diagnosed because they must face the implication of sexual activity outside the relationship. Support and counselling for the couple are needed.

A patient who has genital herpes is faced with the fact that infections can recur and that no cure is available. This can be frustrating and disruptive to the patient's physical, emotional, social, and sexual life. The nurse should help the patient identify and avoid any factors that may precipitate the condition and inform the patient that the frequency and severity of recurrences may decrease over time.

HPV infections involve a prolonged course of treatment. The patient can become frustrated and distressed because of frequent office visits, associated costs, potential for unpleasant adverse effects as a result of treatment, and effects of the infection on future health and sexual relationships. Tremendous support and a willingness to listen to the patient's concerns are needed. Support groups are also available.

Follow-Up.

A nurse working in public health facilities, clinics, or other outpatient settings may care for patients with STIs more often than a nurse in a hospital. This nurse is in a position to explain and interpret treatment measures such as the purpose and possible adverse effects of prescribed drugs and the need for follow-up care.

Single-dose treatment for gonococcal infection, chlamydial infection, and syphilis helps prevent the problems associated with nonadherence to drug therapy. Patients who require multiple-dose therapy should be given special instructions in completing the prescribed regimen and should be informed about problems resulting from nonadherence. All patients should return to the treatment centre for a repeat culture from the infected sites or for serological testing at designated times to determine the effectiveness of the treatment. Explaining to the patient that cures are not always obtained on the first treatment can reinforce the need for a follow-up visit. The patient should also be advised to inform sexual partners of the need for testing and treatment, regardless of whether they are free of symptoms or are experiencing symptoms.

Hygiene Measures.

The nurse must emphasize certain hygiene measures to patients with an STI. An important measure is frequent handwashing and bathing. Bathing and cleaning of the involved areas can provide local comfort and prevent secondary infection. Douching may spread the infection or undermine

local immune responses and is therefore contraindicated. The synthetic materials used in most undergarments frequently increase or exacerbate local irritations by trapping moisture. Cotton undergarments provide better absorption and are cooler and more comfortable for the patient with an STI.

Sexual Activity.

Sexual abstinence is indicated during the communicable phase of the infection. If sexual activity occurs before treatment of the patient has been completed, the use of condoms may prevent the spread of infection and reinfection. Condom usage after treatment should be encouraged to prevent future exposure to infection. The patient can also choose to relate to a partner in an intimate way that avoids both coitus and oral-genital contact. It is important to note that even single-dose treatments can take up to 1 week to be effective, and the patient is infectious during this period.

Ambulatory and Home Care.

Because many STIs are cured with a single dose or short course of antibiotic therapy, many people are casual about the outcome of these diseases. The consequences of this attitude can include delays in treatment, nonadherence to instructions, and subsequent development of complications. The complications are serious and costly; they can result in disfigurement and destruction of important tissues and organs.

Surgery and prolonged therapy are indicated for many patients with infection-related complications. Major surgical procedures such as resection of an aneurysm or aortic valve replacement may be necessary to treat cardiovascular problems caused by syphilis. Pelvic surgery and procedures to correct fertility problems secondary to an STI may include lysis of adhesions, dilation of strictures, reconstructive tuboplasty, and in vitro fertilization.

Evaluation

Expected outcomes for a patient with an STI are that the patient will do the following:

- Describe modes of transmission
- Use appropriate hygienic measures

- Experience no reinfection
- Demonstrate adherence to a follow-up protocol

Case Study

Chlamydial Infection and Gonorrhea

Source: lukas_zb/Shutterstock.

Patient Profile

Cynthia Raeburn is a 23-yr-old woman who is seen at the outpatient clinic with complaints of a purulent yellow-white discharge and frequent urination over the past 2 weeks. She is sexually active with a new partner after breaking up with a long-term boyfriend. She was treated in the past for chlamydia at age 20.

Subjective Data

- Did not use condom or spermicide
- Her sexual partner was recently treated for epididymitis
- Last menstrual period was 3 weeks ago
- Appears very nervous

Objective Data

- Cervical ectopy noted during Pap test
- Mucopurulent cervical discharge

- Nucleic acid amplification test is positive for *Neisseria gonorrhoeae* and *Chlamydia trachomatis*
- Urine pregnancy test is negative
- Patient crying and very upset when informed of positive test results

Collaborative Care

- Doxycycline, 100 mg PO twice a day for 7 days
- Ceftriaxone, 250 mg intramuscularly once

Discussion Questions

1. What were Ms. Raeburn's risk factors for acquiring chlamydial and gonococcal infections?
2. What complications could occur if Ms. Raeburn's infections are not treated?
3. ***Priority decision:*** What is the priority of care for Ms. Raeburn?
4. What instructions should Ms. Raeburn receive to ensure successful treatment? To prevent reinfection? To prevent further transmission of the infection?
5. What impact is her diagnosis likely to have on Ms. Raeburn's self-image? On her relationship with her sexual partner?
6. ***Priority decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
7. ***Evidence-informed practice:*** Ms. Raeburn asks if she should use the spermicide nonoxynol-9 (N-9) to protect herself against STIs. How should the nurse advise her?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Using which of the following methods will a woman have the lowest risk for sexually transmitted pelvic inflammatory disease?
   a. Oral contraceptives
   b. Barrier methods of contraception
   c. An intrauterine device for contraception
   d. A Norplant implant or injectable Depo-Provera for contraception
2. The nurse is obtaining subjective assessment data from a woman reported as a sexual contact of a man with chlamydial infection. The nurse understands which of the following about symptoms of chlamydial infection in women?
   a. They are frequently absent.
   b. They are similar to those of genital herpes.
   c. They include a macular palmar rash in later stages.
   d. They may involve chancres hidden inside the vagina.
3. In which way(s) does a primary HSV infection differ from recurrent HSV episodes? *(Select all that apply)*
   a. Symptoms are less severe during recurrent episodes.
   b. Only primary infections are sexually transmissible.
   c. Systemic manifestations such as fever and myalgia are more common in primary infection.
   d. Transmission of the virus to a fetus is less likely during primary infection.
   e. Lesions from recurrent HSV are more likely to transmit the virus than lesions from primary HSV.
4. Why should the nurse explain to a client with gonorrhea that treatment will include both ceftriaxone and doxycycline?
   a. Most clients need both drugs to eradicate the organism.
   b. Coverage with more than one antibiotic will prevent reinfection.
   c. No single agent successfully eradicates both primary and recurrent infections.

d. The high rate of coexisting chlamydial infection and gonorrhea indicates coverage with both drugs.

5. In assessing clients for STIs, the nurse needs to know that many STIs can be asymptomatic. Which of the following STIs can be asymptomatic? *(Select all that apply)*
   a. Syphilis
   b. Gonorrhea
   c. Genital warts
   d. Genital herpes
   e. Chlamydial infection
6. To prevent infection and the transmission of STIs, the nurse's teaching plan would include an explanation of which of the following?
   a. The appropriate use of oral contraceptives
   b. Sexual positions that can be used to avoid infection
   c. The necessity of annual Pap smears for clients with HPV
   d. Sexual practices that are considered high-risk behaviours
7. Which of the following is an appropriate nursing intervention to provide emotional support to a client with an STI?
   a. Offering information on how safe sexual practices can prevent STIs
   b. Showing concern when listening to the client who expresses negative feelings
   c. Reassuring the client that the disease is highly curable with appropriate treatment
   d. Helping the client who received an STI from his or her sexual partner in forgiving the partner

1. b; 2. a; 3. a, c; 4. d; 5. a, b, c, d, e; 6. d; 7. b.

CHAPTER 56

Nursing Management

Female Reproductive Problems

Written by, Amy McKeever, Kim K. Choma

Adapted by, Maureen A. Barry

LEARNING OBJECTIVES

1. Summarize the etiologies of infertility and the strategies for diagnosis and treatment of women who are infertile.
2. Describe the etiology, clinical manifestations, and nursing and collaborative management of menstrual problems and abnormal vaginal bleeding.
3. Identify the risk factors, clinical manifestations, and collaborative care of ectopic pregnancy.
4. Discuss the changes related to menopause and the nursing and collaborative management of patients with menopausal symptoms.
5. Differentiate among the common problems that affect the vulva, vagina, and cervix and related nursing and collaborative management.
6. Describe the assessment, collaborative care, and nursing management of women with pelvic inflammatory disease and endometriosis.
7. Explain the clinical manifestations, diagnostic studies, collaborative care, and surgical therapy for cervical, endometrial, ovarian, and

vulvar cancers.

8. Summarize the preoperative and the postoperative nursing management for the patient requiring surgery of the female reproductive system.
9. Differentiate among the common problems that occur with cystoceles, rectoceles, and fistulas and the related nursing and collaborative management.

KEY TERMS

abortion, p. 1392
amenorrhea, p. 1395
cystocele, p. 1415
dysmenorrhea, p. 1394
ectopic pregnancy, p. 1397
endometriosis, p. 1404
hysterectomy, p. 1396
infertility, p. 1390
leiomyomas, p. 1405
menopause, p. 1398
pelvic inflammatory disease (PID), p. 1402
perimenopause, p. 1397
postmenopause, p. 1398
premenstrual syndrome (PMS), p. 1393
rectocele, p. 1415
uterine prolapse, p. 1415

Infertility

Infertility is the inability to achieve a pregnancy after at least 1 year of regular unprotected intercourse (Sabanegh & Agarwal, 2011). Current evidence indicates that approximately 16% of couples (one in six) in Canada experience infertility (Government of Canada, 2013). Assessment and therapy measures can be invasive, expensive, and lengthy. Understandably, infertility can be both a physical and emotional crisis.

Etiology and Pathophysiology

Infertility may be caused by either female, male, or combined factors. (Conditions that cause male infertility are discussed in Chapter 57.) In some cases, the cause of infertility may not be identified.

The factors usually causing female infertility include problems with ovulation (anovulation or inadequate corpus luteum), tubal obstruction or dysfunction (endometriosis or damage from pelvic infection), and uterine or cervical factors (fibroid tumours or structural anomalies). Risk factors for infertility include tobacco and illicit drug use and being obese or thin. In women, the risk for infertility starts at about age 30 and increases after age 40 (Schmidt, Sobotka, Bentzen, et al., 2012).

Diagnostic Studies

A detailed history and general physical examination of the woman and her partner provide the basis for selecting diagnostic studies (Table 56-1). The possibility of medical, genetic, or gynecological diseases is explored before tests are performed to determine problems affecting general health as well as fertility. These tests include hormonal levels, ovulatory studies, tubal patency studies, and postcoital studies. Other screening tests for infertility include semen analysis and pelvic ultrasound.

TABLE 56-1
COLLABORATIVE CARE
Infertility

Diagnostic

• History and physical examination of both partners, including psychosocial functioning
• Assessment of possible sexually transmitted infections
• Genetic screening
• Hormone levels
  • Serum hormone levels (e.g., FSH, LH, prolactin)
  • Urinary LH
• Ovulatory study
• Pap test
• Pelvic ultrasonography
• Postcoital test
  • Cervical mucus
  • Semen analysis
  • Sperm penetration assay
• Review of menstrual and gynecological history
• Tubal patency study
  • Hystero-salpingogram

Collaborative Therapy
• Assisted reproductive technologies (ARTs) • Drug therapy (see Table 56-2) • Hormone supplement therapy • Intrauterine insemination

FSH, follicle-stimulating hormone; *LH,* luteinizing hormone.

Ovulatory Studies.

A basal body temperature record is kept to determine whether there is regular ovulation (Figure 56-1). The woman is instructed to take and graph her temperature, referred to as *basal body temperature,* on awakening, before any activity. As ovulation approaches, the production of estrogen increases, which may cause a drop in temperature. When ovulation occurs, progesterone is produced, causing a rise in temperature. Thus a temperature graph helps detect ovulation and suggests the timing of intercourse if pregnancy is desired. Ovulation prediction kits are now available for use by women at home. Other tests for ovulation include cervical and vaginal smears, endometrial biopsy, and plasma progesterone levels.

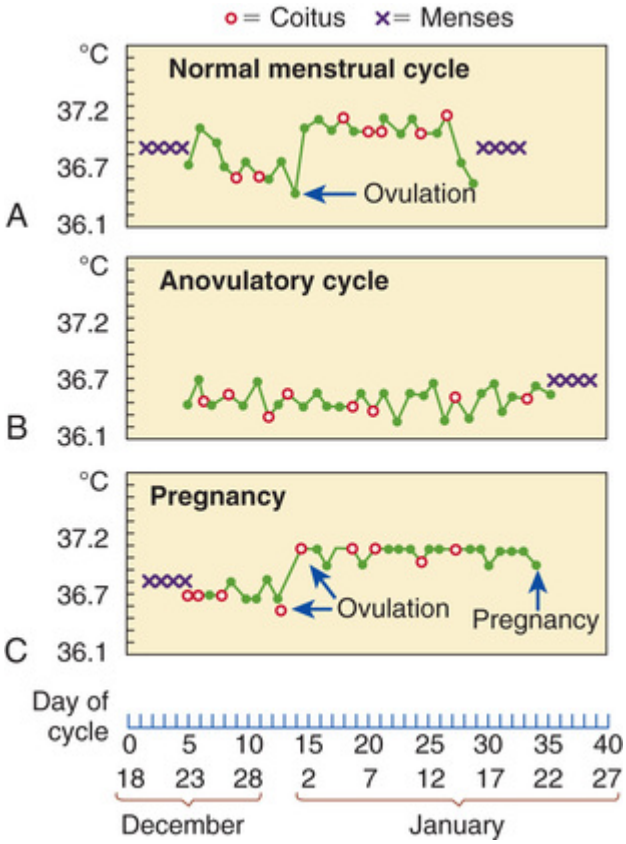

FIGURE 56-1 Basal body temperature chart. **A,** Typical biphasic temperature curve indicative of ovulation and normal progesterone effect. **B,** Irregular monophasic curve characteristic of anovulatory cycles. **C,** Ovulatory curve with sustained temperature elevation following conception and the first missed period.

Tubal Patency Studies.

Tubal factors (occlusion or deformity) are assessed most commonly by means of hystero-salpingogram. This procedure consists of the radiographic visualization of the uterus and tubes by injecting a radiopaque dye through the cervix. Tubal patency, shape, and position and any distortions of the endometrial cavity can be determined. Laparoscopy may be used when a hystero-salpingogram is contraindicated or other pathological pelvic conditions appear likely.

Postcoital Studies.

A postcoital test can determine whether the cervical environment is favourable for the sperm. The couple is asked to have intercourse about the time ovulation is expected and 2 to 12 hours before the office visit. Douching or bathing should be avoided before the test. The cervical and vaginal secretions are aspirated and examined for the number and the motility of sperm present.

Nursing and Collaborative Management Infertility

The management of infertility problems depends on the cause. If infertility is secondary to an alteration in ovarian function, supplemental hormone therapy to restore and maintain ovulation may be attempted. Drug therapy used to treat infertility is presented in Table 56-2. Chronic cervicitis and inadequate estrogenic stimulation are cervical factors causing infertility. Antibiotic therapy is indicated for cervicitis. Inadequate estrogenic stimulation is treated using estrogen.

TABLE 56-2

DRUG THERAPY
Infertility

Drug	Mechanism of Action
Menotropin (Human Menopausal Gonadotropin)	
Repronex	Product made of equal amounts of FSH and LH that promotes the development and maturation of follicles in the ovaries.
Follicle-Stimulating Hormone Agonists	
Follitropin alpha (Gonal-F & Gonal-F pen)	Stimulate follicle growth and maturation by mimicking the actions of the body's natural FSH.
GnRH Antagonists	
Cetrorelix (Cetrotide) Ganirelix (Orgalutran)	Prevent premature LH surges and premature ovulation in women undergoing ovarian stimulation.
GnRH Agonists	
Leuprolide (Lupron, Eligard) Nafarelin (Synarel)	Suppress release of LH and FSH with continuous use. May also be used in the treatment of endometriosis.
Human chorionic gonadotropin hCG (Pregnyl)	Induce ovulation by stimulating the release of eggs from follicles.

FSH, follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *hCG,* human chorionic gonadotropin; *LH,* luteinizing hormone.

When a couple has not succeeded in conceiving during infertility management, an option is intrauterine insemination (IUI) with sperm from the partner or a donor. If this technique does not

succeed, assisted reproductive technologies (ARTs) may be used. ARTs include in vitro fertilization (IVF), gamete intrafallopian transfer (GIFT), zygote intrafallopian transfer (ZIFT), donor gametes, and embryo cryopreservation. IVF is the removal of mature oocytes from the woman's ovarian follicle via laparoscopy, followed by IVF of the ova with the partner's or donor's sperm. When fertilization and cleavage have occurred, the resulting embryos are transferred into the woman's uterus. The procedure requires 2 to 3 days to complete and is used in cases of fallopian tube obstruction, diminished sperm count, and unexplained infertility. Frequently, multiple attempts are needed for successful implantation. IVF is costly and emotionally stressful (Nachtigall, MacDougall, Davis, et al., 2012).

Nurses can assist women experiencing infertility by providing information about the physiology of reproduction and infertility evaluation and addressing the psychological and social distress that can accompany infertility. There is some evidence that psychological stress can have a negative effect on fertility, especially during the time of ovulation (Akhter, Marcus, Kerber, et al., 2016).

The nurse has a major responsibility for teaching and providing emotional support throughout infertility testing and treatment. Feelings of anger, frustration, grief, and helplessness may heighten as additional diagnostic tests are performed. Infertility can generate great tension in a marriage as the couple exhausts financial and emotional resources. Few insurance carriers cover the high cost of infertility testing and treatment. Couples should be encouraged to participate in a support group for infertile couples as well as individual therapy.

Abortion

An **abortion** is the loss or termination of a pregnancy before the fetus has developed to a state of viability. Abortions are classified as *spontaneous* (those occurring naturally) or *induced* (those occurring as a result of mechanical or medical intervention). *Miscarriage* is the common term for the unintended loss of a pregnancy or spontaneous abortion.

Spontaneous Abortion

Spontaneous abortion is the natural loss of pregnancy before 20 weeks of gestation. Fetal chromosomal anomalies may account for many miscarriages before 8 weeks of gestation. Other causes of spontaneous abortions include endocrine abnormalities, maternal infection, acquired anatomical abnormalities (e.g., uterine fibroids, endometriosis), immunological factors, and environmental factors. About 10% to 15% of all clinically recognized pregnancies end as a result of spontaneous abortion (Davidson, London, & Ladewig, 2014).

Uterine cramping coupled with vaginal bleeding often indicates a spontaneous abortion. Cramping is usually absent if the vaginal bleeding is caused by other conditions, such as polyps. Serial measurements of serum β-human chorionic gonadotropin (β-hCG) hormone and vaginal ultrasonography examination of the pelvis are the most reliable indicators of viability of the pregnancy.

Treatment to prevent a possible spontaneous abortion is limited. Although bed rest and avoiding vaginal intercourse are often recommended, there is no evidence that these measures improve the outcome. The woman is advised to report any bleeding to her health care provider. Most women proceed to abortion regardless of treatment. If the products of conception do not pass completely or bleeding becomes excessive, a *dilation and curettage* (D & C) procedure is generally performed (Williams & Pridjian, 2011). The D & C involves dilating the uterine cervix and scraping the endometrium of the uterus to empty the contents of the uterus.

Women who are experiencing bleeding and cramping during pregnancy may be admitted to the hospital. Vital signs and estimated blood loss are monitored. Arranging for someone to stay with the patient provides important emotional support. The nurse should be aware of the grieving process that results from pregnancy loss.

Induced Abortion

Induced abortion is an intentional or elective termination of a pregnancy. Induced abortion is done for personal reasons (at the

request of the woman) or for medical reasons. The number of induced abortions performed in Canada in 2014 was approximately 81 897 (Canadian Institute for Health Information [CIHI], 2014). Induced abortions continue to be most common among women in their early 20s (Sabourin & Burnett, 2012).

Several techniques are used to induce abortion, including menstrual evacuation, suction curettage, dilation and evacuation (D & E), and drug therapy. Deciding which technique to use to terminate a pregnancy depends on the gestational age (length of the pregnancy) and the woman's condition and preference. Suction curettage may be performed up to 14 weeks of gestation and accounts for more than 90% of abortion procedure. D & E is conducted in the second semester. Table 56-3 lists current methods for induced abortion available in Canada.

TABLE 56-3
METHODS FOR INDUCING ABORTION

Method	Length of Pregnancy	Description
Early Abortion		
Methotrexate with misoprostol	≤7 wk	Methotrexate is administered intramuscularly. Misoprostol is given intravaginally, 5–7 days later.
Menstrual extraction	Usually up to 2nd wk after first missed period	Catheter is inserted through cervix into uterus, and suction is applied. Endometrium and contents of uterus aspirated.
Suction aspiration (curettage)	≤14 wk	Cervix is usually dilated, uterine aspirator is introduced, and suction is applied, removing endometrial tissue and implanted pregnancy.
Dilation and evacuation (D & E)	10–16 wk (approximate)	Cervix is dilated, and products of conception are removed by vacuum cannula and use of other instruments as needed.
Late Abortion		
After 20 weeks, late abortion is available in Canada only under special circumstances, such as risk to the health of the mother or serious fetal abnormalities.		

Drug therapy is another method to induce abortion (medical abortion) early in pregnancy. These agents must be given within the first 49 days of pregnancy (day 1 being the first day of the last menstrual period).

Once the decision is made to have an abortion, the woman and her significant others need support and acceptance. The patient should

be prepared for what to expect both emotionally and physically. For some women, grief and sadness can be normal emotions after an abortion. The patient needs to understand the procedure, including instructions prior to the procedure as well as afterwards. The nurse's caring, nonjudgemental attitude can be a positive factor in the patient's experience.

Follow-up care includes instructions on signs and symptoms of possible complications, including abnormal vaginal bleeding, severe abdominal cramping, fever, and foul drainage. The need to avoid intercourse, tampons, and douching until re-examination in 2 weeks should be stressed. Contraception can be started the day of the procedure or during the patient's return visit, in accordance with her needs and desires.

Ethical Dilemmas

Abortion

Situation

A recently married, 39-year-old woman is informed that the results of her amniocentesis indicate that her fetus has major chromosomal abnormalities and is expected to have severe physical and intellectual disabilities. The patient has no children, but her husband has three children from a previous marriage. She asks the nurse what she should do. How would the nurse respond?

Important Points for Consideration

- Decisions about whether to continue a pregnancy with a child who has severe disabilities are extremely personal and emotional. The woman and her husband will need support and information to explore their options and their values.
- Pregnancy counselling is warranted about the woman's choices, her feelings about the pregnancy, her desire to have a child with her husband, her concerns about raising a child with severe

disabilities, her feelings about abortion, and concerns about possible future pregnancies.

- Patient autonomy ensures that a woman decide for herself whether or not to continue a pregnancy.
- Abortion is legal in Canada. Canada is one of a small number of countries without a law restricting abortion. Abortion is governed by provincial or territorial and medical regulations and treated like any other medical procedure. In the first trimester, abortion is a private matter between a woman and her physician. An abortion can be obtained in a clinic or hospital in many, but not all, provinces and territories.
- The role of the health care provider in these difficult situations is to provide education and support in order to facilitate a decision consistent with the patient's values.
- Nurses are bound by core nursing values and ethical responsibilities such as providing safe, compassionate, competent, and ethical care; promoting health and well-being; promoting and respecting informed decision making; honouring dignity; maintaining privacy and confidentiality; promoting justice; and being accountable (Canadian Nurses Association, 2017).

Clinical Decision-Making Questions

1. How would the nurse's feelings about abortion affect her or his ability to care for this patient?
2. What type of counselling and genetic testing are available to the patient regarding genetic abnormalities?

Problems Related to Menstruation

The normal menstrual cycle is discussed in Chapter 53. The hormonal influences related to the menstrual cycle are shown in Figure 53-9. Menstruation may be irregular during the first few years after menarche and the years preceding menopause. Once established, a woman's menstrual cycles usually have a predictable pattern. However, considerable normal variation exists among women in cycle length as well as in the duration, amount, and character of the menstrual flow (see Table 53-2).

Premenstrual Syndrome

Premenstrual syndrome (PMS) is a symptom complex related to the luteal phase of the menstrual cycle that resolves with menstruation (Davidson et al., 2014). The symptoms can be severe enough to impair interpersonal relationships or interfere with usual activities. Because many symptoms are associated with PMS, it is difficult to concisely define. However, PMS symptoms always occur cyclically, during the luteal phase before the onset of menstruation, and are not present at other times of the month. About 40% of all women have been significantly affected by PMS during their lifetime (Lentz, 2013).

Etiology and Pathophysiology

The etiology and pathophysiology of PMS are not well understood. It may have a biological trigger with compounding psychosocial factors. Neurotransmitters, such as serotonin, could also be involved. Some women may have a genetic predisposition to PMS. Other proposed causes include hormone imbalance and nutritional deficiencies. It occurs in 20% to 30% of women who are premenopausal. *Premenstrual dysphoric disorder* (PMDD) is the term applied to a type of PMS that affects 3% to 8% of women who are premenopausal (Biggs & Demuth, 2011). Women with PMDD have a

severe mood disorder (marked depression and anxiety) in addition to PMS (National Library of Medicine, 2015).

Clinical Manifestations

PMS is extremely variable in its clinical manifestations between women and, for an individual woman, from one cycle to another. Common physical symptoms include breast discomfort, peripheral edema, abdominal bloating, sensation of weight gain, episodes of binge eating, and migraine headache. Abdominal bloating and breast swelling are caused by fluid shifts because total body weight does not generally change. Anxiety, depression, irritability, and mood swings are some of the emotional symptoms that women may experience.

Diagnostic Studies and Collaborative Care

PMS can be diagnosed only when other possible causes for the symptoms have been ruled out. A focused health history and physical examination are done to identify any underlying conditions, such as thyroid dysfunction, uterine fibroids, or depression, that may account for the symptoms. No definitive diagnostic test is available for PMS. When PMS or PMDD is a possible diagnosis, a woman is given a symptom diary to record her symptoms prospectively for two or three menstrual cycles. Diagnosis is based on an evaluation of the woman's symptoms.

Nonpharmacological and pharmacological strategies can relieve some PMS symptoms (Table 56-4). However, no single treatment is available. The goal of treatment is to reduce the severity of symptoms and enhance the woman's sense of control and quality of life.

TABLE 56-4
COLLABORATIVE CARE
Premenstrual Syndrome (PMS)

Diagnostic
• History and physical examination • Symptom diary
Collaborative Therapy

• Aerobic exercise
• Drug therapy
  • Combined oral contraceptives
  • Diuretics
  • Prostaglandin inhibitors (e.g., ibuprofen [Advil])
  • Selective serotonin reuptake inhibitors (e.g., sertraline [Zoloft])
• Nutritional therapy
• Stress management and relaxation therapy

Several conservative approaches to managing the symptoms are considered helpful, including stress management, diet changes, exercise, education, and counselling. Techniques for stress reduction include yoga, meditation, imagery, and biofeedback (see Chapter 12). To decrease autonomic nervous system arousal, women should avoid caffeine, reduce dietary intake of refined carbohydrates, exercise on a regular basis, and practise relaxation techniques. Eating complex carbohydrates with high fibre, foods rich in vitamin B_6, and sources of tryptophan (dairy and poultry) is thought to promote serotonin production, which improves the symptoms. Vitamin B_6 may be found in such foods as pork, milk, egg yolk, and legumes.

Exercise results in a release of endorphins, leading to mood elevation. Aerobic exercise can also have a relaxing effect. Because fatigue tends to exaggerate the symptoms of PMS, adequate rest in the premenstrual period is a priority.

Explanations about PMS help the woman understand the complexity of the disorder and ways that she can regain a better sense of control. The patient needs to be assured that her symptoms are real, PMS exists, and she is not imagining the problem. Acknowledgement of having PMS can itself be therapeutic. Teaching the woman's partner about the nature of PMS assists the partner to better understand the disorder and its effects.

Drug Therapy.

Drug therapy is considered when symptoms persist or interfere with daily functioning. At present, no single drug can treat all the symptoms associated with PMS. One therapy may be tried for a time, and if no improvement is observed, another approach is tried. Many treatments are symptom specific. For fluid retention, diuretics such as spironolactone (Aldactone) are used. For reducing cramps, backache, and headache, prostaglandin inhibitors such as ibuprofen (Advil) are used. To improve negative mood, vitamin B_6 supplementation (50 mg daily) may be used. Calcium and magnesium supplementation may also be effective in alleviating psychological and physiological symptoms. For anxiety, buspirone taken during the luteal phase has helped some women. Women with PMDD may benefit from antidepressants, including fluoxetine HCl (Prozac) and tricyclic antidepressants (e.g., amitriptyline).

Other pharmacological treatments are directed at PMS in general. Selective serotonin reuptake inhibitors (SSRIs) (e.g., sertraline [Zoloft]) have provided significant relief to women with severe PMS. Other general treatments include oral contraceptives containing estrogen and progesterone. Evening primrose oil may help some women.

Drug Alert

Oral Contraceptives (Both Estrogen and Progesterone)

- May increase the risk for cervical, liver, and perhaps breast cancer
- May elevate blood pressure and cholesterol (related to estrogen)
- Increase risk for cardiac disease if patient is also smoking
- May have impaired effectiveness if used concurrently with certain antibiotics
- Are contraindicated in patients with migraine headaches and depression

Dysmenorrhea

Dysmenorrhea is abdominal cramping pain or discomfort associated with menstrual flow. The degree of pain and discomfort varies with the individual. The two types of dysmenorrhea are primary (no pathology exists) and secondary (pelvic disease is the underlying cause) (Lentz, 2013). Dysmenorrhea is one of the most common gynecological problems, affecting approximately 50% of all women.

Etiology and Pathophysiology

Primary dysmenorrhea is not a disease. It is caused by an excess of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), an increased sensitivity to it, or both. Stimulation of the endometrium by estrogen followed by progesterone results in a dramatic increase in prostaglandin production by the endometrium. With the onset of menses, degeneration of the endometrium releases prostaglandin. Locally, prostaglandins increase myometrial contractions and constriction of small endometrial blood vessels. This causes tissue ischemia and increased sensitization of the pain receptors, resulting in menstrual pain. Primary dysmenorrhea begins in the first few years after menarche, typically with the onset of regular ovulatory cycles.

Secondary dysmenorrhea is acquired usually after adolescence, occurring most commonly at 30 to 40 years of age. Common pelvic conditions that cause secondary dysmenorrhea include endometriosis, chronic pelvic inflammatory disease (PID), and uterine fibroids. Because secondary dysmenorrhea is caused by multiple conditions, symptoms vary. However, painful menses are present in all situations.

Clinical Manifestations

Primary dysmenorrhea starts 12 to 24 hours before the onset of menses. The pain is most severe the first day of menses and rarely lasts more than 2 days. Characteristic manifestations include lower abdominal pain that is colicky in nature, frequently radiating to the lower back and upper thighs. The abdominal pain is often

accompanied by nausea, diarrhea, loose stools, fatigue, and headache.

Secondary dysmenorrhea occurs usually after the woman has experienced problem-free periods for some time. The pain may be unilateral and it is generally more constant and continues longer than in primary dysmenorrhea. Depending on the cause, symptoms such as *dyspareunia* (painful intercourse), painful defecation, or irregular bleeding may occur at times other than menstruation.

Nursing and Collaborative Management Dysmenorrhea

Evaluation begins with distinguishing primary from secondary dysmenorrhea. A complete health history with special attention to menstrual and gynecological history should be obtained. A pelvic examination is also performed. The probable diagnosis is primary dysmenorrhea if the history reveals an onset shortly after menarche, symptoms are associated only with menses, and the pelvic examination is normal. If any specific cause of dysmenorrhea is evident, the diagnosis is secondary dysmenorrhea.

Treatment for primary dysmenorrhea includes heat, exercise, and drug therapy. Heat is applied to the lower abdomen or back. Regular exercise is thought to be beneficial because it may reduce endometrial hyperplasia and subsequently reduce prostaglandin production. The primary drug therapy is nonsteroidal anti-inflammatory drugs (NSAIDs) such as naproxen (Naprosyn, Aleve), which has antiprostaglandin activity. NSAIDs should be started at the first sign of menses and continued every 4 to 8 hours to maintain a sufficient level of the drug to inhibit prostaglandin synthesis for the usual duration of discomfort.

Oral contraceptives may also be used. They decrease dysmenorrhea by reducing endometrial hyperplasia. Acupuncture and transcutaneous nerve stimulation may be used for women who have inadequate relief from medications or who prefer not to take medications. Patients who are unresponsive to these treatments should be evaluated for chronic pelvic pain (discussed later in this chapter).

Treatment of secondary dysmenorrhea depends on the cause. Some individuals with secondary dysmenorrhea will be helped by the approaches used for primary dysmenorrhea.

Women should be taught why dysmenorrhea occurs as well as how to treat it. Teaching and supportive therapy can provide women with a foundation for coping with this common occurrence and increase feelings of control and self-reliance.

Women often ask what can be done for minor discomforts associated with menstrual cycles. Women should be advised that, during acute pain, relief may be obtained by applying heat to the abdomen or the back and taking NSAIDs for analgesia. The nurse can also suggest noninvasive pain-relieving practices such as relaxed breathing and guided imagery.

Other health care measures to reduce the discomfort of dysmenorrhea include regular exercise and proper nutritional habits. Avoiding constipation, maintaining good body mechanics, and eliminating stress and fatigue, particularly during the time preceding menstrual periods, can also decrease discomfort. Staying active and interested in activities may also help.

Abnormal Vaginal Bleeding

Abnormal vaginal or uterine bleeding is a common gynecological concern. Irregularities include *oligomenorrhea* (long intervals between menses, generally longer than 35 days), **amenorrhea** (absence of menstruation), *menorrhagia* (excessive or prolonged menstrual bleeding), and *metrorrhagia* (irregular uterine bleeding or bleeding between menses). The cause of abnormal bleeding may vary from anovulatory menstrual cycles to more serious causes such as ectopic pregnancy or endometrial cancer.

The woman's age provides direction for identifying the cause of bleeding. For example, a woman who is postmenopausal with abnormal bleeding must always be evaluated for endometrial cancer but does not need to be evaluated for possible pregnancy. For a 20-year-old woman with abnormal bleeding, the possibility of pregnancy must always be considered, and the possibility of endometrial cancer would be unlikely.

Abnormal bleeding may be caused by dysfunction of the hypothalamic-pituitary-ovarian axis, such as a pituitary adenoma. Another cause may be infection. Changes in lifestyle such as marriage, recent moves, a death in the family, financial stress, and other emotional crises can also cause irregular bleeding. Because psychological factors can influence endocrine function, they should be considered when the patient is evaluated.

Types of Irregular Bleeding

Oligomenorrhea and Amenorrhea.

Once pregnancy has been ruled out, anovulation is the most common cause for missing menses. Additional causes of amenorrhea are listed in Table 56-5. *Primary amenorrhea* refers to the failure of menstrual cycles to begin by age 16 years or by age 14 years if secondary sex characteristics are present. *Secondary amenorrhea* refers to cessation of menstrual cycles once established. Women who are pregnant, breastfeeding, or in menopause are not considered to have secondary amenorrhea.

TABLE 56-5
CAUSES OF AMENORRHEA

Natural Amenorrhea
• Breastfeeding • Menopause • Pregnancy
Medications
• Antidepressants • Antipsychotics • Chemotherapy
Lifestyle
• Acute and chronic illness • Excessive exercise • Low body weight • Stress
Hormonal Imbalance
• Pituitary tumours • Polycystic ovary syndrome • Premature menopause
Structural Problems
• Damage to ovaries or uterus from radiation • Structural abnormalities of vagina • Uterine scarring

Ovulation is often erratic for several years following menarche and before menopause. Thus, oligomenorrhea owing to anovulation is common for women at the beginning and end of menstruation. In anovulatory cycles, the corpus luteum that produces progesterone does not form. This may result in a situation referred to as *unopposed estrogen*. When unopposed by progesterone, estrogen can cause excessive build-up of the endometrium. Persistent overgrowth of the

endometrium increases a woman's risk for endometrial cancer. To reduce this risk, progesterone or oral contraceptives are prescribed to ensure that the patient's endometrial lining will be shed at least four to six times per year.

Menorrhagia.

The excessive bleeding associated with menorrhagia can be characterized as an increased duration (>7 days), increased amount (>80 mL), or both. Menorrhagia is a common condition that affects 20% to 30% of all women in the reproductive age (Roa, 2011). Anovulatory uterine bleeding is the most common cause of menorrhagia. An unopposed estrogen state continues to build up the endometrium until it becomes unstable, resulting in menorrhagia. For young women with excessive bleeding, clotting disorders must be considered. Uterine fibroids (also called *leiomyomas*) and endometrial polyps are a common cause of menorrhagia for women in their 30s and 40s.

Metrorrhagia.

Metrorrhagia, also referred to as spotting or breakthrough bleeding, is bleeding between menstrual periods. For all women of reproductive age, pregnancy complications such as spontaneous abortion or ectopic pregnancy must be considered as a possible cause. Other causes include cervical or endometrial polyps, infection, and carcinoma. Spotting is common during the first three cycles of oral contraceptives. If spotting continues beyond that, a different pill formulation can be prescribed once other causes of metrorrhagia have been ruled out. Spotting with long-acting progestin therapy (e.g., Mirena intrauterine device [IUD]) or progestin-only pills (Depo-Provera) is also common. For women who are postmenopausal, endometrial cancer must be considered whenever spotting is experienced. In women who are postmenopausal, exogenous estrogen administration during hormone therapy is a common cause of metrorrhagia.

Diagnostic Studies and Collaborative Care

Because abnormal vaginal bleeding has multiple causes, the diagnostic and collaborative care varies. A health history and physical examination directed at the most likely causes of vaginal bleeding for the woman's age group is the first step. These findings will provide the basis for selecting the necessary laboratory tests and diagnostic procedures. Treatment depends on the etiology of the problem (e.g., menorrhagia, amenorrhea), the degree of threat to the patient's health, and whether the patient wishes to preserve her fertility.

Combined oral contraceptives may be prescribed for a woman with amenorrhea to ensure regular shedding of endometrium if she also wants contraception. Tranexamic acid (Cyklokapron) may be used to treat heavy menstrual bleeding. This drug stabilizes a protein that helps blood to clot. Adverse effects may include headache, back pain, abdominal pain, muscle and joint pain, anemia, and fatigue. Women using hormonal contraception should take tranexamic acid only if there is a strong medical need, since there is an increased risk for blood clots and stroke. Estradiol valerate/dienogest (Natazia) may be given to women with heavy menstrual bleeding who desire an oral contraceptive to prevent pregnancy.

The treatment goal for women with menorrhagia is to minimize further blood loss. If menorrhagia is the result of anovulatory cycles, the endometrium must be stabilized by a combination of oral estrogen and progesterone.

Balloon thermotherapy is a technique for menorrhagia that involves the introduction of a soft, flexible balloon into the uterus. The balloon is inflated with sterile fluid (Figure 56-2). The fluid in the balloon is heated and maintained for 8 minutes, then causing ablation (removal) of the uterine lining. When the treatment is completed, the fluid is withdrawn from the balloon and the catheter is removed from the uterus. The uterine lining sloughs off in the following 7 to 10 days. Uterine balloon thermotherapy is contraindicated for women desiring to maintain their fertility and for women with any suspected uterine abnormalities such as fibroids, suspected endometrial cancer, prior Caesarean section, or myomectomy. With severe bleeding, hospitalization is indicated. All

patients with menorrhagia should be evaluated for anemia and treated as indicated.

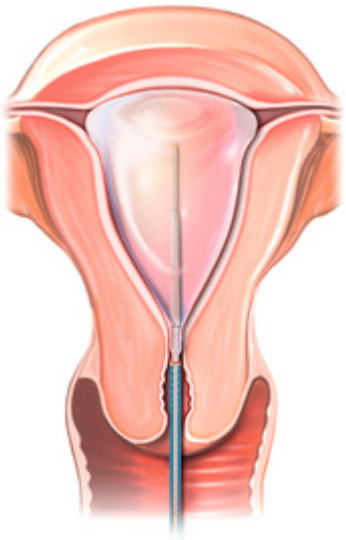

FIGURE 56-2 Balloon thermotherapy for treatment of menorrhagia. A balloon-tipped catheter is inserted into the uterus through the vagina and cervix. The balloon is inflated with a sterile fluid that expands to fit the size and shape of the uterus. The fluid is heated to 87°C and maintained for 8 minutes while the uterine lining is treated. The fluid is then withdrawn from the balloon and the catheter is removed.

Surgical Therapy.

Surgery may be indicated, depending on the underlying cause of the abnormal vaginal bleeding. D & C is used only in cases of acute excess bleeding or for older-adult women when endometrial biopsy and ultrasonography have not provided the necessary diagnostic information. Endometrial ablation for menorrhagia may be done by laser, thermal balloon, cryotherapy, or microwave energy for patients who do not want to maintain their fertility.

If menorrhagia is caused by uterine fibroids, a **hysterectomy** (surgical removal of the uterus) may be performed. A *myomectomy* (removal of fibroids without removal of the uterus) may be performed if the patient wants to preserve her uterus. The

myomectomy is done via laparotomy, laparoscopy, or hysteroscopy. Hormonal regimens and embolization of blood vessels supplying the fibroids are other treatment options.

Nursing Management Abnormal Vaginal Bleeding

Teaching women about the characteristics of the menstrual cycle will assist them to identify normal variations. Table 53-2 in Chapter 53 includes characteristics of the menstrual cycle and related patient teaching. This knowledge can diminish apprehension and dispel misconceptions about the menstrual cycle. If the patient's menstrual cycle pattern does not fall within the normal range, the nurse should urge her to visit her health care provider.

The selection of internal or external sanitary protection is a matter of personal preference. Tampons are convenient and make menstrual hygiene easier, whereas pads may provide better protection. Using a combination of tampons and pads and avoiding prolonged use of superabsorbent tampons may decrease the risk for *toxic shock syndrome* (TSS). TSS is an acute condition caused by a toxin from *Staphylococcus aureus*. Symptoms of TSS may initially include flulike symptoms such as high fever, nausea, vomiting, diarrhea, dizziness, fainting, and disorientation. Other symptoms may include low blood pressure, shock, dehydration, sore throat, muscle pain, peeling skin, and a sunburn-like rash (Government of Canada, 2015).

Whenever excessive, the amount of the patient's vaginal bleeding should be assessed as accurately as possible. The patient should record and report the number and size of pads or tampons used and the degree of saturation. The patient's fatigue level, along with variations in blood pressure and pulse, should be monitored because anemia and hypovolemia may be present. If a surgical procedure is indicated, the nurse should provide appropriate preoperative and postoperative care.

Ectopic Pregnancy

An **ectopic pregnancy** is the implantation of the fertilized ovum anywhere outside the uterine cavity (Figure 56-3). Approximately 3% of all pregnancies are ectopic, and approximately 98% of these

occur in the fallopian tube (McQueen, 2011). The remaining 2% to 3% may be ovarian, abdominal, or cervical (McQueen, 2011).

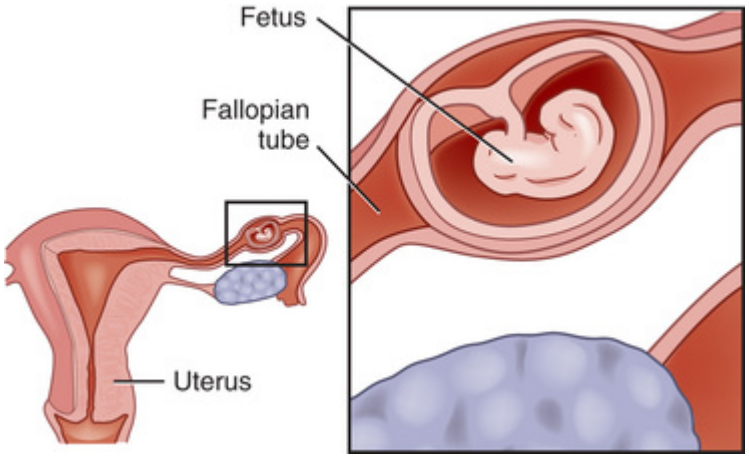

FIGURE 56-3 Ectopic pregnancy occurring in the fallopian tube.

Ectopic pregnancy is a life-threatening condition. Earlier identification has contributed to decreased mortality rates.

Etiology and Pathophysiology

Any blockage of the fallopian tube or reduction of tubal peristalsis that impedes or delays the zygote passing to the uterine cavity can result in tubal implantation. After implantation, the growth of the gestational sac expands the tubal wall. Eventually, the tube ruptures, causing acute peritoneal symptoms. Less acute symptoms usually begin within 6 to 8 weeks after the last normal menstrual period and weeks before rupture would occur.

Risk factors for ectopic pregnancy include a history of PID, prior ectopic pregnancy, current progestin-releasing IUD, progestin-only birth control failure, and prior pelvic or tubal surgery. Additional risk factors for ectopic pregnancy include procedures used in infertility treatment, including in IVF, embryo transfer, and ovulation induction.

Clinical Manifestations

The classic manifestations of ectopic pregnancy are abdominal or pelvic pain, missed menses, and irregular vaginal bleeding. Other manifestations include morning sickness, breast tenderness, gastrointestinal disturbance, malaise, and syncope. Pain is almost always present and is caused by distension of the fallopian tube. It may start unilaterally and then spread to become bilateral. The character of the pain varies among women and can be colicky or vague. If tubal rupture occurs, the pain is intense and may be referred to the shoulder as a result of irritation of the diaphragm by blood released into the abdominal cavity. Symptom severity does not necessarily correlate with the extent of external (vaginal) bleeding present. With rupture, the risk for hemorrhage and hypovolemic shock is present. Suspected rupture is treated as an emergency.

The vaginal bleeding that may accompany ectopic pregnancy is usually described as spotting. However, it is also possible that bleeding may be heavier and can be confused with menses.

Diagnostic Studies

Ectopic pregnancy can be a diagnostic challenge because of its similarity to other pelvic and abdominal disorders, such as salpingitis, spontaneous abortion, ruptured ovarian cyst, appendicitis, and peritonitis. A serum (radioimmunoassay) pregnancy test should be performed. If the test is negative, an ectopic pregnancy is not likely. If ectopic pregnancy cannot be excluded by the pregnancy test, further evaluation is warranted. If the patient is in a stable condition, a combination of serial β-hCG and vaginal ultrasonography is used (Givens & Lipscomb, 2012).

Absence of a normal intrauterine pregnancy means that the diagnosis is probably spontaneous abortion or ectopic pregnancy. With a spontaneous abortion, serial β-hCG levels will decrease over time. A complete blood cell count is obtained when there is any concern regarding the amount of blood loss or if surgery is contemplated.

Nursing and Collaborative Management Ectopic Pregnancy

Surgery remains the primary approach for treating ectopic pregnancies and should be performed immediately. However, medical management with intramuscular injection of methotrexate is being used with increasing success and safety in patients who are hemodynamically stable and where the size of gestation is smaller than 3 cm (Sitka, 2012). A conservative surgical approach limits damage to the reproductive system as much as possible. Removal of the fetus from the tube is preferred to removing the tube. Laparoscopy is preferable to laparotomy because it decreases blood loss and the length of the hospital stay. If the tube ruptures, conservative surgical approaches may not be possible. The patient may need a blood transfusion and supplemental intravenous (IV) fluid therapy to relieve shock and restore a satisfactory blood volume for safe anaesthesia and surgery. The use of laparoscopy has resulted in fewer repeated ectopic pregnancies and a higher rate of future successful pregnancies.

Nursing care depends on the patient's condition. Before the diagnosis has been confirmed, the nurse should be alert to signs of increasing pain and vaginal bleeding, which may indicate that rupture of the tube has occurred. Vital signs are monitored closely, along with observation for signs of shock. Explanations and preparation for diagnostic procedures are given when appropriate. Preparation of the patient for abdominal surgery may follow rapidly. The patient's emotional status should be assessed. Reassurance and support for the surgery should be given to the patient and her family. Postoperatively, the patient may express a fear of future ectopic pregnancies and have many questions about the impact of this experience on her future fertility.

Perimenopause and Postmenopause

Perimenopause is a normal life transition that begins with the first signs of change in menstrual cycles and ends after cessation of menses. **Menopause** is the physiological cessation of menses associated with declining ovarian function. It is made retrospectively after 1 year of *amenorrhea* (absence of menstruation). Menopause starts gradually and is usually associated with changes in menstruation, including menstrual flows that are increased, decreased, irregular, or some combination of these changes and ends with the cessation of menses. **Postmenopause** is a term that refers to the time in a woman's life after menopause.

The age at which menopause occurs ranges from 44 to 55 years, with the average being 51 years. Menopause may occur earlier as a result of illness; surgical removal of the uterus or both ovaries; or the adverse effects of radiation therapy, chemotherapy, or drugs. The age at which menopause occurs is not affected by age at menarche, physical characteristics, number of pregnancies, date of last pregnancy, or oral contraceptive use. However, genetic factors, autoimmune conditions, cigarette smoking, and racial or ethnic factors have been linked to earlier age at menopause.

Changes within the ovary start the cascade of events that finally result in menopause. The regression of the follicles within each ovary begins at puberty and accelerates after age 35. With age, fewer follicles remain that are responsive to follicle-stimulating hormone (FSH). FSH normally stimulates the dominant follicle to secrete estrogen. When the follicles can no longer respond to FSH, ovarian production of estrogen and progesterone declines. However, women who are perimenopausal can get pregnant until menopause has occurred, since many women have long anovulatory cycles interspersed with shorter, ovulatory cycles.

With decreased ovarian function, decreased levels of estrogen cause a gradual increase in FSH and luteinizing hormone (LH) as a result of the negative feedback process. By the time menopause occurs, there is a ten- to twenty-fold increase in FSH. The elevated FSH level may take several years to return to the premenopausal level. The reduced estrogen level also causes a decrease in the frequency of ovulation and results in changes in the reproductive organs and tissues (e.g., atrophy of vaginal tissue).

Clinical Manifestations

Clinical manifestations of perimenopause and postmenopause are presented in Table 56-6. Perimenopause is a time of erratic hormonal fluctuation. Irregular vaginal bleeding is common. With decreasing estrogen, hot flashes and other symptoms begin. The signs and symptoms of diminished estrogen are listed in Table 56-7. The loss of estrogen plays a significant role in the cause of age-related alterations. Changes most critical to a woman's well-being are the increased risks for coronary artery disease (CAD) and osteoporosis (secondary to bone density loss). Other changes include a redistribution of fat, a tendency to gain weight more easily, muscle and joint pain, loss of skin elasticity, changes in hair amount and distribution, and atrophy of external genitalia and breast tissue.

TABLE 56-6

CLINICAL MANIFESTATIONS OF PERIMENOPAUSE AND POSTMENOPAUSE

Perimenopause	Postmenopause
• Atrophy of genito-urinary tissue with decreased support • Irregular menses • Mood changes • Occasional vasomotor symptoms • Osteoporosis • Stress and urge incontinence	• Atrophy of genito-urinary tissue (e.g., vaginal epithelium) • Breast tenderness • Cessation of menses • Stress and urge incontinence • Vasomotor instability (hot flashes and night sweats)

TABLE 56-7
SIGNS AND SYMPTOMS OF ESTROGEN DEFICIENCY

Vasomotor
• Hot flashes • Night sweats
Genito-Urinary
• Atrophic vaginitis • Dyspareunia secondary to poor lubrication • Incontinence
Psychological
• Change in sleep pattern • Decreased REM sleep • Emotional lability
Skeletal
• Increased fracture rate, especially of vertebral bodies but also of humerus, distal radius, and upper femur
Cardiovascular
• Decreased high-density lipoproteins (HDLs) • Increased low-density lipoproteins (LDLs)
Dermatological
• Breast tissue changes • Diminished collagen content of skin

REM, rapid eye movement.

Hallmarks of perimenopause include *vasomotor instability* (hot flashes) and irregular menses. A hot flash (occurs in up to 80% of all women) is described as a sudden sensation of intense heat along with perspiration and flushing (University of California–Berkeley, 2011). These sensations last from several seconds to 5 minutes and occur most often at night, thereby disturbing sleep. The cause of hot flashes, or vasomotor instability, is not clearly understood. It has been theorized that temperature regulators in the brain are in proximity to the area where gonadotropin-releasing hormone (GnRH) is released. The lowered estrogen levels are correlated with dilation of cutaneous blood vessels, resulting in hot flashes and increased sweating. The more sudden the withdrawal of estrogen (e.g., surgical removal of the ovaries), the more likely the symptoms will be severe if no hormone replacement is provided. Symptoms usually subside over time and typically last from 5 to 10 years with or without treatment (Roush, 2012). Hot flashes can be triggered by situations that affect body temperature, such as eating a hot meal, hot weather, drinking an alcoholic beverage, stress, or warm

clothing. Women who smoke are at higher risk for hot flashes because smoking affects estrogen metabolism. In the United States, Black women report the highest incidence of hot flashes, whereas Asian women report the lowest number (Roush, 2012).

Atrophic vaginal changes secondary to decreased estrogen include thinning of the vaginal mucosa and disappearance of rugae. Vaginal secretions also decrease and become more alkaline. As a result of these changes, the vagina is easily traumatized and more susceptible to infection, including a higher risk for human immunodeficiency virus (HIV) infection if exposed. *Dyspareunia* (painful intercourse) may also occur. This can lead to unnecessary and premature cessation of sexual activity. Dryness is a problem that can be easily corrected with water-soluble lubricants or, if needed, with hormonal creams or systemic HT.

Atrophic changes in the lower urinary tract also occur with a decrease in estrogen. Bladder capacity decreases, and the bladder and urethral tissue lose tone. These changes can cause symptoms that mimic a bladder infection (e.g., dysuria, urgency, frequency) when no infection is present.

Whether decreasing estrogen is responsible for the psychological changes associated with perimenopause is unclear. Depression, irritability, and cognitive problems, which are often attributed to menopause, could result from life stressors or sleep deprivation from hot flashes. Depressive symptoms appear to improve when hormone levels stabilize.

Collaborative Care

The diagnosis of perimenopause should be made only after careful consideration of other possible causes for the woman's symptoms. Depression, thyroid dysfunction, anemia, or anxiety could be responsible for the same symptoms. An accurate history of menstrual patterns should be reviewed as part of establishing the diagnosis. Because of the hormonal fluctuations that occur before menopause, routine testing of the serum FSH level is not indicated.

Drug Therapy.

Hormone therapy (HT) was once standard therapy in Canada for treating menopausal symptoms. HT includes estrogen for women without ovaries or estrogen and progesterone for women with a uterus. Findings from the Women's Health Initiative (WHI) clinical trials led to changes in this practice. (National Institutes of Health [NIH], 2015). The data showed that women who had taken estrogen plus progestin had an increased risk for breast cancer, stroke, heart disease, and emboli. However, these women had fewer hip fractures and a lower risk of developing colorectal cancer. Women who took only estrogen (Premarin) had an increased risk for stroke and emboli. However, these women had decreased risk for fractures with no increased risk for heart disease or breast or colorectal cancer. A recent systematic review has updated and validated the results of the WHI trials (Nelson, Walker, Zakher, et al., 2012).

If women wish to consider taking HT for the short-term treatment (less than 5 years) of menopausal symptoms, the risks and benefits of therapy (e.g., minimizes bone loss, hot flashes, vaginal atrophic changes) should be considered carefully. The woman and her health care provider should thoroughly discuss the decision to take HT. If a woman chooses to use HT, the lowest effective dose should be used for the shortest amount of time to manage menopausal symptoms (Stuenkel, Gass, Manson, et al., 2012). Estrogen-alone HT may decrease the risk for coronary heart disease and decrease mortality in women younger than 60 years and within 10 years of menopause (de Villiers, Gass, Haines, et al., 2013; Sood, Faubion, Kuhle, et al., 2014).

The adverse effects of estrogen include nausea, fluid retention, headache, and breast enlargement. Adverse effects of progesterone include increased appetite, weight gain, irritability, depression, spotting, and breast tenderness. A commonly used estrogen preparation is 0.625 mg of conjugated estrogen (Premarin) daily. For symptom relief, a higher dose may be needed. To receive the protective benefit of progesterone, 5 to 10 mg of medroxyprogesterone (Provera) is indicated for 12 days of each month on a cyclical regimen or 2.5 mg if on a continuous regimen. If the estrogen is to be increased for symptom relief, the progesterone should also be increased. Other forms of progesterone include

norethindrone-ethinyl estradiol (Brevicon, Synphasic) and micronized progesterone creams, dermal patches, gels, and lotions; rings placed around the cervix; and subcutaneous pellets. Vaginal creams are especially useful for urogenital symptoms (e.g., dryness). Transdermal estrogen (skin patch or spray) has the advantage of bypassing the liver but has the disadvantage of causing skin irritation.

Drug Alert

Medroxyprogesterone (Depo-Provera, Provera)

- Report immediately the development of sudden loss of vision, severe headache, chest pain, hemoptysis, pain in calves (especially with swelling, redness), numbness in arm or leg, and abdominal pain or tenderness.

SSRI antidepressants, including paroxetine (Paxil), fluoxetine (Prozac), and venlafaxine (Effexor XR), are an effective alternative to HT in reducing hot flashes. This effect is noted even if the user is not depressed. The mechanism of action is unknown. In randomized control trials (RCTs), gabapentin (Neurontin), an anticonvulsant drug, has also been shown to relieve hot flashes (Kaunitz & Manson, 2015).

Selective estrogen receptor modulators (SERMs), such as raloxifene (Evista), are also used in treating menopausal problems. These drugs have some of the positive benefits of estrogen, such as preventing bone loss, without the negative effects, such as endometrial hyperplasia. Raloxifene competes with estrogen for estrogen receptor sites (American Cancer Society, 2014). It decreases bone loss and serum cholesterol but has minimal effects on breast and uterine tissue.

Bisphosphonates, including alendronate (Fosamax) and risedronate (Actonel/Actonel DR), are also used to decrease the risk for osteoporosis in women who are postmenopausal. These drugs

enhance bone mineral density by suppressing resorption. SERMs and bisphosphonates are discussed further in Chapter 66 with respect to their role in the management of osteoporosis.

Nonhormonal Therapy.

Because of the risks associated with HT, many women try other therapies to relieve menopausal symptoms. Paroxetine (Paxil) is a newer nonhormonal treatment that may be used for moderate to severe hot flashes associated with menopause. This drug is an SSRI.

Hot flash frequency and severity can be reduced through measures that lead to a decrease in heat production and an increase in heat loss. Keeping a cool environment and limiting caffeine and alcohol intake lower heat production. Relaxation techniques (e.g., relaxation breathing, imagery) may also help. To promote heat loss at night when hot flashes can disrupt sleep, increase air circulation in the room and avoid bedding that traps the heat (e.g., heavy quilts). Loose-fitting clothes do not retain body heat, whereas clothes with tight necks and wrists do. Cool cloths applied to flushed areas also aid in heat loss.

Daily intake of vitamin E in doses up to 800 IU may also help reduce hot flashes in some women. Changing sleep patterns may be helped by avoiding alcohol and controlling hot flashes. Relaxation techniques can promote a better night's sleep by decreasing anxiety. A regular, moderate program (three to four times per week) of aerobic and weight-bearing exercises can slow the process of bone loss and a tendency toward weight gain.

Nutritional Therapy.

Good nutrition can decrease the risk for cardiovascular disease and osteoporosis in addition to assisting with vasomotor symptoms. A daily intake of about 30 kcal/kg of body weight is recommended. A decrease in metabolic rate and careless eating habits can cause the weight gain and fatigue often attributed to menopause. An adequate intake of calcium and vitamin D helps maintain healthy bones and counteracts loss of bone density. Women who are postmenopausal and are not receiving supplemental estrogen should have a daily calcium intake of at least 1 500 mg, whereas those taking estrogen

replacement need at least 1 000 mg/day. Calcium supplements are best absorbed when taken with meals. Either dietary calcium or calcium supplements may be used (see Chapter 66, Tables 66-12 and 66-13).

The diet should be high in complex carbohydrates and vitamin B complex, especially B_6. Phytoestrogens (soy, tofu, chickpeas, sunflower seeds) may reduce menopausal symptoms. Herbal remedies, such as black cohosh, have become popular in treating menopausal symptoms (see the "Complementary & Alternative Therapies" box). Consultation with an experienced herbal practitioner is recommended before initiating therapy.

Complementary & Alternative Therapies

Herbs and Supplements for Menopause*

Herb	Scientific Evidence	Nursing Implications
Black cohosh	Mixed evidence for use in the treatment of menopausal symptoms†	Generally well tolerated in recommended doses for ≤6 months to relieve symptoms such as hot flashes Should not be used in people with a liver disorder Should not be combined with birth control pills, hormone therapy, or tamoxifen or used by women who are allergic to acetylsalicylic acid (ASA; Aspirin)
Soy	Mixed evidence for treatment of menopausal symptoms‡	Soy isoflavone (rather than soy protein) has shown the most promise for treatment of hot flashes. The long-term effects of a high soy diet have not been well-researched. High soy intake can't be considered safe until more studies are done. In some women, soy causes digestive upset.

*In general, the evidence for use of these herbs as treatments for menopause symptoms is limited by a lack of well-designed, controlled trials.

‡HealthLinksBC. (2015). Soy for Menopause Symptoms. Retrieved from http://www.healthlinkbc.ca/healthtopics/content.asp?hwid=tn9521.

Culturally Competent Care

Menopause

Although all women experience menopause, the perception of menopause varies by culture. Different ethnic groups have different traditions and beliefs regarding menopause, including the use of complementary and alternative therapies to manage symptoms (Im, Ko, Hwang, et al., 2012). In many cultures, menopause is considered a normal part of aging, and little emphasis is placed on the physical and emotional symptoms that accompany the loss of fertility. In cultures in which older adults are revered, menopause is often seen as a liberating transition to a state of being a "wise woman."

North American culture is generally negative toward aging and places a high value on youth. Menopause is often considered a disorder that requires treatment. Menopausal symptoms may be viewed as troublesome, with a strong need to treat hot flashes and mood swings. Numerous substances, from HT to herbal preparations, are often used to treat menopausal symptoms.

Although menopause is experienced by all women, its meaning and symptoms vary. Menopause is a milestone in a woman's life that is embedded in her own personality and culture. Approaching women who are menopausal with this understanding is important to provide culturally competent care.

Nursing Management Perimenopause and Postmenopause

Nurses can play a key role in helping women to understand perimenopausal changes and options to minimize unwanted symptoms that are bothersome (see Table 56-7). Nurses can foster a positive image of perimenopause as a time of vitality and attractiveness. Perimenopause can provide women with a renewed incentive to enhance self-care and well-being. It is important to provide teaching and reassurance to women who are perimenopausal who experience difficulty in managing their symptoms. The fact that symptoms are normal and only temporary should be discussed. Nonpharmacological approaches to managing symptoms should also be reviewed with women who are perimenopausal.

Dry skin can be improved by the use of moisturizing soaps and body lotions. Kegel exercises may help decrease stress incontinence (see Table 48-19). Sexual function can continue with little change in the vast majority of women who are postmenopausal. Cessation of menstruation and ability to bear children should not be equated with cessation of sexual capability.

Femininity and libido do not disappear with menopause. A water-soluble lubricant (e.g., Replens, Astroglide, K-Y Jelly) is often effective in managing atrophic changes in vaginal epithelium. An active sex life helps increase lubrication and maintains the pliability of vaginal tissues. The nurse should provide the patient with an opportunity to candidly discuss concerns related to sexual functioning.

Conditions of Vulva, Vagina, and Cervix

Etiology and Pathophysiology

Infection and inflammation of the vagina, the cervix, and the vulva tend to occur when the natural defences of the acid vaginal secretions (maintained by sufficient estrogen levels) and the presence

of *Lactobacillus* are disrupted. Women's resistance may also be decreased as a result of aging, poor nutrition, and the use of drugs that alter the bacterial flora or mucosa. Organisms gain entrance to the areas through contaminated hands, clothing, douching, and intercourse. Table 56-8 presents the causes, manifestations and diagnostic methods, and collaborative care of common inflammations and infections.

TABLE 56-8
INFECTIONS OF THE LOWER GENITAL TRACT

Infection/Etiology	Manifestations and Diagnostic Methods	Drug Therapy
Vulvo-Vaginal Candidiasis (VVC) (Monilial Vaginitis)		
Candida albicans (fungus)	Commonly found in mouth, gastro-intestinal tract, and vagina; pruritus, thick white, curdlike discharge; KOH microscopic examination—pseudohyphae; pH 4–4.7	Antifungal agents, over-the-counter vaginal suppository and creams (e.g., clotrimazole [Canesten], miconazole [Micozole]) Fluconazole (Diflucan)
Trichomoniasis Vaginitis		
Trichomonas vaginalis (protozoa)	Sexually transmitted; pruritus; frothy greenish or grey discharge; hemorrhagic spots on cervix or vaginal walls; saline microscopic examination—swimming trichomonads; pH >4.5	Metronidazole (Flagyl) for patient and partner
Bacterial Vaginosis		
Gardnerella vaginalis Corynebacterium vaginale	Mode of transmission unclear; watery discharge with fishy odour; may or may not have symptoms; saline microscopic examination—epithelial cells; pH >4.5	Oral or vaginal metronidazole (Flagyl) or clindamycin (Dalacin C) cream 2% Lactobacillus acidophilus taken orally by diet (e.g., yogourt, fermented soy products) or supplements can decrease unwanted vaginal bacteria Examine and treat partner
Cervicitis		
Chlamydia trachomatis Neisseria gonorrhoeae	Sexually transmitted; mucopurulent discharge with postcoital spotting from cervical inflammation; culture for Chlamydia trachomatis and Neisseria gonorrhoeae	Combination gonorrhea infection therapy (e.g., Azithromycin [Zithromax] and cephalosporins [e.g., cefixime and ceftriaxone]) should be used due to increasing antimicrobial resistance. Treat partners with same drugs
Severe Recurrent Vaginitis		
C. albicans (most often)	May be indicative of HIV infection; all women who are unresponsive to first-line treatment should be offered HIV testing	Drug appropriate to opportunistic organism

HIV, human immunodeficiency virus; *KOH*, potassium hydroxide.

Source: Adapted from Public Health Agency of Canada [PHAC]. (2015). *Canadian guidelines on sexually transmitted infections*. Ottawa: Author. Retrieved from http://www.phac-aspc.gc.ca/std-mts/sti-its/cgsti-ldcits/index-eng.php.

Most lower genital tract infections are related to sexual intercourse. Intercourse can transmit organisms, injure tissues, and alter the acid–base balance of the vagina. Vulvar infections caused by viruses such as herpes and genital warts can be sexually transmitted when no lesions are apparent. Oral contraceptives, antibiotics, and

corticosteroids may produce changes in the vaginal pH and trigger an overgrowth of the organisms present. For example, *Candida albicans* may be present in small numbers in the vagina. An overgrowth of this organism causes vulvo-vaginitis.

Clinical Manifestations

Abnormal vaginal discharge and reddened vulvar lesions are common clinical manifestations. In addition to a thick, white, curdlike discharge, women with vulvo-vaginal candidiasis (VVC) often experience intense itching and dysuria, which is the result of urine coming into contact with fissures and irritated areas on the vulva. The hallmark of bacterial vaginosis is the fishy odour of the discharge. Women with cervicitis may notice spotting after intercourse.

Common vulvar lesions include herpes infection and genital warts. Initial or primary herpes infections may be extremely painful. Herpes begins as a small vesicle followed by a superficial red ulcer. Most herpes lesions are painful. Genital warts, caused by the human papilloma virus (HPV), vary in appearance. Irregularly shaped "cauliflower" lesions are common. Genital warts are painless unless traumatized. (Herpes infection and genital warts are discussed in Chapter 55.)

Women who are postmenopausal may develop gynecological problems such as *lichen sclerosis* (Stiles, Redmer, Paddock, et al., 2012). This chronic inflammatory condition is associated with intense itching in the genital skin area (e.g., labia minora, clitoris). The lesions are white with a "tissue paper" appearance initially, although scratching produces changes in the appearance. The cause is unknown. High-potency topical corticosteroid ointment such as clobetasol propionate (Clobex) helps relieve itching.

Collaborative Care

Genital problems are evaluated by taking a history, performing a physical examination, and obtaining the appropriate laboratory and diagnostic studies. Because many problems relate to sexual activity, a sexual history is essential. The nature of the problem determines

the extent of the evaluation. Ulcerative lesions should be cultured for herpes. A blood test for syphilis may be done when ulcerative lesions are present. Genital warts are usually identified by their clinical appearance. Vulvar dystrophies may be examined via colposcopy with a biopsy taken for diagnosis.

Problems involving vaginal discharge are evaluated by microscopy and cultures. The most common vaginal conditions (i.e., bacterial vaginosis, VVC, and trichomoniasis) are diagnosed by a procedure called a *wet mount.* The findings that are characteristic of each condition are shown in Table 56-8. To assess for cervicitis, endocervical cultures are obtained for *Chlamydia* and gonorrhea. If purulent discharge is observed coming from the cervix, a sample of endocervical cells may be taken to be evaluated by Gram staining. The Gram-stained slide is examined with a microscope to identify white blood cells and Gram-negative diplococci (indicative of gonorrhea). (Sexually transmitted infections [STIs] are discussed in Chapter 55.)

Drug therapy is based on the diagnosis and is shown in Table 56-8. Antibiotics taken as directed will cure bacterial infections. Treatment duration and medications vary with specific STIs. Teach patients how to properly take their medications and to follow up to verify a cure. Partners should be treated so that reinfection does not occur.

Women with vaginal conditions or cervical infection should abstain from intercourse for at least 1 week. Douching should be avoided because it has been adversely linked to PID, STIs, and ectopic pregnancy. Sexual partners must be evaluated and treated if the patient is diagnosed with trichomoniasis, chlamydial infection, gonorrhea, syphilis, or HIV.

Treatment of vulvar dystrophies is symptomatic because no cures are available. Treatment involves controlling the itching and the scratching. Interrupting the “itch–scratch cycle” prevents further secondary damage to the skin.

Nursing Management Conditions of Vulva, Vagina, and Cervix

Nurses have the opportunity to teach women about common genital conditions and how to reduce their risks. The ability to recognize symptoms that indicate a problem helps women seek care in a timely manner. Discussing problems concerning one's genitals or sexual intercourse is frequently difficult. The nurse's nonjudgemental attitude makes women feel more comfortable and empowers them to ask questions and seek accurate information.

When a woman is diagnosed with a genital condition, the nurse should ensure that she fully understands the directions for treatment. Taking the full course of medication is especially important to decrease the chance of relapse. Because genitalia are such a private area, use of graphs and models is especially helpful for patient teaching. When a woman will be using a vaginal medication for the first time, showing her the applicator and how to fill it is important. The woman should be taught where and how the applicator should be inserted, using visual aids or models. Vaginal creams should be inserted before going to bed so that the medication will remain in the vagina for a long time. Women using vaginal creams or suppositories may wish to use panty liners during the day, when the residual medication may drain out.

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is an infectious condition of the pelvic cavity that may involve the fallopian tubes (salpingitis), ovaries (oophoritis), and pelvic peritoneum (peritonitis). A tubo-ovarian abscess may also form (Figure 56-4). There are about 100 000 cases of symptomatic PID annually in Canada, but precise numbers are not known as PID is not reportable nationally (Public Health Agency of Canada [PHAC], 2013). PID is referred to as "silent" when women do not perceive any symptoms; other women with PID will be in acute distress.

FIGURE 56-4 Pelvic inflammatory disease. Acute infection of the fallopian tubes and ovaries. The tubes and ovaries have become an inflamed mass attached to the uterus. A tubo-ovarian abscess is also present. Source: Kumar, V., Abbas, A. K., Fausto, N., et al. (2010). *Robbins and Cotran pathologic basis of disease* (8th ed., p. 1010, Figure 22-4A). Philadelphia: Saunders.

Etiology and Pathophysiology

PID is often the result of untreated cervicitis. The organism infecting the cervix ascends higher into the uterus, fallopian tubes, ovaries,

and peritoneal cavity. *C. trachomatis* and *N. gonorrhoeae* are the most common causative organisms of PID. These organisms, as well as anaerobes, mycoplasma, streptococci, and enteric Gram-negative rods, gain entrance during sexual intercourse or after pregnancy termination, pelvic surgery, or childbirth. It is important to remember that not all cases of PID are the result of an STI.

Women at increased risk for chlamydial infections (younger than 24 years of age, with multiple sex partners, or with a new sex partner) should be routinely tested for *C. trachomatis*. Chlamydial infections can be asymptomatic and unknowingly transmitted during intercourse. Silent PID is a major cause of female infertility.

Clinical Manifestations

Women with PID usually go to a health care provider because they are experiencing lower abdominal pain. The pain typically starts gradually and then becomes constant. The intensity may vary from mild to severe. Movement such as walking can increase the pain; pain is also frequently associated with intercourse. Spotting after intercourse and purulent cervical or vaginal discharge may also be noted. Fever and chills may also be present. Women with less acute symptoms notice increased cramping pain with menses, irregular bleeding, and some pain with intercourse. Women who have mild symptoms may go untreated either because they did not seek care or the health care provider misdiagnosed their complaints.

A pelvic examination assists in the diagnosis of PID. Women with PID have pelvic organ tenderness, as indicated by adnexal tenderness (tenderness of uterine appendages such as fallopian tubes, ovaries, and ligaments that hold the uterus in place), positive cervical motion tenderness or uterine compression tenderness during bimanual examination (Brunham, Gottlieb, & Paavonen, 2015). Additional criteria useful for diagnosis include fever and abnormal discharge (vaginal or cervical) as well as lower genital tract inflammation. Cultures for *N. gonorrhoeae* and *C. trachomatis* are also obtained, and a pregnancy test should be done to rule out ectopic pregnancy. Drug therapy begins when minimal diagnostic criteria are met. Thus, treatment is not delayed for culture results.

When the patient's pain or obesity compromises the pelvic examination and a tubo-ovarian abscess may be present, vaginal ultrasonography is indicated.

Complications

Immediate complications of PID include septic shock and *Fitz–Hugh–Curtis syndrome,* which occurs when PID spreads to the liver and causes acute perihepatitis. The patient has symptoms of right upper quadrant pain, but liver function tests are normal. Tubo-ovarian abscesses may "leak" or rupture, resulting in pelvic or generalized peritonitis. As the general circulation is flooded with bacterial endotoxins from the infected areas, septic shock may result. Emboli sms may occur as the result of thrombo-phlebitis of the pelvic veins.

PID can cause adhesions and strictures to develop in the fallopian tubes. Ectopic pregnancy may result when a tube is partially obstructed because the sperm can pass through the stricture but the fertilized ovum cannot reach the uterus. After one episode of PID, the risk of having an ectopic pregnancy increases ten-fold. Further damage can obstruct the fallopian tubes and cause infertility.

Collaborative Care

PID is usually treated on an outpatient basis. The patient is given a combination of antibiotics such as cefoxitin and doxycycline to provide broad coverage against the causative organisms. With effective antibiotic therapy, the pain should subside. The patient must have no intercourse for 3 weeks. Her partner(s) must be examined and treated. An important part of care is physical rest and oral fluids. Re-evaluation in 48 to 72 hours, even if symptoms are improving, is an essential part of outpatient care.

If outpatient treatment is unsuccessful or if the patient is acutely ill or in severe pain, admission to hospital is indicated. If a tubo-ovarian abscess is present, hospitalization is necessary. Maximum doses of parenteral antibiotics are given in hospital. Corticosteroids may be added to the antibiotic regimen to reduce inflammation, allowing for faster recovery and improvement in subsequent

fertility. Application of heat to the lower abdomen or sitz baths may be used to improve circulation and decrease pain. Bed rest in the semi-Fowler's position promotes drainage of the pelvic cavity by gravity and may prevent the development of abscesses high in the abdomen. Analgesics to relieve pain and IV fluids to prevent dehydration are also used.

Surgery is indicated for abscesses that fail to resolve with IV antibiotics. The abscess may be drained by laparoscopy or laparotomy. In extreme cases of infection or severe chronic pelvic pain, a hysterectomy may be performed. When surgery is necessary, every attempt is made to preserve fertility in women of child-bearing age.

Nursing Management Pelvic Inflammatory Disease

Subjective and objective data that should be obtained from women with PID are presented in Table 56-9. Prevention, early recognition, and prompt treatment of vaginal and cervical infections can help prevent PID and its serious complications. Nurses should urge women to seek medical attention for any unusual vaginal discharge or possible infection of their reproductive organs. Women should be helped to understand that not all discharge is indicative of infection, but that early diagnosis and treatment of an infection, if present, can prevent serious complications. Women should be informed of the methods to decrease the risk of getting STIs and to recognize the signs of infection in their partner(s).

TABLE 56-9

NURSING ASSESSMENT
Pelvic Inflammatory Disease

Subjective Data
Important Health Information
Past health history: use of IUD; previous PID, gonorrhea, or chlamydial infection; multiple sexual partners; exposure to partner with urethritis; infertility Medications: Use of and allergy to any antibiotics Surgery or other treatments: Recent abortion or pelvic surgery
Symptoms
• Abnormal vaginal bleeding and menstrual irregularity; vaginal discharge • Lower abdominal and pelvic pain; low back pain; pain on fundal palpation and cervical motion; onset of pain just after a menstrual cycle; dysmenorrhea, dyspareunia, dysuria, vulvar pruritus • Malaise • Nausea, vomiting; chills; fever • Urinary frequency, urgency
Objective Data
General
Fever
Reproductive
Mucopurulent cervicitis, vulvar maceration, vaginal discharge (from heavy and purulent to thin and mucoid), tenderness on motion of cervix and uterus; presence of inflammatory masses on palpation
Possible Findings
Leukocytosis; ↑ erythrocyte sedimentation rate; positive culture of secretions or endocervical fluid; pelvic inflammation and positive endometrial biopsy on laparoscopic examination; abscess or inflammation on ultrasonography

IUD, intrauterine device; *PID*, pelvic inflammatory disease.

The patient may have guilt feelings about having PID, especially if it was associated with an STI. She may also be concerned about the complications associated with PID, such as adhesions and strictures of the fallopian tubes, infertility, and the increased incidence of ectopic pregnancy. Discussion with the patient regarding her feelings and concerns can assist her to cope more effectively with them.

For patients requiring hospitalization, nurses have an important role in implementing drug therapy, monitoring the patient's health status, and providing symptom relief and patient teaching. Vital signs and character, amount, colour, and odour of the vaginal discharge should be recorded. Explanations about the need for limited activity, maintaining a semi-Fowler's position, and increased fluid intake should increase patient cooperation. Assessing the

degree of abdominal pain will provide information about the effectiveness of drug therapy.

Chronic Pelvic Pain

Chronic pelvic pain refers to pain in the pelvic region (below the umbilicus and between the hips) that lasts 6 months or longer (Shin & Howard, 2011). It accounts for 10% of all visits to gynecologists and is the reason for 20% to 30% of all laparoscopies. Up to one-third of women who have PID have chronic pelvic pain (Apte, Nelson, & Brisme, et al., 2012).

The cause of chronic pelvic pain is often hard to find. Many different conditions can cause pelvic pain. Gynecological etiologies include dysmenorrhea, endometriosis, PID, ovarian cysts, uterine fibroids, pelvic adhesions, and ectopic pregnancies. Abdominal etiologies include irritable bowel syndrome, interstitial cystitis, appendicitis, and colitis. Psychological factors (e.g., depression, chronic stress, history of sexual or physical abuse) may increase the risk of developing chronic pelvic pain. Emotional distress makes pain worse, and living with chronic pain contributes to emotional distress.

Chronic pelvic pain has many different clinical manifestations, including severe and steady pain, intermittent pain, dull and achy pain, pelvic pressure or heaviness, and sharp pain or cramping. In addition, pain may occur during intercourse or while having a bowel movement.

Determining the cause of chronic pelvic pain often involves a process of elimination. In addition to a detailed history and physical examination (including a pelvic examination), the patient may be asked to keep a journal of the onset of symptoms and any precipitating factors.

Diagnostic tests may include cultures from cervix or vagina (used to detect STIs), ultrasound, computed tomographic (CT) scan, or magnetic resonance imaging (MRI) to detect abnormal structures or growths. Laparoscopy may be used to visualize the pelvic organs. This procedure is especially useful in detecting endometriosis and chronic PID.

If the cause of chronic pelvic pain is found, treatment focuses on that cause. If no cause can be found, treatment involves managing the pain. Over-the-counter pain medications (e.g., acetylsalicylic acid [ASA: Aspirin], ibuprofen, acetaminophen) may provide some relief. Sometimes, stronger pain drugs may be needed. Birth control pills or other hormonal medications may help relieve cyclic pelvic pain related to menstrual cycles. If an infection is the source of the problem, antibiotics are used.

Tricyclic antidepressants (e.g., amitriptyline, nortriptyline) have pain-relieving and antidepressant effects. These drugs may help improve chronic pelvic pain even in women who do not have depression. The patient may be encouraged to get counselling for any emotional issues.

Laparoscopic surgery may be used to remove pelvic adhesions or endometrial tissue. As a last resort, a hysterectomy may be done.

Endometriosis

Endometriosis is the presence of endometrial epithelial cells in sites outside the uterine cavity (Donegan, 2012). The most frequent sites are in or near the ovaries, uterosacral ligaments, and utero-vesical peritoneum (Figure 56-5). However, endometrial tissues can be in many other locations, such as the stomach, the lungs, the intestines, and the spleen. The tissue responds to the hormones of the ovarian cycle and undergoes a “mini-menstrual cycle” similar to the uterine endometrium.

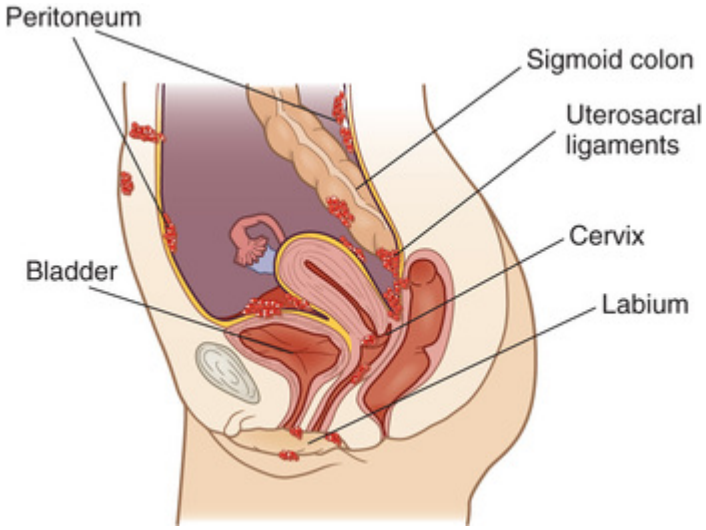

FIGURE 56-5 Common sites of endometriosis.

The typical patient with endometriosis is in her late twenties or early thirties and has never had a full-term pregnancy. Although it is not a life-threatening condition, endometriosis can cause considerable pain. It is also a common cause of infertility and increases the risk for ovarian cancer. Endometriosis is one of the most common gynecological problems, but is it difficult to know the number of women with the condition as many do not have symptoms. Current estimates suggest that 6% to 10% of women in the reproductive years have endometriosis (National Institute for Child Health and Development [NICHD], 2013).

Etiology and Pathophysiology

Although the etiology of endometriosis is poorly understood, many theories have been proposed. A widely held view is that retrograde menstrual flow passes through the fallopian tubes carrying viable endometrial tissues into the pelvis (Mayo Clinic, 2013). The tissue attaches to various sites, as shown in Figure 56-6. Another theory suggests that undifferentiated embryonic peritoneal cavity cells remain dormant in the pelvic tissue until the ovaries produce sufficient hormones to stimulate their growth. Other proposed causes are a genetic predisposition and altered immune function.

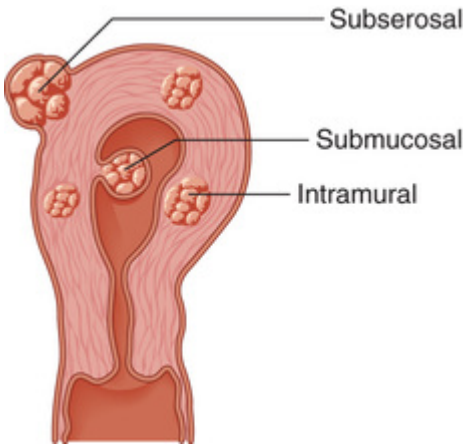

FIGURE 56-6 Leiomyomas. Uterine section shows the whorl-like appearance and locations of leiomyomas, which are also called *uterine fibroids.* Source: McCance, K. L., Huether, S. E., Brashers, V. L., et al. (2014). *Pathophysiology: The biologic basis for disease in adults and children* (7th ed., p. 823, Figure 24-15A). St. Louis: Mosby.

Clinical Manifestations

Patients with endometriosis have a wide range of clinical manifestations and severity. The magnitude of a woman's symptoms does not necessarily correlate with the clinical extent of her endometriosis. Dysmenorrhea after years of relatively pain-free menses and infertility may serve as a clue to the presence of endometriosis. The most common manifestations are secondary dysmenorrhea, infertility, pelvic pain, dyspareunia, and irregular bleeding. Less common manifestations include backache, painful bowel movements, and dysuria. With menopause, estrogen is no longer produced in the ovaries, and the symptoms may disappear.

When the ectopic endometrial tissues "menstruate," the blood collects in cystlike nodules that have a characteristic bluish-black colour. Nodules in the ovaries are sometimes called *chocolate cysts* because of the thick, chocolate-coloured material they contain. When a cyst ruptures, the pain may be acute, and the resulting irritation promotes the formation of adhesions, which fix the affected area to another pelvic structure. Endometrial adhesions may become severe enough to cause a bowel obstruction or painful micturition.

Collaborative Care

Endometriosis may be suspected from a woman's history of the characteristic symptoms and the health care provider's palpation of firm nodular lumps in the adnexa on bimanual examination. However, laparoscopy is necessary for a definitive diagnosis. The treatment of endometriosis is influenced by the patient's age, desire for pregnancy, symptom severity, and the extent and the location of the disease. When symptoms are not disruptive, a "watch-and-wait" approach is used (Table 56-10). When endometriosis is identified as a probable cause of infertility, therapy proceeds more rapidly.

TABLE 56-10

COLLABORATIVE CARE
Endometriosis

Diagnostic
• History and physical examination • Laparoscopy • MRI • Pelvic examination • Pelvic ultrasonography
Collaborative Therapy
• Conservative therapy (watch and wait)
Drug Therapy
• Danazol (Cyclomen) • GnRH agonists (e.g., leuprolide [Lupron]) • Nonsteroidal anti-inflammatory drugs • Oral contraceptives
Surgical Therapy
• Laparotomy to remove implants and adhesions • Total abdominal hysterectomy and bilateral salpingo-oophorectomy (TAH-BSO)

GnRH, gonadotropin-releasing hormone; *MRI*, magnetic resonance imaging.

Drug Therapy.

Drug therapy is used to reduce symptoms. Pain may be relieved with NSAIDs such as ibuprofen (Advil) and diclofenac (Voltaren). Drugs to inhibit estrogen production by the ovaries are often given to shrink the endometrial tissue. Ovulation is suppressed by progestin agents such as medroxyprogesterone. Another approach to hormonal treatment is danazol (Cyclomen), a synthetic androgen

that inhibits the anterior pituitary. This drug causes atrophy of ectopic endometrial tissue. Subjective relief of symptoms is noted within 6 weeks of danazol use. The adverse effects of weight gain, acne, hot flashes, and hirsutism and the expense of this drug restrict its use.

Another class of drugs used is gonadotropin-releasing hormone (GnRH) agonists (e.g., leuprolide [Lupron], nafarelin [Synarel]). These drugs result in amenorrhea. Adverse effects are usually the same as those of menopause (hot flashes, vaginal dryness, emotional lability). Loss of bone density has also been reported in women who remain on the therapy longer than 6 months. Endometriosis is controlled but not cured by HT. Persistent lesions give rise to subsequent recurrences once the menstrual cycle is re-established.

Drug Alert

Leuprolide (Lupron)

- Assess patient for pregnancy before initiating therapy
- Monitor patient for dysrhythmias, palpitations
- Instruct patient to use nonhormonal contraceptive measures during therapy

Surgical Therapy.

The only cure for endometriosis is surgical removal of all the endometrial implants. Surgical therapy may be conservative or definitive. Conservative surgery is done to confirm the diagnosis or to remove implants. It involves removal or destruction of endometrial implants and lysing or excision of adhesions by means of laparoscopic laser surgery or laparotomy. GnRH agonist therapy (e.g., leuprolide) can be administered for 4 to 6 months to reduce the size of the lesions before surgery. By reducing the extent of the surgery, this preoperative drug treatment helps reduce the development of adhesions that may further threaten fertility.

Definitive surgery involves removal of the uterus, fallopian tubes, ovaries, and as many endometrial implants as possible.

For women wishing to get pregnant, conservative surgical therapy is used to remove implants blocking the fallopian tube. Adhesions are removed from the tubes, the ovaries, and the pelvic structures. Efforts are made to conserve all tissues necessary to maintain fertility.

The woman should be actively involved in making the decision about preserving part or all of her ovaries if surgically possible. Her feelings about maintaining her cyclical ovarian function must be explored. The health care provider should assess the woman's risk for ovarian cancer and provide this information for her consideration.

Nursing Management Endometriosis

Education of the patient and reassurance that a life-threatening situation does not exist may permit her to accept a conservative and progressive treatment. When the symptoms are less severe, teaching about nondrug comfort measures may be helpful. Nurses must assist patients to understand the drugs that have been ordered to treat their condition. The action of the prescribed drug should be explained as well as the possible adverse effects. Psychological support may be needed for women experiencing severe disabling pain, sexual difficulties secondary to dyspareunia, and infertility.

If conservative surgery is the treatment selected, the nursing care is similar to the general preoperative and postoperative care of a patient undergoing laparotomy (see Nursing Care Plan [NCP] 45-2 for the patient following laparotomy, available on the Evolve website). If definitive surgery is planned, the nursing care is similar to care for the patient undergoing an abdominal hysterectomy (NCP 56-1). The nurse must know the extent of the procedure so that appropriate preoperative teaching can be done.

Benign Tumours of the Female Reproductive System

Leiomyomas

Etiology and Pathophysiology

Leiomyomas (uterine fibroids) are benign smooth muscle tumours that occur most commonly within the uterus (see Figure 56-6). Estimates of the prevalence of fibroids in women range from 20% to 77%, but the literature provides weak evidence of the overall burden of disease posed by uterine fibroids (Munro, 2011). The cause of leiomyomas is unknown. They appear to depend on ovarian hormones because they grow slowly during the reproductive years and undergo atrophy after menopause.

Clinical Manifestations

The majority of women with leiomyomas do not have any symptoms. When present, the most common symptoms include abnormal uterine bleeding, pain, and symptoms associated with pelvic pressure. Increased bleeding is thought to be associated with the increased endometrial surface area that is associated with leiomyomas. Pain is associated with infection or twisting of the pedicle from which the tumour is growing. Devascularization and blood vessel compression may also contribute to pain. Pressure on surrounding organs may result in rectal, bladder, and lower abdominal discomfort. Large tumours may cause a general enlargement of the lower abdomen. These tumours are sometimes associated with miscarriage and infertility.

Collaborative Care

Clinical diagnosis is based on the characteristic pelvic findings of an enlarged uterus distorted by nodular masses. Treatment depends on the symptoms, the patient's age, her desire to preserve her fertility,

and the location and size of the tumour or tumours. If the symptoms are minimal, the health care provider may elect to follow the patient closely for a time.

Persistent, heavy menstrual bleeding causing anemia and large or rapidly growing tumours are indications for surgery. The leiomyomas are removed by hysterectomy or myomectomy for women who wish to maintain their fertility. In this case, only the fibroids are removed to preserve the uterus. Small tumours may be removed using a hysteroscope and laser resection instruments.

Uterine artery embolization is an increasingly used alternative treatment for uterine fibroids (Gupta, Sinha, Lumsden, et al., 2012). Embolic material (small plastic or gelatin beads) is injected into the uterine artery and carried to the fibroid branches.

Cryosurgery is another option. In cases of large leiomyomas, a GnRH agonist (e.g., leuprolide [Lupron]) may be used preoperatively to shrink the size of the tumour. However, the risks and benefits of this drug should be fully discussed, including the potential for irreversible loss of bone mass. The treatment should not be used on women who wish to preserve their fertility.

Another treatment option uses MRI-guided focused ultrasonography to target and destroy uterine fibroids. Treatment requires repeated targeting and heating of the fibroid tissue while the patient lies inside the MRI machine. The procedure can last as long as 3 hours.

Cervical Polyps

Cervical polyps are benign pedunculated lesions that generally arise from the endocervical mucosa and are seen protruding through the cervical os during a speculum examination. Polyps are a characteristic bright cherry red and are soft and fragile in consistency. They are generally small, measuring less than 3 cm in length, and may be single or multiple. Their cause is unknown. Symptoms are usually not present, but metrorrhagia and bleeding after straining for a bowel movement and coitus can occur. Polyps are prone to infection. When the polyp is small, it can be excised in an outpatient procedure. If the point of attachment of the polyp

cannot be identified and is not accessible to cautery, a polypectomy is performed in an operating room. All tissue removed is sent for pathological review because polyps occasionally undergo malignant changes.

Benign Ovarian Tumours

There are many different types of benign tumours. The cause of most of them is unknown. They can be divided into cysts and neoplasms. *Cysts* are usually soft, are surrounded by a thin capsule, and may be detected during the reproductive years. Follicle and corpus luteum cysts are common ovarian cysts (Figure 56-7). Multiple small ovarian follicles may occur in a condition called *polycystic ovary syndrome* (PCOS) (discussed in the next section). Epithelial ovarian neoplasms may be cystic or solid, small or extremely large. Cystic teratomas, or dermoid cysts, originate from germ cells and can contain bits of any type of body tissue, such as hair or teeth.

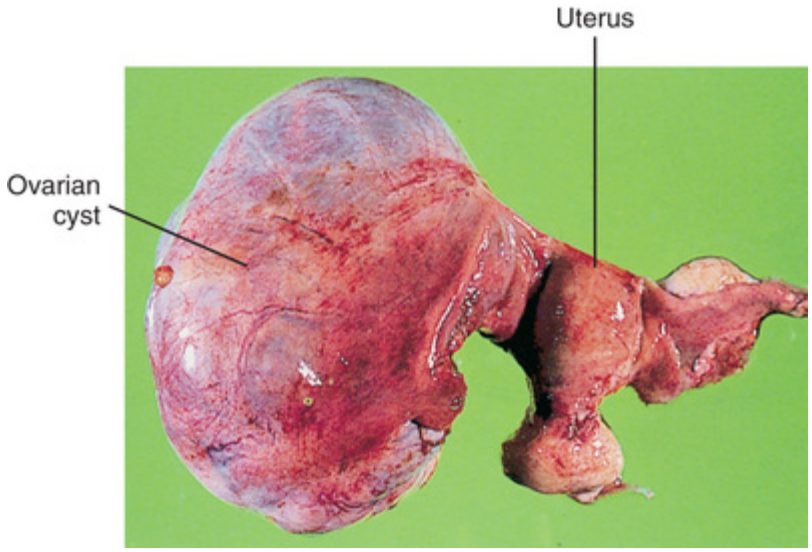

FIGURE 56-7 Large ovarian cyst. Source: Symonds, E. M., & MacPherson, M. B. A. (1994). *Colour atlas of obstetrics and gynecology.* London: Mosby.

Ovarian masses are often asymptomatic until they are large enough to cause pressure in the pelvis. Constipation, menstrual

irregularities, urinary frequency, a full feeling in the abdomen, anorexia, and peripheral edema may occur, depending on the size and the location of the tumour. There may be an increase in abdominal girth. Pelvic pain may be present if the tumour is growing rapidly. Severe pain results when the cyst twists on its pedicle (ovarian torsion).

In some cases, an ovarian cyst can rupture. A ruptured ovarian cyst is not only extremely painful, but it can lead to serious complications, such as hemorrhage and infection.

Pelvic examination reveals a mass or an enlarged ovary that demands further investigation. If the mass is cystic and smaller than 8 cm, the patient is asked to return for re-examination in 4 to 6 weeks. If the mass is cystic and greater than 8 cm or is solid, laparoscopic surgery or laparotomy is performed. Immediate surgery is necessary if ovarian torsion occurs, causing the ovary to rotate and cutting off circulation. Surgical techniques are used to save as much of the ovary as possible.

Polycystic Ovary Syndrome

PCOS is a chronic disorder in which many benign cysts form on the ovaries. It most commonly occurs in women younger than 30 years and is a cause of infertility. It affects about 5% to 10% of women of reproductive age (Lobo, 2013). PCOS is caused by hormonal abnormalities in which the ovaries produce estrogen and excess testosterone but not progesterone. Fluid-filled cysts develop from mature ovarian follicles that fail to rupture (thereby releasing an egg) each month (Figure 56-8). This problem affects both ovaries.

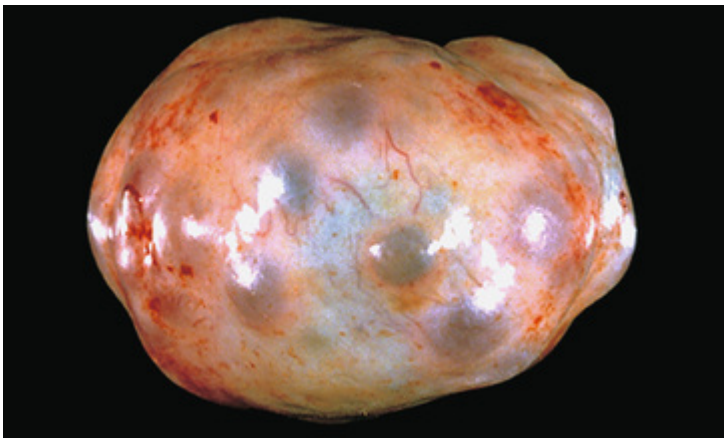

FIGURE 56-8 Polycystic ovary syndrome. Multiple fluid-filled cysts in the ovary. Source: Patton, K. T. & Thibodeau, G. (2013). *Anatomy and physiology* (8th ed., p. 1089, Figure 35-23). St Louis: Mosby.

Clinical manifestations include irregular menstrual periods, amenorrhea, hirsutism, and obesity. Of these manifestations, obesity in particular has been associated with severe symptoms such as excess androgens, oligomenorrhea, amenorrhea, and infertility. Many women start with normal menstrual periods that, after 1 to 2 years, become irregular and then infrequent. If PCOS is left untreated, cardiovascular disease and abnormal insulin resistance with type 2 diabetes mellitus may develop (Toulis, Goulis, Mintziori, et al., 2011; Androgen Excess and PCOS Society [AE-PCOS], 2012).

Pelvic ultrasonography will reveal enlarged ovaries with multiple small cysts. Successful management includes early diagnosis and treatment to improve quality of life and decrease the risk for complications. Oral contraceptives are useful in regulating menstrual cycles. Hirsutism may be treated with spironolactone (Aldactone). Hyperandrogenism can be treated with flutamide and a GnRH agonist such as leuprolide (Lupron). Metformin (Glucophage) reduces hyperinsulinemia and has been shown to improve hyperandrogenism and restore ovulation. For women desiring to become pregnant, fertility drugs may be used to induce ovulation. If all other treatments are unsuccessful, a hysterectomy with bilateral salpingo-oophorectomy may be performed.

Patient teaching for the patient with PCOS includes the importance of weight management and exercise to decrease insulin resistance. Obesity exacerbates the problems related to PCOS. Lipid

profile and fasting glucose levels should be monitored. Hirsutism is cosmetically distressing for many women. It is important to support the patient as she explores measures to remove unwanted hair (e.g., depilating agents, electrolysis). Regular follow-up care is important to monitor the effectiveness of therapy and to detect any complications.

Cancer of the Female Reproductive System

Cervical Cancer

Cervical cancer is the second most common cancer affecting women in the world, with 80% to 85% of these cases occurring in under-resourced countries. Noninvasive cervical cancer is about four times more common than invasive cervical cancer. Based on 2012 estimates, the lifetime probability of a woman developing cervical cancer in Canada is 1 in 152, and the lifetime probability of dying from cervical cancer is 1 in 426 (Canadian Cancer Society's Advisory Committee on Cancer Statistics, 2017). An increased risk for cervical cancer is associated with low socioeconomic status, early sexual activity (before 17 years of age), multiple sexual partners, infection with HPV, immuno-suppression, and smoking.

The number of deaths from cervical cancer in women who undergo regular screening and follow-up has fallen steadily since the 1950s. This is attributable to better and earlier diagnosis with the widespread use of the Papanicolaou (Pap) test. In addition to being used to detect cancer, the Pap test is also used to detect precancerous changes. By treating precancerous lesions, progression to cervical cancer can be prevented.

Etiology and Pathophysiology

The progression from normal cervical cells to dysplasia and then to cervical cancer appears to be related to repeated injuries to the cervix. The progression occurs slowly over years. A strong relationship exists between dysplasia and HPV infections. Cancer rates are expected to decline further with vaccines (e.g., Gardasil, Cervarix) now being used for the prevention of HPV (NIH, 2014).

Clinical Manifestations

Precancerous changes are asymptomatic. This highlights the importance of routine screening. The peak incidence of noninvasive cervical cancer is in women in their early 30s. The average age for women with invasive cervical cancer is 50 (Figure 56-9). Early cervical cancer is generally asymptomatic, but leukorrhea (also called *leucorrhea*) and intermenstrual bleeding (abnormal vaginal bleeding between menstrual periods) eventually occur. The discharge is usually thin and watery but becomes dark and foul smelling as the disease advances, suggesting the presence of an infection. The vaginal bleeding is initially only spotting. As the tumour enlarges, the bleeding becomes heavier and more frequent. Pain is a late symptom and is followed by weight loss, anemia, and cachexia.

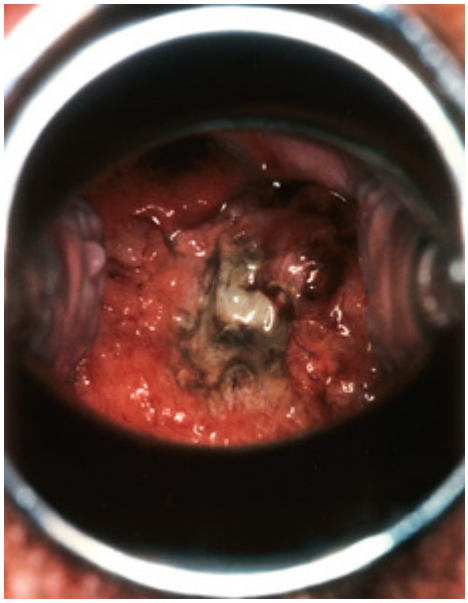

FIGURE 56-9 Cervical cancer. View through a speculum inserted into the vagina. Source: Drake, R. L., Vogl, W., & Mitchell, A. W. M. (2010). *Gray's anatomy for students* (2nd ed., p. 457, Figure 5.55). Edinburgh: Churchill Livingstone.

Diagnostic Studies

Cervical cancer screening is recommended in Canada for sexually active women between the ages of 21 and 69. Some provinces or territories may offer screening at earlier or later ages. The Canadian Cancer Society (CCS, 2016a) recommends that women have a Pap test every 1 to 3 years, depending on the screening guidelines in their province or territory and depending on their previous test results. After age 69, women should talk to their health care provider about the possibility of stopping the Pap test following two or three previously normal (negative) Pap results. Women who have sex with women, women who are no longer sexually active, women who have had a partial hysterectomy and transgender men who are sexually active should follow the same cervical screening guidelines. Women with previous abnormal Pap tests may be screened more often (CCS, 2016a). Women who have had a total hysterectomy do not need to be screened for cervical cancer, unless the surgery was done for cervical precancer or cancer.

Evidence-Informed Practice

Translating Research Into Practice

Hanna Khan is a 38-yr-old woman who had a tubal ligation in the outpatient surgery unit. She had a kidney transplant less than a year ago and is taking immuno-suppressant medications to prevent rejection. In preparing Ms. Khan for discharge, the nurse reminds her that she needs to have regular Pap tests to screen for cervical cancer. She expresses concern over the distance she has to travel to see her family doctor. She does not drive and is a single mother with three young children at home. She tells the nurse that she does not remember when she last had a Pap test done.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
For women after age 21 who have had three normal Pap tests, the Canadian Cancer Society recommends screening every 1 to 3 years.	The nurse knows that she is at higher risk for cervical cancer due to the immuno-suppression drugs that she is taking for her recent kidney transplant.	Ms. Khan is concerned about the difficulty getting to see her family doctor. She adds that no one in her family has ever had cervical cancer.

Decision and Action

Her nurse explains the Canadian Cancer Society recommendations and her increased risk for cervical cancer. She tells the nurse that she understands and will schedule a follow-up appointment, but unless she gets some help with child care and travel costs, she will probably not be able to get yearly Pap tests.

Reference for Evidence

Canadian Cancer Society. *Screening for cervical cancer*. [Retrieved from] http://www.cancer.ca/en/cancer-information/cancer-type/cervical/screening/?region=on; 2016.

Women with a history of cervical cancer should continue with screening for at least 20 years, as recommended by their health care provider. A woman who has been vaccinated against HPV needs to continue following the screening guidelines for her age group.

The two types of HPV that have been associated with most cases of cervical cancer (types 16 and 18) can be identified through deoxyribonucleic acid (DNA) testing. HPV DNA tests help to determine if women with abnormal Pap test results need further follow-up. Women aged 30 to 65 who have the HPV DNA test and the Pap test (co-testing) can be screened every 5 years rather than every 3 years.

Pap tests are less than 100% accurate. There are problems with both false-positive and false-negative reports. ThinPrep, a newer, liquid-based technique for Pap tests, has reduced the number of inaccurate Pap test results.

The finding of an abnormal Pap smear indicates the need for follow-up. Women with minor changes may be followed with a repeated Pap test in 4 to 6 months for 2 years. Up to 80% of abnormal Pap tests may revert to normal results spontaneously. Women with more prominent changes will receive additional procedures, such as colposcopy and biopsy, before a definitive diagnosis can be made. Colposcopy helps identify possible epithelial abnormalities and suggests areas for biopsy. Biopsies are sent for pathology evaluation. Colposcopy and biopsy have improved diagnosis and allow more focused treatments.

The type and the extent of the biopsy vary with the abnormality seen. A punch biopsy may be done on an outpatient basis with special punch biopsy forceps. The excision of a cone-shaped section of the cervix may be used for both diagnosis and treatment.

Conization is accomplished using one of several techniques, depending on the health care provider's experience and the availability of equipment. *Cryotherapy* (freezing) and laser cone vaporization destroy the tissue. Laser cone excision and *loop electrosurgery excision procedure* (LEEP) remove the identified tissue and allow for histological examination to ensure that all microinvasive tissue has been removed. These procedures can be performed as outpatient procedures with mild analgesics or sedation. Complications of these procedures include excessive bleeding and possible cervical stenosis after healing.

Collaborative Care

Vaccines against HPV (e.g., Gardasil, Cervarix) reduce the incidence of both cervical-related neoplasia and cervical cancer caused by infection from HPV types 16 and 18. HPV types 16 and 18 together cause 70% of cervical cancers (Maine, Hurlburt, & Greeson, 2011; CCS, 2016b). According to the National Advisory Committee on Immunization (NACI, 2012), the primary group recommended for vaccination is females aged 9 to 13. Gardasil is also recommended in males between 9 and 26 years of age, and in males ≥9 years of age who have sex with males (PHAC, 2017). Since the fall of 2008, all provinces and territories have introduced or announced HPV immunization programs into their routine immunization schedules for young girls (NACI, 2012). (HPV vaccines are discussed further in Chapter 55.)

The treatment of cancer of the cervix is guided by the stage of the tumour and the patient's age and general state of health (Table 56-11). There are four procedures in which fertility can be preserved. Conization may be the only type of therapy needed for noninvasive cervical cancer if analysis of removed tissue demonstrates that a wide area of normal tissue surrounds the excised tissue. Laser treatments can be used in which a directed infrared beam is employed to destroy abnormal tissue. Cautery and cryosurgery may also be used.

TABLE 56-11

STAGING AND TREATMENT OF CERVICAL CANCER

Stage	Extent	Treatment
0	In situ	Cervical conization, hysterectomy, cryosurgery, laser surgery
I	Confinement to cervix	Radiation, radical hysterectomy
II	Spread beyond cervix to upper two-thirds of vagina but not to tissues around uterus	Radiation, cisplatin-based chemotherapy, radical hysterectomy
III	Spread to pelvic wall, involvement of lower third of vagina, or has caused kidney problems (or both of the latter two)	Radiation, cisplatin-based chemotherapy
IV	Spread to other parts of the body such as bladder, rectum, liver, lungs, and bones	Radiation, surgery (e.g., pelvic exenteration), cisplatin-based chemotherapy

Source: Modified from National Cancer Institute (NCI). (2016). *Cancer cervical treatment: Stages of cervical cancer*. Retrieved from www.cancer.gov/cancertopics/pdq/treatment/cervical/Patient/page2.

Invasive cancer of the cervix is treated with surgery, irradiation, and chemotherapy as single treatments or in combination. Surgical procedures include hysterectomy, radical hysterectomy (involving adjacent structures), and rarely, pelvic exenteration. (Surgical therapy is discussed earlier in this chapter; pelvic exenteration is discussed later in the chapter.) Radiation may be external (e.g., cobalt) or internal implants (e.g., cesium, radium) may be used. Standard radiation treatment is 4 to 6 weeks of external radiation followed with one or two treatments with internal implants (brachytherapy). (Radiation therapy is discussed in Chapter 18 and in NCP 18-1, available on the Evolve website.) Cisplatin-based chemotherapy regimens benefit patients with cancer that has spread beyond the cervix.

Endometrial or Uterine Cancer

Cancer of the endometrium is the most common gynecological malignancy, accounting for nearly 50% of female genital tract neoplasms. The probability of a Canadian woman developing uterine cancer in her lifetime is 1 in 40. In 2015, it was estimated that there would be 6 300 new cases of endometrial cancer in Canada and that 1 050 women would die from the condition (Canadian Cancer

Society's Advisory Committee on Cancer Statistics, 2015). Endometrial cancer has a relatively low mortality rate, since most cases are diagnosed early. The survival rate is 95% if the cancer has not spread at the time of diagnosis.

Etiology and Pathophysiology

The major risk factor for endometrial cancer is estrogen, especially unopposed estrogen (Arora & Quinn, 2012). Additional risk factors include increasing age, nulliparity (women who have never been pregnant), late menopause, obesity, smoking, diabetes mellitus, and having a personal or family history of hereditary nonpolyposis colorectal cancer (HNPCC) (see the "Genetics in Clinical Practice" box on HNPCC in Chapter 45). Obesity is a risk factor because adipose cells store estrogen, thus increasing endogenous estrogen. Pregnancy and oral contraceptives are protective factors.

Endometrial cancer arises from the lining of the endometrium. Most tumours are adenocarcinomas. The precursor may be a hyperplasic state that progresses to invasive carcinoma. Hyperplasia occurs when estrogen is not counteracted by progesterone. The cancer extends directly into the cervix and through the uterine serosa. As invasion of the myometrium occurs, regional lymph nodes, including the paravaginal and para-aortic, become involved. Hematogenous metastases develop concurrently. The usual sites of metastases are the lung, bones, the liver, and eventually, the brain. Malignant cells can be found in the peritoneal cavity, probably having arrived by transport through the fallopian tubes.

Prognostic factors include histological differentiation, myometrial invasion, peritoneal cytology, lymph node and adnexal metastases, and tumour size. Endometrial cancer grows slowly, metastasizes late, and is amenable to therapy if diagnosed early.

Clinical Manifestations

The first sign of endometrial cancer is abnormal uterine bleeding, usually in women who are postmenopausal. Because women who are perimenopausal have sporadic periods for a time, it is important that this sign not be ignored or attributed to menopause.

Pain occurs late in the disease process. Other manifestations that may arise are related to metastasis to other organs. Metastatic spread occurs in a characteristic pattern. Spread to the pelvic and para-aortic nodes is common. When distant metastasis occurs, it most commonly involves the lungs, liver, bones, brain, and vagina.

Collaborative Care

Endometrial biopsy is the primary diagnostic procedure for endometrial cancer. Endometrial biopsy is done on an outpatient basis. Any abnormal or unexpected bleeding in a postmenopausal woman requires obtaining a tissue sample to exclude endometrial cancer. It is recommended that an endometrial biopsy be performed at menopause and then periodically in women who are at risk. The Pap test is not a reliable diagnostic tool for endometrial cancer, but it can rule out cervical cancer.

Most cases of endometrial cancer are diagnosed at an early stage, when surgery alone may result in cure. Treatment of endometrial cancer is a total abdominal hysterectomy and bilateral salpingo-oophorectomy (TAH-BSO) with lymph node biopsies. The lack of estrogen and progesterone receptors is a poor prognostic indicator. Surgery may be followed by radiation, either to the pelvis or the abdomen, externally or intravaginally, to decrease local recurrence.

No tumour markers with high sensitivity and high specificity for endometrial cancer are known at present, although CA-125 is often used in clinical practice. CA-125 has been used in surveillance of advanced endometrial cancer. In patients who have increased CA-125 values pretreatment, this test might prove useful in post-treatment surveillance.

Treatment of advanced or recurrent disease is difficult. Progesterone HT (e.g., megestrol [Megace OS]) is the treatment of choice when the progesterone receptor status is positive and the tumour is well differentiated (Jelovac & Armstrong, 2011). Tamoxifen (Nolvadex-D), either alone or in combination with progesterone therapy, is also effective in women with advanced or recurrent endometrial cancer. Chemotherapy is considered when progesterone therapy is unsuccessful. The most common agents

used are doxorubicin, cisplatin (Cisplatin), carboplatin, and paclitaxel.

Ovarian Cancer

Ovarian cancer is a malignant neoplasm of the ovaries. In 2015, it was estimated that there would be 2 800 new cases of ovarian cancer in Canada and that 1 750 women would die from the condition (Canadian Cancer Society's Advisory Committee on Cancer Statistics, 2015). Ovarian cancer has the highest mortality rate of all gynecological cancers because most women have advanced disease at diagnosis (Jelovac & Armstrong, 2011). In Canada, the lifetime probability of a woman dying from ovarian cancer is 1 in 91 (Canadian Cancer Society's Advisory Committee on Cancer Statistics, 2015). It occurs most frequently in women between 55 and 65 years of age.

Etiology and Pathophysiology

The cause of ovarian cancer is not known. Women who have mutations of the *BRCA* genes have increased susceptibility for ovarian and breast cancer (Jelovac & Armstrong, 2011). The *BRCA* genes are tumour suppressor genes that inhibit tumour growth when functioning normally. When they mutate, they lose their tumour suppressor ability. This loss results in an increased risk for women to develop ovarian or breast cancer (see the "Genetics in Clinical Practice" box).

Genetics in Clinical Practice

Ovarian Cancer

Genetic Basis

- Mutations in genes *BRCA1* and *BRCA2*

- Autosomal dominant transmission
- Mutations can be passed down from either mother or father

Incidence

- About 10% of cases of ovarian cancer are related to hereditary factors.
- Women with *BRCA1* mutations have a 25% to 40% lifetime risk of developing ovarian cancer.
- Women with *BRCA2* mutations have a 10% to 20% lifetime risk of developing ovarian cancer.
- Family history of both breast and ovarian cancer increases the risk of having a *BRCA* mutation.
- *BRCA* mutations occur in 10% to 20% of patients with ovarian cancer who have no family history of breast or ovarian cancer.

Genetic Testing

- DNA testing is available for *BRCA1* and *BRCA2* genetic mutations.

Clinical Implications

- Bilateral oophorectomy reduces the risk for ovarian cancer in women with *BRCA1* and *BRCA2* mutations.
- Genetic counselling and testing for *BRCA* mutations should be considered for women whose personal or family history puts them at high risk for a genetic predisposition to ovarian cancer.

The major risk factor for ovarian cancer is family history (one or more first-degree relatives with ovarian cancer). A family history of breast or colon cancer is also a risk factor. Other risk factors include a personal history of breast or colon cancer and HNPCC (see the "Genetics in Clinical Practice" box on HNPCC in Chapter 45).

Nulliparity also places women at higher risk. Other risk factors include increasing age, high-fat diet, increased number of ovulatory cycles (usually associated with early menarche and late menopause), HT, and possibly the use of infertility drugs. Breastfeeding, multiple pregnancies, oral contraceptive use (>5 years), and early age at first birth seem to reduce the risk for ovarian cancer. These factors may have a protective effect because they reduce the number of ovulatory cycles and, thus, reduce the exposure to estrogen.

About 90% of ovarian cancers are epithelial carcinomas that arise from malignant transformation of the surface epithelial cells. Epithelial ovarian cancer is primarily a disease of women who are postmenopausal and in the sixth or seventh decade of life (Jelovac & Armstrong, 2011). Germ cell tumours account for the other 10%. Histological grading is an important prognostic determinant. Tumours are graded according to the level of differentiation, ranging from *well differentiated* (grade I), *moderately well differentiated* (grade II), and *poorly differentiated* (grade III) to *undifferentiated* (grade IV). Grade IV lesions carry a poorer prognosis than the other grades.

Intraperitoneal dissemination is a common characteristic of ovarian cancer. It metastasizes to the uterus, bladder, bowel, and omentum. In advanced disease, it can spread to the stomach, colon, liver, and other parts of the body.

Clinical Manifestations

Nonspecific symptoms that warrant further evaluation include pelvic or abdominal pain, bloating, urinary urgency or frequency, and difficulty eating or feeling full quickly (Jelovac & Armstrong, 2011). Women who have one or more of these symptoms, especially if they are new, persistent (occur at least 12 days per month), or worsening, need to see their health care provider. Vaginal bleeding rarely occurs, and pain is not an early symptom. Later signs are increased abdominal girth, unexplained weight loss or gain, and menstrual changes.

Diagnostic Studies

No screening test exists for ovarian cancer. Because early ovarian cancer has vague symptoms, yearly bimanual pelvic examinations should be performed to identify the presence of an ovarian mass (Table 56-12). Women who are postmenopausal should not have palpable ovaries, so a mass of any size should be suspected as possible ovarian cancer. An abdominal or transvaginal ultrasonography can be used to detect ovarian masses. An exploratory laparotomy may be used to establish the diagnosis and stage the disease.

TABLE 56-12
COLLABORATIVE CARE
Ovarian Cancer

Diagnostic
• History and physical examination • Abdominal and transvaginal ultrasonography • CA 125 levels • Laparotomy for diagnostic staging • Pelvic examination
Collaborative Therapy

• Surgery
  • Abdominal hysterectomy and bilateral salpingo-oophorectomy with pelvic lymph node biopsies
  • Debulking for advanced disease
• Chemotherapy
  • Adjuvant and palliative
• Radiation therapy
  • Adjuvant and palliative

CA, carbohydrate antigen.

A test called OVA1 can help detect whether a pelvic mass is benign or malignant before it is surgically removed. OVA1 uses a blood sample to test for levels of five proteins that change due to ovarian cancer. It is not intended for ovarian cancer screening or for a definitive diagnosis of ovarian cancer.

For women with a high risk for ovarian cancer, screening using a combination of the tumour marker (carbohydrate antigen-125 [CA-125]) and ultrasonography is recommended in addition to a yearly pelvic examination. CA-125 is positive in 80% of women with epithelial ovarian cancer and is used to monitor the course of the disease. However, levels of CA-125 may be elevated with other malignancies (e.g., pancreatic cancer) or with benign conditions such

as fibroids or endometriosis. A large, recent clinical trial has reported that screening by CA-125 and ultrasound did not result in fewer deaths from ovarian cancer (Buys, Partridge, Black, et al., 2011). Currently only 20% of ovarian cancers are diagnosed at an early stage.

Collaborative Care

Women identified as being at high risk based on family and health history may require counselling regarding options such as prophylactic oophorectomy and oral contraceptives. It is important to note that, although oophorectomy will significantly reduce the risk for ovarian cancer, it will not completely eliminate the possibility of the disease.

Ovarian cancer staging is critical for guiding treatment decisions. Stage I describes disease limited to the ovaries; stage II, disease limited to the true pelvis; stage III, disease limited to the abdominal cavity; and stage IV, distant metastatic disease. The overall survival rate is 90% with early disease, 36% with local spread, and 20% with distant metastases.

Most patients with ovarian cancer have widespread disease at presentation. The initial treatment for all stages of ovarian cancer is surgery, which is usually a total abdominal hysterectomy (TAH) and bilateral salpingo-oophorectomy (BSO) with omentectomy and removal of as much of the tumour as possible (i.e., tumour debulking). Surgery facilitates chemotherapy by reducing the number of cells that the chemotherapy has to kill.

Depending on the differentiation of the cells and the stage of cancer, other treatment options include intraperitoneal and systemic chemotherapy, intraperitoneal instillation of radioisotopes, and external abdominal and pelvic radiation therapy. If a patient is clinically free of symptoms after completing treatment, a "second-look" surgical procedure is often performed to determine whether there is any evidence of disease. If no disease is found, the patient is monitored for recurrent disease.

Chemotherapy usually consists of a combination of a platinum compound, such as cisplatin or carboplatin, and a taxane, such as

paclitaxel or docetaxel (Taxotere). The typical course of chemotherapy involves three to six cycles. A cycle is a schedule that allows regular doses of a drug, followed by a rest period.

Other chemotherapy drugs used include topotecan (Hycamtin), etoposide (Vepesid), gemcitabine, and oxaliplatin (Eloxatin). These drugs may be used to treat recurrent disease or as a palliative measure to shrink the tumour to relieve pressure and pain.

Vaginal Cancer

Primary vaginal cancers are rare. The peak incidence is between 50 and 70 years of age. Vaginal tumours are usually secondary sites or metastases of other cancers such as cervical or endometrial carcinomas. The most common type of vaginal cancer is squamous cell carcinoma. Intrauterine exposure to DES (a synthetic form of estrogen no longer in use) places a woman at risk for clear cell adenocarcinoma of the vagina.

Treatment of vaginal cancer depends on the type of cells involved and the stage of the disease, the size of the tumour, and the location of the tumour. Squamous cell carcinomas can be treated with both surgery and radiation.

Vulvar Cancer

Cancer of the vulva is relatively rare. Similarly to cervical cancer, preinvasive lesions, referred to as *vulvar intraepithelial neoplasia* (VIN), precede invasive vulvar cancer. The invasive form occurs mainly in women older than 60 years, with the highest incidence being in women in their 70s.

Patients with vulvar neoplasia may have symptoms of vulvar itching or burning, pain, bleeding, or discharge. Women who are immuno-suppressed or have diabetes mellitus, hypertension, or chronic vulvar dystrophies are at a higher risk of developing vulvar cancers. Several subtypes of HPV have been identified in some but not all vulvar cancers. Vaccines (Gardasil, Cervarix) are now available to protect against some vaginal and vulvar cancers that are caused by these HPV subtypes. (HPV vaccines are discussed further in Chapter 55.)

Diagnosis of vulvar cancer is determined by the pathology report on the biopsy of the suspicious lesion. VIN can be treated topically with imiquimod cream (Aldara) or surgery.

Laser therapy may be used to kill cancer cells. Surgery is the most common treatment for cancer of the vulva. The goal of surgery is to remove all the cancer without any loss of the woman's sexual function. A local excision with removal of the lesion and surrounding tissue may be done. For more extensive lesions, vulvectomy may be done (various types of vulvectomies are presented in Table 56-13). If the cancer is extensive, a pelvic exenteration may be done. The patient may have chemotherapy or radiation therapy after surgery, as adjuvant measures.

TABLE 56-13

SURGICAL PROCEDURES INVOLVING THE FEMALE REPRODUCTIVE SYSTEM

Type of Surgery	Description
Abdominal Hysterectomy	
Total hysterectomy	Uterus and cervix removed using large abdominal incision (bikini cut)
Total abdominal hysterectomy and bilateral salpingo-oophorectomy (TAH-BSO)	Uterus, cervix, fallopian tubes, and ovaries removed using large abdominal incision
Radical hysterectomy	Panhysterectomy, partial vaginectomy, and dissection of lymph nodes in pelvis
Vaginal Hysterectomy	Uterus and cervix removed through a cut in the top of vagina
Laparoscopic Hysterectomy	Laparoscope (video camera and small surgical instruments)
Laparoscopic-assisted vaginal hysterectomy (LAVH)	Incision made at top of vagina; uterus and cervix removed through the vagina; laparoscope inserted into abdomen to assist in the procedure
Laparoscopic supracervical hysterectomy	Uterus removed using only laparoscopic instruments; cervix is left intact
Robot-Assisted Surgery	Robot (special machine) used to do surgery through small abdominal incisions; most often used when a patient has cancer or is very overweight and vaginal surgery is not safe
Vulvectomy	Surgical procedure to remove part or all of the vulva
Skinning vulvectomy	Removal of top layer of vulvar skin where the cancer is found; skin grafts from other parts of the body may be needed to cover the area
Simple vulvectomy	Entire vulva is removed
Radical vulvectomy	Entire vulva, including clitoris, labia majora and minora, and nearby tissue, is removed; nearby lymph nodes may also be removed
Vaginectomy	Removal of vagina
Pelvic Exenteration	Radical hysterectomy, total vaginectomy, removal of bladder with diversion of urinary system and resection of colon and rectum with colostomy

Surgical Procedures: Female Reproductive System

A variety of surgical procedures are performed when benign or malignant tumours of the genital tract are found (Table 56-13). A *hysterectomy* (removal of the uterus) is the type of surgery performed for excision of cancerous tumours of the female reproductive system. A hysterectomy may be done abdominally, vaginally, or laparoscopically. The abdominal route is used when large tumours are present and the pelvic cavity is to be explored or when the tubes and ovaries are to be removed at the same time (Figure 56-10). The abdominal route can present more postoperative problems because it involves an incision and the opening of the abdominal cavity.

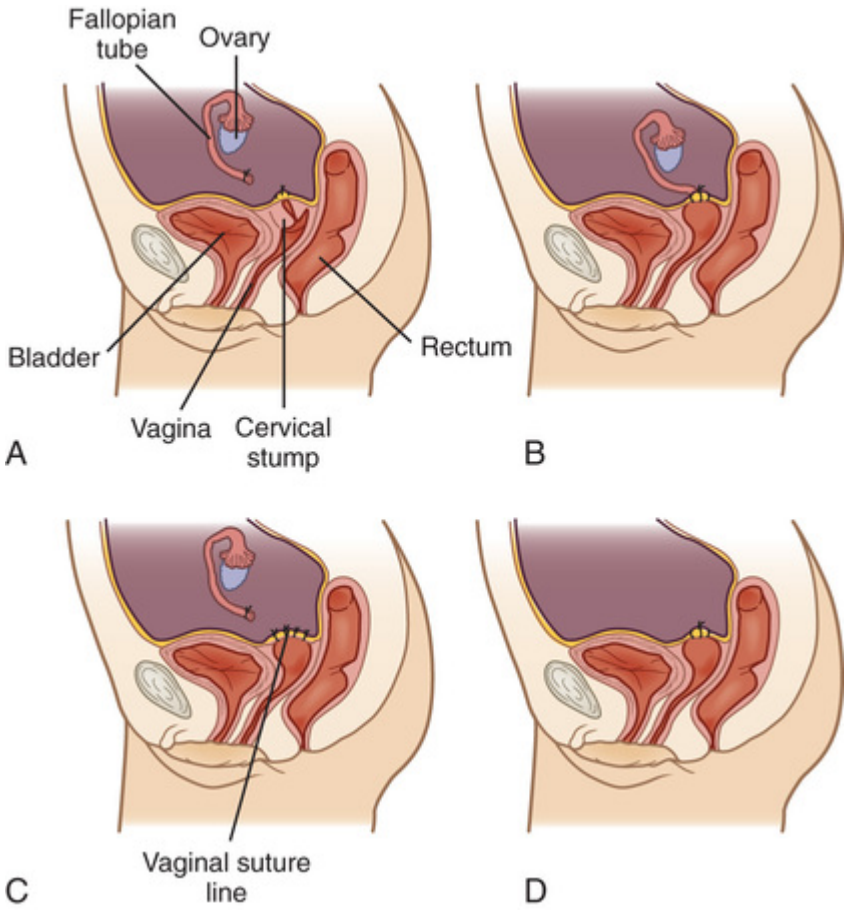

FIGURE 56-10 **A,** Cross-section of subtotal hysterectomy. Note that the cervical stump, fallopian tubes, and ovaries remain. **B,** Cross-section of total hysterectomy. Note that the fallopian tubes and ovaries remain. **C,** Cross-section of vaginal hysterectomy. Note that the fallopian tubes and ovaries remain. **D,** Total hysterectomy, salpingectomy, and oophorectomy. Note that the uterus, fallopian tubes, and ovaries are completely removed.

A vaginal route is often used when vaginal repair is done in addition to removal of the uterus. In both vaginal and abdominal hysterectomies, the ligaments that support the uterus are attached to the vaginal cuff to maintain the normal depth of the vagina. Laparoscopic procedures have the advantage of quicker recovery time and fewer complications (Koehler, Gottschalk, Chiantera, et al., 2013).

Radiation Therapy: Cancers of the Female Reproductive System

Radiation is used to cure or control or as a palliative measure for cancers of the female reproductive system, either alone or in combination with other treatments. The goal of radiation therapy is to deliver a specific amount of high-energy (or ionizing) radiation to the cancer with minimal damage to the normal surrounding tissue. Radiation therapy may be external or internal (brachytherapy).

External Radiation Therapy

With external radiation therapy, a source outside of the body delivers electromagnetic radiation in the form of waves. (External radiation therapy and related nursing care are discussed in Chapter 18 and in NCP 18-1, available on the Evolve website.)

Internal Radiation Therapy (Brachytherapy)

Brachytherapy allows the radiation to be placed near or into the tumour. This method can deliver a high dose of radiation directly to the tumour (Viswanathan, 2012). The dose decreases sharply as distance from the source increases, causing less damage to the surrounding normal tissue. A variety of forms are used to deliver the therapy, including wires, capsules, needles, tubes, and seeds. Brachytherapy is used in the management of cervical and endometrial cancer because of the accessibility of these body parts and the favourable results obtained. Radium and cesium are two commonly used isotopes.

To prepare the patient for the treatment, the nurse gives a cleansing enema to prevent straining at stool, which could cause displacement of the isotope. An indwelling catheter is inserted to prevent a distended bladder from coming into contact with the radioactive source.

A variety of applicators have been developed for intrauterine treatment. Applicators are inserted into the endometrial cavity and the vagina in the operating room. When the applicator contains the radioactive material, this is known as *preloading.* In *afterloading,* the

applicator is implanted in the operating room but is not loaded with the radioactive material until its correct placement is verified and the patient has been returned to her room.

Radiation exposure to the patient is precisely controlled. The radiation exposure to the physician and other personnel involved in the implantation is reduced when the afterload technique is used. The applicator is secured with vaginal packing and is left in place for 24 to 72 hours.

During the treatment, the patient is placed in a lead-lined private room, on absolute bed rest. She may be turned from side to side. The presence of an intrauterine applicator produces uterine contractions that may require analgesics. The destruction of cells results in a foul-smelling vaginal discharge, and a deodorizer is helpful. Nausea, vomiting, diarrhea, and malaise may develop as a systemic reaction to the radiation.

At the end of the prescribed period of radiation, the radioactive material and the catheter are removed. The patient is allowed off bed rest and is discharged from the hospital when stable. Late complications that may arise include fistulas (vesico-vaginal, uretero-vaginal), cystitis, phlebitis, hemorrhage, and fibrosis. If fibrosis occurs, the vaginal wall becomes smaller in diameter and shorter. Dilation of the vagina through intercourse or the use of sequentially sized dilators may be indicated. The patient is urged to report any unusual symptoms or complaints to her physician. (Brachytherapy and related nursing care are discussed in Chapter 18.)

Nursing Management Cancers of the Female Reproductive System

Nursing Assessment

Malignant tumours of the female reproductive system can be found in the cervix, endometrium, ovaries, vagina, and vulva. The patient with any of these malignant tumours may experience a variety of clinical manifestations, including leukorrhea, other types of vaginal discharge, irregular vaginal bleeding, increase in abdominal pain and pressure, bowel and bladder dysfunction, and vulvar itching and burning. Assessment for these signs and symptoms is an important nursing responsibility.

Nursing Diagnoses

Nursing diagnoses for the female patient with cancer of the reproductive system include, but are not limited to, the following:

- *Anxiety* related to *threat to current status, threat of death* (cancer diagnosis)
- *Acute pain* related to *biological injury agent* (enlarging tumour)
- *Disturbed body image* related to *alteration in self-perception* (loss of body part, loss of good health)
- *Ineffective sexuality pattern* related to *insufficient knowledge about alternatives related to sexuality* (physiological limitations, fatigue)
- *Grieving* (related to poor prognosis of advanced disease)

Planning

The overall goals are that the patient with cancer of the female reproductive system will (1) actively participate in treatment decisions, (2) achieve satisfactory pain and symptom management, (3) recognize and report problems promptly, (4) maintain preferred lifestyle as long as possible, and (5) continue to practise cancer detection strategies.

Nursing Implementation

Health Promotion.

Through their contact with women in a variety of settings, nurses can teach women the importance of routine screening for cancers of the reproductive system. Cancer may be prevented when screening reveals precancerous conditions of the vulva, cervix, endometrium, and rarely, the ovaries. Also, routine screening increases the chance that a cancer will be identified in its early stage. When cancer is identified earlier, treatment can be more conservative and the woman's prognosis improves. Regular pelvic examinations and Pap tests (as indicated) will allow the health care provider to detect lesions on the vulva or any uterine or ovarian irregularities and screen for cervical cancer. Nurses can assist women to view routine cancer screening and vaccination against cervical cancer as important self-care activities.

Educating women about risk factors for cancers of the reproductive system is also important. Limiting sexual activity during adolescence, using condoms, having fewer sexual partners, and not smoking reduce the risk for cervical cancer. When high-risk behaviours are identified, nurses should assist women to identify lifestyle changes to decrease risk.

Acute Intervention Related to Surgery.

All patients experience a degree of anxiety when surgery is contemplated, but the prospect of major gynecological surgery increases these concerns. Some women may experience guilt, anger, or embarrassment. Still others may focus on the effect the surgery will have on their reproductive and sexual functions. Some women

view the whole process as annoying, whereas others are relieved by the thought of no longer having menstrual periods or becoming pregnant. The nurse should try to understand the patient's fears and concerns. Each patient needs to be assessed as an individual. Being willing to listen can provide considerable psychological support for patients.

Physically, the patient is prepared preoperatively for surgery with the standard perineal or abdominal preparation. A vaginal douche and enemas may be given (based on the surgeon's preference). The bladder should be emptied before the patient is sent to the operating room. An indwelling catheter is sometimes inserted preoperatively (see Chapter 20 for discussion of general preoperative patient care).

Hysterectomy.

Postoperatively, the patient who has had a hysterectomy will have an abdominal dressing (abdominal hysterectomy) or a sterile perineal pad (vaginal hysterectomy). (See NCP 56-1 for care of the patient after a total abdominal hysterectomy. See Chapter 22 for potential surgical complications, wound care, and other postoperative care.) The dressing should be observed frequently for any sign of bleeding during the first 8 hours after surgery.

The patient may experience urinary retention postoperatively because of temporary bladder atony resulting from edema or nerve trauma. At times, an indwelling catheter is used for 1 to 2 days postoperatively to maintain constant drainage of the bladder and prevent strain on the suture line. If an indwelling catheter is not used, catheterization may be necessary if the patient has not urinated for 8 hours postoperatively. If residual urine is suspected after the removal of an indwelling catheter, intermittent catheterization is done to prevent bladder infection caused by pooling of urine. Accidental ligation of a ureter is a serious surgical complication. Report any complaint of backache or decreased urine output to the surgeon.

Abdominal distension may develop from the sudden release of pressure on the intestines when a large tumour is removed or from paralytic ileus secondary to anaesthesia and manipulation of the bowel. Food and fluids may be restricted if the patient is nauseated.

Early ambulation is encouraged to relieve abdominal pain related to flatus and to prevent abdominal distension.

Special care must be taken to prevent the development of deep venous thrombosis (DVT). Frequent changes of position, avoidance of the high Fowler's position, and avoidance of pressure under the knees minimize stasis and pooling of blood. Leg exercises should be encouraged to promote circulation.

The loss of the uterus may bring about a grief response in some women, similar to any significant personal loss. The ability to bear children may be associated with her perception of womanhood. Grief from this loss is normal. Eliciting the woman's feelings and concerns about her surgery will provide the needed information to give understanding care.

When surgery removes the ovaries as well, women experience surgical menopause. Estrogen is no longer available from the ovaries, so symptoms of estrogen deficiency will arise. To counter this, HT may be initiated in the early postoperative period.

Discharge teaching should prepare the patient for what to expect following surgery (e.g., she will not menstruate). Teaching should include specific activity restrictions. Intercourse should be avoided until the wound is healed (~4 to 6 weeks). If a vaginal hysterectomy is performed, the woman needs to know that there may be a temporary loss of vaginal sensation. She should be reassured that sensation will return in several months.

Physical restrictions are limited for a short time. Heavy lifting should be avoided for 6 to 8 weeks. The patient should be assured that once healing is complete, all previous activity can be resumed.

Salpingectomy and Oophorectomy.

Postoperative care of the woman who has undergone removal of a fallopian tube (salpingectomy) or an ovary (oophorectomy) is similar to that for any patient having abdominal surgery. However, if a large ovarian cyst is removed, there may be abdominal distension caused by the sudden release of pressure in the intestines. An abdominal binder may provide relief until the distension subsides.

When both ovaries are removed (bilateral oophorectomy), surgical menopause results. The symptoms are similar to those of regular

menopause but may be more severe because of the sudden withdrawal of hormones. Attempts may be made to leave at least a portion of an ovary.

Vulvectomy.

Although cancer of the vulva is relatively uncommon, it is important that the nurse recognize the extent of the vulvectomy and the significant effect it is likely to have on the patient's life. An honest, open attitude with the patient and her partner preoperatively can be most helpful in the postoperative period.

After a vulvectomy (see Table 56-13), the patient returns to the unit with a wound in the perineal area extending to the groin. The wound may be covered or left exposed and frequently has drains attached to portable suction (e.g., Hemovac, Jackson-Pratt). Often, a heavy pressure dressing is in place for the first 24 to 48 hours. The wound is cleaned with normal saline solution, twice daily. The normal saline can be applied with an aseptic bulb syringe or a Water Pik machine. A heat lamp or a hair dryer may be used to dry the area. Wound care must be meticulous to prevent infection, which results in delayed healing.

Special attention to bowel and bladder care is needed. A low-residue diet and stool softeners prevent straining and wound contamination. An indwelling catheter is used to provide urinary drainage. Great care is taken not to dislodge the catheter because extensive edema makes its reinsertion difficult. Heavy, taut sutures are often used to close the wounds, resulting in severe discomfort for the patient. In other instances, the wound may be allowed to heal by granulation. Analgesics may be required frequently to control pain. Careful positioning of the patient through the use of strategically placed pillows provides comfort. Anticoagulant therapy to prevent DVT is common.

Because the surgery causes mutilation of the perineal area and the healing process is slow, the patient is likely to become discouraged. Opportunities for the patient to express her feelings and concerns about the operation should be provided. The patient needs specific instructions in self-care before she is discharged. She should be told to report any unusual odour, fresh bleeding, breakdown of incision,

or perineal pain. Home care nursing can benefit the patient during her adjustment period.

Sexual function is often retained. Whether clitoral sensation is retained may be critical to some women, particularly if it was a primary source of orgasmic satisfaction. A discussion of alternative methods of achieving sexual satisfaction may also be indicated.

Pelvic Exenteration.

When other forms of therapy fail to control the spread of cancer and no metastases have been found outside of the pelvis, pelvic exenteration may be performed. This radical surgery usually involves removal of the uterus, ovaries, fallopian tubes, vagina, bladder, urethra, and pelvic lymph nodes. In some situations, the descending colon, rectum, and anal canal may also be removed. Candidates for this procedure are selected on the basis of their likelihood of surviving the surgery and their ability to adjust to and accept the resulting limitations.

Postoperative care is similar to that of a patient who has had a radical hysterectomy, an abdominal perineal resection, and an ileostomy or colostomy. The physical, emotional, and social adjustments to life on the part of the woman and her family are great. There are urinary or fecal diversions in the abdominal wall, a reconstructed vagina, and the onset of menopausal symptoms.

The patient's rehabilitative process should keep pace with her acceptance of the situation. Much understanding and support is needed from the nursing staff during a long recovery period. The patient should be gently encouraged to regain her independence. She needs to verbalize her feelings about her altered body structure. Inclusion of the family in the plan of care is important.

The patient will need to return to her health care provider at specified intervals. Early recurrence of the cancer may be identified and treated. At this time, the patient's physical and emotional adjustment to the changes in body image produced by the surgery and her ability to carry out any treatment measures can also be assessed. Additional teaching and counselling can then be provided.

Acute Intervention With Radiation Therapy.

When the patient is to receive external radiation, she should be told to urinate immediately before the treatment to minimize radiation exposure to the bladder. She should be advised about radiation adverse effects, including enteritis and cystitis. These are natural reactions to radiotherapy and do not indicate an overdose. The patient should be fully informed of the possible adverse effects and measures to use to reduce their impact.

Nursing management of the patient receiving brachytherapy requires special considerations. Efficient organization of nursing care is essential so that the nurse does not stay in the immediate area of the patient any longer than is necessary to give proper care and attention. No individual nurse should attend the patient for more than 30 minutes per day. The nurse should stay at the foot of the bed or at the entrance to the room to minimize radiation exposure. Visitors need to be told to stay about 2 m away from the bed and limit visits to less than 3 hours a day. The reasons for these precautions must be explained fully to the patient and her visitors. (A more detailed discussion of nursing care of the patient receiving brachytherapy is given in Chapter 18.)

Evaluation

The expected outcomes are that the patient with cancer of the female reproductive system will do the following:

- Actively participate in treatment decisions
- Achieve satisfactory pain and symptom management
- Recognize and report problems promptly
- Maintain preferred lifestyle as long as possible
- Continue to practise cancer-detection strategies

Problems With Pelvic Support

The most commonly occurring problems with pelvic support are uterine prolapse, cystocele, and rectocele. Pelvic organ prolapse (POP) is a common condition involving the loss of fibromuscular support of the pelvic viscera, causing the descent or herniation of the pelvic organs into the vagina. The general prevalence of POP is thought to be 41% of parous women, with the prevalence of cystocele varying from 25% to 34%, rectocele varying from 13% to 19%, and uterine prolapse varying from 4% to 14% (Ciangola, Perrone, & Franceschilli, 2014).

Although vaginal birth increases the risk for these problems, these conditions can occur in women who have never experienced childbirth. Obesity, chronic coughing, and straining during bowel movements can increase the likelihood of these problems. The decreased estrogen that normally accompanies perimenopause also reduces some connective tissue support.

Uterine Prolapse

Uterine prolapse is the downward displacement of the uterus into the vaginal canal as a result of impaired pelvic support (Prasad & Alvero, 2013) (Figure 56-11). Prolapse is rated by degrees. In first-degree prolapse, the cervix rests in the lower part of the vagina. Second-degree prolapse means the cervix is at the vaginal opening. Third-degree prolapse means the uterus protrudes through the introitus (entrance to the vaginal canal).

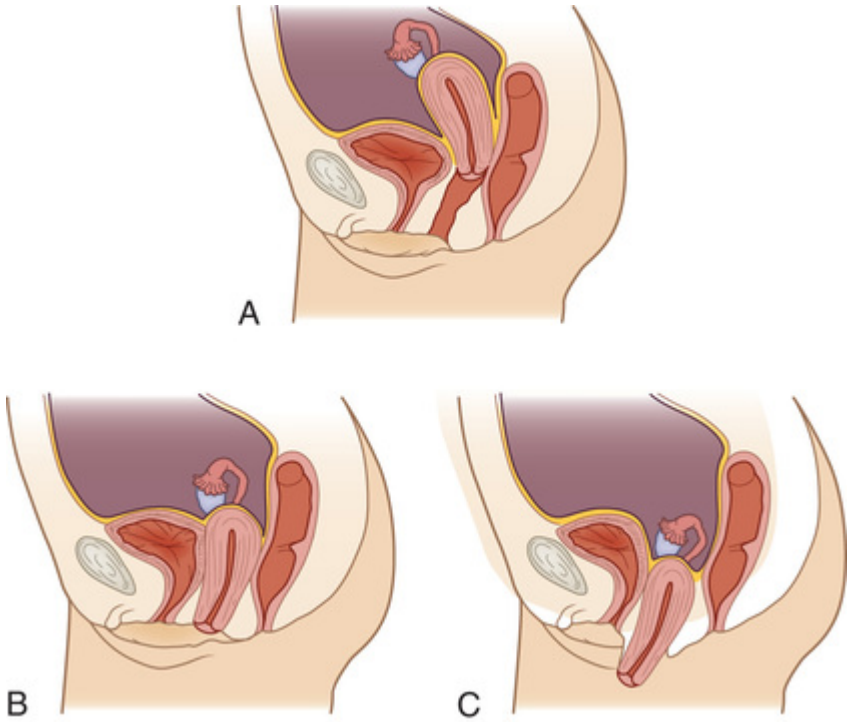

FIGURE 56-11 Uterine prolapse. **A,** First-degree prolapse. **B,** Second-degree prolapse. **C,** Third-degree prolapse.

Symptoms vary with the degree of prolapse. The patient may describe a feeling of "something coming down." She may have dyspareunia, a dragging or heavy feeling in the pelvis, backache, and bowel or bladder problems if cystocele or rectocele is also present. Stress incontinence is a common and troubling problem. When third-degree uterine prolapse occurs, the protruding cervix and vaginal walls are subjected to constant irritation, and tissue changes may occur.

Therapy depends on the degree of prolapse and how much the woman's daily activities have been affected. Pelvic floor muscle training (PFMT) or Kegel exercises may be effective for some women (Hagen & Thakar, 2015) (see Chapter 48, Table 48-19). There is some evidence that proper training and consistent interpersonal support from health care providers increases the effectiveness of PFMT (Hagen & Thakar, 2015). If PFMT does not provide improvement, a pessary may be used. A *pessary* is a device that is placed in the vagina to help support the uterus (Figure 56-12). The pessary can help prevent worsening of the POP, decrease the frequency or severity of symptoms, and delay need for surgical intervention. A

wide variety of pessary shapes exist, including rings, arches, and balls. They can be made from materials such as rubber, clear plastic, soft plastic with metal reinforcements, or silicone. When a woman first receives a pessary, she needs instructions for its cleaning and for follow-up. Pessaries that are left in place for long periods are associated with erosion, fistulas, and an increased incidence of vaginal carcinoma.

FIGURE 56-12 Various types of pessaries. Source: Huckfinne/Wikimedia Commons.

If more conservative measures are not successful, surgery is indicated. Surgery generally involves a vaginal hysterectomy with anterior and posterior repair of the vagina and the underlying fascia.

Cystocele and Rectocele

Cystocele or anterior wall prolapse occurs when support between the vagina and the bladder is weakened (Figure 56-13). Similarly, a **rectocele** or posterior wall prolapse results from weakening between the vagina and the rectum (see Figure 56-13). Cystocele and rectocele are common problems, and in many women they are asymptomatic.

With large cystoceles, complete emptying of the bladder can be difficult, predisposing women to bladder infections. A woman with a large rectocele may not be able to completely empty her rectum when defecating unless she helps push the stool out by putting her fingers in her vagina.

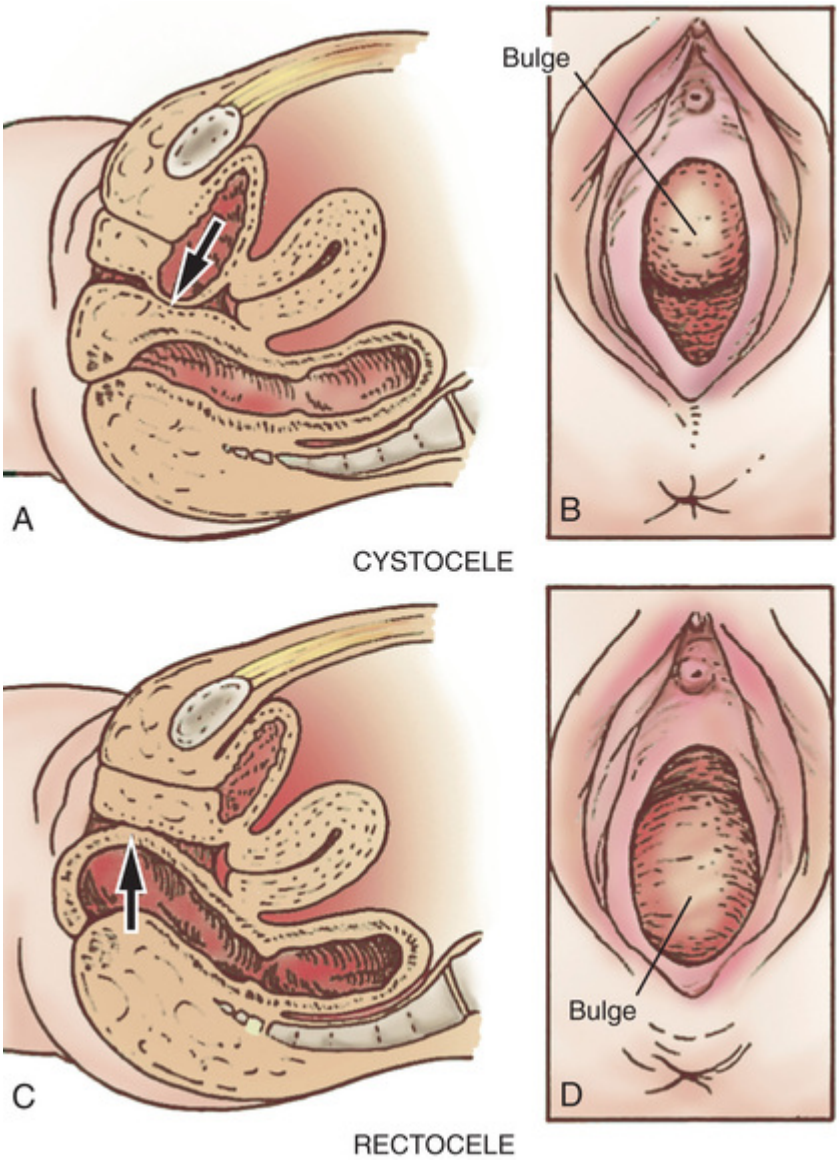

FIGURE 56-13 **A,** Cystocele. Note the bulging of the anterior vaginal wall. The urinary bladder is displaced downward. **B,** The cystocele pushes the anterior vaginal wall downward into the vagina. **C,** Rectocele. Note the bulging of the posterior vaginal wall. **D,** The rectocele pushes the posterior vaginal wall into the vagina. Source: Black, J. M., & Hawks, J. H. (2009). *Medical-surgical nursing: Clinical management for positive outcomes* (8th ed., p. 930, Figure 39-7). St. Louis: Saunders.

As with uterine prolapse, pelvic floor muscle training (PFMT) or Kegel exercises (see Chapter 48, Table 48-19) may be used to strengthen the weakened perineal muscles if the cystocele or rectocele is not too problematic. A pessary may be helpful for

cystoceles. Surgery designed to tighten the vaginal wall is generally the method of treatment. A cystocele is corrected with a procedure called an *anterior colporrhaphy,* whereas a *posterior colporrhaphy* is done for a rectocele. If further surgery is needed to relieve stress incontinence, procedures to support the urethra and restore the proper angle between the urethra and the posterior bladder wall are used.

Nursing Management Problems With Pelvic Support

Nurses can assist women to avoid or decrease problems with pelvic support by teaching them how to do PFMT or Kegel exercises. Women of all ages can benefit from these exercises. However, the exercises are especially important following childbirth or whenever women begin to have incontinence. To instruct a patient in this exercise, she should be told to pull in or contract her muscles as if she were trying to stop the flow of urine. She should hold the contraction for several seconds and then relax. Sets of 5 to 10 contractions each should be done, several times daily.

If vaginal surgery is necessary, the preoperative preparation may include a cleansing douche the morning of surgery. A cathartic and a cleansing enema are usually given when a rectocele repair is scheduled.

In the postoperative period, the goals of care are to prevent wound infection and pressure on the vaginal suture line. This necessitates perineal care at least two to three times per day and after each urination or defecation. An ice pack applied locally may relieve the initial perineal discomfort and swelling. Later, sitz baths may be used.

After an anterior colporrhaphy, often, an indwelling catheter is left in the bladder for 2 to 3 days to allow the local edema to subside. Alternatively, a suprapubic catheter can be inserted at the time of surgery. The catheter keeps the bladder empty, preventing strain on the sutures. The amount of urine left in the bladder after voiding is checked for the first few voidings to make sure it is less than 150 mL. This is checked by intermittent catheterization after the patient has voided (postresidual) or by using a bladder scanner or by opening the valve on the suprapubic catheter. After posterior colporrhaphy, straining at stool is avoided by means of a low-residue diet and daily stool softeners to prevent constipation.

Discharge instructions should be reviewed before the patient leaves the hospital. They include the use of a mild laxative as

needed; restriction of heavy lifting and prolonged standing, walking, or sitting; and avoidance of intercourse until the physician gives permission. There may be a temporary loss of vaginal sensation, which can last for several months.

Fistula

A *fistula* is an abnormal opening between internal organs or between an organ and the exterior of the body (Figure 56-14). Gynecological procedures cause most urinary tract fistulas. Other causes include injury during childbirth and disease processes, such as cancer. Fistulas may develop between the vagina and the bladder, the urethra, the ureter, or the rectum. When *vesico-vaginal* fistulas (between the bladder and the vagina) develop, some urine leaks into the vagina, whereas with recto-vaginal fistulas (between the rectum and the vagina), flatus and feces escape into the vagina. In both instances, excoriation and irritation of the vaginal and vulvar tissues occur and may lead to severe infections. In addition to wetness, offensive odours may develop, causing embarrassment and severely limiting socialization.

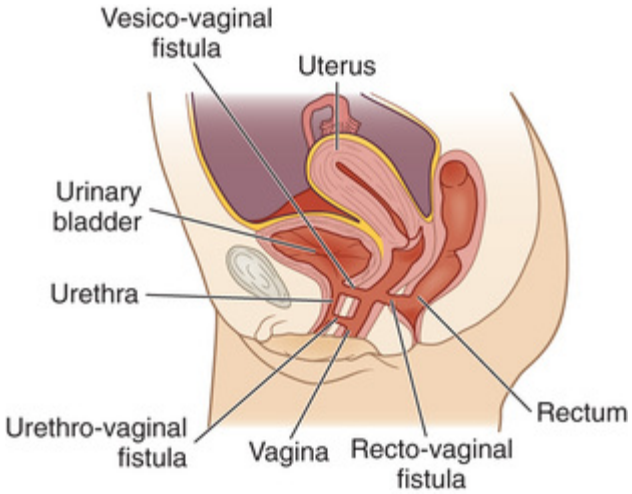

FIGURE 56-14 Common fistulas involving the vagina.

Because small fistulas may heal spontaneously within a matter of months, treatment may not be needed. If the fistula does not heal,

surgical excision is required. Inflammation and tissue edema must be eliminated before surgery is attempted. This may involve a wait of up to 6 months for the surgery. The fistulectomy may result in the patient's having an ileal conduit or temporary colostomy.

Nursing Management Fistulas

Perineal hygiene is of great importance, both preoperatively and postoperatively. The perineum should be cleansed every 4 hours. Warm sitz baths should be taken three times daily if possible. Perineal pads should be changed frequently. The patient should be encouraged to maintain an adequate fluid intake. Encouragement and reassurance are needed to help the patient cope with her problems.

Postoperatively, nursing care emphasis is on avoidance of stress on the repaired areas and prevention of infection. Care should be taken so that the indwelling catheter, usually in place for 7 to 10 days, is draining at all times. Oral fluids should be urged to provide for internal catheter irrigation. Minimal pressure and strict asepsis are used if catheter irrigation becomes necessary. The first stool after bowel surgery may be purposely delayed to prevent contamination of the wound. Later, stool softeners or mild laxatives may be given. (See Chapter 48 and NCP 48-3, available on the Evolve website, for care of a patient with an ileal conduit and Chapter 45 and NCP 45-4 for care of a patient with a colostomy.) Surgical repair of fistulas is not always effective, even in the best conditions. Therefore, supportive nursing care for the patient and her significant others is especially important.

Case Study

Uterine Prolapse and Vaginal Hysterectomy

Source: Billon Photos/Shutterstock.

Patient Profile

Thérèse Pelletier is a 62-year-old woman who has developed lower pelvic discomfort and stress incontinence. She has type 2 diabetes and hypertension. She is the mother of four children. A second-degree uterine prolapse is diagnosed. She was treated conservatively with a pessary, but her symptoms did not improve. She comes to the hospital for a vaginal hysterectomy and anteroposterior vaginal repair.

Subjective Data

- Was initially reluctant about surgery
- Concerned about her dyspareunia and her husband's reaction to the surgery
- Concerned she may have uterine cancer
- States that she has stress incontinence and pelvic discomfort

Objective Data

Physical Examination

- Second-degree uterine prolapse on vaginal examination
- Blood pressure (BP) 150/100 mm Hg, pulse 110 beats/min, respirations 20 breaths/min

Laboratory Studies

- Hemoglobin 100 g/L
- Hemoglobin A_{1C} 9%

Postoperative Status

- Returned to room with suprapubic urinary catheter in place
- Vaginal packing in place
- Sequential compression devices on lower extremities
- Patient-controlled analgesia (PCA) pump for pain management

Discussion questions

1. What are the common causes of uterine prolapse?
2. Ms. Pelletier asks about the effect of the surgery on her sexuality. How would the nurse respond?
3. ***Priority decision:*** What are the priorities of care for Ms. Pelletier?
4. What possible complications (including reasons for their development) can arise after vaginal hysterectomy?
5. What does Ms. Pelletier need to be taught before discharge related to her diabetes and hypertension?
6. ***Priority decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. A couple will be undergoing infertility assessment. Which of the following facts should the nurse mention when discussing what the couple should expect during the assessment?
   a. Ovulatory studies can help determine tube patency.
   b. A hystero-salpingogram is a common diagnostic study.
   c. The cause will remain unexplained for 40% of couples.
   d. If postcoital studies are normal, tests for infection will be done.
2. Which of the following is the most appropriate question to ask the client with painful menstruation to differentiate primary from secondary dysmenorrhea?
   a. "Does your pain become worse with activity or overexertion?"
   b. "Have you had a recent personal crisis or change in your lifestyle?"
   c. "Is your pain relieved by nonsteroidal anti-inflammatory medications?"
   d. "When in your menstrual history did the pain with your period begin?"
3. The nurse is caring for a client after an ectopic pregnancy was surgically removed. What should the nurse advise the recovering client?
   a. She has an increased risk for salpingitis.
   b. Bed rest must be maintained for 12 hours to assist healing.
   c. Having one ectopic pregnancy increases her risk for another.
   d. Intrauterine devices and infertility treatments should be avoided.
4. The nurse is teaching a client who chooses not to take hormone therapy how to prevent or decrease age-related changes that occur after menopause. Which of the following is the most important self-care measure that the nurse should teach?

a. Maintaining usual sexual activity
b. Increasing the intake of dairy products
c. Performing regular aerobic, weight-bearing exercise
d. Taking vitamin E and B-complex vitamin supplements

5. The client has a history indicating thick, white, and curdlike vaginal discharge and vulvar pruritus. What are these symptoms most consistent with?
   a. Trichomoniasis
   b. Monilial vaginitis
   c. Bacterial vaginosis
   d. Chlamydial cervicitis
6. Why does the nurse caring for a client with pelvic inflammatory disease place her in a semi-Fowler's position?
   a. To relieve severe pain
   b. To promote drainage to prevent abscesses
   c. To improve circulation and promote healing
   d. To prevent complication of bowel obstruction
7. Which of the following is a nursing responsibility related to the care of the client receiving brachytherapy for endometrial cancer?
   a. Maintaining absolute bed rest
   b. Keeping the client in high Fowler's position
   c. Allowing visitors to stay if they remain 1 m from the bed
   d. Limiting direct nurse-to-client contact to 30 minutes per shift
8. Postoperative goals in caring for the client who has undergone an abdominal hysterectomy include which of the following? *(Select all that apply)*
   a. Monitoring urine output
   b. Changing position frequently
   c. Restricting all food for 24 hours
   d. Observing perineal pad for bleeding
   e. Encouraging leg exercises to promote circulation

9. Which of the following are included in the postoperative nursing care for the woman with a gynecological fistula? *(Select all that apply)*

   a. Ambulation

   b. Bladder training

   c. Warm sitz baths

   d. Perineal hygiene

   e. Use of stool softeners

1. b, 2. d, 3. c, 4. c, 5. b, 6. b, 7. a, 8. a, b, e, 9. c, d.

CHAPTER 57

Nursing Management

Male Reproductive Problems

Written by, Susanne A. Quallich

Adapted by, Shelley L. Cobbett

LEARNING OBJECTIVES

1. Describe the pathophysiology, clinical manifestations, and collaborative care of benign prostatic hyperplasia.
2. Discuss the nursing management of benign prostatic hyperplasia.
3. Describe the pathophysiology, clinical manifestations, and collaborative care of prostate cancer.
4. Explain the nursing management of prostate cancer.
5. Specify the pathophysiology, clinical manifestations, and nursing and collaborative management of prostatitis and problems of the penis and scrotum.
6. Explain the clinical manifestations and collaborative care of testicular cancer.
7. Describe the pathophysiology, clinical manifestations, and nursing and collaborative management of problems related to male sexual function.
8. Summarize the psychological and emotional implications related to male reproductive problems.

KEY TERMS

benign prostatic hyperplasia (BPH), p. 1421

epididymitis, p. 1436

epispadias, p. 1436

erectile dysfunction (ED), p. 1439

hydrocele, p. 1437

hypospadias, p. 1436

orchitis, p. 1437

paraphimosis, p. 1436

phimosis, p. 1436

prostate-specific antigen (PSA), p. 1423

prostatitis, p. 1434

radical prostatectomy, p. 1430

spermatocele, p. 1437

testicular torsion, p. 1438

transurethral resection of the prostate (TURP), p. 1426

varicocele, p. 1437

vasectomy, p. 1439

Problems of the male reproductive system can involve a variety of structures, including the prostate, the penis, the urethra, the ejaculatory duct, the scrotum, the testes, the epididymis, the vas deferens, and the rectum (Figure 57-1).

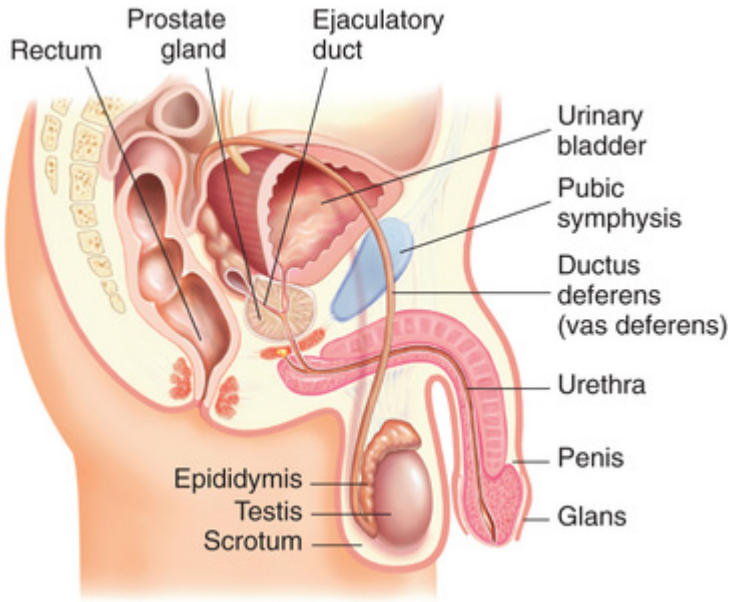

FIGURE 57-1 Areas of the male reproductive system in which problems are likely to develop.

Problems of the Prostate Gland

Benign Prostatic Hyperplasia

Benign prostatic hyperplasia (BPH) is a benign, noninflammatory enlargement of the prostate gland. It is the most common urological problem in male adults (National Institute of Health, 2014). About 50% of all men in their lifetime will develop BPH. Of these men, almost half of them will have bothersome lower urinary tract symptoms (Rosenberg, Witt, Miner, et al., 2014). Research is not clear about whether having BPH leads to an increased risk of developing prostate cancer (Weight, Kim, Jacobson, et al., 2013; Ørsted & Bojesen, 2013).

Etiology and Pathophysiology

Although the cause of BPH is not completely understood, it is thought that BPH results from hormonal changes associated with the aging process (Rosenberg, Witt, Miner, et al., 2014). Possible causes include excessive accumulation of dihydroxytestosterone (DHT) (the principal intraprostatic androgen), stimulation by estrogen, and local growth hormone action.

Typically, BPH develops in the inner part of the prostate. (Prostate cancer is most likely to develop in the outer part.) This enlargement gradually compresses the urethra, eventually leading to partial or complete obstruction (Figure 57-2). The compression of the urethra ultimately leads to the development of clinical symptoms. There is no direct relationship between the size of the prostate and the severity of symptoms or degree of obstruction. The location of the enlargement is most significant in the development of obstructive symptoms (Figure 57-3). For example, it is possible for mild hyperplasia to cause severe obstruction; likewise, it is possible for extreme hyperplasia to cause few obstructive symptoms.

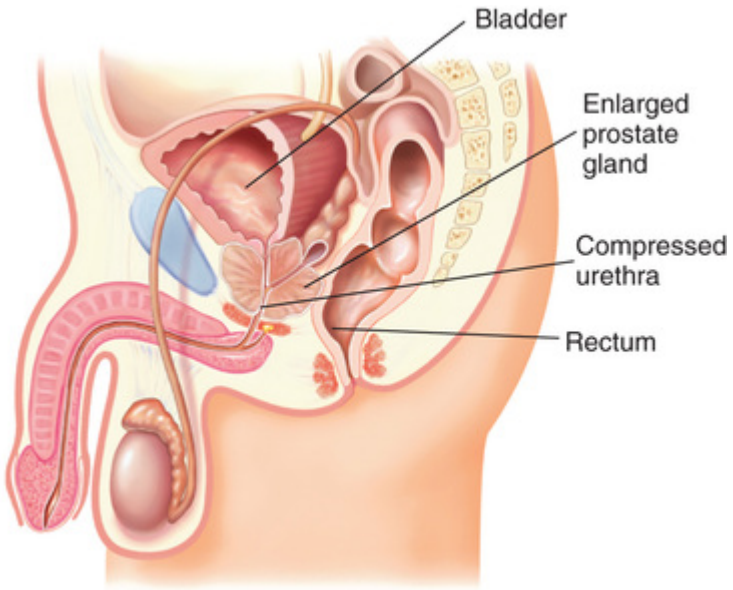

FIGURE 57-2 Benign prostatic hyperplasia. The enlarged prostate compresses the urethra.

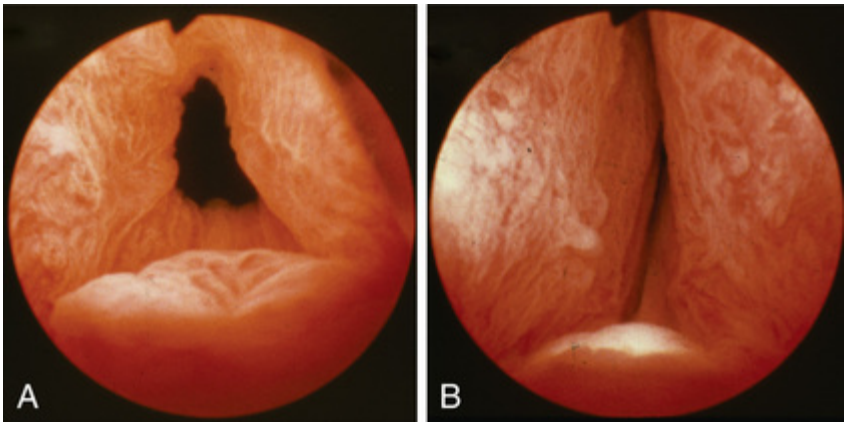

FIGURE 57-3 Views of the prostate by cystoscopy. **A,** Normal appearance. **B,** Moderate benign prostatic hyperplasia with urethral obstruction. Source: Townsend, C. M., Beauchamp, R. D., Evers, B. M., et al. (2012). *Sabiston textbook of surgery* (19th ed.). Philadelphia: Saunders.

Risk factors for BPH include aging, obesity (in particular, large waist circumference), lack of physical activity, smoking, and diabetes (Trumble, Stieglitz, Eid Rodriguez, et al., 2015). A positive family history of BPH in first-degree relatives may also be a risk factor.

Clinical Manifestations

Manifestations of BPH mainly result from urinary obstruction. Symptoms are usually gradual in onset and may not be noticed until prostatic enlargement has been present for some time. Early symptoms are usually minimal because the bladder can compensate for a small amount of resistance to urine flow. The symptoms gradually worsen as the degree of urethral obstruction increases.

Symptoms can be divided into two groups: obstructive and irritative. *Obstructive symptoms* include a decrease in the calibre and force of the urinary stream, difficulty in initiating voiding, intermittency (stopping and starting stream several times while voiding), and dribbling at the end of urination. *Irritative symptoms,* which include urinary frequency, urgency, dysuria, bladder pain, nocturia, and incontinence, are associated with inflammation or infection. Nocturia is often the first symptom that the patient notices. The American Urological Association (AUA) Symptom Index for BPH (Table 57-1) is a widely used tool to assess voiding symptoms associated with obstruction (Barry, Fowler, O'Leary, et al., 1992). Although this tool is not diagnostic, it is useful in determining the degree of symptoms. Higher scores on this tool indicate greater symptom severity.

TABLE 57-1

AMERICAN UROLOGICAL ASSOCIATION SYMPTOM INDEX TO DETERMINE SEVERITY OF PROSTATIC PROBLEMS

American Urological Association (AUA) Symptom Score*						
(Circle one number on each line.)						
Questions to Be Answered	**Not at All**	**Less Than 1 Time in 5**	**Less Than Half the Time**	**About Half the Time**	**More Than Half the Time**	**Almost Always**
Over the past month: 1. How often have you had a sensation of not emptying your bladder completely after you finished urinating?	0	1	2	3	4	5
2. How often have you had to urinate again <2 hr after you finished urinating?	0	1	2	3	4	5
3. How often have you found you stopped and started again several times when you urinated?	0	1	2	3	4	5
4. How often have you found it difficult to postpone urination?	0	1	2	3	4	5
5. How often have you had a weak urinary stream?	0	1	2	3	4	5
6. How often have you had to push or strain to begin urination?	0	1	2	3	4	5
7. How many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	0 (None)	1 (1 time)	2 (2 times)	3 (3 times)	4 (4 times)	5 (≥5 times)
Sum of circled numbers (AUA Symptom Score):* _____						

*Score is interpreted as 0–7, mild; 8–19, moderate; 20–35, severe.

Complications

Complications of urinary obstruction are relatively uncommon in BPH. Acute urinary retention is a complication that is manifested by the sudden and painful inability to urinate. Treatment involves the insertion of a catheter to drain the bladder. Surgery may also be indicated.

Another common complication is urinary tract infection (UTI) and, potentially, sepsis secondary to UTI. Incomplete bladder emptying (associated with partial obstruction) results in residual

urine, providing a favourable environment for bacterial growth. Calculi may develop in the bladder because of the alkalinization of the residual urine. Although bladder stones are more common in men with BPH, the risk for renal calculi is not significantly increased. Additional complications include renal failure caused by *hydronephrosis* (distension of the pelvis and the calyces of the kidney by urine that cannot flow through the ureter to the bladder), pyelonephritis, and bladder damage if treatment for acute urinary retention is delayed.

Diagnostic Studies

The primary methods used to diagnose BPH include a history and physical examination (See Table 57-2). The prostate can be palpated by digital rectal examination (DRE) to estimate its size, symmetry, and consistency. In BPH, the prostate is symmetrically enlarged, firm, and smooth.

TABLE 57-2
COLLABORATIVE CARE
Benign Prostatic Hyperplasia

Diagnostic
• History and physical examination • Digital rectal examination (DRE) • Urinalysis with culture • Serum creatinine • Prostate-specific antigen (PSA) • Postvoid residual • Uroflowmetry • Transrectal ultrasonography (TRUS) • Cysto-urethroscopy
Collaborative Therapy
• Conservative therapy (active surveillance or "watchful waiting")
Drug Therapy
• 5α-Reductase inhibitors • α-Adrenergic receptor blockers • Erectogenic drugs
Invasive Therapy*
• Open prostatectomy • Transurethral incision of the prostate (TUIP) • Transurethral resection of the prostate (TURP)
Minimally Invasive Therapy*
• Intraprostatic urethral stents • Laser prostatectomy • Transurethral electrovaporization of the prostate (TUVP) • Transurethral microwave thermotherapy (TUMT) • Transurethral needle ablation (TUNA)

*See Table 57-3.

Additional diagnostic tests may be indicated, depending on the type and the severity of symptoms and clinical findings. A urinalysis with culture is routinely done to determine the presence of infection. Bacteria, white blood cells, or microscopic hematuria indicate infection or inflammation.

A blood test for **prostate-specific antigen (PSA),** a glycoprotein found only in the epithelial cells of the prostate, may be done to rule out prostate cancer. Elevated PSA levels indicate a pathological condition of the prostate, although not necessarily prostate cancer. PSA levels may be slightly elevated in patients with BPH. Serum creatinine levels may be ordered to rule out renal insufficiency. Because symptoms of BPH are similar to those of a neurogenic bladder, a neurological examination may also be performed.

In patients with an abnormal DRE and elevated PSA, a *transrectal ultrasonography* (TRUS) scan is typically indicated. This examination allows for accurate assessment of prostate size and is helpful in differentiating BPH from prostate cancer. Biopsies can be taken during the ultrasonography procedure. *Uroflowmetry,* a study that measures the volume of urine expelled from the bladder per second, is helpful in determining the extent of urethral blockage and thus the type of treatment needed. Postvoid residual urine volume is often measured to determine the degree of urine flow obstruction. *Cysto-urethroscopy,* a procedure allowing internal visualization of the urethra and the bladder, is performed if the diagnosis is uncertain and in patients scheduled for prostatectomy.

Collaborative Care

The goals of collaborative care are to restore bladder drainage, relieve the patient's symptoms, and prevent or treat the complications of BPH. Treatment is generally based on the degree to which the symptoms bother the patient or the presence of complications rather than the size of the prostate. Alternatives to surgical intervention for some patients now include drug therapy and minimally invasive procedures, for example, holmium laser enucleation (Lingeman, 2011).

The most conservative initial treatment for BPH is referred to as *active surveillance* or *watchful waiting.* When there are no symptoms or only mild ones (AUA symptom scores <7), a wait-and-see approach is taken. Because symptoms may come and go, a conservative approach has value. Dietary changes (decreasing intake of caffeine, artificial sweeteners, and spicy or acidic foods), avoiding medications such as decongestants and anticholinergics, and restricting evening fluid intake may improve symptoms. A timed voiding schedule may reduce or eliminate symptoms, thus negating the need for further intervention. If the patient begins to have signs or symptoms that indicate an increase in obstruction, further treatment is indicated.

Drug Therapy.

Drugs that have been used to treat BPH with variable degrees of success include 5α-reductase inhibitors and α-adrenergic receptor blockers. Combination therapy has been shown to be more effective in reducing symptoms than using one medication alone (Ismaila et al., 2013).

5α-Reductase Inhibitors.

These drugs work by reducing the size of the prostate gland. Finasteride (Proscar) blocks the enzyme 5α-reductase, which is necessary for the conversion of testosterone to DHT, the principal intraprostatic androgen. This medication causes regression of hyperplastic tissue through suppression of androgens. Finasteride is an appropriate treatment option for individuals who score between 12 and 26 on the AUA Symptom Index (see Table 57-1). Although more than 50% of men who are treated with the medication show symptom improvement, it takes about 6 months to be effective, and the medication must be taken on a continuous basis to maintain therapeutic results. Serum PSA levels decrease by almost 50% when taking finasteride. Therefore, PSA levels should be doubled when comparing the patient's current levels to premedication levels.

Dutasteride (Avodart) is a dual inhibitor of 5α-reductase types 1 and 2 isoenzymes. (Finasteride inhibits only the type 2 isoenzyme.) The combination of a 5α-reductase inhibitor (dutasteride) and an α-adrenergic receptor blocker (tamsulosin) is now available in a single oral medication (Jalyn). Adverse effects of 5α-reductase inhibitors include decreased libido, decreased volume of ejaculate, and erectile dysfunction (ED).

Drug Alert

Finasteride (Proscar)

- Patient should be aware of the increased risk for orthostatic hypotension with concomitant use of ED drugs.

- Women who may be or are pregnant should not handle finasteride tablets due to potential risk to male fetus (anomaly).

α-Adrenergic Receptor Blockers.

α-Adrenergic receptor blockers are another drug treatment option for BPH. These agents selectively block α_1-adrenergic receptors, which are abundant in the prostate and are increased in hyperplastic prostate tissue. Although α-adrenergic blockers are more commonly used for treatment of hypertension, these drugs promote smooth muscle relaxation in the prostate, facilitating urinary flow through the urethra. These agents demonstrate a 50% to 60% efficacy in improvement of symptoms, which occurs within 2 to 3 weeks.

Several α-adrenergic blockers, including silodosin (Rapaflo), alfuzosin (Xatral), prazosin, doxazosin (Cardura), terazosin, and tamsulosin, are currently being used. Adverse effects include postural hypotension, dizziness, fatigue, retrograde ejaculation, and nasal congestion. It must be pointed out that, although these drugs offer symptomatic relief of BPH, they do not treat hyperplasia.

Erectogenic Drugs.

Tadalafil (Cialis) has been used in men who have symptoms of BPH alone or in combination with ED. The drug has shown effectiveness in reducing symptoms for both these conditions (Roehrborn, Casabé, Glina, et al., 2015) (see "Erectile Dysfunction" later in this chapter).

Herbal Therapy.

Herbal extracts have been used in the management of lower urinary symptoms associated with BPH. In particular, some patients take plant extracts such as saw palmetto (*Serenoa repens*). However, research indicates that saw palmetto has no benefit over a placebo (Barry, Cantor, Roehrborn, et al., 2013; Andriole, McCullum-Hill, Sandhu, et al., 2013). ProstateEZE Max, an oral herbal preparation containing *Cucurbita pepo*, *Epilobium parviflorum*, lycopene, *Pygeum africanum*, and *Serenoa repens*, is being considered in the management of symptoms of BPH (see the Complementary & Alternative Therapies box on ProstateEZE Max).

Complementary & Alternative Therapies

ProstateEZE Max

Clinical Uses

Benign prostatic hyperplasia (BPH); physical symptoms of BPH

Effects

Appears to have a significant positive effect on the physical symptoms of BPH including a decrease in urinary frequency, urgency, dysuria, and nocturia.

Nursing Implications

Generally well tolerated. No adverse reactions were reported in this trial. No known drug interactions. Patient should be advised to consult a physician for the correct diagnosis of BPH.

Source: Coulson, S., Rao, A., Beck, S., et al. (2013). A phase II randomised double-blind placebo-controlled clinical trial investigating the efficacy and safety of ProstateEZE Max: A herbal medicine preparation for the management of symptoms of benign prostatic hypertrophy. *Complementary Therapies in Medicine, 21*(3), 172–179. doi:10.1016/j.ctim.2013.01.007

Minimally Invasive Therapy.

Minimally invasive therapies are becoming more common as an alternative to watchful waiting and invasive treatment (Table 57-3). They generally do not require hospitalization or catheterization and are associated with few adverse events.

TABLE 57-3
TREATMENT FOR BENIGN PROSTATIC HYPERPLASIA

Description	Advantages	Disadvantages
Minimally Invasive		
Transurethral Microwave Thermotherapy (TUMT)		
Use of microwave radiating heat to produce coagulative necrosis of the prostate	Outpatient procedure Erectile dysfunction, urinary incontinence, and retrograde ejaculation are rare	Potential for damage to surrounding tissue Urinary catheter needed after procedure
Transurethral Needle Ablation (TUNA)		
Low-wave radiofrequency used to heat the prostate, causing necrosis	Outpatient procedure Erectile dysfunction, urinary incontinence, and retrograde ejaculation are rare Precise delivery of heat to desired area Very little pain experienced	Urinary retention common Irritative voiding symptoms Hematuria
Laser Prostatectomy		
Use of a laser beam to cut or destroy part of the prostate Techniques available: • Visual laser ablation of prostate (VLAP) • Contact laser • Photovaporization of prostate (PVP) • Interstitial laser coagulation (ILC)	Short procedure Comparable results to TURP Minimal bleeding Fast recovery time Rapid symptom improvement Very effective	Catheter (up to 7 days) needed after procedure due to edema and urinary retention Delayed sloughing of tissue Takes several weeks to reach optimal effect Retrograde ejaculation
Transurethral Electrovaporization of Prostate (TUVP)		
Electrosurgical vaporization and desiccation used together to destroy prostatic tissue	Minimal risks Minimal bleeding and sloughing	Retrograde ejaculation Intermittent hematuria
Intraprostatic Urethral Stents		
Insertion of self-expandable metallic stent into the urethra, where enlarged area of prostate occurs	Safe and effective Low risk	Stent may move Long-term effect unknown
Invasive (Surgery)		
Transurethral Resection of Prostate (TURP)		
Use of excision and cauterization to remove prostate tissue cystoscopically Remains the standard for treatment of BPH	Erectile dysfunction unlikely	Bleeding Retrograde ejaculation
Transurethral Incision of Prostate (TUIP)		
Involves transurethral incisions into prostatic tissue to relieve obstruction Effective for men with small to moderate prostates	Outpatient procedure Minimal complications Low occurrence of erectile dysfunction or retrograde ejaculation	Urinary catheter needed after procedure
Open Prostatectomy		

Description	Advantages	Disadvantages
Surgery of choice for men with large prostates, bladder damage, or other complicating factors Involves external incision with two possible approaches (see Figure 57-6)	Complete visualization of prostate and surrounding tissue	Erectile dysfunction Bleeding Postoperative pain Risk for infection

Transurethral Microwave Thermotherapy.

Transurethral microwave thermotherapy (TUMT) is an outpatient procedure that involves the delivery of microwaves directly to the prostate through a transurethral probe to raise the temperature of the prostate tissue to about 45°C. The heat causes death of tissue, thus relieving the obstruction. A rectal temperature probe is used during the procedure to ensure that the temperature is kept below 43.5°C to prevent rectal tissue damage. The procedure takes about 90 minutes.

Postoperative urinary retention is a common complication. Thus the patient is generally sent home with an in-dwelling catheter for 2 to 7 days to maintain urinary flow and to facilitate the passing of small clots or necrotic tissue. Antibiotics, pain medication, and bladder antispasmodic medications are used to treat and prevent postprocedure problems. The procedure is not appropriate for men with rectal problems. Anticoagulant therapy should be stopped 10 days before treatment. Mild adverse effects include occasional problems of bladder spasm, hematuria, dysuria, and retention.

Transurethral Needle Ablation.

Transurethral needle ablation (TUNA) is another procedure that increases the temperature of prostate tissue, causing localized necrosis. TUNA differs from TUMT in that low-wave radiofrequency is used to heat the prostate. Only prostate tissue in direct contact with the needle is affected, thus allowing greater precision in removal of the target tissue. The extent of tissue removed by this process is determined by the amount of tissue contact (needle length), amount of energy delivered, and duration of treatment. The majority of the patients undergoing TUNA have an improvement in symptoms.

This procedure is performed in an outpatient unit or physician's office using local anaesthesia and IV or oral sedation. The TUNA procedure lasts approximately 30 minutes. The patient typically experiences little pain with an early return to regular activities. Complications include urinary retention, UTI, and irritative voiding symptoms (e.g., frequency, urgency, dysuria). Some patients require a urinary catheter for a short time. Patients often have hematuria for up to a week.

Laser Prostatectomy.

The use of laser therapy through visual or ultrasound guidance is an effective alternative to transurethral resection of the prostate (TURP) in treating BPH. The laser beam is delivered transurethrally through a fibre instrument and is used for cutting, coagulation, and vaporization of prostatic tissue. There are a variety of laser procedures using different sources, wavelengths, and delivery systems. Retreatment rates are comparable to those of a TURP (Chughtai, Simma-Chiang, Lee, et al., 2015).

One common procedure is *visual laser ablation of the prostate* (VLAP), which uses the laser beam to produce deep coagulation necrosis. The affected prostate tissue gradually sloughs in the urinary stream. It takes several weeks before the patient reaches optimal results after this type of laser therapy. At the completion of VLAP, a urinary catheter is inserted to allow for drainage.

Contact laser techniques involve the direct contact of the laser with the prostate tissue, producing an immediate vaporization of the tissue. Blood vessels near the laser tip are immediately cauterized. Thus bleeding during the procedure is rare. A three-way catheter with slow-drip irrigation is placed immediately after the procedure for a short time. Typically, the catheter is removed within 6 to 8 hours after the procedure. Advantages of this procedure over TURP include minimal bleeding both during and after the procedure, faster recovery time, and ability to perform the surgery on patients taking anticoagulants.

Photovaporization of the prostate (PVP) uses a high-powered green laser light to vaporize prostate tissue. Improvements in urine flow and symptoms are almost immediate after the procedure. Bleeding is

minimal, and a catheter is usually inserted for 24 to 48 hours afterward. PVP works well for larger prostate glands.

Another approach to laser prostatectomy is *interstitial laser coagulation* (ILC). The prostate is viewed through a cystoscope. A laser is used to treat precise areas of the enlarged prostate quickly by placement of interstitial light guides directly into the prostate tissue.

Intraprostatic Urethral Stents.

Symptoms from obstruction in patients who are poor surgical candidates can be relieved with intraprostatic urethral stents. The stents are placed directly into the prostatic tissue. Complications include chronic pain, infection, and encrustation. The long-term effects are not known.

Invasive Therapy (Surgery).

Invasive treatment of symptomatic BPH involves surgery. The choice of the treatment approach depends on the size and location of the prostatic enlargement and patient factors such as age and surgical risk. Invasive treatments are summarized in Table 57-3.

Invasive therapy is indicated when the decrease in urine flow is sufficient to cause discomfort, persistent residual urine, acute urinary retention because of obstruction with no reversible precipitating cause, or hydronephrosis. Intermittent catheterization or insertion of an in-dwelling catheter can temporarily reduce symptoms and bypass the obstruction. However, long-term catheter use should be avoided because of the increased risk for infection.

Transurethral Resection of the Prostate.

Transurethral resection of the prostate (TURP) is a surgical procedure involving the removal of prostate tissue using a resectoscope inserted through the urethra. TURP has long been considered the "gold standard" surgical treatment for obstructing BPH. Although it remains the most common operation performed, there has been a decrease in the number of TURP procedures in recent years owing to the development of less invasive technologies (Herrmann, Liatsikos, Nagele, et al., 2012).

TURP is performed under a spinal or general anaesthetic. No external surgical incision is made. Instead, a resectoscope is inserted through the urethra to excise and cauterize obstructing prostatic tissue (Figure 57-4). A large three-way in-dwelling catheter with a 30-mL balloon is inserted into the bladder after the procedure to provide hemostasis and to facilitate urinary drainage. Usually for the first 24 hours, the bladder is irrigated, either continuously or intermittently, to prevent obstruction from mucus and blood clots.

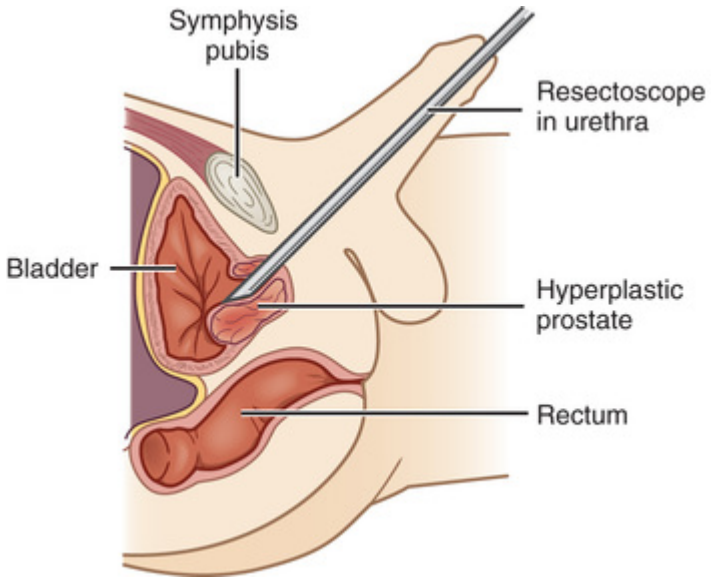

FIGURE 57-4 Transurethral resection of the prostate.

The outcome for 80% to 90% of patients is excellent, with marked improvements in symptoms and urinary flow rates. TURP is a surgical procedure with relatively low risk. Postoperative complications include bleeding, clot retention, bladder spasms, and dilutional hyponatremia associated with irrigation. Because bleeding is a common complication, patients taking acetylsalicylic acid (ASA; Aspirin) or warfarin (Coumadin) or other anticoagulants must discontinue these medications several days before surgery.

Transurethral Incision of the Prostate.

Transurethral incision of the prostate (TUIP) is a surgical procedure that is indicated for men with moderate to severe symptoms and

small prostates who are poor surgical candidates. It is done under local anaesthesia and is as effective as TURP in symptom relief.

Prostatectomy.

Prostatectomy is the surgery of choice for large prostates and is discussed later in this chapter.

Nursing Management Benign Prostatic Hyperplasia

Because the nurse is most directly involved in the care of patients with BPH who are having invasive procedures, the focus of nursing management in this section is on preoperative and postoperative care.

Nursing Assessment

Subjective and objective data that should be obtained from a patient with BPH are presented in Table 57-4.

TABLE 57-4

NURSING ASSESSMENT
Benign Prostatic Hyperplasia

Subjective Data
Important Health Information
Past health history: Family history of BPH; obesity; diet high in fat or zinc *Medications:* Estrogen or testosterone supplementation *Surgeries or other treatments:* Previous treatment for BPH
Symptoms
• Voluntary fluid restriction; urinary urgency; urinary dysuria; diminution in calibre and force of urinary stream; hesitancy in initiating voiding; postvoiding dribbling; urinary retention; incontinence; nocturia; bladder discomfort; anxiety about sexual functioning
Objective Data
General
Older-adult male
Urinary
Distended bladder on palpation; smooth, firm, elastic enlargement of prostate on rectal examination
Possible Findings
Enlarged prostate on ultrasonography; vesicle neck obstruction on cysto-urethroscopy; residual urine with postvoiding catheterization; presence of WBCs, bacteria, or microscopic hematuria with infection; ↑ serum creatinine levels with renal involvement

BPH, benign prostatic hyperplasia; *WBCs*, white blood cells.

Nursing Diagnoses

Nursing diagnoses for a patient with BPH preoperatively may include but are not limited to the following:

- *Acute pain* related to *biological injury agent* (bladder distention secondary to enlarged prostate)
- *Risk for infection* as evidenced by *insufficient knowledge to avoid pathogens, stasis of body fluid* (indwelling catheter, urinary stasis)

Nursing diagnoses for a patient with BPH who has invasive therapy (surgery) are presented in Nursing Care Plan (NCP) 57-1, available on the Evolve website.

Planning

The overall preoperative goals for patients having invasive procedures are (a) restoration of urinary drainage; (b) treatment of any UTI; and (c) an understanding of the upcoming procedure, the implications for sexual functioning, and urinary control. The overall postoperative goals are (a) no complications, (b) restoration of urinary control, (c) complete bladder emptying, and (d) the ability for satisfying sexual expression.

Nursing Implementation

Health Promotion.

The cause of BPH is largely attributed to the aging process. Health promotion focuses on early detection and treatment. The Canadian Task Force on Preventive Health Care (Bell, Connor Gorber, Shane, et al., 2014) recommends that men not be screened for prostate cancer with the PSA test, because available evidence does not support PSA screening as a means of reducing prostate cancer, and it clearly shows an increased risk for harm (e.g., bleeding, infection, incontinence, a false-positive result and the possibility of

overdiagnosis). Some men may be interested in PSA screening despite the advice of their health care provider about their personal risk of developing prostate cancer and the benefits and risks of having a PSA test. PSA is indicated as a surveillance test for men with prostate cancer. The Canadian Cancer Society (2017a) recommends a yearly medical history and DRE for men over 50 years of age in an effort to detect prostate problems early. When symptoms of prostatic hyperplasia become evident, further diagnostic screening may be necessary (see Table 57-2).

Some men find that the ingestion of alcohol and caffeine increases prostatic symptoms because the diuretic effect of these substances increases bladder distension. Compounds found in common cough and cold remedies such as pseudoephedrine (e.g., Sudafed) and phenylephrine (e.g., Dimetapp) often worsen the symptoms of BPH. These drugs are α-adrenergic agonists that cause smooth muscle contraction.

Patients with obstructive symptoms should be advised to urinate every 2 to 3 hours and when first feeling the urge. Doing so will minimize urinary stasis and acute urinary retention. Fluid intake should be maintained at a normal level to prevent dehydration or fluid overload. The patient may believe that, if he restricts his fluid intake, symptoms will be less severe, but this only increases the chances of an infection. However, if the patient increases his intake too rapidly, bladder distension can develop because of the prostatic obstruction.

Acute Intervention.

The following discussion focuses on preoperative and postoperative care for the patient undergoing a TURP.

Preoperative Care.

Urinary drainage must be restored before surgery. Prostatic obstruction may result in acute retention or inability to void. A urethral catheter such as a coudé (curved-tip) catheter may be needed to restore drainage. In many health care settings, 10 mL of sterile 2% lidocaine gel is injected into the urethra before insertion of

the catheter. The lidocaine gel not only acts as a lubricant but also provides local anaesthesia and helps open the urethral lumen. If a sizable obstruction of the urethra exists, the urologist may insert a filiform catheter with sufficient rigidity to pass the obstruction. Aseptic technique is important at all times to avoid introducing bacteria into the bladder. (Urinary catheters are discussed in Chapter 48.)

Antibiotics are usually administered before any invasive procedure. Any infection of the urinary tract must be treated before surgery. Restoring urine drainage and encouraging a high fluid intake (2 to 3 L/day unless contraindicated) are also helpful in managing the infection.

Patients are often concerned about the impact of the impending surgery on sexual functioning. Patients and their partners should be provided an opportunity to express their concerns. They should be informed that surgery may affect sexual function and that most types of prostatic surgery result in some degree of retrograde ejaculation. The patient should know that the amount of ejaculate may decrease or be totally absent. As a result, orgasmic sensations felt during ejaculation may decrease. Retrograde ejaculation is not harmful because the semen is eliminated during the next urination.

Postoperative Care.

The main complications following surgery are hemorrhage, bladder spasms, urinary incontinence, and infection. The plan of care should be adjusted to the type of surgery, the reasons for surgery, and the patient's response to surgery.

After surgery, the patient will have a standard catheter or a triple-lumen catheter. Bladder irrigation is typically done to remove clotted blood from the bladder and to ensure drainage of urine. The bladder is irrigated either manually on an intermittent basis or, more commonly, as continuous bladder irrigation (CBI) with sterile normal saline solution or another prescribed solution. If manual irrigation of the bladder is ordered, instill 50 mL of irrigating solution (commonly normal saline) and then withdraw with a syringe to remove clots that may be in the bladder and catheter. Painful bladder spasms often occur as a result of manual irrigation.

With CBI, irrigating solution is continuously infused and drained from the bladder. The rate of infusion is based on the colour of drainage. Ideally, the urine drainage should be light pink without clots. The inflow and outflow of irrigant must be continuously monitored. If outflow is less than inflow, the bladder should be assessed immediately and the catheter patency checked. If the outflow is blocked and patency cannot be re-established by manual irrigation, the CBI must be stopped and the health care provider notified.

Careful aseptic technique is essential when irrigating the bladder because bacteria can easily be introduced into the urinary tract. Proper care of the catheter is also important. To prevent urethral irritation and minimize the risk for bladder infection, the nurse should secure the catheter to the leg with tape or a catheter strap. The catheter should be connected to a closed drainage system and should not be disconnected unless it is being removed, changed, or irrigated. The secretions that accumulate around the meatus can be cleansed daily with soap and water.

Blood clots are expected for the first 24 to 36 hours after prostate surgery. However, large amounts of bright-red blood in the urine can indicate hemorrhage. Postoperative hemorrhage may occur from displacement of the catheter, dislodgement of a large clot, or increases in abdominal pressure. Release or displacement of the catheter dislodges the balloon that provides counter-pressure on the operative site. Traction on the catheter may be applied to provide counter-pressure (tamponade) on the bleeding site in the prostate, thereby decreasing bleeding. Such traction can result in local necrosis if pressure is applied for too long. Therefore, pressure should be relieved on a scheduled basis by qualified personnel. Activities that increase abdominal pressure, such as sitting or walking for prolonged periods and straining to have a bowel movement (Valsalva manoeuvre), should be avoided in the postoperative recovery period.

Bladder spasms are a distressing complication for patients after transurethral procedures. They occur as a result of irritation of the bladder mucosa from the insertion of the resectoscope, presence of a catheter, or clots leading to obstruction of the catheter. Patients

should be instructed not to urinate around the catheter because it increases the likelihood of spasm. If bladder spasms develop, the catheter should be checked for clots. Any clots discovered should be removed by irrigation so that urine can flow freely. Antispasmodics (e.g., belladonna and opium suppositories, oxybutynin [Oxytrol]), along with relaxation techniques, are used to relieve the pain and decrease spasm. The catheter is often removed 2 to 4 days after surgery. The patient should urinate within 6 hours after catheter removal. If he cannot, a catheter is reinserted for a day or two. If the problem continues, the nurse may need to instruct the patient in clean intermittent self-catheterization (see Chapter 48).

Sphincter tone may be poor immediately after catheter removal, resulting in urinary incontinence or dribbling. This is a common but distressing situation for patients. Sphincter tone can be strengthened with Kegel exercises (pelvic floor muscle technique) practised 10 to 20 times per hour while awake (see Table 48-19 in Chapter 48). Patients should be encouraged to practise starting and stopping the stream several times during urination. This facilitates learning of the pelvic floor exercises. It usually takes several weeks to achieve urinary continence. In some instances, control of urine may never be fully regained. Continence can improve for up to 12 months. If continence has not been achieved by that time, patients may be referred to a continence clinic. A variety of methods, including biofeedback, have been used to achieve positive results. Patients can also be instructed to use a penile clamp, condom catheter, or incontinence pads or briefs to avoid embarrassment from dribbling. In severe cases, an occlusive cuff that serves as an artificial sphincter can be surgically implanted to restore continence. The nurse should assist the patient in finding ways to manage the problem that will allow him to continue socializing and interacting with others.

Patients should be observed for signs of postoperative infection. If an external wound is present (from an open prostatectomy), the nurse should assess the area for redness, heat, swelling, and purulent drainage. Special care must be taken if a perineal incision is present because of the proximity of the anus. Rectal procedures, such as taking rectal temperatures and administering enemas,

should be avoided. The insertion of well-lubricated belladonna and opium suppositories is acceptable.

Dietary intervention and stool softeners are important in the postoperative period to prevent patients from straining while having bowel movements. Straining increases the intra-abdominal pressure, which can lead to bleeding at the operative site. Adequate fluid intake and a diet high in fibre facilitate the passage of stool.

Ambulatory and Home Care.

Discharge planning and home care issues are important aspects of care after prostate surgery. Instructions patients will need include those for (a) caring for an in-dwelling catheter (if one is left in place); (b) managing urinary incontinence; (c) maintaining oral fluids between 2 000 and 3 000 mL/day; (d) observing for signs and symptoms of UTI and wound infection; (e) preventing constipation; (f) avoiding heavy lifting (>4.5 kg); and (g) refraining from driving or having intercourse after surgery as directed by the physician.

Patients may experience a change in sexual functioning following surgery, for example, retrograde ejaculation or physiological ED (if the nerves are cut or damaged during surgery). Patients may experience anxiety over the change because of a perceived loss of sex role, lower self-esteem, or perceived decrease in the quality of sexual interaction with a partner. The nurse should discuss these changes with the patient and his partner and allow them to ask questions and express their concerns. Sexual counselling and treatment options may be necessary if ED becomes a chronic or permanent problem. (ED is discussed later in this chapter.) Although some patients experience concerns regarding change in sexual functioning, this is not a universal concern. It may take up to 1 year for complete sexual functioning to return.

The bladder may take up to 2 months to return to its normal capacity. Patients should be instructed to drink at least 2 to 3 L of fluid per day and to urinate every 2 to 3 hours to flush the urinary tract. The nurse should also teach the patient to avoid or limit the intake of bladder irritants such as caffeine products, citrus juices, and alcohol. Because the patient may be experiencing incontinence

or dribbling, he may incorrectly believe that decreasing fluid intake will relieve this problem. Urethral strictures may result from instrumentation or catheterization. Treatment may include intermittent clean self-catheterization (which will need to be taught to the patient) or a urethral dilation.

Patients who have had any procedure other than complete removal of the prostrate will need to continue having yearly DREs because hyperplasia or cancer can occur in the remaining prostatic tissue.

Evaluation

Expected outcomes for a patient with BPH are presented in NCP 57-1, available on the Evolve website.

Prostate Cancer

Prostate cancer is a malignant tumour of the prostate gland. In 2017, it was estimated that 21 300 new cases of prostate cancer would be diagnosed in Canada that year and that 4 100 men would die of it (Canadian Cancer Society's Advisory Committee on Cancer Statistics, 2017), meaning that, on average, 59 Canadians are diagnosed with prostate cancer each day and 11 men die from it. Prostate cancer is the most common cancer among men, excluding skin cancer. The majority (>75%) of cases occur in men older than age 65. However, many cases occur in younger men, who sometimes have a more aggressive type of cancer.

There were peaks in the incidence of newly diagnosed cases of prostate cancer in 1993 and 2001. These peaks were followed by a decline. These increases were attributed to the widespread use of PSA as a screening procedure and were in fact linked to two waves of intense screening. The age-standardized incidence rate has been in decline since 2001 (1.6% per year) (Canadian Cancer Society's Advisory Committee on Cancer Statistics, 2017).

Etiology and Pathophysiology

Prostate cancer is an androgen-dependent adenocarcinoma that is usually slow growing. It can spread by three routes: (a) through direct extension, (b) through the lymph system, or (c) through the bloodstream. Spread by direct extension involves the seminal vesicles, the urethral mucosa, the bladder wall, and the external sphincter. The cancer later spreads through the lymphatic system to the regional lymph nodes. The veins from the prostate seem to be the mode of spread to the pelvic bones, the head of the femur, the lower lumbar spine, the liver, and the lungs.

Age, ethnicity, and family history are three nonmodifiable risk factors for prostate cancer. The incidence of prostate cancer rises markedly after age 50 with a median age at diagnosis of 67 years old (Siegel, DeSantis, Virgo, et al., 2012). Men of Asian ancestry have lower rates of prostate cancer, while men of African ancestry have a higher risk of developing prostate cancer (Canadian Cancer Society, 2017b). See the "Determinants of Health" box for other risk factors. Research suggests that consumption of tomatoes and tomato-based products may protect patients against prostate cancer (Zu, Mucci, Rosner, et al., 2014).

Clinical Manifestations and Complications

Prostate cancer is usually asymptomatic in the early stages. Eventually, the patient may have symptoms similar to those of BPH, including dysuria, hesitancy, dribbling, frequency, urgency, hematuria, nocturia, retention, interruption of urinary stream, and inability to urinate. Pain in the lumbosacral area that radiates down to the hips or the legs, when coupled with urinary symptoms, may indicate metastasis.

Early recognition and treatment are required to control growth, prevent metastasis, and preserve quality of life. The tumour can spread to pelvic lymph nodes, bones, bladder, lungs, and liver. Once the tumour has spread to distant sites, the major problem becomes the management of pain. As the cancer spreads to the bones (a common site of metastasis), pain can become severe, especially in the back and the legs because of compression of the spinal cord and destruction of bone (Figure 57-5).

Determinants of Health

Prostate Cancer

Biology, Genetic Endowment, and Culture

- Canadian men of African descent have the highest rates of prostate cancer, while Canadians of Asian descent have the lowest rates.
- Men of African descent are diagnosed at a younger age, have more aggressive tumours, and are diagnosed at a more advanced stage than White men.

- Prostate cancer is one of the most commonly occurring cancers in First Nations men.*
- There is a genetic link to the development of prostate cancer, especially if a first-degree relative has a history of the disease.
- The *BRCA2* gene, which is linked with breast cancer, is also linked with prostate cancer.
- Long-term exposure to high levels of testosterone DHT may increase the risk for prostate cancer.

Personal Health Practices and Coping Skills

- Eating a diet high in fat increases the risk for prostate cancer.
- Consuming large amounts of dairy products increases the risk, as calcium is linked to prostate cancer.
- Consuming red meat (e.g., beef, pork) cooked at high temperatures and processed meat (e.g., bacon, hot dogs) increases the risk for prostate cancer.
- Being overweight or obese is linked to being diagnosed with advanced or aggressive prostate cancer.

Physical Environment; Employment/Working Conditions

- Occupational exposure to chemical carcinogens such as insecticides, cadmium, or rubber manufacturing is linked to prostate cancer.

Diagnostic Studies

The primary screening tool for prostate cancer is a digital rectal examination (DRE). On DRE, an abnormal prostate may feel hard, nodular, and asymmetrical. The DRE, however, is not a definitive diagnostic test for prostate cancer. If the DRE is abnormal, biopsy of the prostate tissue is indicated and necessary to confirm the diagnosis of prostate cancer. The biopsy is typically done using TRUS because it allows the physician to visualize the prostate and pinpoint abnormalities. When a suspicious area is located, a biopsy needle is inserted into the prostate to obtain a tissue sample. A pathological examination of the specimen is done to assess for malignant changes.

The PSA test is no longer recommended as the risks may outweigh the benefits (Bell, Connor Gorber, Shane, et al., 2014). Although specific recommendations regarding PSA screening vary, there is general agreement that men should talk to their health care provider about their personal risk of developing prostate cancer and the potential risks (e.g., subsequent evaluation and treatment that may be unnecessary) and benefits (early detection of prostate cancer) of PSA screening before being tested.

PSA is, however, used to monitor the success of treatment. When treatment for prostate cancer has been successful, PSA levels should fall to undetectable levels. Regular measurement of PSA levels following treatment is important to evaluate the continuing

effectiveness of treatment and the possible recurrence of prostate cancer.

Elevated levels of prostatic isoenzyme of serum acid phosphatase (prostatic acid phosphatase [PAP]) is an indicator of prostate cancer, especially if there is extracapsular spread. In advanced prostate cancer, serum alkaline phosphatase is increased as a result of bone metastasis.

A recent development in the diagnosis of prostate cancer is the discovery of the gene—*Prostate Cancer Associated 3* (non–protein coding) (*PCA3*)—that is specific to prostate cancer cells and, if present in the urine, indicates prostate cancer. The *PCA3* test is more accurate than the PSA test because benign enlargement of the prostate will not cause an increase in *PCA3*, whereas it can cause an increase in the PSA test. The *PCA3* test offers a potential solution to the clinical diagnostic challenge posed by the PSA test.

Once a diagnosis of prostate cancer is confirmed, other tests used to determine the location and the extent of the spread of the cancer may include bone scan, computed tomography (CT), and magnetic resonance imaging (MRI) using an endorectal probe.

Collaborative Care

Early-stage prostate cancer is a curable disease in most men. The prostate cancer is staged and graded based on findings from diagnostic studies. Two common classification systems for staging prostate cancer, the Whitmore–Jewett and tumour–nodes–metastasis (TNM) systems, are both based on the size (volume) of the tumour and spread (Table 57-5). Both classification systems are used in Canada, with description and treatment based upon the Whitmore–Jewett classification (i.e., stage A, B, C, or D) and description of the extent of the cancer based upon the TNM system. Approximately 80% of patients with prostate cancer are initially diagnosed when the cancer is in either a local or a regional stage. The lifetime probability of a man developing prostate cancer in Canada is 1 in 7 (Canadian Cancer Society's Advisory Committee on Cancer Statistics, 2017).

TABLE 57-5

WHITMORE–JEWETT STAGING CLASSIFICATION OF PROSTATE CANCER

Stage A: Clinically Unrecognized	
A_1	<5% of prostatic tissue neoplastic
A_2	>5% of prostatic tissue neoplastic, all high-grade tumours
Stage B: Clinically Intracapsular	
B_1	Nodule <2 cm and surrounded by palpably normal tissue
B_2	Nodule >2 cm or multiple nodules
Stage C: Clinically Extracapsular	
C_1	Minimal extracapsular extension
C_2	Large tumours involving seminal vesicles, adjacent structures, or both
Stage D: Metastatic Disease	
D_1	Pelvic lymph node metastases or ureteral obstruction causing hydronephrosis
D_2	Distant metastases to bone, viscera, or other soft tissue structures

Grading of the tumour is done based on tumour histology using the Gleason scale. With this scale, tumours are graded from 1 to 5 based on the degree of glandular differentiation. Grade 1 represents the most well differentiated (most like the original cells), and grade 5 represents the most poorly differentiated (undifferentiated). Gleason grades are given to the two most commonly occurring patterns of cells and added together. The Gleason score is a number from 2 to 10. This scale is used to predict how quickly the cancer will progress.

The collaborative care of the patient with prostate cancer depends on the stage of the cancer and the overall health of the patient. At all stages, there is more than one possible treatment option. The decision of which treatment course to pursue is made jointly by the patient and the health care team based on a careful analysis of the facts and the patient's preference (Canadian Cancer Society, 2017b). Table 57-6 summarizes the various treatment options available.

TABLE 57-6
COLLABORATIVE CARE
Prostate Cancer

Diagnostic
• History and physical examination • Digital rectal examination • Prostatic acid phosphatase • Transrectal ultrasonography • Biopsy of prostate and lymph nodes • CT scan, MRI, bone scan (to evaluate for metastatic disease)
Collaborative Therapy
Active Surveillance
• Watchful waiting with annual physical exam including DRE
Surgery
• Radical prostatectomy • Cryotherapy • Orchiectomy (for metastatic disease)
Radiation Therapy
• External beam for primary, adjuvant, and recurrent disease • Brachytherapy
Drug Therapy
• Androgen deprivation therapy • Chemotherapy for metastatic disease

CT, computed tomography; *MRI,* magnetic resonance imaging.

Conservative Therapy.

Prostate cancer is relatively slow growing, and an active surveillance approach to the management of prostate cancer is indicated. This strategy is appropriate when the patient has (a) a life expectancy of less than 10 years (low risk of dying of the disease), (b) serious coexisting medical conditions, and (c) a low-grade, low-stage tumour. These patients are typically followed with frequent PSA measurements, along with DRE, to monitor the progress of the disease. A significant change in either PSA or DRE or the development of symptoms warrants a re-evaluation of treatment options.

Surgical Therapy

Radical Prostatectomy.

With **radical prostatectomy,** the entire prostate gland, the seminal vesicles, and part of the bladder neck (ampulla) are surgically removed. The entire prostate is removed because the cancer tends to be in many different locations within the gland. In addition, a retroperitoneal lymph node dissection is usually done as a separate procedure. Surgery is usually not considered an option for advanced stage disease (except to relieve symptoms associated with obstruction) because metastasis has already occurred. The two most common approaches for radical prostatectomy are retropubic and perineal resection (Figure 57-6). With the *retropubic* approach, a low midline abdominal incision is made to access the prostate gland, and the pelvic lymph nodes then can be dissected. With the *perineal* resection, an incision is made between the scrotum and the anus.

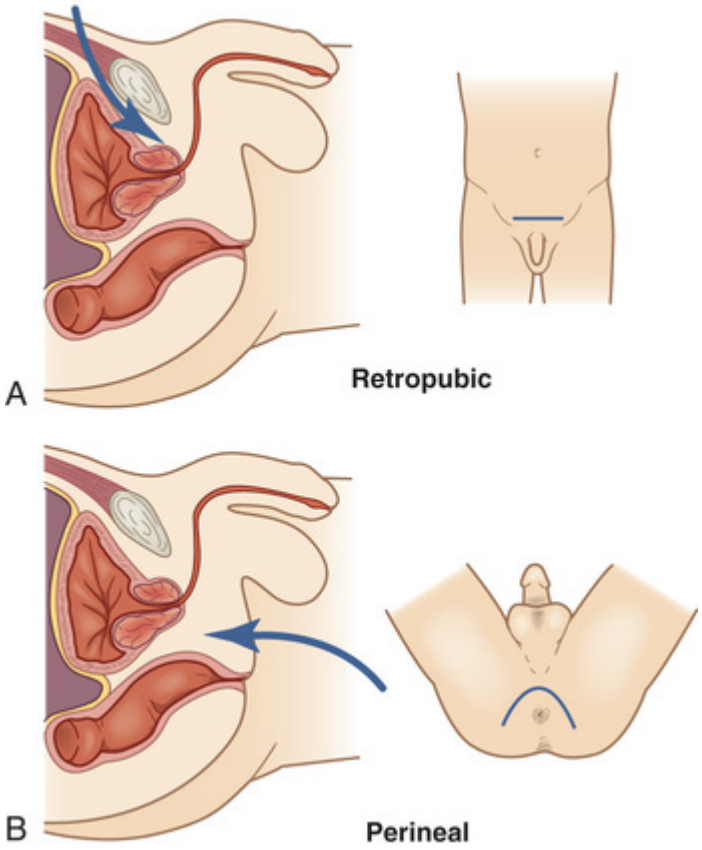

FIGURE 57-6 Common approaches used to perform a prostatectomy. **A,** Retropubic approach involves a midline abdominal incision. **B,** Perineal approach involves an incision between the scrotum and the anus.

A *laparoscopic* approach to prostatectomy is being used in some settings. In this method, four small incisions are made into the abdomen. It results in less bleeding, less pain, and a faster recovery compared with other approaches.

A *robotic-assisted* (e.g., da Vinci system) prostatectomy is a type of laparoscopy in which the surgeon sits at a computer console while controlling high-resolution cameras and microsurgical instruments. Robotics is being used more, since it allows for increased precision, visualization, and dexterity by the surgeon when removing the prostate gland. Compared with traditional approaches, robotic-assisted radical prostatectomy has resulted in similar surgical outcomes with improved recovery time (Trinh, Sammon, Sun, et al., 2012).

After surgery, the patient has a large in-dwelling catheter with a 30-mL balloon placed in the bladder via the urethra. This catheter is typically left in place for 1 to 2 weeks. A drain is left in the surgical site to aid in the removal of drainage from the area. This drain is typically removed after a couple of days. Because the perineal approach has a higher risk for postoperative infection (owing to the location of the incision related to the anus), careful dressing changes and perineal care after each bowel movement are important to promote comfort and prevent infection. Depending on the type of surgery, the length of hospital stay postoperatively ranges from 1 to 3 days.

Two major adverse outcomes following a radical prostatectomy are ED and urinary incontinence (Boorjian, Eastham, Graefen, et al., 2012). The incidence of ED is dependent on the patient's age, preoperative sexual functioning, whether nerve-sparing surgery was performed, and the surgeon's expertise. Problems with urinary control occur in nearly all men for the first few months following surgery because the bladder must be reattached to the urethra after the prostate is removed. Over time, the bladder adjusts, and most men regain control (Gandaglia, Gallina, Suardi, et al., 2014). Kegel exercises strengthen the urinary sphincter and may help improve incontinence. Other common complications associated with surgery include hemorrhage, urinary retention, infection, wound dehiscence, deep-vein thrombosis, and pulmonary emboli.

Nerve-Sparing Procedure.

In proximity to the prostate gland are neuro-vascular bundles that maintain erectile functioning. The preservation of these bundles during a prostatectomy is possible while still removing all of the cancer. This procedure is not indicated for patients with cancer outside of the prostate gland. Although the risk for ED is significantly reduced with this procedure, there is no guarantee that potency will be maintained. However, most men younger than 50 years with good preoperative erectile function and low-stage prostate cancer can expect a return of potency after nerve-sparing prostatectomy.

Cryosurgery.

Cryotherapy (cryoablation) is a surgical technique for prostate cancer that destroys cancer cells by freezing the tissue. It has been used both as an initial treatment and as a second-line treatment after radiation treatment failures. A TRUS probe is inserted to visualize the prostate gland. Probes containing liquid nitrogen are then inserted into the prostate. Liquid nitrogen delivers freezing temperatures, destroying the tissue. The treatment takes about 2 hours under general or spinal anaesthesia and does not involve an abdominal incision. Possible complications of prostatic cryosurgery include damage to the urethra and, in rare cases, a urethro-rectal fistula (an opening between the urethra and the rectum) or a urethro-cutaneous fistula (an opening between the urethra and the skin). Tissue sloughing, ED, urinary incontinence, prostatitis, and hemorrhage have also been reported.

Radiation Therapy.

Radiation therapy is a common treatment option for prostate cancer, especially for men older than 70, patients who are poor surgical risks, or those who wish to avoid surgery. Radiation therapy may be offered as the only treatment, or it may be offered in combination with surgery or with hormonal therapy. Salvage radiation therapy given for cancer recurrence after a radical prostatectomy may improve survival in some men.

External Beam Irradiation.

External beam is the most widely used method of delivering radiation treatments in those with prostate cancer. This therapy can be used to treat patients with prostate cancer confined to the prostate or surrounding tissue. Patients are treated on an outpatient basis 5 days a week for 4 to 8 weeks. Each treatment lasts only a few minutes. Adverse effects from radiation can be acute (occurring during treatment or within 90 days following) or delayed (occurring months or years after treatment). Common adverse effects involve the skin (dryness, redness, irritation, pain), gastro-intestinal (GI) tract (diarrhea, abdominal cramping, bleeding), urinary tract (dysuria, frequency, hesitancy, urgency, nocturia), sexual

functioning (ED), fatigue, and bone marrow suppression (Cameron, Springer, Fox-Wasylyshyn, et al., 2012). These problems usually resolve 2 to 3 weeks after the completion of radiation therapy. In patients with localized prostate cancer, cure rates using external beam radiation are comparable with those using radical prostatectomy.

Brachytherapy.

Brachytherapy involves the implantation of radioactive seeds into the prostate gland, allowing higher radiation doses directly in the tissue while sparing the surrounding tissue (rectum and bladder). The radioactive seeds are placed in the prostate gland with a needle through a grid template guided by TRUS (Figure 57-7). The grid template and ultrasonography ensure accurate placement of the seeds. Because brachytherapy is a one-time outpatient procedure, many patients find it more convenient than external beam radiation treatment. Brachytherapy is best suited for patients with early-stage prostate cancer. The most common adverse effect is the development of urinary irritative or obstructive problems. The AUA Symptom Index (see Table 57-1) can be used to measure urinary function for patients undergoing brachytherapy and can be incorporated into postoperative nursing management. For those with more advanced tumours, brachytherapy may be offered in combination with external beam radiation treatment (Pieters, Rezaie, Geijsen, et al., 2011). (Brachytherapy is discussed further in Chapter 18.)

O., Niederhuber, J. D., et al. (Eds.). (2008). *Abeloff's clinical oncology* (4th ed., Figure 88-12A). Edinburgh: Churchill Livingstone.

Drug Therapy.

The forms of drug therapy available for the treatment of prostate cancer are androgen deprivation (hormone) therapy, chemotherapy, or a combination of both.

Androgen Deprivation Therapy.

Prostate cancer growth is largely dependent on the presence of androgens. *Androgen deprivation therapy* (ADT) reduces the levels of circulating androgens to diminish the tumour's growth. Androgen deprivation can be produced by inhibiting androgen production or

blocking androgen receptors (Table 57-7). One of the biggest challenges with ADT is that almost all tumours treated become resistant to this therapy *(hormone refractory)* within a few years. An elevated PSA level is often the first sign that this therapy is no longer effective. Osteoporosis and fractures may occur in prostate cancer patients receiving ADT. Drugs recommended to reduce bone mineral loss in these patients include zoledronic acid (Aclasta) and raloxifene (Evista) (VanderWalde & Hurria, 2011).

TABLE 57-7

DRUG THERAPY
Androgen Deprivation Therapy for Prostate Cancer

Therapy	Mechanism of Action	Adverse Effects
Androgen Synthesis Inhibitors		
LH-RH Agonists		
Goserelin (Zoladex) Leuprolide (Lupron, Eligard) Buserelin (Suprefact) Triptorelin (Trelstar)	Reduce secretion of LH and FSH Decrease testosterone production	Hot flashes, gynecomastia, decreased libido, ED Depression and mood changes
LH-RH Antagonist Degarelix (Firmagon)	Block LH receptors Immediately suppress testosterone	Pain, redness, and swelling at injection site Elevated liver enzymes
CYP17 Enzyme Inhibitor		
Abiraterone (Zytiga)	Inhibits CYP17, an enzyme needed for production of testosterone Inhibits testosterone synthesis from the testes, adrenal glands, and prostate cancer cells	Joint swelling, fluid retention, muscle discomfort, hot flashes, diarrhea
Androgen Receptor Blockers		
Bicalutamide (Casodex) Flutamide Nilutamide (Anandron) Enzalutamide (Xtandi)	Block the action of testosterone by competing with receptor sites	Loss of libido, ED, and hot flashes Breast pain and gynecomastia may also occur

CYP17, cytochrome P450 17α–hydroxy/17,20-lyase; *ED,* erectile dysfunction; *FSH,* follicle-stimulating hormone; *LH,* luteinizing hormone; *LH-RH,* luteinizing hormone–releasing hormone.

Androgen Synthesis Inhibitors.

Luteinizing hormone–releasing hormone (LH-RH) is released from the hypothalamus to stimulate the anterior pituitary to produce luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH stimulates the testicular Leydig cells to produce testosterone. LH-RH agonists superstimulate the pituitary, ultimately resulting in down-regulation of the LH-RH receptors, leading to a refractory condition in which the anterior pituitary is unresponsive to LH-RH. These drugs cause an initial transient increase in LH and testosterone called a "flare," and a worsening of symptoms may occur during this time. However, with continued administration, LH and testosterone levels decrease. LH-RH agonists include leuprolide (Lupron, Eligard), goserelin (Zoladex), buserelin (Suprefact) and triptorelin (Trelstar). These medications essentially produce a chemical castration similar to the effects of an orchiectomy. They are administered by subcutaneous or intramuscular injections on a regular basis, and they must be taken indefinitely. Leuprolide acetate implant (Viadur) is a subcutaneous implant that delivers leuprolide continuously for 1 year (Warlick, Weight, & Konety, 2014).

Degarelix (Firmagon) is an LH-RH antagonist that lowers testosterone levels. Unlike the LH-RH agonists, degarelix does not cause a testosterone flare because it acts directly to block LH and FSH receptors. It is given as a subcutaneous injection.

Abiraterone (Zytiga) works by inhibiting an enzyme, CYP17, which is needed for the production of testosterone. This medication is given orally.

Androgen Receptor Blockers.

Another classification of antiandrogens is drugs that compete with circulating androgens at the receptor sites. Flutamide, nilutamide (Anandron), enzalutamide (Xtandi), and bicalutamide (Casodex) are androgen receptor blockers. They are often used in combination with an LH-RH agonist (e.g., goserelin, leuprolide), resulting in a combined androgen blockade.

Orchiectomy.

Testosterone, produced by the testes, stimulates growth of the prostate cancer. A bilateral orchiectomy is the surgical removal of the testes that may be done alone or in combination with prostatectomy. An orchiectomy is one treatment option for cancer control in patients in an advanced stage of prostate cancer. Another possible benefit of this procedure is the rapid relief of bone pain associated with advanced tumours. Orchiectomy may also induce sufficient shrinkage of the prostate to relieve urinary obstruction in later stages of disease when surgery is not an option.

Adverse effects of orchiectomy include hot flashes, ED, loss of sex drive, osteoporosis, and irritability. Weight gain and loss of muscle mass, which are also common, can alter a man's physical appearance, possibly affecting self-esteem and leading to grief and depression. Because this procedure is permanent, many men prefer drug therapy to orchiectomy.

Chemotherapy.

The use of chemotherapy has primarily been limited to treatment for those with hormone-resistant prostate cancer (HRPC) in late-stage disease. In HRPC the cancer progresses despite treatment. This progression occurs in patients who have taken an antiandrogen for a certain period of time. The goal of chemotherapy is mainly palliation. Some of the more commonly used chemotherapeutic drugs include docetaxel (Taxotere), mitoxantrone, cyclophosphamide (Procytox), idarubicin, cabazitaxel (Jevtana), and paclitaxel (Abraxane).

Radiotherapy.

Radium-223 dichloride (Xofigo) can be used in the treatment of patients with castration-resistant prostate cancer, symptomatic bone metastases, and no known visceral metastatic disease. It is an alpha particle–emitting radiotherapy drug that mimics calcium and forms complexes with hydroxyapatite at areas of increased bone turnover, such as bone metastases.

Culturally Competent Care

Prostate Cancer

Nurses need to be aware of ethnic and cultural considerations when providing information about the risk for prostate cancer and screening recommendations. They must consider not only the ethnic differences in the incidence of prostate cancer but also differences in health-promotion practices.

Despite the importance of annual checkups and a DRE, individuals in lower socioeconomic groups frequently do not use such services. Although exposure to electronic and print media is successful in informing some men about prostate cancer, significant differences of effectiveness exist based on demographic variables such as ethnicity, age, education level, and socioeconomic level. Nurses should consider patients individually and determine the best method to communicate this information to each in order to achieve the greatest degree of understanding and participation in prostate cancer screening.

Nursing Management Prostate Cancer

Nursing Assessment

Subjective and objective data that should be obtained from a patient with prostate cancer are presented in Table 57-8.

TABLE 57-8

NURSING ASSESSMENT
Prostate Cancer

Subjective Data
Important Health Information
Past health history: Family history of prostate cancer; diet high in fat *Medications:* Use of testosterone supplements or any other medications affecting urinary tract such as morphine, anticholinergics, monoamine oxidase inhibitors, and tricyclic antidepressants *Surgeries or other treatments:* History of urinary tract infections or prostate problems
Symptoms
• *Urinary:* Hesitancy or straining to start stream; weak stream; urinary urgency or frequency; dysuria; retention with dribbling; hematuria; nocturia • *Other:* Low back pain radiating to legs or pelvis; bone pain (possible indicators of metastasis); anorexia, weight loss (possible indicators of metastasis); increasing fatigue and malaise; anxiety related to self-concept or sexuality
Objective Data
General
Older-adult male; pelvic lymphadenopathy (late sign)
Urinary
Distended bladder on palpation; unilaterally hard, enlarged, fixed prostate on rectal examination
Musculo-Skeletal
Pathological fractures (metastasis)
Possible Findings
↑ Serum PSA; ↑ serum PAP (metastasis); nodular and irregular prostate on ultrasonography, positive biopsy results; anemia

PAP, prostatic acid phosphatase; *PSA,* prostate-specific antigen.

Nursing Diagnoses

Nursing diagnoses for the patient with prostate cancer depend on the stage of the cancer. General nursing diagnoses may include the following.

- *Decisional conflict* related to *conflicting information sources, inexperience with decision-making* (numerous alternative treatment options)
- *Acute pain* related to *biological injury agent, physical injury agent* (prostatic enlargement, surgery)
- *Impaired urinary elimination* related to *multiple causality* (obstruction of the urethra by the prostate, loss of bladder tone)
- *Sexual dysfunction* related to *vulnerability* (effects of treatment)
- *Anxiety* related to *threat to current status, threat of death* (effect of treatment on sexual function, uncertain outcome of disease process)

Planning

The overall goals are that the patient with prostate cancer will (a) be an active participant in the treatment plan, (b) have satisfactory pain control, (c) follow the therapeutic plan, (d) understand the effect of the therapeutic plan on sexual function, and (e) find a satisfactory way to manage the impact on bladder or bowel function.

Nursing Implementation

Health Promotion.

One of the nurse's most important roles in relation to prostate cancer is to encourage patients, in consultation with their health care providers, to have annual health checkups, including a DRE, starting at age 50 (or younger if risk factors are present).

Evidence-Informed Practice

Translating Research Into Practice

George Nandi is a 56-year-old man who has gone to the occupational health nurse at his place of employment in a manufacturing company for his regular blood pressure check. His father and uncle have a history of prostate cancer. He tells the nurse that he has heard "all over the news" about screening for prostate cancer. He has been getting a blood test for prostate-specific antigen (PSA) yearly and asks if he needs to continue.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
PSA screening saves lives when performed appropriately in men at *high risk* of developing prostate cancer.	The nurse knows that Mr. Nandi is in a high-risk category for prostate cancer. He has African ancestry. He is more than 50 yr old, and he has first-degree relatives with prostate cancer. Based on these risk factors, the nurse encourages him to have an annual health examination, including DRE and a *PCA3* urine test.	Mr. Nandi wants the best preventive measures to screen for prostate cancer. He was involved in the care of both his father and uncle when they were sick, and he does not want what happened to them to happen to him.

Decision and Action

The nurse encourages Mr. Nandi to discuss his concerns about annual PSA testing with his primary health care provider and for him to have a thorough discussion about the use of *PCA3* testing to screen for prostate cancer. The nurse also discusses the potential influence of risk factors and diet on developing prostate cancer and teaches him about food to avoid or limit (e.g., red meat, high-fat dietary products) and those to increase (e.g., vegetables, fruits).

Reference for Evidence

Canadian Cancer Society. *Finding prostate cancer early*. [Retrieved from] http://www.cancer.ca/en/cancer-information/cancer-type/prostate/finding-cancer-early/?region=on; 2017 [Bell, N., Connor Gorber, S., Shane, A., et al. (2014). Guidelines. Recommendations on screening for prostate cancer with the prostate-specific antigen test. *Canadian Medical Association Journal, 186*(16), 1225–1234. doi:10.1503/cmaj.140703].

Acute Intervention.

Preoperative and postoperative phases of radical prostatectomy are similar to surgical procedures for BPH (see pp. 1426–1428). Nursing interventions for a patient who undergoes radiation therapy and chemotherapy are discussed in Chapter 18. An additional consideration is the psychological response of the patient to a diagnosis of cancer. The nurse should provide sensitive, caring support for the patient and his family to help them cope with the diagnosis of cancer. Prostate support groups are available for men and their families to encourage them to be active, informed participants in their own care.

Ambulatory and Home Care.

The nurse should teach appropriate catheter care if the patient is discharged with an in-dwelling catheter. The patient should be instructed to clean the urethral meatus with soap and water once a day; maintain a high fluid intake; keep the collecting bag lower than the bladder at all times; keep the catheter securely anchored to the inner thigh or the abdomen; and report any signs of bladder infection, such as bladder spasms, fever, or hematuria. If urinary incontinence is a problem, patients should be encouraged to practise pelvic floor muscle exercises (Kegel exercises) at every urination and throughout the day. Continuous practice during the 4- to 6-week

healing process improves the success rate. Products for incontinence specifically designed for men are available through home care product catalogues and many retail stores.

Palliative and end-of-life care are often appropriate and beneficial to the patient and family (see Chapter 13). Common problems experienced by patients with advanced prostate cancer include fatigue, bladder outlet obstruction and ureteral obstruction (caused by compression of the urethra or ureters or both from tumour mass or lymph node metastasis), severe bone pain and fractures (caused by bone metastasis), spinal cord compression (from spinal metastasis), and leg edema (caused by lymphedema, deep-vein thrombosis, or another medical condition). Nursing interventions must focus on all of these problems. However, management of pain is one of the most important aspects of nursing care for these patients. Pain control involves ongoing pain assessment, administration of prescribed medications (both opioid and nonopioid agents), and nonpharmacological methods of pain relief (e.g., relaxation breathing). (Pain management is discussed further in Chapter 10.)

Evaluation

The outcomes for the patient with prostate cancer are that he will:

- Be an active participant in the treatment plan
- Have satisfactory pain control
- Follow the therapeutic plan
- Understand the effect of the treatment on sexual function
- Find a satisfactory way to manage the impact on bladder or bowel function

Prostatitis

Etiology and Pathophysiology

Prostatitis is a broad term that describes a group of acute or chronic inflammatory conditions affecting the prostate gland, usually as a result of infection. It is the most common urological problem in men younger than 50 years, and nearly 50% of men will have some form of prostatitis in their lifetime (Canadian Cancer Society, 2017c). Classifications for prostatitis include four categories: (a) acute bacterial prostatitis, (b) chronic bacterial prostatitis, (c) chronic prostatitis–chronic pelvic pain syndrome, and (d) asymptomatic inflammatory prostatitis (Anothaisintawee, Attia, Nickel, et al., 2011).

Both acute and chronic bacterial prostatitis generally result from organisms reaching the prostate gland by one of the following routes: ascending from the urethra, descending from the bladder, or invading via the bloodstream or the lymphatic channels. Common causative organisms are *Escherichia coli, Klebsiella, Pseudomonas, Enterobacter, Proteus, Chlamydia trachomatis, Neisseria gonorrhoeae,* and group D streptococci. Chronic bacterial prostatitis differs from acute prostatitis in that it involves recurrent episodes of infection.

Chronic prostatitis–chronic pelvic pain syndrome describes a syndrome with prostate and urinary pain in the absence of an obvious infectious process. The etiology of this syndrome is not known. It may occur after a viral illness, or it may be associated with sexually transmitted infections, particularly in younger adults. A culture reveals no causative organisms. However, leukocytes may be found in prostatic secretions.

Asymptomatic inflammatory prostatitis is usually diagnosed in individuals who have no symptoms but are found to have an inflammatory process in the prostate. These patients are usually diagnosed during the evaluation of other genito-urinary tract problems. Leukocytes are present in the seminal fluid from the prostate, but the cause of this process is unclear.

Clinical Manifestations and Complications

Common clinical manifestations of acute bacterial prostatitis include fever, chills, back pain, and perineal pain, along with acute urinary symptoms such as dysuria, urinary frequency, urgency, and cloudy

urine (Anothaisintawee, Attia, Nickel, et al., 2011). The patient may also have acute urinary retention caused by prostatic swelling. With DRE, the prostate is extremely swollen, very tender, and firm. The complications of prostatitis are epididymitis and cystitis. Sexual functioning may be affected as evidenced by postejaculation pain, libido problems, and ED. Prostatic abscess is also a potential but uncommon complication.

Chronic bacterial prostatitis and chronic prostatitis–pelvic pain syndrome manifest with similar symptoms that are generally milder than those associated with acute bacterial prostatitis. These include irritative voiding symptoms (frequency, urgency, dysuria), backache, perineal or pelvic pain, and ejaculatory pain. Obstructive symptoms are uncommon unless the patient has coexisting BPH. With DRE, the prostate feels enlarged and firm (often described as "boggy") and is slightly tender with palpation. Chronic prostatitis can predispose the patient to recurrent UTIs.

The clinical features of prostatitis can mimic those of a UTI. However, acute cystitis (inflammation of the bladder associated with bacterial infection) is not common in men.

Diagnostic Studies

Because patients with prostatitis have urinary symptoms, a urinalysis and urine culture are indicated; often white blood cells and bacteria are present. If the patient has a fever, white blood cell count and blood cultures are also indicated. The PSA test may be done to rule out prostate cancer. However, PSA levels are often elevated with prostatic inflammation. Thus the test is not considered diagnostic in itself.

Microscopic evaluation and culture of expressed prostate secretion are considered useful in the diagnosis of prostatitis. Expressed prostate secretion is obtained using a premassage and postmassage test (HealthLinkBC, 2016). The patient is asked to void into a specimen cup just before and just after a vigorous prostate massage. Prostatic massage (for expressed prostate secretion) should be avoided if acute bacterial prostatitis is suspected because compression is extremely painful and can increase the risk for

bacteria spread. TRUS has not been particularly useful in the diagnosis of prostatitis. However, transabdominal ultrasonography or MRI may be done to rule out an abscess on the prostate.

Nursing and Collaborative Management Prostatitis

Antibiotics commonly used for acute and chronic bacterial prostatitis include trimethoprim–sulfamethoxazole and ciprofloxacin (Cipro). Doxycycline or tetracycline may be prescribed for patients who have multiple sex partners. Antibiotics are usually given orally for up to 4 weeks for acute bacterial prostatitis. However, if the patient has high fever or other signs of impending sepsis, hospitalization and intravenous antibiotics are prescribed. Patients with chronic bacterial prostatitis are given oral antibiotic therapy for 4 to 12 weeks. A short course of oral antibiotics is usually prescribed for those with chronic prostatitis–chronic pelvic pain syndrome. However, antibiotic therapy often is ineffective for patients whose prostatitis is not caused by bacteria.

Although patients with acute and chronic bacterial prostatitis tend to experience a great amount of discomfort, the pain resolves as the infection is treated. Pain management for patients with chronic prostatitis–chronic pelvic pain syndrome is more difficult because the pain persists for weeks to months. Anti-inflammatory agents are the most common agents used for pain control in prostatitis, but these provide only moderate pain relief. Opioid pain medications can be used, but if the pain is chronic in nature, multimodal therapies should be considered. Relaxation of muscle tissue in the prostate using α-adrenergic blockers has been shown to be effective in reducing discomfort for some men (Azoulay, Eberg, Benayoun, et al., 2015).

Acute urinary retention can develop in acute prostatitis, necessitating bladder drainage with suprapubic catheterization. Passage of a catheter through the inflamed urethra in acute prostatitis is contraindicated. Repetitive prostatic massage may be recommended as adjunct therapy for prostatitis for men. This measure relieves congestion within the prostate by squeezing out excess prostatic secretions, thus providing pain relief. Prostatic massage is performed by using the index finger of a gloved hand

and pressing down on the prostate, covering the entire gland's surface in longitudinal strokes. Measures to stimulate ejaculation (masturbation and intercourse) help drain the prostate and provide some relief.

Because the prostate can serve as a source of bacteria, patients experiencing prostatitis should maintain a high fluid intake. The nurse should therefore encourage the patient to drink plenty of fluids. This is especially important for those with acute bacterial prostatitis because of the increased fluid needs associated with fever and infection. Management of fever is also an important nursing intervention.

Problems of the Penis

Health problems of the penis are rare if sexually transmitted infections are excluded (see Chapter 55). Problems of the penis may be classified as congenital, problems of the prepuce, problems with the erectile mechanism, and cancer.

Congenital Problems

Hypospadias is a urological abnormality in which the urethral meatus is located on the ventral surface of the penis anywhere from the corona to the perineum. Hormonal influences in utero, environmental factors, and genetic factors are possible causes. Surgical repair of hypospadias may be necessary if it is associated with *chordee* (a painful downward curvature of the penis during erection) or if it prevents intercourse or normal urination. Surgery may also be done for cosmetic reasons or emotional well-being.

Epispadias, an opening of the urethra on the dorsal surface of the penis, is a complex birth defect that is usually associated with other genito-urinary tract defects. Corrective surgery to place the urethra in a normal position in the penis is usually done in early childhood.

Problems of the Prepuce

Problems of the prepuce are rare in Canada because, up until the 1990s, circumcision was a routine procedure for most male infants. Circumcision, the surgical removal of the foreskin of the penis, is a procedure done to male infants for religious or cultural reasons.

Phimosis is a constriction of the uncircumcised foreskin around the head of the penis, making retraction over the glans penis difficult. It is caused by edema or inflammation of the foreskin, usually associated with poor hygiene techniques that allow bacterial and yeast organisms to become trapped under the foreskin (Figure 57-8, *A*). The goal of treatment is to return the foreskin to its natural position over the glans penis through manual reduction. One strategy involves pushing the glans back through the prepuce by

applying constant thumb pressure while the index fingers pull the prepuce over the glans. Ice, hand compression, or both on the foreskin, glans, and penis may be used before this technique to reduce edema. Topical corticosteroid cream applied two or three times daily to the exterior and interior of the tip of the foreskin may also be effective.

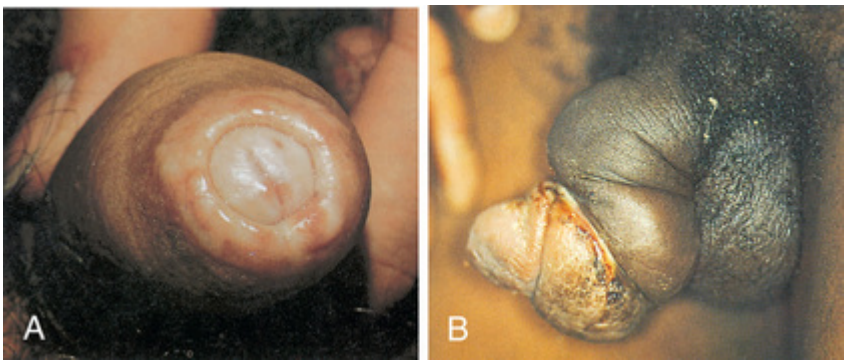

FIGURE 57-8 **A,** Phimosis: inability to retract the foreskin due to secondary lesions on the prepuce. **B,** Paraphimosis: ulcer with edema from foreskin remaining contracted over the prepuce.

Paraphimosis is narrowing or edema of the retracted uncircumcised foreskin, preventing normal return over the glans and causing strangulation. This can occur when the foreskin is pulled back for cleansing, for the use of a urinary catheter, or during intercourse and is not returned to the forward position. Antibiotics, warm soaks, and sometimes circumcision or dorsal slitting of the prepuce may be required. Careful cleaning followed by replacement of the foreskin generally prevents these problems (see Figure 57-8, *B*).

Problems of Erectile Mechanism

Priapism is a painful erection lasting longer than 4 hours and may constitute a medical emergency (Song & Moon, 2013). Causes of priapism include thrombosis of the corpus cavernosal veins, leukemia, sickle cell anemia, diabetes mellitus, degenerative lesions of the spine, neoplasms of the brain or spinal cord, prolonged

foreplay, injection of vasoactive medications into the corpus cavernosa, and use of certain medications and cocaine. Treatment may include sedatives, injection of smooth muscle relaxants directly into the penis, aspiration and irrigation of the corpora cavernosa with a large-bore needle, and the surgical creation of a shunt to drain the corpora. Complications may include penile tissue necrosis caused by lack of blood flow or hydronephrosis from bladder distension. With immediate medical treatment, the risk for permanent ED is low.

Peyronie's disease, sometimes referred to as *curved* or *crooked penis,* is caused by plaque formation in one of the corpora cavernosa of the penis. The palpable, nontender, hard plaque formation is usually found on the posterior surface. It may result from trauma to the penile shaft or may occur spontaneously. The plaque prevents adequate blood flow into the spongy tissue, which results in a curvature during erection. The condition is not dangerous but can result in painful erections, ED, or embarrassment. Patients may improve over time, stabilize, or need surgery.

Cancer of the Penis

Cancer of the penis is rare. Major risk factors include human papilloma virus infection, smoking, and psoriasis (Latendresse & McCance, 2011), as well as not having been circumcised as an infant (Lawindy, Rodriguez, Horenblas, et al., 2011). The tumour may appear as a superficial ulceration or a pimple-like nodule. The nontender warty lesion may be mistaken for a venereal wart. The majority of malignancies (95%) are well-differentiated squamous cell carcinomas. Treatment in the early stages is laser removal of the growth. A radical resection of the penis may be done if the cancer has spread. Surgery, radiation, or chemotherapy may be tried, depending on the extent of the disease, lymph node involvement, or metastasis.

Problems of the Scrotum and Testes

Inflammatory and Infectious Problems

Skin Problems

The skin of the scrotum is susceptible to a number of common skin diseases. The most common conditions of the scrotal skin are fungal infections, dermatitis (neurodermatitis, contact dermatitis, seborrheic dermatitis), and parasitic infections (scabies, lice). These conditions involve discomfort for the patient but are associated with few, if any, severe complications (see Chapter 26).

Epididymitis

Epididymitis is an inflammation of the epididymis (Figure 57-9), usually secondary to an infectious process (sexually or nonsexually transmitted) and rarely as a result of trauma or urinary reflux down the vas deferens from the urethra. Swelling may progress to the point that the epididymis and the testis are indistinguishable. In men younger than 40 years of age, the most common cause is gonorrhea or chlamydial infection. UTI and prostatitis are common causes in older men. The use of antibiotics is important for both partners if the transmission is through sexual contact. Patients should be encouraged to refrain from sexual intercourse during the acute phase. If they do engage in intercourse, a condom should be used. Conservative treatment consists of bed rest with elevation of the scrotum, use of ice packs, and analgesics. Ambulation places the scrotum in a dependent position and increases pain. Most tenderness subsides within 1 week, although swelling may last for weeks or months.

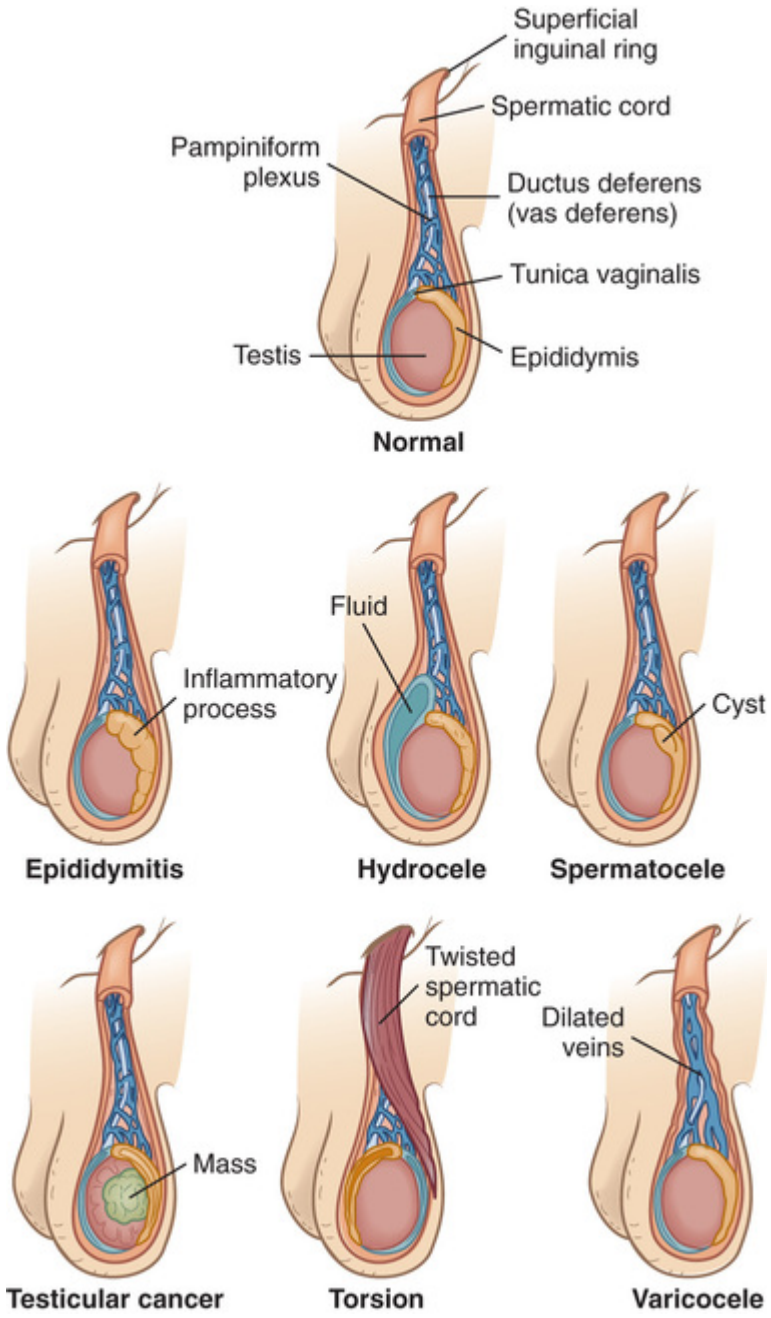

FIGURE 57-9 Scrotal masses.

Orchitis

Orchitis refers to an acute inflammation of the testis. In orchitis, the testis is painful, tender, and swollen. It generally occurs after an episode of bacterial or viral infections such as mumps, pneumonia, tuberculosis, or syphilis. It can also be caused by epididymitis,

prostatectomy, trauma, infectious mononucleosis, influenza, catheterization, or complicated UTI. Mumps orchitis is a condition contributing to infertility, and its incidence could easily be decreased by childhood vaccination against mumps. Treatment involves the use of antibiotics (if the organism is known), pain medications, or bed rest with the scrotum elevated on an ice pack.

Congenital Problems

Cryptorchidism (undescended testes) is failure of the testes to descend into the scrotal sac before birth. It is the most common congenital testicular condition. It may occur bilaterally or unilaterally and may be the cause of infertility if corrective surgery is not done by 2 years of age. The incidence of testicular cancer is also higher if the condition is not corrected before puberty. Surgery is performed to locate and suture the testis or testes to the scrotum.

Maternal use of acetaminophen during pregnancy may increase the risk of male offspring being born with cryptorchidism; however, there is little evidence that implicates maternal use of ibuprofen or acetylsalicylic acid (Jensen, Henriksen, Rebordosa, et al., 2011).

Acquired Problems

Hydrocele

A **hydrocele** is a nontender, fluid-filled mass that results from interference with lymphatic drainage of the scrotum and swelling of the tunica vaginalis that surrounds the testis (Figure 57-10; see also Figure 57-9). Diagnosis is fairly simple because the mass can be seen by shining a flashlight through the scrotum (transillumination). No treatment is indicated unless the swelling becomes very large and uncomfortable, in which case aspiration or surgical drainage of the mass is performed.

FIGURE 57-10 Hydrocele. Source: Swartz, M. H. (2010). *Textbook of physical diagnosis: History and examination* (6th ed., p. 537, Figure 18-28). Philadelphia: Saunders.

Spermatocele

A **spermatocele** is a firm, sperm-containing, painless cyst of the epididymis that may be visible with transillumination (see Figure 57-9). The cause is unknown, and surgical removal is the treatment. It is important for men to see their doctor if they feel any scrotal lumps. Patients would be unable to distinguish this cyst from cancer when performing self-examination.

Varicocele

A **varicocele** is a dilation of the veins that drain the testes (see Figure 57-9). The scrotum feels wormlike when palpated. The cause of the problem is unknown. The varicocele is usually located on the left side of the scrotum as a consequence of retrograde blood flow from the left renal vein. Surgery is indicated for patients who are infertile because persistent varicoceles are associated with 40% to 50% of cases of infertility. Repair of the varicocele may be through injection of a sclerosing agent or by surgical ligation of the spermatic vein.

Testicular Torsion

Testicular torsion involves a twisting of the spermatic cord that supplies blood to the testes and epididymis, causing an interruption

to the blood supply (see Figure 57-9). It is most commonly seen in males younger than age 20. The patient experiences severe scrotal pain, tenderness, swelling, nausea, and vomiting. Urinary symptoms, fever, and white blood cells or bacteria in the urine are absent. The pain does not usually subside with rest or elevation of the scrotum. Nuclear technetium scan of the testes or Doppler ultrasonography is typically performed to assess blood flow within the testicle. The cremasteric reflex is absent on the side of the swelling, and a decrease in or absence of blood flow confirms the diagnosis. Unless the torsion resolves spontaneously, surgery to untwist the cord and restore the blood supply must be performed immediately. Torsion constitutes a surgical emergency because, if the blood supply to the affected testicle is not restored within 4 to 6 hours, ischemia to the testis will occur, leading to necrosis and the possible need for removal.

Testicular Cancer

Etiology and Pathophysiology

Testicular cancer is relatively rare, accounting for less than 1% of all cancers found in males. It has a 5-year survival rate of 96% (Canadian Cancer Society, 2017d). Testicular cancer is the most common type of cancer in young men between 15 and 29 years of age (Canadian Cancer Society, 2017e). Testicular cancer occurs more commonly in the right testicle than in the left (Latendresse & McCance, 2011). Testicular tumours are also more common in males who have had undescended testes (cryptorchidism), a family history of testicular cancer or anomalies, or Klinefelter's syndrome (Canadian Cancer Society, 2017f). Other predisposing factors include orchitis, human immunodeficiency virus infection, maternal exposure to diethylstilbestrol, and testicular cancer in the contralateral testis.

Most testicular cancers develop from embryonic germ cells. The two types of germ cell cancers are seminomas and nonseminomas. Although seminoma germ cell cancers are the most common, they are the least aggressive. Nonseminoma testicular germ cell tumours are rare but are very aggressive. Non–germ cell tumours arise from

other testicular tissue and include Leydig cell and Sertoli cell tumours. These account for less than 10% of testicular cancers.

Clinical Manifestations and Complications

Testicular cancer may have a slow or rapid onset depending on the type of tumour. The patient may notice a painless lump in his scrotum as well as scrotal swelling and a feeling of heaviness. The scrotal mass usually is nontender and very firm. Some patients complain of a dull ache or heavy sensation in the lower abdomen, the perianal area, or the scrotum. Acute pain is the presenting symptom in about 10% of patients. Manifestations associated with advanced disease are varied and include lower back or chest pain, cough, and dyspnea.

Diagnostic Studies

Palpation of the scrotal contents is the first step in diagnosing testicular cancer. A cancerous mass is firm and does not transilluminate. Ultrasonography of the testes is indicated whenever testicular cancer is suspected (e.g., palpable mass) or when persistent or painful testicular swelling is present. If a testicular neoplasm is suspected, blood is obtained to determine the serum levels of alpha-fetoprotein, lactate dehydrogenase, and human chorionic gonadotropin. (Alpha-fetoprotein is discussed in Chapter 18.) A chest radiograph and CT scan of the abdomen and pelvis are done to detect metastasis. Anemia may be present, and liver function may be elevated in metastatic disease.

Nursing and Collaborative Management Testicular Cancer

Testicular Self-Examination

As with many forms of cancer, the survival of the patient is closely associated with early recognition of the tumour. The scrotum is easily examined, and beginning tumours are usually palpable. Every male from the age of 15 years of age should be taught and encouraged to perform a monthly testicular self-examination (TSE) so that he knows what is normal for his testicles and can notice any changes. Male patients, especially those with a history of undescended testis or a previous testicular tumour, should be taught how to perform TSE.

Guidelines for TSE of the scrotum are presented in Table 57-9 and Figure 57-11. The procedure is not difficult. Some men may indicate reluctance to examine their own genitals, but with encouragement, they can learn this simple procedure. They should be encouraged to perform TSEs frequently until they are comfortable with the procedure and then examine the scrotum once a month.

TABLE 57-9

PATIENT & CAREGIVER TEACHING GUIDE
Testicular Self-Examination

The nurse should include the following instructions when teaching a patient how to perform testicular self-examination:

1. Just after a shower or bath is the best time to examine the testes. Warm temperatures make the testes hang lower in the scrotum.
2. Stand in front of a mirror. Look for any swelling on the skin of the scrotum.
3. Hold your scrotum in the palms of your hands so that you can feel the size and weight of each testicle. It is normal for one testicle to be larger and hang lower than the other.
4. Gently roll each testicle between your thumb and your fingers (see Figure 57-11, *A*). Feel for lumps or bumps. If you feel a soft, tender tube cord leading upward from the back of each testicle, that is normal (see Figure 57-11, *B*).
5. Notify the health care provider at once if any abnormalities are found.

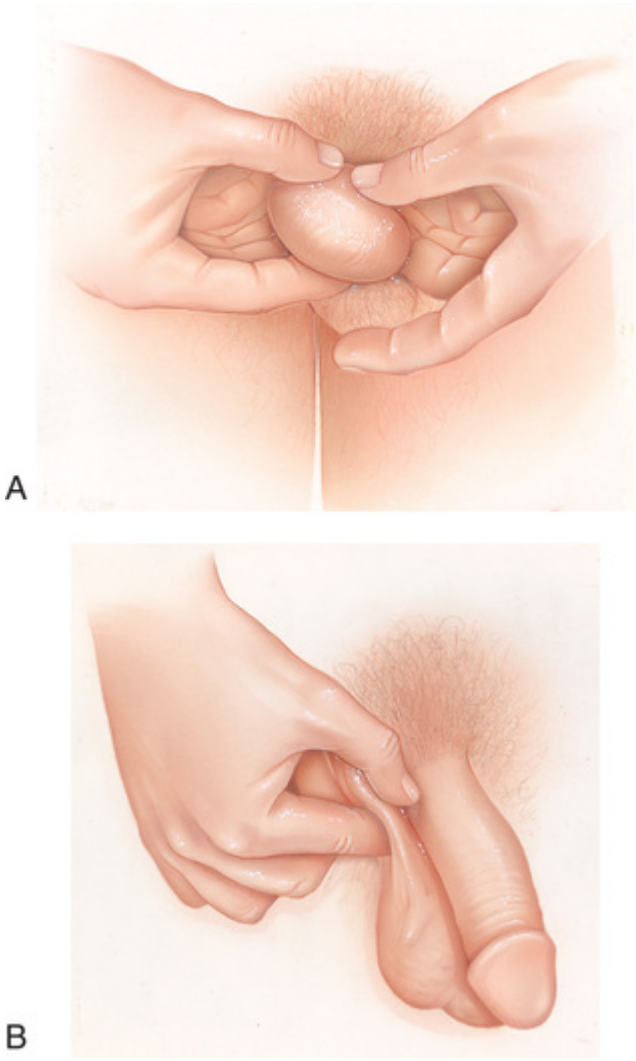

FIGURE 57-11 Testicular self-examination. **A,** The testicle is checked for smoothness by rolling it between the thumb and the fingers. **B,** The spermatic cord or vas deferens can be felt toward the back of the testicle and should feel soft and tender. Source: *The wellness way: Testicular examination.* Copyright 1987, 1994, 2000, 2001, 2002. The StayWell Company.

Videotapes and illustrations on shower hangers are available as teaching aids and ideally should be introduced during high school or college physical education classes. Free information is available through the Canadian Cancer Society and on various medical websites.

Collaborative Care

Collaborative care of testicular cancer generally involves an orchiectomy or a radical orchiectomy (surgical removal of the affected testis, the spermatic cord, and regional lymph nodes). Postorchiectomy treatment involves surveillance, radiation therapy, or chemotherapy, depending on the stage of the cancer. Chemotherapy protocols use combination therapy: bleomycin, etoposide (Vepesid), and cisplatin; or etoposide (Vepesid), ifosfamide (Ifex), and cisplatin. (Testicular germ cell tumours are more sensitive to systemic chemotherapy than any other adult solid tumour.)

Of patients with testicular cancer, 97% obtain complete remission if the disease is detected in the early stages (Canadian Cancer Society, 2017d). As a result of treatment successes, the majority of men with testicular cancer become long-term survivors. Treatment-related toxicity, however, is a significant issue. All patients with testicular cancer, regardless of pathological condition or stage, require meticulous follow-up and regular physical examinations, chest radiographic examinations, CT scans, and assessment of human chorionic gonadotropin and alpha-fetoprotein. The goal is to detect relapse when the tumour burden is minimal. Secondary malignancies that occur as a result of chemotherapy and radiation are described in Chapter 18 and in the NCPs 18-1 and 18-2, available on the Evolve website.

Men with testicular cancer should have the opportunity to discuss fertility and sperm banking before any treatment. The nurse should be sensitive to any psychosocial problems this type of cancer can have on a man's feelings of self-worth or sexual performance. Treatment has the potential to interfere with both erections and fertility.

Sexual Functioning

Vasectomy

Vasectomy is the bilateral surgical ligation or resection of the vas deferens performed for the purpose of sterilization (Figure 57-12). The procedure requires only 15 to 30 minutes and is usually performed on an outpatient basis with the patient under local anaesthesia. Vasectomy is considered a permanent form of sterilization, although some successful reversals *(vasovasotomy)* have been reported.

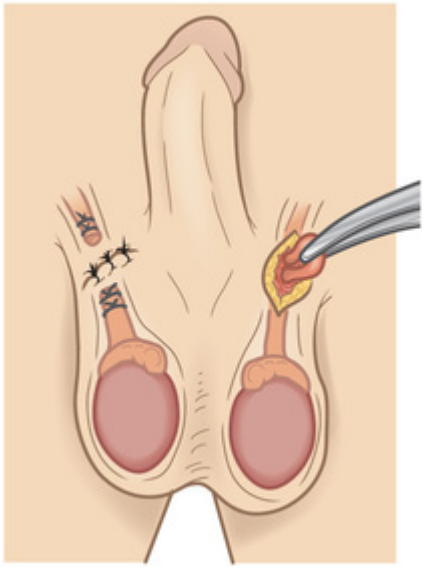

FIGURE 57-12 Vasectomy procedure. The vas deferens is ligated or resected for the purpose of sterilization.

After vasectomy, the patient should not notice any difference in the look or feel of the ejaculate because its major component is seminal and prostatic fluid. The patient will need to use an alternative form of contraception until semen examination reveals no sperm. This usually requires at least 10 ejaculations or 6 weeks, until sperm distal to the surgical site are evacuated. Sperm cells continue to be produced by the testes but are absorbed by the body rather

than being passed through the vas deferens. Occasionally, postoperative hematoma and swelling of the scrotum occur.

Vasectomy does not affect the production of hormones, the ability to ejaculate, or the physiological mechanisms related to erection or orgasm. Psychological adjustment may be a problem after surgery. It may be difficult for the patient to separate vasectomy from castration at a subconscious level. Some men may develop ED or may feel the need to prove their masculinity by becoming much more sexually active than they were in the past. Careful discussion of the procedure and its outcome before the surgery can be helpful in detecting patients who may have problems with psychological adjustment. Surgery should be delayed for these patients. (The Ethical Dilemmas box discusses sterilization.)

Ethical Dilemmas

Sterilization

Situation

A 43-year-old male patient is requesting a vasectomy and informs the nurse that he does not wish to discuss it with his wife. The physician's policy is to have the spouse or partner sign a form acknowledging the patient's desire to be sterilized. This patient explains that, although his wife wants to have more children, the one they already have is all he wants.

Important Points for Consideration

- Patient autonomy suggests that matters of reproduction are left to the privacy and discretion of the individual. Competent adults may legally choose to be sterilized for medical reasons or for convenience.
- To prevent possible future harm, this man should include his wife in the decision to permanently eliminate his ability to procreate.

- In most provinces and territories, women can terminate a pregnancy without proof that their partners are aware of their intentions. Sterilization, conversely, can be considered a more permanent decision that has consequences for both parties in the relationship.
- This physician's standard is to have evidence of the spouse's or significant other's knowledge of the intent for sterilization. The nurse should inform the man of the standard in this particular physician's practice and the benefits to the integrity of his marriage.
- If the patient is still unwilling to discuss the matter with his wife, either the nurse or the physician should inform the man that they will not participate in deception and he is free to select another physician to perform the procedure.

Clinical Decision-Making Questions

1. How should the nurse approach this situation?
2. Should the nurse tell the wife of her husband's plans?
3. Are there ever circumstances in which deception of a patient or family would be justified?

Erectile Dysfunction

Erectile dysfunction (ED) is the inability to attain or maintain an erect penis that allows satisfactory sexual performance. Although sexual function is a topic that many individuals are uncomfortable discussing, health care providers must be able and willing to address ED. Treatment may include phosphodiesterase type 5 inhibitors, a class of medications used to treat ED, including tadalafil (Cialis), vardenafil (Levitra), and sildenafil (Viagra).

The effects of ED can lead to anxiety and depression as well as potentially interfere with a man's self-esteem, confidence, relationships, and overall sense of well-being. ED is a condition that is significant because of its prevalence; it is estimated that its prevalence among men in Canada aged 40 to 88 is 49.4%, with

estimates that approximately 3 million Canadians over the age of 40 years are affected by ED (Bella, Lee, Carrier, et al., 2015). The problem is increasing in all segments of the sexually active male population and affects both the man and his partner. In younger men, the increase is attributed to substance use, such as recreational drugs and alcohol. Middle-aged men are affected by medical conditions such as diabetes, hypertension, renal disease, organ transplants, coronary artery bypass graft surgeries, and cancer or the therapy for these problems. Men are living longer and expect to remain sexually active, regardless of any existing medical conditions.

Etiology and Pathophysiology

ED can result from a number of factors in two general categories: physiological (organic) and psychological. Common causes of *physiological ED* (Table 57-10) include vascular disease (most common cause), diabetes mellitus, adverse effects from medications, result of surgery (such as prostatectomy), trauma, chronic illness, and decreased gonadal hormone secretion (Elliott, 2011). Although studies suggest a link between cardiovascular disease (CVD) and ED, whether ED is a risk factor for CVD is controversial (Dong, Zhang, & Qin, 2011). (See the Evidence-Informed Practice box.) *Psychological ED* can be caused by a number of issues but is most often associated with stress, difficulty in a relationship, depression, or low self-esteem.

TABLE 57-10
RISK FACTORS FOR ERECTILE DYSFUNCTION

Vascular
• Atherosclerosis • Hypertension • Peripheral vascular disease
Drug-Induced
• Alcohol • Antiandrogens • Antilipidemic agents • Antihypertensives • Diuretics (chlorothiazide, spironolactone [Aldactone]) • Major tranquilizers (diazepam [Valium], alprazolam [Xanax]) • Marijuana, cocaine • Nicotine • Tricyclic antidepressants (e.g., amitriptyline [Elavil])
Endocrine
• Diabetes mellitus • Obesity • Testosterone deficiency
Genito-Urinary
• Radical prostatectomy • Prostatitis • Renal failure
Neurological
• Parkinson's disease • Cerebro-vascular disease • Trauma to the spinal cord • Tumours or transection of spinal cord
Psychological
• Anxiety • Depression • Fear of failure to perform • Stress
Other
• Aging

Evidence-Informed Practice

Research Highlight

Do Lifestyle Changes and Cardiovascular Medication Improve Erectile Dysfunction?

Clinical Question

For patients with erectile dysfunction (P), what is the effect of lifestyle modifications and drugs for cardiovascular risk factors (I) on severity of dysfunction (O)?

Best Available Evidence

Systematic review and meta-analysis of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence

- Six RCTs (n = 740, mean age of 55 yr old) that examined the effect of lifestyle interventions and drugs targeting cardiovascular (CV) risk factors on erectile dysfunction (ED).
- Interventions lasting at least 6 weeks included diet, exercise, maintenance of an active lifestyle, and drugs to reduce CV risk factors (i.e., statins to lower cholesterol).
- Changes in lifestyle with improved lipid values were related to a decrease in the severity of ED.

Conclusion

- Sexual function was significantly improved in men with ED through lifestyle modification and drugs for CV risk factors.

Implications for Nursing Practice

- Emphasis on the importance of a healthy diet and regular physical activity for men experiencing ED.
- Counselling that declining sexual health should be brought to the attention of the health care provider for early identification of CV risk factors.

P, Patient population of interest; *I*, intervention or area of interest; *O*, outcomes of interest (see Chapter 1).

Reference for Evidence

Gupta BP, Murad MH, Clifton MM, et al. The effect of lifestyle modification and cardiovascular risk factor reduction on erectile dysfunction: A systematic review and meta-analysis. *Archives of Internal Medicine*. 2011;171(20):1797–1803; 10.1001/archinternmed.2011.440.

Normal physiological age-related changes are associated with changes in erectile function and may be an underlying cause of ED for some men. Table 53-4 in Chapter 53 lists age-related changes in sexual function. The nurse should be able to explain these age-related changes if necessary to reassure an anxious older man regarding normal changes in his sexual abilities. (The male sexual response is discussed in Chapter 53.)

Clinical Manifestations and Complications

The typical symptom of ED is a patient's self-report of problems associated with sexual performance. He usually describes an inability to attain or maintain an erection. The symptoms may occur only occasionally, may be continual with a gradual onset, or may occur with a sudden onset. A gradual onset of symptoms is usually associated with physiological factors, whereas a sudden or rapid onset of symptoms may be associated with psychological issues.

A man's inability to perform sexually can cause great distress in his interpersonal relationships and may interfere with his concept of himself as a man. It can also affect the relationship between the man and his partner. Problems with ED can lead to a number of personal issues, including anger, anxiety, and depression.

Diagnostic Studies

The first step in diagnosis and management of ED begins with a thorough sexual, health, and psychosocial history. Self-administered assessment and treatment-related questionnaires have been

developed and may prove useful as primary screening tools, for example, the Erection Quality Scale (Rosen, Wincze, Mollen, et al., 2007). Second, a physical examination should be performed that focuses on secondary sexual characteristics, including pubic hair distribution, size and appearance of the penis and scrotum, and rectal examination. A DRE should be done to assess prostate size, consistency, and presence of nodules. Assessment of blood pressure, palpation of peripheral pulses, and sensation of the genitalia should also be included.

Further examination or diagnostic testing is typically based on findings from the history and physical examination. Serum glucose and lipid profile bloodwork is recommended to rule out diabetes mellitus. Hormonal levels for testosterone, prolactin, LH, and thyroid may help identify endocrine-related problems, and a complete blood count may be helpful in identifying unrecognized systemic diseases.

Other diagnostic tests may be conducted to diagnose ED. Nocturnal penile tumescence and rigidity testing is a noninvasive method that involves the continuous measurement of penile circumference and axial rigidity during sleep. Such measurements are used to differentiate between physiological and psychological causes of ED as well as to evaluate the effectiveness of drug therapy. Vascular studies, including penile arteriography, penile blood flow study, and duplex Doppler ultrasonography studies, are used to assess penile blood inflow and outflow. Such studies help assess vascular problems interfering with erection.

Collaborative Care

The goal of ED therapy is for the patient and his partner to achieve a satisfactory sexual relationship. The treatment for ED is based on the underlying cause. A variety of treatment options are available (Bella, Lee, Carrier, et al., 2015) (Table 57-11). The results of these interventions are usually most satisfactory when both partners are involved in the decision-making process and have realistic expectations of the treatment.

TABLE 57-11

COLLABORATIVE CARE
Erectile Dysfunction

Diagnostic
• History and physical examination • Nocturnal penile tumescence and rigidity testing • Serum glucose and lipid profile • Sexual history • Testosterone, prolactin, and thyroid hormone levels • Vascular studies
Collaborative Therapy
• Drug therapy [sildenafil (Viagra), vardenafil (Levitra), tadalafil (Cialis)] • Intracavernosal self-injection • Intraurethral medication pellet • Modify reversible causes • Penile implants • Sexual counselling • Topical gels • Vacuum constriction device (VCD)

It is important to determine whether ED is reversible before treatment is started. For example, if ED appears to be an adverse effect of prescribed drugs, alternative agents or treatments should be explored. When there is an established diagnosis of testicular failure (hypogonadism), androgen replacement therapy may sometimes be effective in improving erectile function. For individuals who have ED that is psychological in nature, counselling should be provided by a qualified therapist for the patient (and possibly his partner).

Erectogenic Drugs.

Sildenafil (Viagra), tadalafil (Cialis), and vardenafil (Levitra) are erectogenic drugs (Lee, 2011). These drugs are phosphodiesterase type 5 (PDE5) inhibitors that cause smooth muscle relaxation and increased blood flow into the corpus cavernosum, thus promoting penile erection. They are taken orally about 30 to 60 minutes before sexual activity, but not more than once a day. These drugs have been found to be generally safe and effective for the treatment of most types of ED.

Adverse effects include headaches, dyspepsia, flushing, and nasal congestion. Additional rare adverse effects are blurred or blue-green visual disturbances, sudden hearing loss, and priapism. The patient

should be instructed to seek immediate medical attention if any of these rare reactions occur. Because these drugs may potentiate the hypotensive effect of nitrates (e.g., nitroglycerin), they are contraindicated for individuals taking nitrates.

Drug Alert

Sildenafil (Viagra)

- Should not be used with nitrates (nitroglycerin) in any form
- Can potentiate hypotensive effects of nitrates

Vacuum Constriction Devices.

Vacuum constriction devices (VCDs) are suction devices that can be applied to the flaccid penis to produce an erection by pulling blood up into the corporeal bodies. A penile ring or constrictive band is placed around the base of the penis to retain venous blood, thereby preventing the erection from subsiding. Special care must be taken in using these devices to prevent tissue bruising.

Vasoactive Drugs.

Vasoactive drugs can be administered as a topical gel, by injection into the penis (intracavernosal self-injection), or by insertion of a medicated pellet (alprostadil) into the urethra using an intraurethral device. These vasoactive drugs enhance blood flow into the penile arteries. Current vasoactive medications include papaverine, alprostadil (Caverject), and phentolamine.

Penile Implants.

Surgical implantation of semirigid or inflatable penile prostheses is shown in Figure 57-13. These surgical procedures are highly invasive and associated with potential complications. Thus, they are usually indicated only for men with severe ED for which other interventions are ineffective.

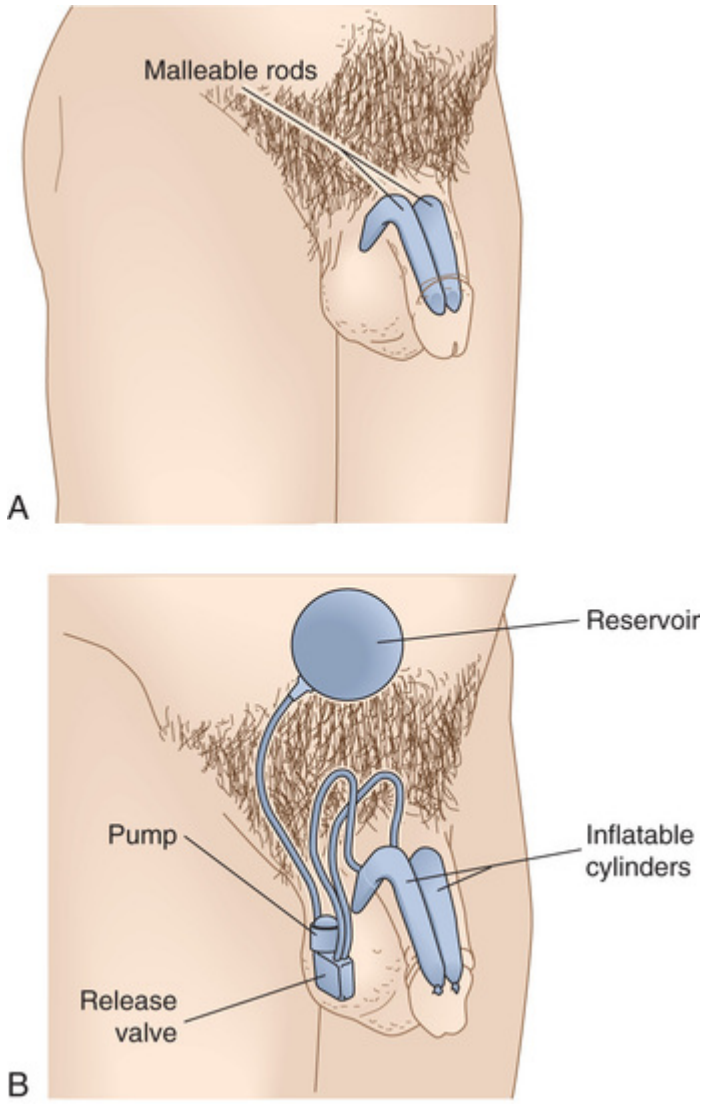

FIGURE 57-13 Penile implants. **A,** A malleable implant is always erect but can be bent close to the body for concealment. **B,** An inflatable implant consists of cylinders in the penis, a small pump in the scrotum, and a reservoir in the lower abdomen. When activated, the pump fills the cylinders with fluid from the reservoir. A small release valve permits the fluid to drain back into the reservoir after intercourse.

The devices are implanted into the corporeal bodies to provide an erection firm enough for penetration. The semirigid malleable implant is displayed in Figure 57-13, *A*. The inflatable implant consists of cylinders in the penis, a small pump in the scrotum, and a reservoir in the lower abdomen (Figure 57-13, *B*). The main problems

associated with penile prostheses are mechanical failure, infection, and erosions.

Sexual Counselling.

Sexual counselling is often recommended before and after treatment. It should address psychological or interpersonal factors that may enhance sexual expression as well as other factors that are of concern. Counselling can be effective for the individual patient, but it is typically preferred to include his partner, particularly if he is involved in a long-term relationship. The ability for both partners to be pleased enhances a patient's satisfaction levels. Counselling should begin after the start of medical treatment for ED.

Nursing Management Erectile Dysfunction

Patients experiencing ED require a great deal of emotional support for both themselves and their partners. Men often do not feel comfortable discussing these types of problems with others because of society's expectations of a man's sexual abilities. They need reassurance that confidentiality will be maintained. Men may experience and demonstrate isolation from support systems, and they may also lose self-esteem. In conjunction with medical treatment, counselling and therapy may be necessary for couples to establish realistic expectations and develop meaningful communication patterns.

The majority of men delay seeking medical assistance. Once they do, they are often highly motivated and expect immediate solutions to their problems. The health care team should provide a support system and accurate information as soon as possible. Nurses are in a unique position of conducting routine health assessments on men seeking any form of medical treatment. These assessments provide an opportunity to ask questions pertaining to general health as well as sexual health and function. Given the opportunity and recognition that someone cares and can provide them with answers, men are less hesitant to answer these questions.

Andropause

Andropause is a gradual decline in androgen secretion that occurs in most men as they age and can begin as early as age 40. The primary male androgen that is reduced is testosterone. Factors that determine the rate of decline are not clearly known. Signs and symptoms associated with a lowered level of testosterone include loss of libido, fatigue, ED, depression and mood swings, and sleep disturbances. Symptoms are often attributed to normal aging and frequently are not reported by the patient (Figure 57-14). The long-term effects, including a loss of muscle mass and strength, may contribute to an

increased risk for falls and fractures (LeBlanc, Wang, Lee, et al., 2011).

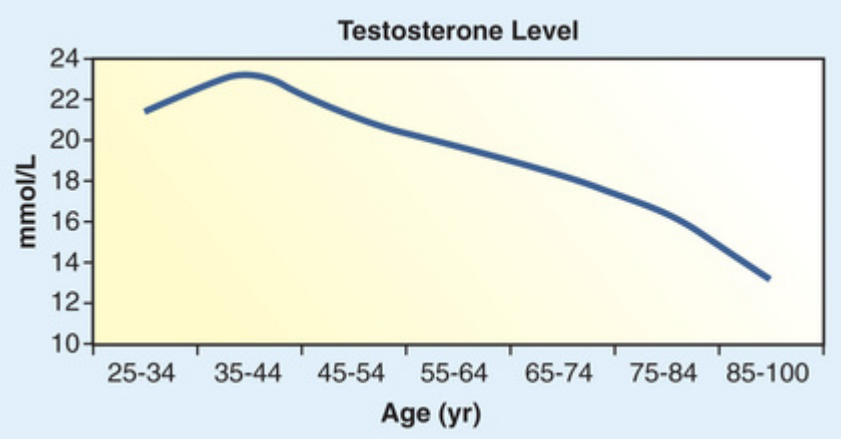

FIGURE 57-14 Changes in testosterone plasma level in men as they age.

Infertility

Infertility in a couple is defined as the inability to conceive after 1 year of frequent, unprotected intercourse. Infertility is a disorder of a couple, not of one individual. For this reason, both partners must be involved in determining the cause of infertility. In about 33% of the cases, the cause primarily involves the man. Male infertility can be caused by disorders of the hypothalamic–pituitary system, disorders of the testes, and abnormalities of the ejaculatory system.

The physical causes are generally divided into three categories: pretesticular, testicular, and post-testicular. The *pretesticular or endocrine causes* occur in only about 3% of the cases and can generally be treated with medication or surgery. Seventy-five percent of all male infertility factors are attributable to primary *testicular causes,* with genetic factors identified in about 15% of these cases (Krausz, 2011). Other factors that influence the testes include infection (e.g., mumps virus, sexually transmitted infections, bacterial infections), congenital anomalies, medications, radiation, substance use (alcohol, nicotine, drugs), and environmental hazards. *Post-testicular causes* account for approximately 5% to 7% of the cases, with obstruction,

infection, or the result of a surgical procedure being the primary causes. The remaining 40% are classified as *idiopathic,* or of unknown cause.

A careful health history and examination may reveal the cause of a patient's infertility. Thus, the history is a starting point for determining cause and treatment. The history should include age; occupation; past injury, surgery, or infections to the genital tract; lifestyle issues such as use of hot tubs, weight training, or wearing of tight undergarments; sexual practices; frequency of intercourse; and emotional factors such as stress levels and the desire for children. The use of drugs, such as chemotherapeutic drugs, anabolic steroids (testosterone), sulphasalazine, cimetidine, and recreational drugs, should be documented because these can reduce sperm count. A physical examination can disclose a varicocele, Peyronie's disease, or other physical abnormalities.

The first test in an infertility study is a semen analysis. The test determines the sperm concentration (count >20 million/mL), forward progressive motility (at least 60% with a grade >2), and morphology (at least 60% have a normal oval head and long tail). Additional tests that may be helpful in determining the etiology include plasma testosterone and serum LH and FSH measurements. A test for sperm penetration abilities may also be done. The specific cause of infertility is often not determined.

Nurses should be concerned and tactful in dealing with male patients undergoing infertility studies. Many men equate fertility and masculinity. The nurse must be sensitive to the problem of gender identity in the infertile man.

Treatment options for men include medications, conservative lifestyle changes (e.g., avoidance of scrotal heat, substance abuse, high stress), in vitro fertilization techniques, and corrective surgery. Infertility can seriously strain a marriage, and the couple may require counselling and discussion of alternatives if conception is not achieved. (Female infertility is discussed in Chapter 56.)

Case Study

Benign Prostatic Hyperplasia

Source: sirtravelalot/Shutterstock.com

Patient Profile

LeRon Wilson, a 60-year-old married man, comes to the primary health outpatient clinic because of an inability to void for the past 13 hours and pain in the lower abdomen.

Subjective Data

- Complains of urge to void
- Is very restless, anxious, and agitated

Objective Data

- Has prostate enlargement on digital rectal examination
- Has hematuria, bacteria, and white blood cells in urine
- Has a tender and palpable bladder above umbilicus

Collaborative Care

- In-dwelling catheter inserted by a urology resident
- Admitted to hospital

Discussion Questions

1. What risk factors for prostate problems are present in Mr. Wilson?
2. Explain the etiology of the objective symptoms Mr. Wilson exhibited.
3. Discuss the drug options available to Mr. Wilson.
4. Discuss the invasive options available to Mr. Wilson.
5. Mr. Wilson asks about the effect of the various treatment options on his ability to have sex. How should the nurse respond?
6. ***Priority decision:*** What are the priority nursing diagnoses based on the assessment data presented? Are there any collaborative problems?
7. ***Priority decision:*** What is the priority nursing intervention for Mr. Wilson?
8. On further assessment, the nurse notes that Mr. Wilson has a nursing diagnosis of *decisional conflict*. How should the nurse help him resolve this conflict related to treatment options?
9. ***Evidence-informed practice:*** What information should the nurse offer to Mr. Wilson when he asks if he should start taking saw palmetto to prevent future UTIs?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. An older male client is experiencing difficulty in initiating voiding and a feeling of incomplete bladder emptying. What are these symptoms of BPH primarily caused by?
   a. Obstruction of the urethra
   b. Untreated chronic prostatis
   c. Decreased bladder compliance
   d. Excessive secretion of testosterone
2. Postoperatively, a client who has had a laser prostatectomy has continuous bladder irrigation with a three-way urinary catheter with a 30-mL balloon. When he complains of bladder spasms with the catheter in place, what should the nurse do?
   a. Deflate the catheter balloon to 10 mL to decrease bulk in the bladder.
   b. Deflate the catheter balloon and then reinflate to ensure that it is patent.
   c. Encourage the client to try to have a bowel movement to relieve colon pressure.
   d. Explain that this feeling is normal and that he should not try to urinate around the catheter.
3. Which factors would place a client at higher risk for prostate cancer? *(Select all that apply)*
   a. Older than 65 years
   b. Asian or Indigenous Canadian
   c. Long-term use of an in-dwelling urethral catheter
   d. Father diagnosed and treated for early-stage prostate cancer
   e. Previous history of undescended testicle and testicular cancer
4. A client scheduled for a prostatectomy for prostate cancer expresses the fear that he will have erectile dysfunction (ED). In

responding to this client, what should the nurse keep in mind?

a. ED can occur even with a nerve-sparing procedure.

b. Retrograde ejaculation affects sexual function more frequently than erectile dysfunction.

c. The most common complication of this surgery is postoperative bowel incontinence.

d. Preoperative sexual function is the most important factor in determining postoperative erectile dysfunction.

5. What should the nurse explain to the client with chronic bacterial prostatitis who is undergoing antibiotic therapy? *(Select all that apply)*

a. All clients require hospitalization.

b. Pain will lessen once the infection is resolved.

c. Course of treatment is generally 4 to 12 weeks.

d. Long-term therapy may be indicated in immuno-compromised clients.

e. If the condition is unresolved and untreated, he is at risk for prostate cancer.

6. Which manifestations of testicular cancer would the nurse observe for when assessing a client for this disease?

a. Acute back spasms and testicular pain

b. Rapid onset of scrotal swelling and fever

c. Fertility problems and bilateral scrotal tenderness

d. Painless mass and sensation of heaviness in the scrotal area

7. What should the nurse explain to the client who has had a vasectomy?

a. The procedure blocks the production of sperm.

b. ED is temporary and will return with continued sexual activity.

c. The ejaculate will be about half the volume it was before the procedure.

d. An alternative form of contraception will be necessary for 6 to 8 weeks.

8. What measure should the nurse use to decrease the client's discomfort over care related to his reproductive organs?
   a. Relate his sexual concerns to his sexual partner.
   b. Arrange to have only male nurses care for the client.
   c. Maintain a nonjudgemental attitude toward his sexual practices.
   d. Use only technical terminology when discussing reproductive function.

1. b; 2. d; 3. a, d; 4. a; 5. b, c; 6. d; 7. d; 8. c.

SECTION 11

Problems Related to Movement and Coordination

OUTLINE

Introduction

Source: Takuji Oishi/Shutterstock.com.

CHAPTER 58

Nursing Assessment

Nervous System

Written by, Linda Littlejohns

Adapted by, Jana Lok

LEARNING OBJECTIVES

1. Describe the functions of neurons and glial cells.
2. Explain the electrochemical aspects of nerve impulse transmission.
3. Explain the anatomical location and functions of the cerebrum, brain stem, cerebellum, spinal cord, peripheral nerves, and cerebro-spinal fluid.
4. Identify the major arteries supplying the brain.
5. Describe the functions of the 12 cranial nerves.
6. Compare the functions of the two divisions of the autonomic nervous system.
7. Describe age-related changes in the neurological system and differences in assessment findings.
8. Identify the significant subjective and objective data related to the nervous system that should be obtained from a patient.
9. Select appropriate techniques in the physical assessment of the nervous system.
10. Differentiate normal from common abnormal findings of a physical assessment of the nervous system.
11. Describe the purpose, the significance of results, and the nursing responsibilities related to diagnostic studies of the nervous system.

Structures and Functions of the Nervous System

The human nervous system is a highly specialized system responsible for the control and integration of the body's many activities. The nervous system has two main divisions: the **central nervous system (CNS)** and the **peripheral nervous system (PNS).** The CNS consists of the brain, the spinal cord, and cranial nerves I and II. The PNS consists of cranial nerves III to XII, the spinal nerves, and the peripheral components of the autonomic nervous system (ANS).

Cells of the Nervous System

The nervous system is made up of two types of cells: neurons and glial cells. **Neurons** are the primary functional unit of the nervous system. Glial cells provide structural support and are more numerous than neurons.

Neurons.

Neurons come in many different shapes and sizes, but they share three characteristics: (a) *excitability,* or the ability to generate a nerve impulse; (b) *conductivity,* or the ability to transmit an impulse; and (c) the ability to *influence* other neurons, muscle cells, and glandular cells by transmitting nerve impulses to them.

A typical neuron consists of a cell body, an axon, and several dendrites (Figure 58-1). The cell body, which contains the nucleus and the cytoplasm, is the metabolic centre of the neuron. *Dendrites* are short processes extending from the cell body. They receive nerve impulses from the axons of other neurons and conduct impulses toward the cell body. The nerve *axon* projects varying distances from the cell body, ranging from several micrometres to more than a metre. Its function is to carry nerve impulses to other neurons or to end organs. The end organs are smooth and striated muscles and glands. Axons may be myelinated or unmyelinated. Many axons present in the CNS and the PNS are covered by a segmentally interrupted myelin sheath composed of a white lipid substance that acts as an insulator for the conduction of impulses. In general, the smaller fibres are unmyelinated.

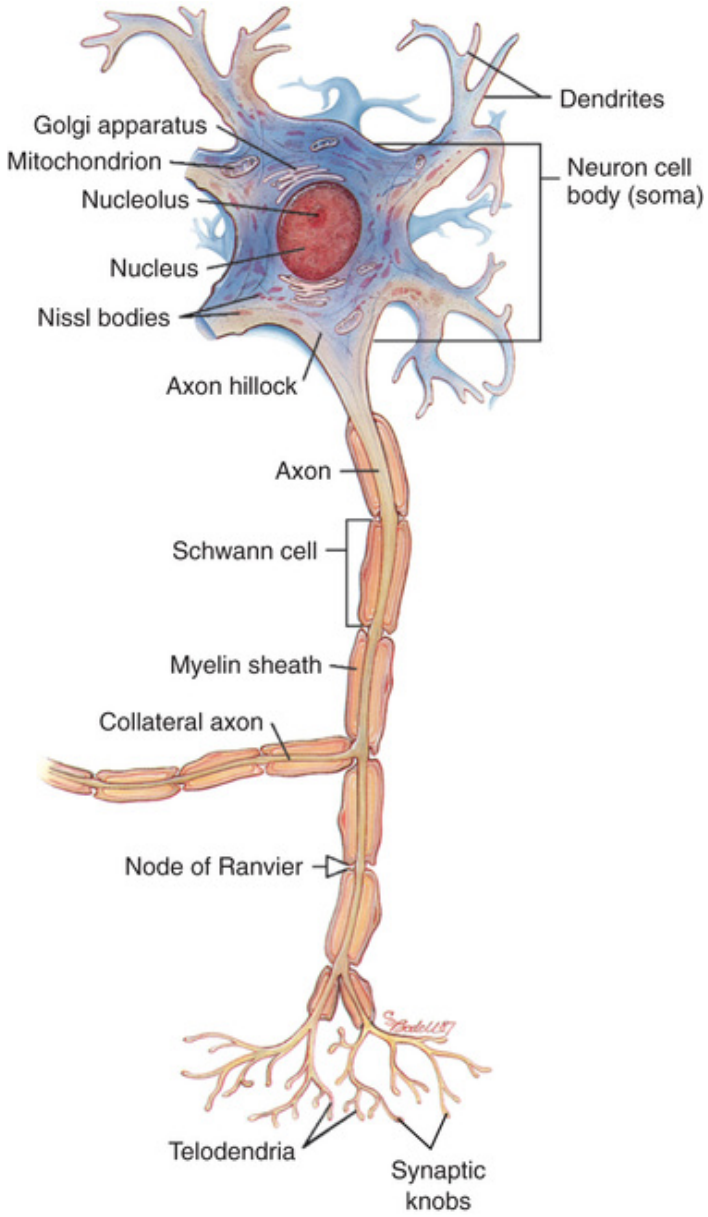

FIGURE 58-1 Structural features of neurons: dendrites, cell body, and axons. Source: Adapted from Patton, K. T., & Thibodeau, G. A. (2010). *Anatomy and physiology* (7th ed., p. 379, Figure 12-5). St. Louis: Mosby.

Glial Cells.

Glial cells provide support, nourishment, and protection to neurons. They constitute almost half the brain and spinal cord mass and are five to ten times more numerous than neurons. Different types of glial cells include astrocytes (most abundant), oligodendrocytes, ependymal cells, and microglia. *Astrocytes* provide structural support to neurons and their

delicate processes, form the blood–brain barrier with the endothelium of the blood vessels, and play a role in synaptic transmission (conduction of impulses between neurons). They are found primarily in grey matter. When the brain is injured, astrocytes act as phagocytes for neuronal debris. They help restore the neurochemical milieu and provide support for repair. Proliferation of astrocytes contributes to the formation of scar tissue (gliosis) in the CNS.

Oligodendrocytes are specialized cells that produce the myelin sheath of nerve fibres in the CNS and are found primarily in the white matter of the CNS. (Schwann cells myelinate the nerve fibres in the periphery.)

Ependymal cells line the brain ventricles and aid in the secretion of cerebro-spinal fluid. *Microglia,* a type of macrophage, are relatively rare in normal CNS tissue. They are phagocytes and are important in host defence.

Neurogenesis

Neurons have long been thought to be nonmitotic—that is, after being damaged, neurons could not be replaced. The discovery of neuronal stem cells now demonstrates that neurogenesis can occur in adult brains after cerebral injury (Gopurappilly, Pal, Krishna Mamidi, et al., 2011). Neuroglia are mitotic and can replicate. In general, when neurons are destroyed, the tissue is replaced by the proliferation of neuroglial cells. Most primary CNS tumours involve glial cells. Primary malignancies involving neurons are rare.

If the axon of a nerve cell is damaged, the cell attempts to repair itself. Damaged nerve cells attempt to grow back to their original destinations by sprouting many branches from the damaged ends of their axons. Unfortunately, axons in the CNS are less successful than peripheral axons in regenerating. Endogenous inhibitors (e.g., neurite outgrowth inhibitor, myelin-associated glycoprotein) decrease axon regeneration.

In the PNS (outside the brain and the spinal cord), injured nerve fibres can successfully regenerate by growing within the protective myelin sheath of the supporting Schwann cells if the cell body is intact. The final result of nerve regeneration depends on the number of axon sprouts that join with the appropriate Schwann cell columns and re-innervate appropriate end organs.

Evidence-Informed Practice

Research Highlight

Can Enteric Glia Regenerate Axons Following Spinal Cord Injury?

Clinical Question

Following spinal cord injuries (P), can transplanted enteric glia (I) promote axonal regeneration (O)?

Best Available Evidence

- Dr. Shucui Jiang and her research team at McMaster University, Ontario, are developing a new therapy that harvests enteric (intestinal) glia cells and transplants them to sites of injury to promote regeneration of injured spinal cord nerve fibres.

Critical Appraisal and Synthesis of Evidence

- This research is still in its experimental stage. Research using animal models has shown that enteric glial cells induce regeneration of damaged spinal cords, reduce tissue damage, and promote functional recovery.

Conclusion

- Research has shown that transplanting enteric glial cells can promote axonal regeneration following spinal cord injury. Current studies are exploring the mechanisms through which enteric glia mediate neuronal regeneration as well as trying to isolate and obtain human enteric glia.

Implications for Nursing Practice

1. Damage to the spinal cord is one of the most traumatic events that affect an individual's life. Unfortunately, there are few viable treatment options.
2. This research provides new insight into future treatment options for spinal cord injuries.

P, Patient population of interest; *I,* intervention or area of interest; *O,* outcomes of interest (see Chapter 1).

Reference for Evidence

Nerve Impulse

The function of a neuron is to initiate, receive, and process messages about events both within and outside the body. The initiation of a neuronal message *(nerve impulse)* involves the generation of an action potential. An *action potential* is a rapid, self-propagating and transient change in the voltage across a cell membrane (caused by the influx of Na^+ followed by an efflux of K^+). An action potential is generated when a stimulus causes the resting membrane potential (−70 mV) to depolarize (to about +30 mV) within a short time period (1–2 ms). Once an action potential is initiated, a series of action potentials travel along the axon. When the impulse reaches the end of the nerve fibre, it is transmitted across the junction between nerve cells *(synapse)* by a chemical interaction involving neurotransmitters. This chemical interaction generates another set of action potentials in the next neuron. These events are repeated until the nerve impulse reaches its destination.

Because of its insulating capacity, myelination of nerve axons facilitates the conduction of an action potential. Many peripheral nerve axons have gaps, termed *nodes of Ranvier,* at regular intervals in the myelin sheath surrounding them. An action potential travelling down one of these axons hops from node to node without traversing the insulated membrane segment between nodes, which makes the action potential travel much faster than it would otherwise. This process is called *saltatory* (hopping) conduction. In an unmyelinated fibre, the wave of depolarization traverses the entire length of the axon, and each portion of the membrane becomes depolarized in turn. Figure 58-2 depicts a comparison of nerve impulse transmission of myelinated and unmyelinated fibres.

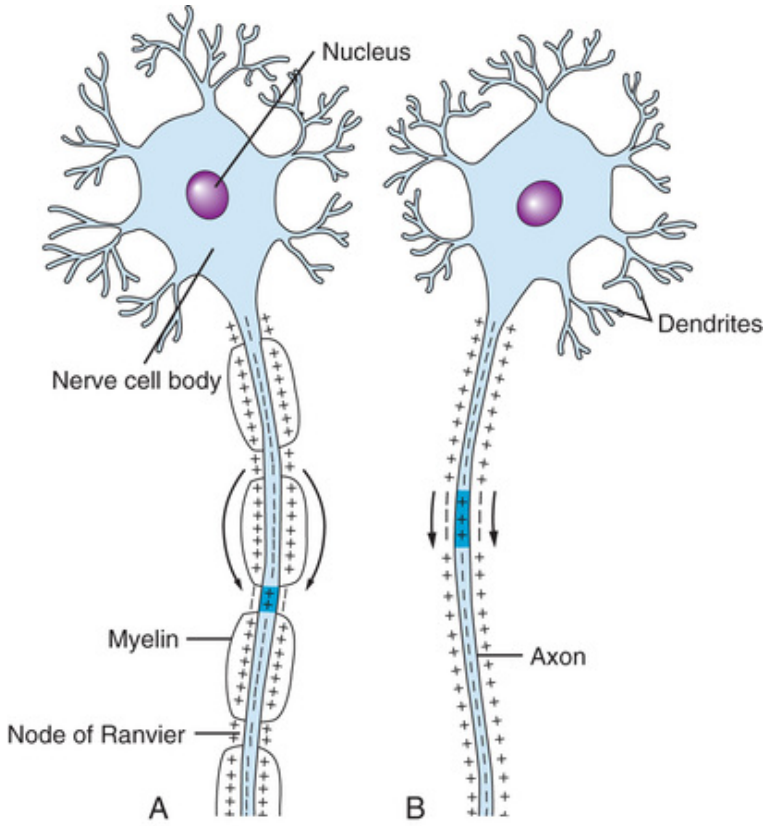

FIGURE 58-2 Nerve impulse transmission. **A,** Saltatory conduction in a myelinated nerve. **B,** Depolarization in an unmyelinated fibre.

Synapse.

A **synapse** is the structural and functional junction between two neurons. It is the point at which the nerve impulse is transmitted from one neuron to another or from a neuron to glands or muscles. The essential structures of synaptic transmission are a presynaptic terminal, a synaptic cleft, and a receptor site on the postsynaptic cell (Figure 58-3). There are two types of synapses: electrical and chemical. In an electrical synapse, an action potential moves from neuron to neuron directly, by allowing electrical current to flow between neurons. In a chemical synapse, an action potential reaches the end of the axon (presynaptic terminal); then it causes release of a chemical substance (neurotransmitter) from tiny vesicles within the axon terminal. The neurotransmitter then crosses the microscopic space (synaptic cleft) between the two neurons and attaches to receptor sites of the receiving (postsynaptic) neuron. Parts of the synapse

include the neurotransmitters, the inactivators, and the receptors (see Figure 58-3).

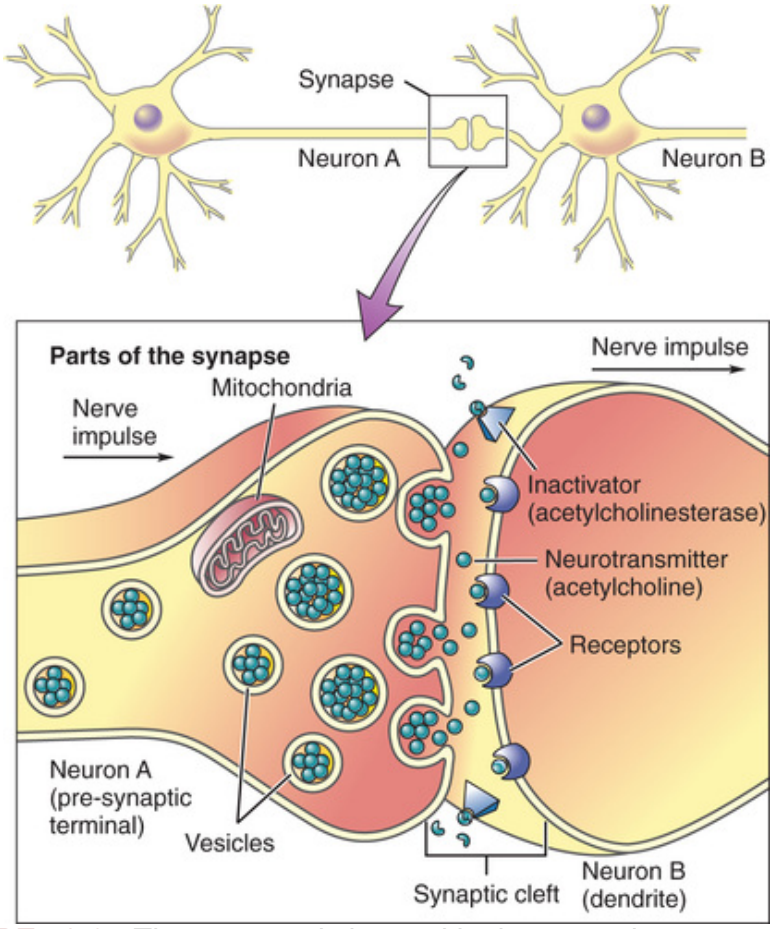

FIGURE 58-3 The synapse is located in the space between neuron A and neuron B. Parts of the synapse include the neurotransmitters, the inactivators, and the receptors. The neurotransmitters are located in the vesicles of neuron A. The inactivators are located on the membrane of neuron B. The receptors are located on the membrane of neuron B. Source: Adapted from Herlihy, B. (2007). *The human body in health and illness* (3rd ed., p. 170, Figure 10-9). Philadelphia: W. B. Saunders.

Neurotransmitters.

A **neurotransmitter** is a chemical agent that affects the transmission of an impulse across the synaptic cleft. Examples of neurotransmitters are presented in Table 58-1. Excitatory neurotransmitters activate postsynaptic receptors, causing an influx of Na^+, increasing the likelihood that an action

potential will be generated. Inhibitory neurotransmitters activate postsynaptic receptors, causing an efflux of K^+, inhibiting the likelihood that an action potential will be generated.

TABLE 58-1
EXAMPLES OF NEUROTRANSMITTERS

Substance	Clinical Relevance*
Acetylcholine	The number of acetylcholine-secreting neurons decreases in Alzheimer's disease; myasthenia gravis results from a reduction in acetylcholine receptors.
Amines	
Epinephrine	Acts as a hormone when secreted by the neurosecretory cells of the adrenal medulla.
Norepinephrine	Cocaine and amphetamines increase the release and block the reuptake of norepinephrine, resulting in overstimulation of postsynaptic neurons.
Serotonin	Involved in moods, emotions, and sleep.
Dopamine	Involved in emotions and moods and regulating motor control. Parkinson's disease results from destruction of dopamine-secreting neurons.
Amino Acids	
γ-Aminobutyric acid (GABA)	Drugs that increase GABA function have been used to treat seizure disorders.
Glutamate and aspartate	Sustained release of glutamate triggers neuronal apoptosis.
Neuropeptides	
Endorphins and enkephalins	The opioids morphine and heroin bind to endorphin and enkephalin receptors on presynaptic neurons and reduce pain by blocking the release of neurotransmitter (see Chapter 10).
Substance P	A neurotransmitter in pain transmission pathways; morphine blocks its release.

*These are examples only; most of the neurotransmitters are also found in other locations and may have additional functions.

Each of the hundreds to thousands of synaptic connections of a single neuron has an influence on that neuron. The net effect of the input is sometimes excitatory and sometimes inhibitory. In general, the net effect depends on the number of presynaptic neurons that are releasing neurotransmitters on the postsynaptic cell. A presynaptic cell that releases an excitatory neurotransmitter does not always cause the postsynaptic cell to depolarize enough to generate an action potential. However, when many presynaptic cells release excitatory neurotransmitters on a single neuron, the sum of their input is enough to generate an action potential.

Neurotransmitters continue to combine with the receptor sites at the postsynaptic membrane until they are inactivated by enzymes, are taken up by the presynaptic endings, or diffuse away from the synaptic region. In addition, the action of neurotransmitters can be affected by drugs and toxins, which can modify their function or block their attachment to receptor sites on the postsynaptic membrane.

Central Nervous System

The major structural components of the CNS are the cerebrum (cerebral hemispheres), brain stem, cerebellum, and spinal cord.

Spinal Cord.

The spinal cord is continuous with the brain stem and exits from the cranial cavity through the foramen magnum. A cross-section of the spinal cord reveals grey matter that is centrally located in an H-shape and is surrounded by white matter (Figure 58-4). The grey matter contains the cell bodies of voluntary motor neurons and preganglionic autonomic motor neurons, as well as cell bodies of association neurons (interneurons). The white matter contains the axons of the ascending sensory and the descending (suprasegmental) motor fibres. The myelin surrounding these fibres gives them their white appearance. Specific ascending and descending pathways in the white matter can be identified. The spinal pathways or tracts are named for the point of origin and the point of destination (e.g., spino-cerebellar tract [ascending], cortico-spinal tract [descending]).

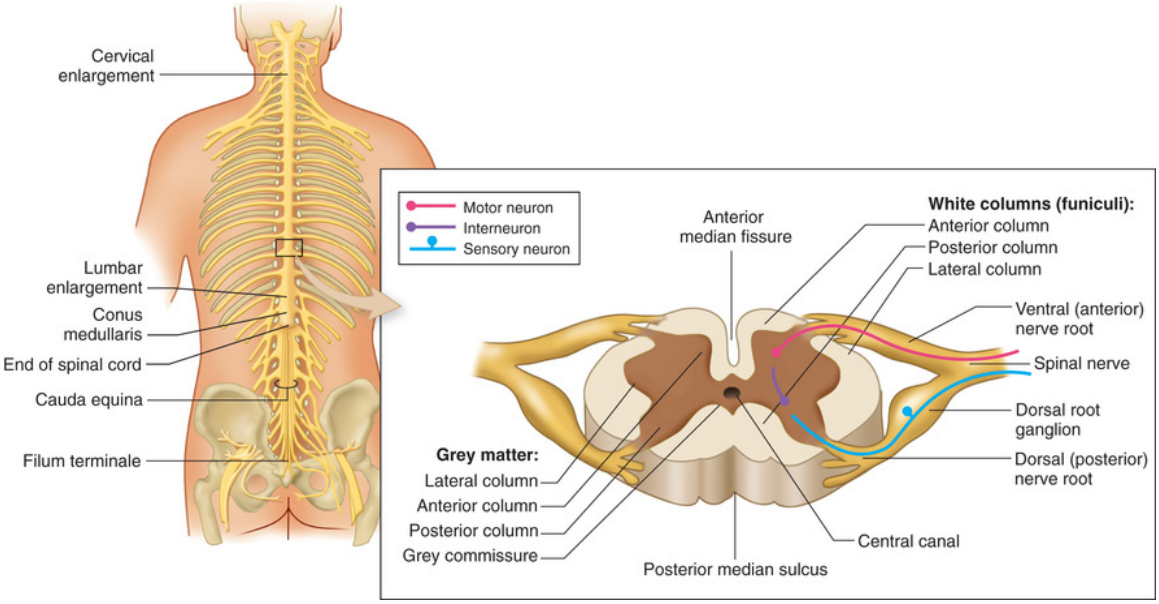

FIGURE 58-4 Spinal cord. The inset illustrates a transverse section of the spinal cord shown in the broader view. Source: Adapted from Patton, K. T., & Thibodeau, G. A. (2013). *Anatomy and physiology* (8th ed., p. 426, Figure 14-6). St. Louis: Mosby.

Ascending Tracts.

In general, the ascending tracts carry specific sensory information to higher levels of the CNS. This information comes from special sensory endings (receptors) in the skin, the muscles and joints, the viscera, and the blood vessels and enters the spinal cord by way of the dorsal roots of the spinal nerves. The fasciculus gracilis and the fasciculus cuneatus (together, commonly called the *dorsal* or *posterior column*) carry information and transmit impulses concerned with touch, deep pressure, vibration, position sense, and kinesthesia (appreciation of movement, weight, and body parts). The *spino-cerebellar tracts* carry information about muscle tension and body position to the cerebellum for coordination of movement. The *spino-thalamic tracts* carry pain and temperature sensations. Thus, the ascending tracts are organized by sensory modality as well as by anatomy.

Other ascending tracts may also participate in transmission of sensory information. The symptoms of various neurological diseases suggest the existence of alternative pathways for touch, position sense, and vibration.

Descending Tracts.

Descending tracts carry impulses that are responsible for muscle movement. Among the most important descending tracts are the cortico-bulbar and cortico-spinal tracts, collectively termed the *pyramidal tract.* These tracts carry volitional (voluntary) impulses from the cortex to the cranial and the peripheral nerves. Another group of descending motor tracts carries impulses from the extrapyramidal system, which includes all motor systems (except the pyramidal system) concerned with voluntary movement. It includes descending pathways originating in the brain stem, basal ganglia, and cerebellum. The motor output exits the spinal cord by way of the ventral roots of the spinal nerves.

Lower Motor Neurons.

Lower motor neurons (LMNs) are the final common pathway through which descending motor tracts influence skeletal muscle, the effector organ for movement. The cell bodies of LMNs, which send axons to innervate the skeletal muscles of arms, trunk, and legs, are located in the anterior horn of the corresponding segments of the spinal cord (e.g., cervical segments contain LMNs for the arms). LMNs for skeletal muscles of eyes, face, mouth, and throat are located in the corresponding segments of the brain stem. These cell bodies and their axons make up the somatic motor components of the cranial nerves. LMN lesions generally cause

weakness or paralysis, denervation atrophy, hyper-reflexia or areflexia, and decreased muscle tone (flaccidity).

Upper Motor Neurons.

Upper motor neurons (UMNs) originate in the cerebral cortex and project downward. The cortico-bulbar tract ends in the brain stem, and the cortico-spinal tract descends into the spinal cord. These neurons influence skeletal muscle movement. UMN lesions generally cause weakness or paralysis, disuse atrophy, hyper-reflexia, and increased muscle tone (spasticity).

Reflex Arc.

A **reflex** is defined as an involuntary response to a stimulus. The components of a monosynaptic reflex arc (the simplest kind of reflex arc) are a receptor organ, an afferent neuron, an effector neuron, and an effector organ (e.g., skeletal muscle). The afferent neuron synapses with the efferent neuron in the grey matter of the spinal cord. A reflex arc is shown in Figure 58-5. In more complex (polysynaptic) reflex arcs, the effector neuron is influenced by other neurons (interneurons) in addition to the afferent neuron. In the spinal cord, reflex arcs play an important role in maintaining muscle tone, which is essential for body posture.

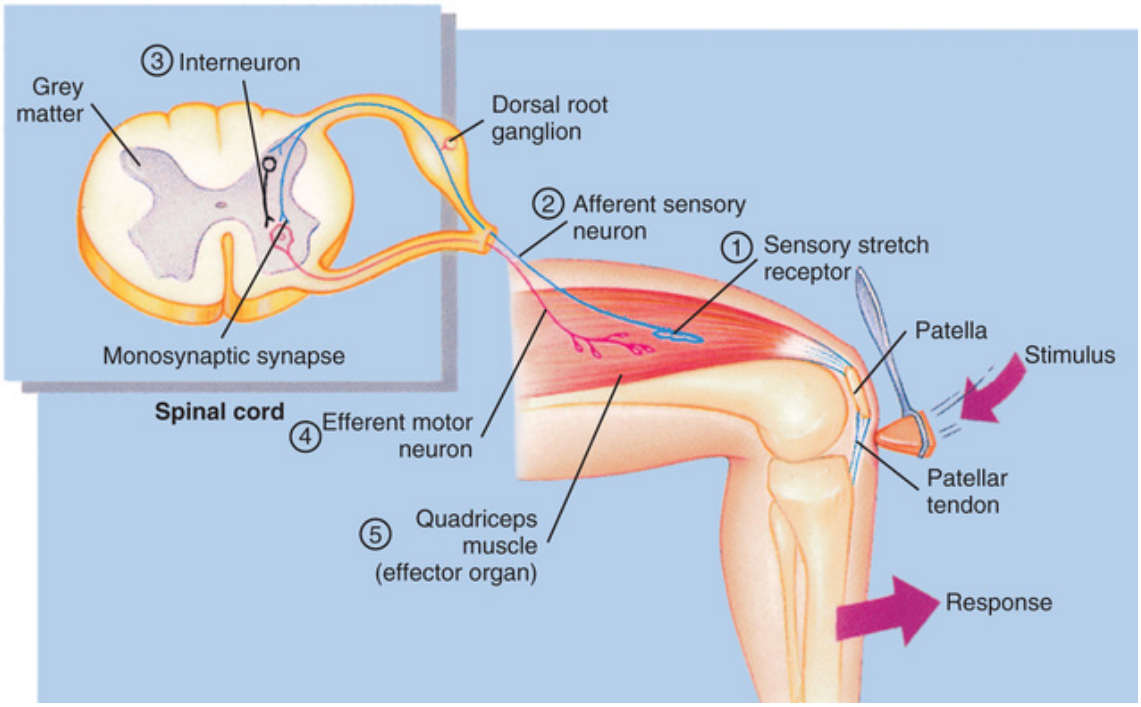

FIGURE 58-5 Basic diagram of the patellar "knee-jerk" reflex arc. The impulse travels through the (1) sensory stretch receptor and (2) afferent sensory neuron, through the (3) interneuron, and back through the (4) efferent motor neuron and to the (5) quadriceps muscle (effector organ). Source: Adapted from Thibodeau, G. A., & Patton, K. T. (2008). *Structure and function of the body* (13th ed., p. 192, Figure 8-5). St. Louis: Mosby.

Brain.

The brain can be divided into three major components: cerebrum, brain stem, and cerebellum.

Cerebrum.

The *cerebrum* is composed of the right and left cerebral hemispheres and divided into four major lobes: frontal, temporal, parietal, and occipital (Figure 58-6).

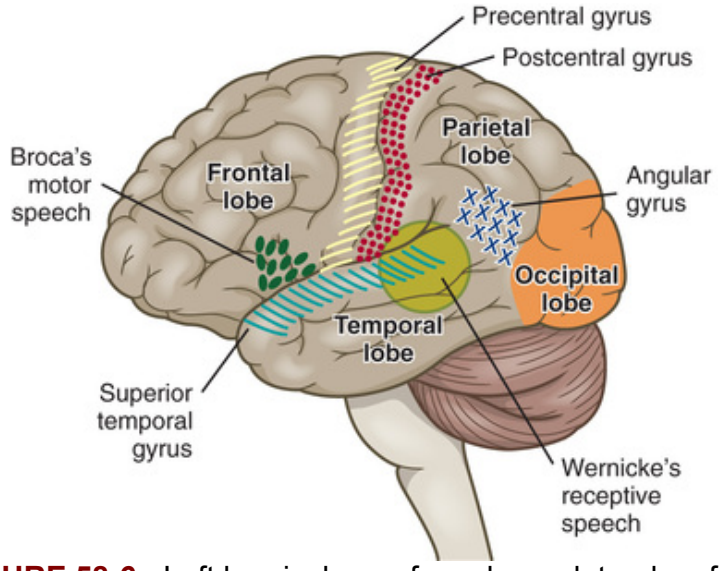

FIGURE 58-6 Left hemisphere of cerebrum, lateral surface, showing major lobes and areas of the brain.

The functions of the cerebrum are multiple and complex. Specific areas of the cerebral cortex are associated with specific functions. Table 58-2 summarizes the location and function of the parts of the cerebrum. The *frontal lobe* controls higher cognitive function, memory, voluntary eye movements, voluntary movements, and, usually in the left hemisphere, expressive speech and language in Broca's area. The *temporal lobe* contains integration of somatic, visual, and auditory data and, usually in the left hemisphere, Wernicke's area, which is responsible for receptive language. The *parietal lobe* is composed of the sensory cortex and controlling and interpreting spatial information. Processing of visual data takes place in the *occipital lobe.*

TABLE 58-2
LOCATION AND FUNCTION OF THE PARTS OF THE CEREBRUM

Part	Location	Function
Cortical Areas		
Motor		
Primary	Precentral gyrus	Facilitates motor control and movement on the opposite side of the body
Supplemental	Anterior to precentral gyrus	Facilitates proximal muscle activity, including activity for stance and gait, spontaneous movement, and coordination
Sensory		
Somatic	Postcentral gyrus	Processes sensory response from the opposite side of body
Visual	Occipital lobe	Registers visual images
Auditory	Superior temporal gyrus	Registers auditory inputs
Association areas	Parietal lobe	Integrates somatic and sensory inputs
	Posterior temporal lobe	Integrates visual and auditory inputs for language comprehension
	Anterior temporal lobe	Integrates past experiences
	Anterior frontal lobe	Controls higher-order processes (e.g., judgement, insight, reasoning, problem solving, planning)
Language		
Comprehension	Wernicke's area, usually in the left hemisphere	Integrates auditory language (understanding of spoken words)
Expression	Broca's area, usually in the left hemisphere	Regulates verbal expression
Other Functions		
Basal ganglia	Near lateral ventricles of both cerebral hemispheres	Control and facilitate learned and automatic movements
Thalamus	Below basal ganglia	Relays sensory and motor inputs to cortex and other parts of cerebrum
Hypothalamus	Below thalamus	Regulates endocrine and autonomic functions (e.g., feeding, sleeping, emotional and sexual responses)
Limbic system	Lateral to hypothalamus	Influences affective (emotional) behaviour and basic drives such as feeding and sexual behaviour

The basal ganglia, the thalamus, the hypothalamus, and the limbic system are also located in the cerebrum. The basal ganglia are a group of paired structures located centrally in the cerebrum and the midbrain; most of them are on both sides of the thalamus. The function of the basal ganglia is to modulate initiation, execution, and completion of voluntary movements and automatic movements associated with skeletal muscle activity, such as swinging of the arms during walking, swallowing saliva, and blinking.

The *thalamus* (part of the diencephalon) lies directly above the brain stem (Figure 58-7) and is the major relay centre for sensory and other afferent (e.g., cerebellar) inputs to the cerebral cortex. The *hypothalamus* is located just inferiorly to the thalamus and slightly in front of the midbrain. It regulates the ANS and the endocrine system. The limbic system is located near the inner surfaces of the cerebral hemispheres (Figure 58-8)

and is concerned with emotion, aggression, feeding behaviour, and sexual response.

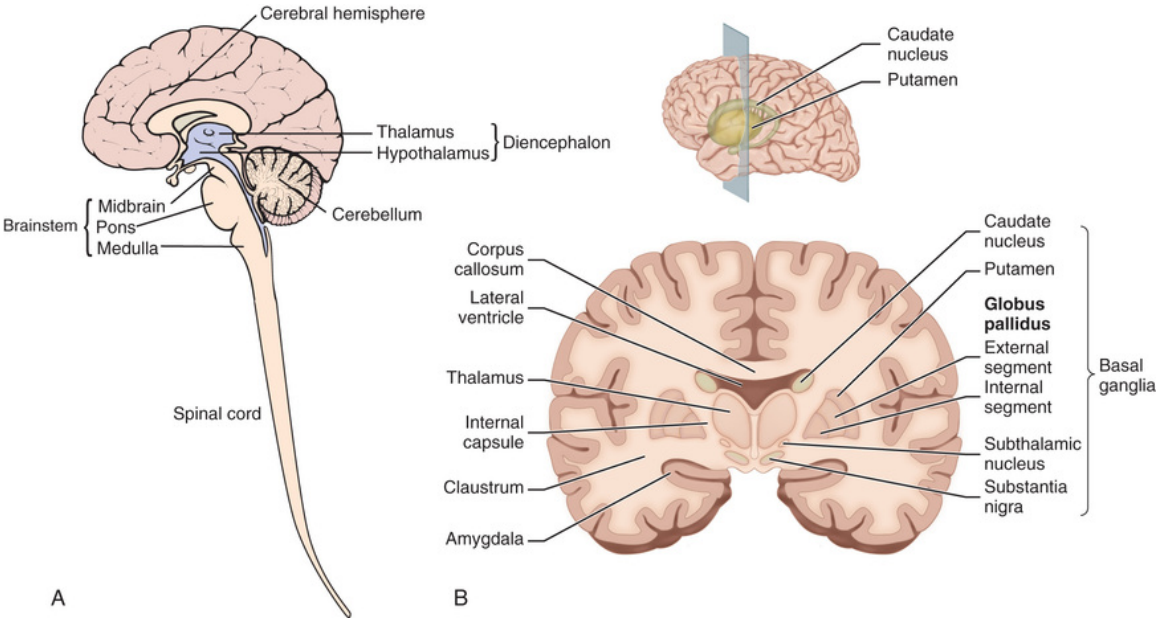

FIGURE 58-7 The central nervous system. **A,** Side view of major divisions. **B,** Coronal overview of the components of the basal ganglia. Source: **B,** Based on Nieuwenhuys, Voogd, and van Huijzen, 1981.

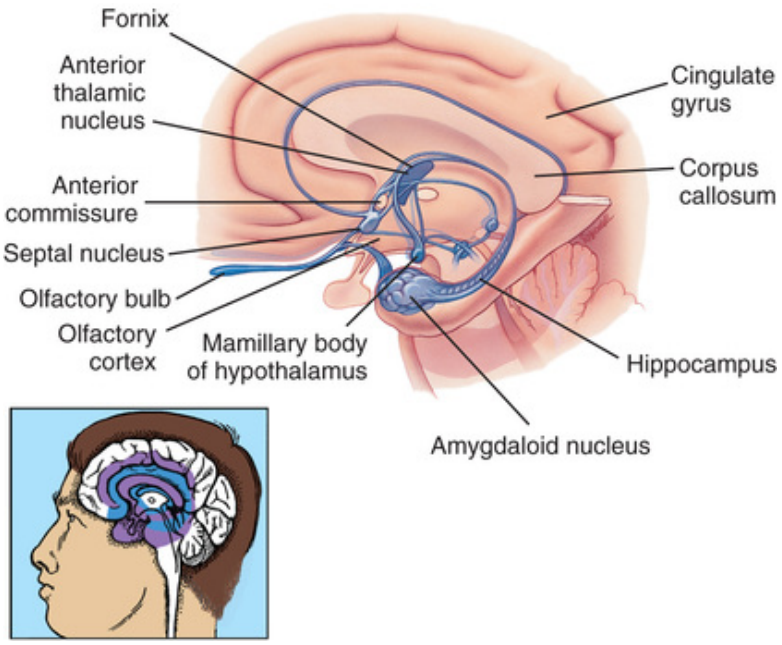

FIGURE 58-8 Structures of the limbic system. Source: Adapted from Patton, K. T., & Thibodeau, G. A. (2010). *Anatomy and physiology* (7th ed., p. 436, Figure 13-22). St. Louis: Mosby.

Brain Stem.

The *brain stem* includes the midbrain, the pons, and the medulla (see Figure 58-7). Ascending and descending fibres pass through the brain stem between the cerebrum and the cerebellum. The cell bodies, or nuclei, of cranial nerves III through XII are in the brain stem. Also located in the brain stem is the *reticular formation,* a diffusely arranged group of neurons and their axons that extends from the medulla to the thalamus and the hypothalamus. The functions of the reticular formation include relaying sensory information, influencing excitatory and inhibitory control of spinal motor neurons, and controlling vasomotor and respiratory activity. The reticular activating system is part of the reticular formation and is the regulatory system for arousal, a component of consciousness.

The vital centres concerned with respiratory, vasomotor, and cardiac function are located in the medulla. The brain stem also contains the centres for sneezing, coughing, hiccupping, gagging, vomiting, sucking, and swallowing.

Cerebellum.

The *cerebellum* is located in the posterior part of the cranial fossa, inferior to the occipital lobe. The cerebellum coordinates voluntary movement and

maintains trunk stability and equilibrium. To perform these functions, the cerebellum receives information from the cerebral cortex, the muscles, the joints, and the inner ear. It influences motor activity through its axonal connections to the motor cortex, the brain stem nuclei, and their descending pathways.

Ventricles and Cerebro-Spinal Fluid.

The ventricles are four cavities within the brain, filled with cerebro-spinal fluid (CSF), that connect with one another and with the spinal canal. The lower portion of the fourth ventricle becomes the central canal in the lower part of the brain stem. The spinal canal is located in the centre of the spinal cord and extends the full length of the spinal cord. Figure 58-9 depicts the ventricles and the flow of cerebro-spinal fluid in the CNS.

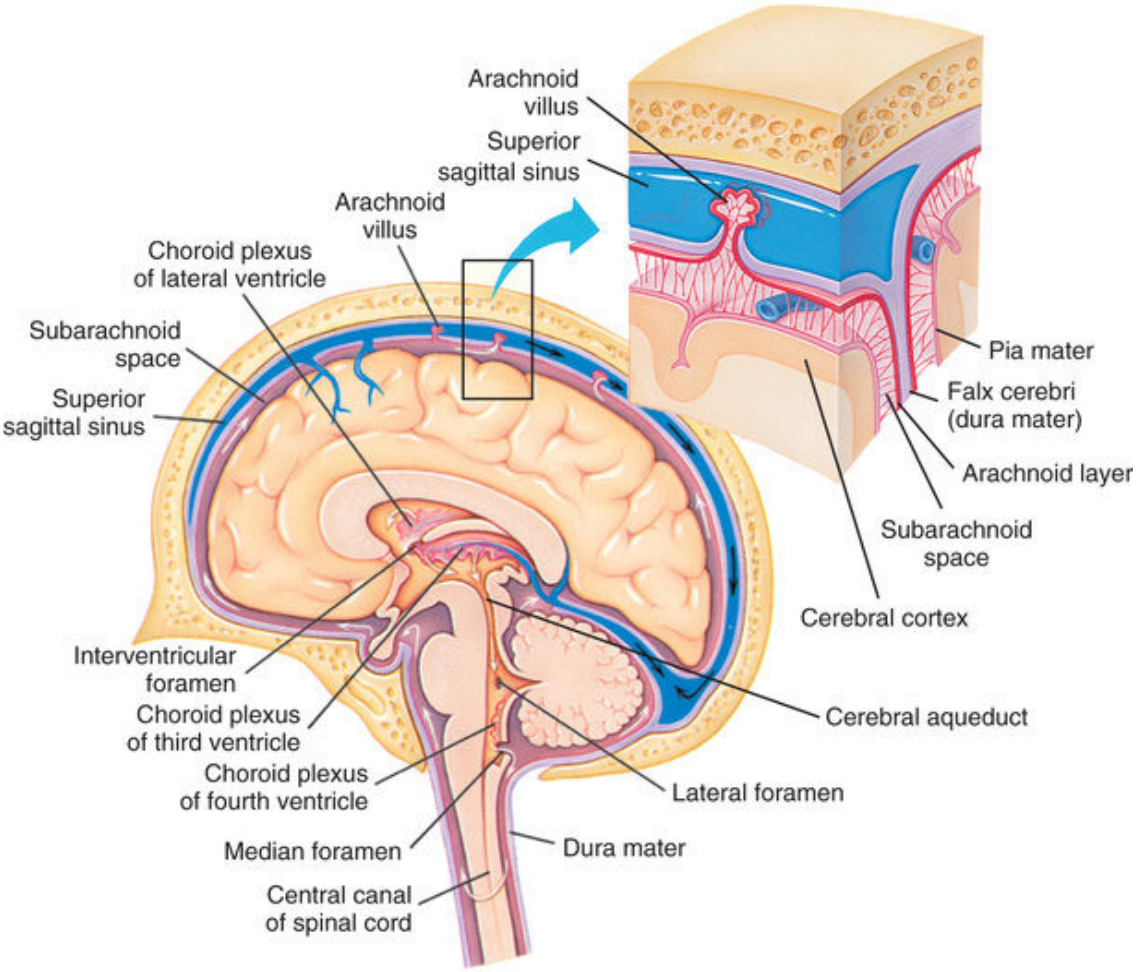

FIGURE 58-9 Flow of cerebro-spinal fluid (CSF).The fluid produced by filtration of blood by the choroid plexus of each ventricle flows inferiorly through the lateral ventricles, the interventricular foramen, the third ventricle, the cerebral aqueduct, the fourth ventricle, and the subarachnoid space and to the blood.

Source: Adapted from Patton, K. T., & Thibodeau, G. A. (2010). *Anatomy and physiology* (7th ed., p. 417, Figure 13-5). St. Louis: Mosby.

Cerebro-Spinal Fluid.

Cerebro-spinal fluid (CSF) is a clear, colourless fluid similar to blood plasma and interstitial fluid (McCance & Huether, 2014). CSF circulates within the subarachnoid space that surrounds the brain, the brain stem, and the spinal cord; provides cushioning for the brain and the spinal cord; allows fluid shifts from the cranial cavity to the spinal cavity; and carries nutrients. CSF is produced primarily by the choroid plexus in the lateral, third, and fourth ventricles. It flows from the lateral ventricles to the third ventricle via the interventricular foramen and then moves from the third to

the fourth ventricle through the cerebral aqueduct. Finally, CSF flows into the subarachnoid space through the lateral and median foramen (see Figure 58-9). It is absorbed primarily through the *arachnoid villi* (tiny projections into the subarachnoid space), into the intradural venous sinuses, and eventually into the venous system. Although CSF is continually being formed, many physiological factors influence its rate of absorption and formation. The ventricles and the central canal are normally filled with an average of 135 mL of CSF. A disturbance in the formation, flow, or absorption of CSF can lead to hydrocephalus.

The analysis of CSF composition provides useful diagnostic information relating to certain nervous system diseases. CSF pressure is often measured in patients with actual or suspected intracranial diseases. Increases in intracranial pressure, indicated by increased CSF pressure, can lead to herniation of the brain and compression of vital brain stem structures. The signs marking this event are part of the herniation (see Chapter 59).

Peripheral Nervous System

The PNS includes all of the neuronal structures that lie outside the CNS. It consists of the spinal and cranial nerves, their associated ganglia (groupings of cell bodies), and portions of the ANS.

Spinal Nerves.

The spinal cord is a series of spinal segments, one on top of another. In addition to the cell bodies, each segment contains a pair of dorsal (afferent) sensory nerve fibres or roots and ventral (efferent) motor fibres or roots, which innervate a specific region of neck, trunk, or limbs. This combined motor–sensory nerve is called a *spinal nerve* (Figure 58-10). The cell bodies of the voluntary motor system are located in the anterior horn of the spinal cord grey matter. The cell bodies of the autonomic (involuntary) motor system are located in the anterolateral portion of spinal cord grey matter. The cell bodies of sensory fibres are located in the dorsal root ganglia just outside the spinal cord. On exiting the spinal column, each spinal nerve divides into ventral and dorsal rami, a collection of motor and sensory fibres that eventually extend to peripheral structures (e.g., skin, muscles, viscera).

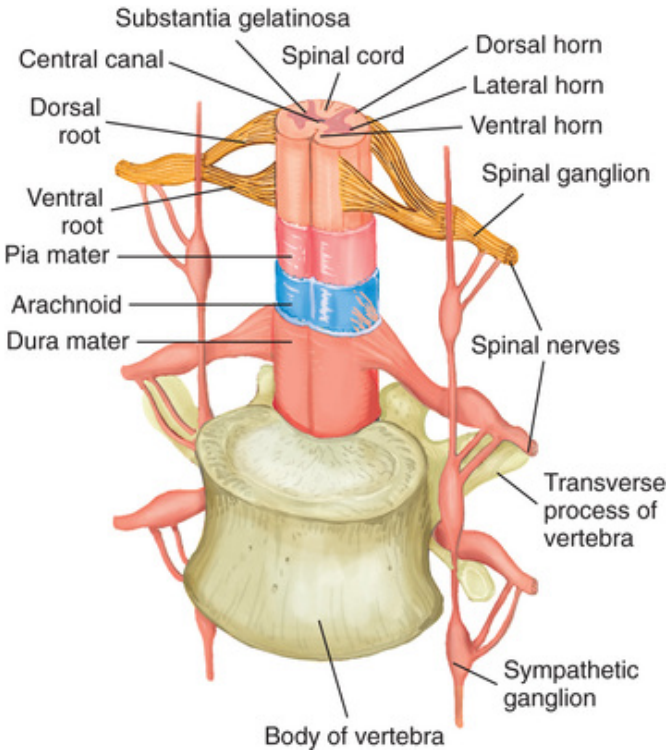

FIGURE 58-10 Illustration of a cross-section of spinal cord, showing attachments of spinal nerves and coverings of the spinal cord. Source: Adapted from Thibodeau, G. A., & Patton, K. T. (2008). *Structure and function of the body* (13th ed., p. 205, Figure 8-13). St. Louis: Mosby.

A **dermatome** is the area of skin innervated by the sensory fibres of a single dorsal root of a spinal nerve. The locations of dermatomes indicate the general pattern of somatic sensory innervation by spinal segments. A *myotome* is a muscle group innervated by the primary motor neurons of a single ventral root. The dermatomes and myotomes of a given spinal segment overlap with those of adjacent segments because of the development of ascending and descending collateral branches of nerve fibres (Figure 58-11).

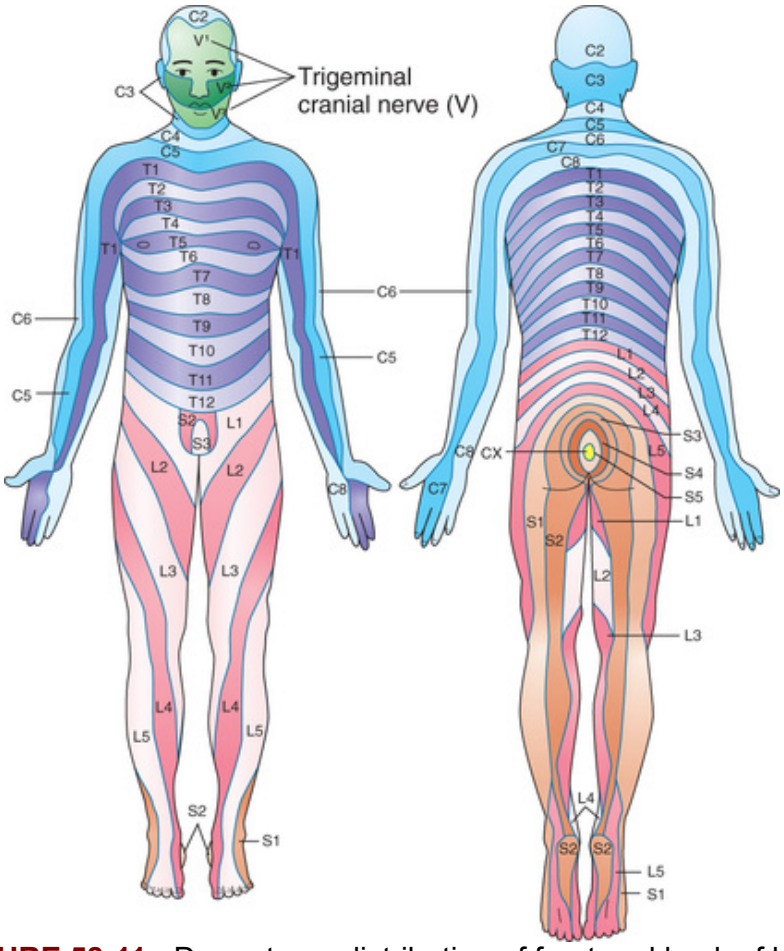

FIGURE 58-11 Dermatome distribution of front and back of body surface. Source: McCance, K. L., & Huether, S. E. (2014). *Pathophysiology: The biologic basis for disease in adults and children* (7th ed., p. 471, Figure 15-24). St. Louis: Mosby.

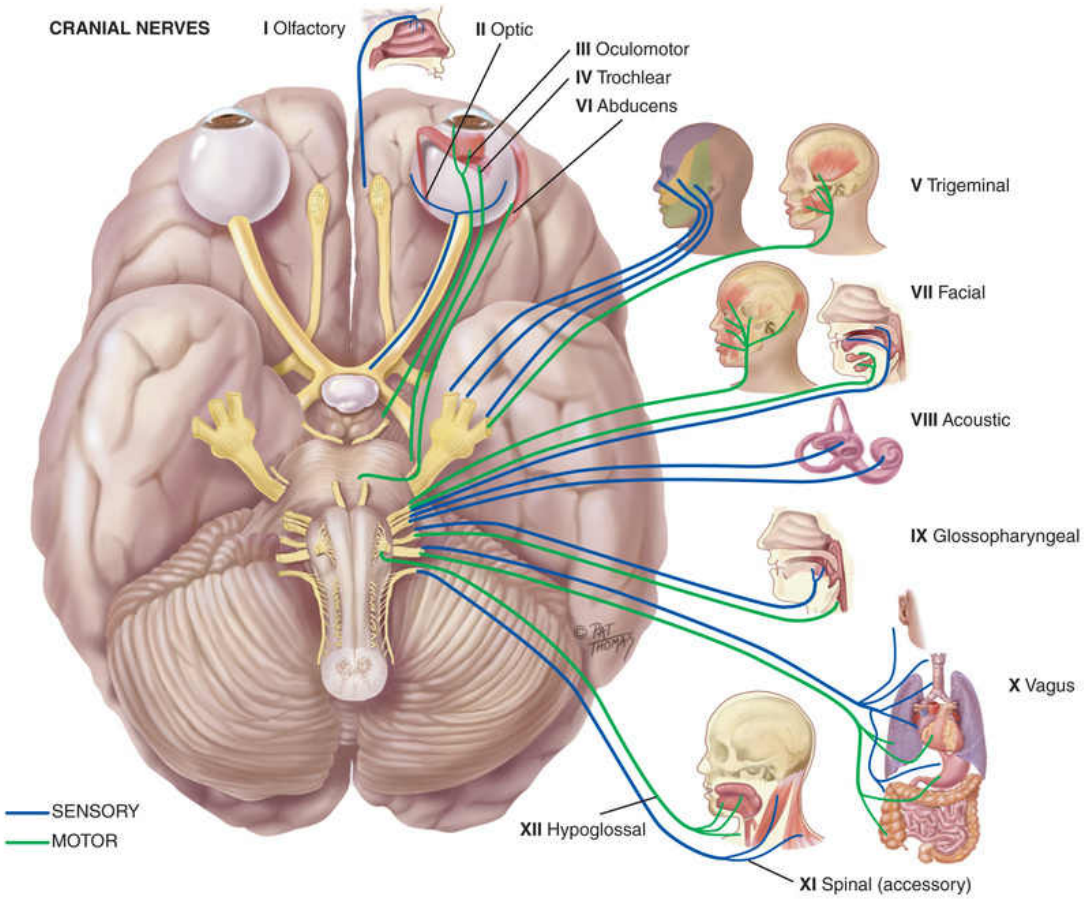
Cranial Nerves.

The **cranial nerves (CNs)** are the 12 paired nerves composed of cell bodies with fibres that exit from the cranial cavity. Unlike the spinal nerves, which always have both afferent sensory and efferent motor fibres, some CNs are only sensory, some only motor, and some both. Figure 58-12 summarizes the cranial nerves and their functions and position in relation to the brain and the spinal cord. Just as the cell bodies of the spinal nerves are located in specific segments of the spinal cord, the cell bodies (nuclei) of the cranial nerves are located in specific segments of the brain. Exceptions are the nuclei of the olfactory and optic nerves. The primary cell bodies of the olfactory nerve are located in the nasal epithelium, and those of the optic nerve are in the retina.



Cranial Nerve	Type	Function
I: Olfactory	Sensory	Smell
II: Optic	Sensory	Vision
III: Oculomotor	Mixed*	Motor—most EOM movement, opening of eyelids Parasympathetic—pupil constriction, lens shape
IV: Trochlear	Motor	Down and inward movement of eye
V: Trigeminal	Mixed	Motor—muscles of mastication Sensory—sensation of face and scalp, cornea, mucous membranes of mouth and nose
VI: Abducens	Motor	Lateral movement of eye
VII: Facial	Mixed	Motor—facial muscles, close eye, labial speech, close mouth Sensory—taste (sweet, salty, sour, bitter) on anterior two-thirds of tongue Parasympathetic—saliva and tear secretion
VIII: Acoustic	Sensory	Hearing and equilibrium
IX: Glossopharyngeal	Mixed	Motor—pharynx (phonation and swallowing) Sensory—taste on posterior one third of tongue, pharynx (gag reflex) Parasympathetic—parotid gland, carotid reflex
X: Vagus	Mixed	Motor—pharynx and larynx (vocalizing and swallowing) Sensory—general sensation from carotid body, carotid sinus, pharynx, viscera Parasympathetic—carotid reflex
XI: Spinal (accessory)	Motor	Movement of trapezius and sternocleidomastoid muscles
XII: Hypoglossal	Motor	Movement of tongue

Mixed refers to a nerve carrying a combination of fibres: motor + sensory; motor + parasympathetic; or motor + sensory + parasympathetic.

FIGURE 58-12 The cranial nerves and their functions. Source: Jarvis, C. (2014). *Physical examination & health assessment* (2nd Canadian ed., p. 662, Figure 25-7). (A. J. Brown, J. MacDonald-Jenkins, & M. Luctkar-Flude). Toronto: Saunders/Elsevier.

Autonomic Nervous System.

The **autonomic nervous system (ANS)** governs involuntary functions of cardiac muscle, smooth (involuntary) muscle, and glands.

The ANS is divided into two components, sympathetic and parasympathetic, that are anatomically and functionally different. These two systems function together to maintain a relatively balanced internal environment. The ANS is both an efferent and an afferent system. It consists of preganglionic nerves and postganglionic nerves.

The preganglionic cell bodies of the *sympathetic nervous system* (SNS) are located in spinal segments T1 through L2. The major neurotransmitter released by the postganglionic fibres of the SNS is norepinephrine, and the neurotransmitter released by the preganglionic fibres is acetylcholine.

In contrast, the preganglionic cell bodies of the *parasympathetic nervous system* (PSNS) are located in the brain stem and in the sacral spinal segments (S2 through S4). Acetylcholine is the neurotransmitter released at both preganglionic and postganglionic nerve endings.

The ANS provides dual and often reciprocal innervation to many structures. For example, the SNS increases the rate and force of the heart contraction, and the PSNS decreases the rate and force. Table 58-3 lists the effects of the SNS and PSNS.

TABLE 58-3

EFFECTS OF SYMPATHETIC AND PARASYMPATHETIC NERVOUS SYSTEMS

Visceral Effector	Effect of Sympathetic Nervous System*	Effect of Parasympathetic Nervous System†
Heart	Increase in rate and strength of heartbeat (β-receptors)	Decrease in rate and strength of heartbeat
Smooth muscle of blood vessels		
• Skin blood vessels	Constriction (α-receptors)	No effect
• Skeletal muscle blood vessels	Dilation (β-receptors)	No effect
• Coronary blood vessels	Dilation (β-receptors), constriction (α-receptors)	Dilation (β-receptors)
• Abdominal blood vessels	Constriction (α-receptors)	No effect
• Blood vessels of external genitals	Ejaculation (contraction of smooth muscle in male ducts [e.g., epididymis, ductus deferens])	Dilation of blood vessels, causing penile erection
Smooth muscle of hollow organs and sphincters		
• Bronchi	Dilation (β-receptors)	Constriction (α-receptors)
• Digestive tract, except sphincters	Decrease in rate of peristalsis (β-receptors)	Increase in rate of peristalsis
• Sphincters of digestive tract	Contraction (α-receptors)	Relaxation
• Urinary bladder	Relaxation (β-receptors)	Contraction
• Urinary sphincters	Contraction (α-receptors)	Relaxation
Eye		
Iris	Contraction of radial muscle, dilation of pupil	Contraction of circular muscle, constriction of pupil
• Ciliary	Relaxation, accommodation for far vision	Contraction, accommodation for near vision
Hairs (pilomotor muscles)	Contraction producing goose pimples or piloerection (α-receptors)	No effect
Glands		
• Sweat	Increase in sweat (neurotransmitter, acetylcholine)	No effect
Digestive (e.g., salivary, gastric)	Decrease in secretion of saliva; not known for others	Increase in secretion of saliva and gastric hydrochloric acid (HCl)
• Pancreas, including islets	Decrease in secretion	Increase in secretion of pancreatic juice and insulin
• Liver	Increase in glycogenolysis (β-receptors), increase in blood glucose level	No effect
Adrenal medulla‡	Increase in epinephrine secretion	No effect

*Neurotransmitter is norepinephrine unless otherwise stated.

†Neurotransmitter is acetylcholine unless otherwise stated.

‡Sympathetic preganglionic axons terminate in contact with secreting cells of the adrenal medulla. Thus, the adrenal medulla functions as what is sometimes called a *giant sympathetic postganglionic neuron.*

Source: Adapted from Patton, K. T., & Thibodeau, G. A. (2010). *Anatomy and physiology* (7th ed., p. 483, Table 14-6). St. Louis: Mosby.

The result of SNS stimulation is activation of mechanisms required for the "fight or flight" response that occurs throughout the body. In contrast, the PSNS is geared to act in localized and discrete regions. It serves to conserve and restore the energy stores of the body.

Cerebral Circulation

Knowledge of the distribution of the major arteries of the brain and the area supplied is essential for understanding and evaluating the signs and symptoms of cerebro-vascular disease and trauma. The blood supply of the brain arises from the internal carotid arteries (anterior circulation) and the vertebral arteries (posterior circulation) (see Figure 58-13).

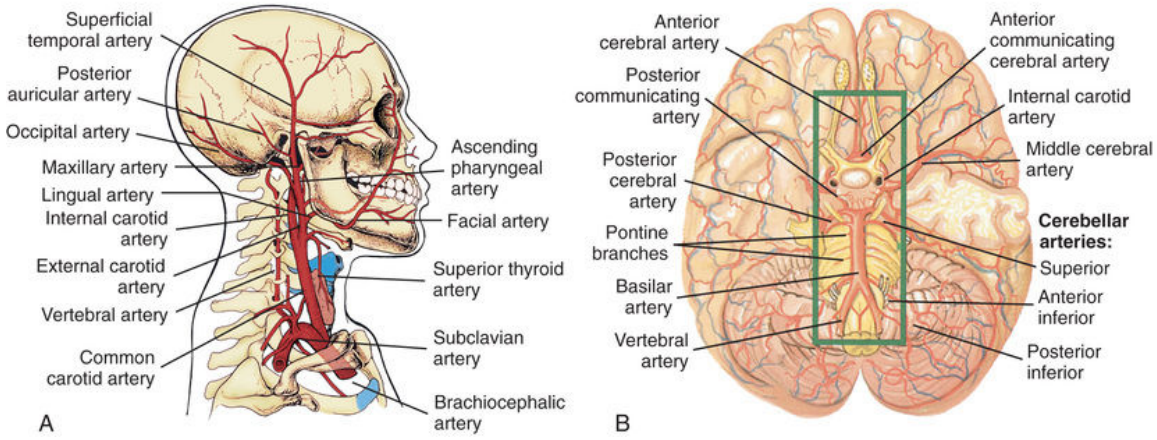


FIGURE 58-13 Arteries of the head and neck. **A,** Right lateral view: brachiocephalic artery, right common carotid artery, right subclavian artery, and their branches. The major arteries to the head are the common carotid and vertebral arteries. **B,** Inferior view of the brain, showing the vertebral, basilar, and internal carotid arteries and their branches. Source: Adapted from Patton, K. T., & Thibodeau, G. A. (2010). *Anatomy and physiology* (7th ed., p. 633, Figure 18-19). St. Louis: Mosby.

The internal carotid arteries provide blood flow to the anterior and middle portions of the cerebrum. The vertebral arteries join to form the basilar artery and provide blood flow to the brain stem, cerebellum, and posterior cerebrum. The *circle of Willis* arises from the basilar artery and the two internal carotid arteries (Figure 58-14). This vascular circle may act as a safety valve when differential pressures are present in these arteries. It also may function as an anastomotic pathway when a major artery on one side of the brain becomes occluded. Superior to the circle of Willis, three

pairs of arteries supply blood to the left and right hemispheres. The anterior cerebral artery feeds the medial and anterior portions of the frontal lobes. The middle cerebral artery feeds the outer portions of the frontal, parietal, and superior temporal lobes. The posterior cerebral artery feeds the medial portions of the occipital and inferior temporal lobes. Venous blood drains from the brain through the dural sinuses, which form channels that drain into the two jugular veins.

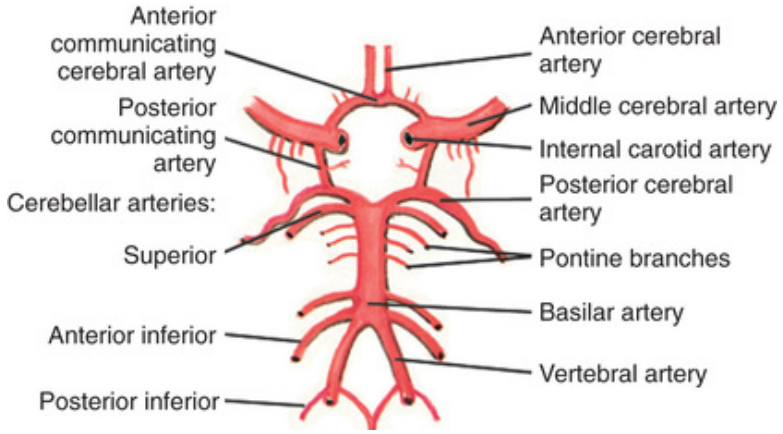

FIGURE 58-14 Arteries at the base of the brain. The arteries that compose the circle of Willis are the two anterior cerebral arteries, joined to each other by the anterior communicating cerebral artery and to the posterior cerebral arteries by the posterior communicating arteries. Source: Adapted from Patton, K. T., & Thibodeau, G. A. (2010). *Anatomy and physiology* (7th ed., p. 634, Figure 18-20). St. Louis: Mosby.

Blood–Brain Barrier.

The **blood–brain barrier** is a physiological barrier between blood capillaries and brain tissue (McCance & Huether, 2014). This barrier protects the brain from certain potentially harmful agents, while allowing nutrients and gases to enter. Because the blood–brain barrier affects the penetration of drugs, only certain ones can enter the CNS from the bloodstream. Lipid-soluble compounds enter the brain quickly, whereas water-soluble and ionized drugs enter the brain and spinal cord slowly. Damage to the blood–brain barrier results in the penetration of drugs and other substances into brain tissue.

Protective Structures

Meninges.

The **meninges** are three layers of protective membranes that surround the brain and the spinal cord: dura mater, arachnoid, and pia mater (see Figure 58-9). The thick *dura mater* forms the outermost layer. The *falx cerebri* is a fold of the dura that separates the two cerebral hemispheres and prevents expansion of brain tissue in situations such as the presence of a rapidly growing tumour or acute hemorrhage. The *tentorium cerebelli* is a fold of dura that separates the cerebral hemispheres from the posterior fossa, which contains the brain stem and the cerebellum. Expansion of mass lesions in the cerebrum forces the brain to herniate through the opening created by the brain stem. This condition is termed *tentorial herniation* (see Chapter 59).

The *arachnoid layer* is a delicate, impermeable membrane that lies between the thick dura mater and the pia mater (the delicate, innermost layer of the meninges). The area between the arachnoid layer and the pia mater is the *subarachnoid space* and is filled with CSF. Structures such as arteries, veins, and cranial nerves passing to and from the brain and the skull must pass through the subarachnoid space. A larger subarachnoid space in the region of the third and fourth lumbar vertebrae is the area used to obtain CSF during a lumbar puncture. (The spinal cord itself ends between the first and second lumbar vertebrae.)

Skull.

The bony skull protects the brain from external trauma. It is composed of 8 cranial bones and 14 facial bones. Although the top and the sides of the inside of the skull are relatively smooth, the bottom surface is uneven; it has many ridges, prominences, and foramina (holes through which blood vessels and nerves enter the intracranial vault). The largest hole is the foramen magnum, through which the brain stem extends to the spinal cord. This foramen is the only major space for the expansion of brain contents when increased intracranial pressure occurs.

Vertebral Column.

The vertebral column protects the spinal cord, supports the head, and provides flexibility. The vertebral column is made up of 33 individual vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 sacral (fused into one, the sacrum), and 4 coccygeal (fused into one, the coccyx). Each vertebra has a central opening through which the spinal cord passes. The vertebrae are

held together by a series of ligaments. Intervertebral discs occupy the spaces between vertebrae. Figure 58-15 depicts the vertebral column in relation to the trunk.

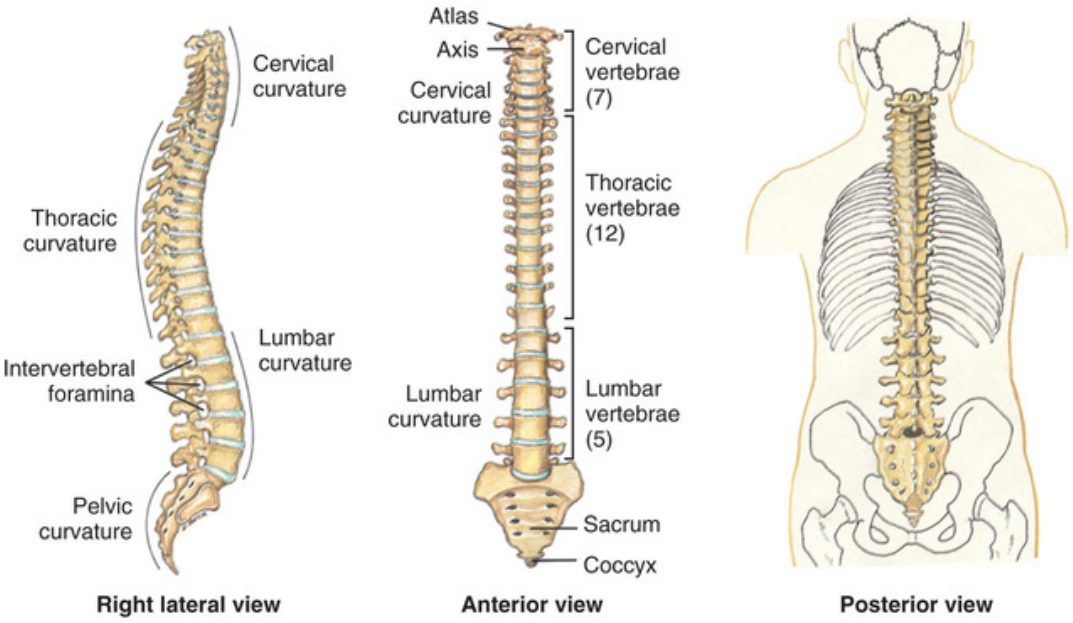

FIGURE 58-15 Vertebral column (three views). Source: Adapted from Patton, K. T., & Thibodeau, G. A. (2010). *Anatomy and physiology* (7th ed., p. 237, Figure 8-13). St. Louis: Mosby.

Age-Related Considerations

Effects of Aging on the Nervous System

Several parts of the nervous system are affected by aging. In the CNS, neurons are lost in certain areas of the brain stem, the cerebellum, and the cerebral cortex. This loss is a gradual process that begins in early adulthood. With loss of neurons, the ventricles widen. Brain weight also decreases by 10% to 15% between the second and ninth decades of life (Porter & Kaplan, 2011). Cerebral blood flow decreases, and CSF production declines. Changes in neurotransmitters of the dopaminergic and cholinergic systems result in decreasing amounts of acetylcholine, serotonin, and catecholamines.

In the PNS, degenerative changes in myelin cause a decrease in nerve conduction. Coordinated neuro-muscular activity, such as the maintenance of blood pressure in response to changing from a lying to a standing position, is altered with aging. As a result, older adults are more likely to experience orthostatic hypotension. Similarly, coordination of neuro-muscular activity to maintain body temperature is also less efficient with aging, making older adults less able to adapt to extremes in environmental temperature and more vulnerable to both hypothermia and hyperthermia.

In general, the intellectual performance of older adults who do not have brain dysfunction remains fairly consistent. A slowdown in central processing may result in needing longer to perform certain tasks. Sensory changes, including decreases in taste and smell perception, may result in decreased dietary intake in older adults. Changes in pain perception may occur. Decline in visual and auditory acuity can result in perceptual challenges. Problems with balance and coordination can increase older adults' risk for falls and subsequent fractures.

Changes in assessment findings result from age-related alterations in the various components of the nervous system. Age-related changes in the nervous system and differences in assessment findings are presented in Table 58-4.

TABLE 58-4

AGE-RELATED DIFFERENCES IN ASSESSMENT
Nervous System

Component	Changes	Differences in Assessment Findings
Central Nervous System		
Brain	Reduction in cerebral blood flow and metabolism	Alterations in certain mental functions
	Decrease in efficiency of temperature-regulating mechanism	Decrease in body temperature, impairment of ability to adapt to environmental temperature
	Decrease in neurotransmitter volume, disruption in integration as result of loss of neurons	Conduction of nerve impulses slowed, response time slowed
	Decrease in oxygen supply, changes in basal ganglia caused by vascular changes	Changes in gait and ambulation; diminished kinesthetic sense
	Cerebral tissue atrophy and increased size of ventricles	Altered balance, vertigo, syncope; increased postural hypotension; decreased proprioception; decreased sensation
Peripheral Nervous System		
Cranial and spinal nerves	Loss of myelin and decrease in conduction time in some nerves	Decrease in reaction time in specific nerves
	Cellular degeneration, death of neurons	Decrease in speed and intensity of neuronal reflexes
Functional Divisions		
Motor	Decrease in muscle bulk	Diminished strength and agility
	Decrease in electrical activity	Increased reaction and movement time
Sensory*	Decrease in sensory receptors caused by degenerative changes and involution of fine corpuscles of nerve endings	Diminished sense of touch; inability to localize stimuli; decrease in appreciation of touch, temperature, and peripheral vibrations
	Decrease in electrical activity	Slowing of or alteration in sensory reception
	Atrophy of taste buds	Signs of malnutrition, weight loss
	Degeneration and loss of fibres in olfactory bulb	Diminished sense of smell
	Degenerative changes in nerve cells in vestibular system of inner ear, cerebellum, and proprioceptive pathways in nervous system	Poor ability to maintain balance, widened gait
Reflexes	Possible decrease in deep tendon reflexes	Below-average reflex score
	Decrease in sensory conduction velocity as result of myelin sheath degeneration	Sluggish reflexes, lengthened reaction time
Reticular Formation		
Reticular activating system	Modification of hypothalamic function, reduction in stage IV sleep	Increase in frequency of spontaneous awakening, together with tiredness, interrupted sleep, insomnia
Autonomic Nervous System		
SNS and PSNS	Morphological changes in features of ganglia, slowing of ANS responses	Orthostatic hypotension, systolic hypertension

*Specific changes related to the eye and the ear are described in Chapter 24.

ANS, autonomic nervous system; *PSNS,* parasympathetic nervous system; *SNS,* sympathetic nervous system.

Assessment of the Nervous System

Because of the complexity of the nervous system, neurological assessment is challenging and lengthy. Involving family members in the assessment is critical because patients with neurological problems often experience cognitive, emotional, and motivational deficits. Careful observation is an especially important nursing skill because many neurological changes are subtle.

Subjective Data

The history should begin with an open-ended and indirect inquiry that allows the patient to describe the chief complaint and current health (Jarvis, 2014). Three points should be considered in documenting the history of a patient with neurological problems. First, questions about symptoms should be open-ended. It is better to ask, "What is your headache like?" rather than "Do you experience headaches?" It is also better to allow the patient to provide the details, for example, "Is there anything about your right side that bothers you?" than to ask leading questions like, "Is your headache throbbing?" or "Are you weak on the right side?" Second, the mode of onset and the course of the illness are especially important aspects of the history. The nature of a neurological disease process can often be described by these facts alone, and the nurse should obtain all pertinent data in the history of the present illness, especially data related to the characteristics and progression of the symptoms. Third, because many neurological diseases affect a patient's mental functioning, mental status must be assessed accurately before the nurse assumes that the history is factual. If the patient is not considered a reliable historian, the history should be obtained from a person who has first-hand knowledge of the patient's problems and complaints. In many cases, a complete health history cannot be obtained, and the nurse must proceed with only objective data.

Important Health Information

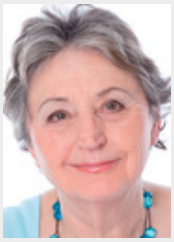
Past Health History.

The health history helps guide the approach for the neurological examination; that is, it can direct the nurse toward the parts of the nervous system that must be closely assessed. If the patient's primary complaint is

dizziness, the examination may be focused on visual, vestibular, and cerebellar functions rather than on somatic motor and sensory functions.

Case Study

Patient Introduction



Source: Jeanette Dietl/Shutterstock.com.

Evelyn Jones is a 66-year-old woman who arrives in the emergency department after falling in the middle of the night when she tried to get up to go to the bathroom. She states that she fell because she could not control her left leg. Her husband brought her to the hospital but states that he had a really hard time getting her to the car.

Critical Thinking

Throughout this assessment chapter, think about Ms. Jones's concerns, with the following questions in mind:

1. What are the possible causes for her acute leg weakness?
2. What type of assessment would be most appropriate for Ms. Jones: comprehensive, focused, or emergency? What would the priority assessment be?
3. What questions should the nurse ask Ms. Jones?
4. What should be included in the physical assessment? What should the nurse be looking for?
5. What diagnostic studies might be ordered?

See pp. 1463, 1467, and 1468 for more information on Ms. Jones.

Medications.

Special attention should be given to obtaining a careful medication history, especially the use of sedatives, opioids, tranquilizers, mood-elevating drugs, over-the-counter medications, and herbal remedies. Many drugs can cause adverse neurological effects.

Surgery or Other Treatments.

The nurse should inquire about any surgery involving any part of the nervous system, such as the head or brain, the spine or spinal cord, or the sensory organs. If a patient has had surgery, the date, the cause, the procedure, the recovery, and the current status should be investigated.

The perinatal history may reveal exposure to toxic agents such as viruses, alcohol, tobacco, drugs, and radiation, which are known to adversely influence the development of the nervous system. The history may reveal a difficult labour and delivery, which can cause brain damage as a result of hypoxia, forceps delivery, or Rh incompatibility.

Growth and developmental history can be important in ascertaining whether nervous system dysfunction was present at an early age. The nurse should specifically inquire about major developmental tasks such as walking and talking. Successes at school or identified problems in an educational setting are other important developmental data to gather. Often, this information is not available when an older patient is interviewed.

Health Status.

Key questions to ask a patient with a neurological problem are presented in Table 58-5.

TABLE 58-5

HEALTH HISTORY
Nervous System

Headaches
• Have you had any unusually frequent or severe headaches? • When did this start? How often does this happen? • Show me where you feel the pain in your head. • What do you think the headaches are caused by?
Head Injury
• Please describe any head injuries you have had. • Which part of your head was injured? • Did you lose consciousness? For how long?
Dizziness or Vertigo
• Have you ever felt light-headed or faint? • When does this feeling occur? Do activity or change in position bring this on? • Do you ever feel something called *vertigo* (a spinning sensation)? Does the room spin (objective vertigo)? Do you feel you are spinning (subjective vertigo)?
Seizures
• Have you ever had seizures or convulsions? When did they start? How often did they or do they occur? • When a seizure starts, do you have any warning? What do you experience? • Where in your body do the seizures begin? On one side or both? Do they travel through your body? Are your muscles tense or limp? • Are there other signs that go along with the seizures (loss of consciousness, colour change in face or lips, eyelid fluttering, eye-rolling, lip smacking, or incontinence)? • After the seizure, are you told that you fall asleep or experience confusion, weakness, headache, or muscle ache? • What seems to bring on the seizures (activity, discontinuing medications, fatigue, stress)? • Are you taking medication for the seizures? • How have the seizures affected your daily life?
Tremors
• Have you experienced any shaking or tremors in the hands or the face? When did these start? • Are the tremors worse with anxiety? With deliberate movement? With rest? • Are the tremors better with rest? With activity? With alcohol? • Do the tremors affect your daily activity?
Weakness
• Do you have any weakness or problem moving any body part? Is the weakness just in one body part or everywhere? • Does this occur with any particular movement? (Example: difficulty getting out of a chair may signal proximal or large muscle weakness, whereas distal or small muscle weakness makes it difficult to open a jar or write.)
Coordination
• Do you have any problems with coordination or balance when walking? • Do you lean to one side? • Do you have any problems with falling? Which way? • Do your legs give out from under you? • Do you have any clumsy movement?
Numbness or Tingling
• Have you experienced any numbness or tingling? Does it feel like pins and needles? When did this start? Is it worse with activity? • Show me where you feel this.
Difficulty Swallowing
• Do you have any difficulty swallowing? Does this occur with solids or liquids? • Have you experienced excessive salivation or drooling?
Difficulty Speaking
• Have you had any problems with forming words or with saying what you meant to say? • When did this start? How long did it last?
Significant Past History
• Have you ever had a stroke, a spinal cord or head injury, or meningitis or encephalitis?

• Do you have any congenital defects? • Have you had past problems with alcohol or drug use?
Environmental and Occupational Hazards
• Are you exposed to any environmental or occupational hazards such as insecticides, lead, or organic solvents? • Are you taking any medications now, including pain medications? • How much alcohol do you drink? Each day? Each week? • Do you use any mood-altering drugs: marijuana, barbiturates, tranquilizers?
Additional History for Older Adults
• Have you had any increase in falls? Is this related to dizziness? Does this occur with movement (e.g., change of position) or after taking medications? • Have you had any changes in memory or mental function? Have you felt any confusion? Has it come on suddenly or gradually? • Have you noticed any tremors? Are they in your hands or face? Do they change with activity, rest, use of alcohol? Do they interfere with your daily life? • Have you had any sudden vision changes? Did this occur with weakness or loss of consciousness?

Source: Adapted from Jarvis, C. (2014). *Physical examination & health assessment* (2nd Canadian ed., pp. 666–668). (A. J. Brown, J. MacDonald-Jenkins, & M. Luctkar-Flude, Canadian Eds.). Toronto: Saunders/Elsevier.

General Health Practices.

The nurse should ask about the patient's general health practices that may affect the nervous system, such as substance use and smoking, nutrition, participation in physical and recreational activities, use of seat belts and helmets, and control of hypertension. The nurse should ask about previous hospitalizations for neurological problems. A careful family history may determine whether the neurological problem has a hereditary or congenital background.

Genetics in Clinical Practice

- Huntington's disease is a genetically transmitted, autosomal dominant disorder.
- Major neurological disorders that may have a genetic basis are multiple sclerosis, headaches, Parkinson's disease, and Alzheimer's disease. The presence of these problems in a family history increases the likelihood of similar problems occurring in the patient.
- A careful family history may determine whether a neurological problem has a genetic basis.

If the patient has an existing neurological problem, the nurse should ask about how it affects daily living and the ability to carry out self-care. After a careful review of information, and with the patient's permission, the

nurse may find it helpful to ask someone who knows the patient well whether any mental or physical changes have been noticed in the patient. The patient with a neurological problem may not be aware of it or may be unable to provide enough specific data to aid in the diagnosis.

Nutritional Problems.

Neurological problems can result in inadequate nutrition. Problems related to chewing, swallowing, facial nerve paralysis, or muscle coordination could make it difficult for affected patients to ingest adequate nutrients. Also, certain vitamins, such as thiamine (B_1), niacin (B_3), and pyridoxine (B_6), are essential for the maintenance and health of the CNS. Deficiencies in one or more of these vitamins could result in such nonspecific complaints as depression, apathy, neuritis, weakness, mental confusion, and irritability. Risk for cobalamin (vitamin B_{12}) deficiency is higher in older adults because they may have problems with vitamin absorption. Untreated, this deficiency may cause a decline in mental function (Lachner, Steinle, & Regenold, 2014).

Bowel and Bladder Problems.

Bowel and bladder problems are often associated with neurological conditions, such as stroke, head injury, spinal cord injury, multiple sclerosis, and dementia. To plan appropriate interventions, it is important to determine whether the bowel or bladder problem was present before or after the neurological event. Incontinence of urine and feces and urinary retention are the most common elimination problems associated with a neurological problem or its treatment (Coggrave, Norton, & Cody, 2014; Panicker, Fowler, & Kessler, 2015). For example, nerve root compression leads to a sudden onset of incontinence. The details of the problem—such as number of episodes, accompanying sensations or lack of sensations, and measures taken to control the problem—must be documented carefully.

Motor Problems.

Many neurological disorders can cause problems in the patient's mobility, strength, and coordination. Neurological problems can result in changes in the patient's usual activity and exercise patterns. These problems can also result in falls (Homann, Plaschg, Grunder, et al., 2013). Many activities of daily living, such as getting out of a bed or chair, ambulating, preparing meals, and performing personal hygiene, can be affected and should be

assessed. The ability to perform fine motor tasks may be affected, which increases the possibility of personal injury.

Sleep Problems.

Sleep pattern disruptions can be both a cause of and a response to many neurologically related concerns. Discomfort from pain and inability to move and change to a position of comfort because of muscle weakness and paralysis could interfere with sound sleep. Hallucinations resulting from dementia or drugs can also interrupt sleep. The nurse should carefully document the sleep problem and the patient's methods of dealing with the problem.

Cognition and Sensory Problems.

Because the nervous system controls cognition and sensory integration, many neurological disorders affect these functions. The nurse should assess orientation, memory, language, calculation ability, problem-solving ability, insight, and judgement. A structured mental status questionnaire is often used to evaluate these functions and provide baseline data.

Information about sensory changes related to hearing, sight, and touch should be sought. The patient should be questioned about problems with vertigo and sensitivity to heat and cold.

Ability to both use and understand language is a cognitive function that the nurse should assess. Appropriateness of responses is a useful indicator of cognitive and perceptual ability, but it is culturally determined.

Pain is a common event associated with many health problems. Pain is often the reason why patients seek health care. A patient's pain should be assessed carefully (see Chapter 10).

Emotional Problems.

Neurological disease can drastically alter control over one's life and create dependency on others for daily needs. A patient's physical appearance and emotional control can be affected. The nurse should ask in a sensitive manner about the patient's evaluation of self-worth, perception of abilities, body image, and general emotional pattern. The physical sequelae of a neurological problem can seriously strain the patient's coping abilities. The nurse should determine whether coping abilities are sufficient to meet the challenges faced by the patient.

Relationship Problems.

The patient should be asked whether a neurological problem has resulted in changes to roles such as spouse, parent, or breadwinner. Physical impairments such as weakness and paralysis can alter or limit participation in usual roles and activities. Cognitive changes, however, can permanently change a person's ability to maintain previous roles. These changes can dramatically affect both the patient and significant others. Dependent relationships can develop.

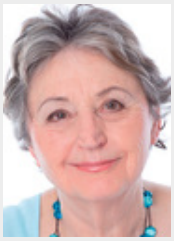
Sexual Problems.

Because many nervous system disorders can affect sexual functioning, sexual health may be an important part of the assessment for some patients. Cerebral lesions may inhibit the desire phase or the reflex responses of the excitement phase. Brain stem and spinal cord lesions may partially or completely interrupt the connections between the brain and the effector systems necessary for intercourse.

Neuropathies and spinal cord lesions that affect sensation, especially in the erotic zones, may decrease desire. Autonomic neuropathies and lesions of the sacral cord and the cauda equina may prevent reflex activities of the sexual response. The nurse should determine whether the patient and the partner are satisfied with their sexual activity. The use or need for alternative methods of achieving sexual satisfaction should be explored. Despite neurologically related changes in sexual functioning, many people can achieve satisfying expression of intimacy and affection.

Case Study

Subjective Data



Source: Jeanette Dietl/Shutterstock.com.

A subjective assessment of Ms. Jones revealed the following information:

History of Current Illness. States that she fell due to sudden weakness in her left leg. States that she had a brief episode of left-sided weakness and tingling of the face, arm, and hand, 3 months ago. The symptoms totally resolved and she did not seek treatment. Denies dizziness, change in hearing, or memory deficits. Has never been hospitalized for a neurologic problem. Is depressed and fearful. Concerned she is having a stroke.
Past Health History: Hyperlipidemia, hypertension.
Medications: Pravastatin 40 mg/day PO; lisinopril 10 mg/day PO.
Functional Assessment: Has smoked one pack of cigarettes per day since she was 28 years old. Drinks alcohol occasionally. Hypertension controlled when on medication but has not taken her lisinopril for a few weeks because she did not have enough money for the refill and was waiting for her next Social Assistance cheque. Ms. Jones is 160 cm tall and weighs 73 kg. States that up until tonight she was able to walk slowly, but her knees and hips hurt.

See pp. 1461, 1467, and 1468 for more information on Ms. Jones.

Objective Data

Physical Examination.

The standard neurological examination helps determine the presence, the location, and the nature of disease of the nervous system. In this examination, six categories of functions are assessed: mental status, function of cranial nerves, motor function, cerebellar function, sensory function, and reflex function. The choice of particular parts of the examination depends on what information is needed. The nurse should develop a systematic and consistent approach to assessment.

Mental Status.

Assessment of mental status (cerebral functioning) gives an indication of how the patient is functioning. It involves determination of complex and high-level cerebral functions that are governed by many areas of the cerebral cortex. Much of the mental status examination can be conducted during the routine history and may not need to be evaluated further. For example, language and memory can be assessed when the patient is asked for details of the illness and significant past events. The patient's cultural and educational background should be taken into account when mental status is evaluated.

The components of the mental status examination are as follows:

- *General appearance and behaviour:* This component includes motor activity, body posture, dress and hygiene, facial expression, and speech.
- *Level of consciousness (LOC):* This is the most sensitive indicator of changes in neurological status (McCance & Huether, 2014). LOC concerns arousal and wakefulness and the ability to respond to the environment. The Glasgow Coma Scale is often used to assess a patient's response to stimuli (see Chapter 59 and Table 59-5).
- *Cognition:* The nurse should note the patient's orientation to time, place, person, and situation. Further assessment of memory, intellectual ability, insight, judgement, problem solving, and calculation may be warranted (see Chapter 62). The nurse should consider whether the patient's plans and goals match the patient's physical and mental capabilities. Problems with memory may have implications for retention of new information, and impaired judgement and insight may jeopardize the patient's safety.
- *Mood and affect:* The nurse should note restlessness, agitation, anger, depression, or euphoria and the appropriateness of these states. The nurse should also note whether the patient's affect is appropriate for the situation.
- *Thought content:* The nurse should note the presence or report of illusions, hallucinations, delusions, or paranoia.

Function of Cranial Nerves.

Testing of each cranial nerve (CN) is an essential component of the neurological examination (see Figure 58-12).

Olfactory Nerve.

After determining that both nostrils are patent, the olfactory nerve (CN I) is tested by asking the patient to close one nostril, close both eyes, and sniff from a bottle containing coffee, spice, soap, or some other readily recognized odour. The same procedure is done for the other nostril. In general, olfaction is not tested unless the patient has some disturbance with smell. Chronic rhinitis, sinusitis, and heavy smoking can often decrease the sense of smell. Disturbance in ability to smell may be associated with a tumour involving the olfactory bulb, or it may be the result of a basilar skull fracture that has damaged the olfactory fibres as they pass through the delicate cribriform plate of the skull.

Optic Nerve.

Visual fields and visual acuity are assessed to test the function of the optic nerve (CN II). Visual fields are assessed by gross confrontation. The nurse, positioned directly opposite the patient, asks the patient to close one eye, look directly at the bridge of the nurse's nose, and indicate when an object (finger, pencil tip, head of pin) presented from the periphery of each of the four visual field quadrants becomes visible (Figure 58-16). The same test is repeated for the other eye. The nurse is used as a control because both nurse and patient are sharing the same visual field. It is important to remember that the nasal side of the visual field is narrower because of the nasal bridge. Visual field defects may arise from lesions of the optic nerve, the optic chiasm, or the tracts that extend through the temporal, parietal, and occipital lobes. Visual field changes resulting from brain lesions are usually a *hemianopia* (one-half of the visual field is affected), a *quadrantanopsia* (one-fourth of the visual field is affected), or monocular (one eye is affected).

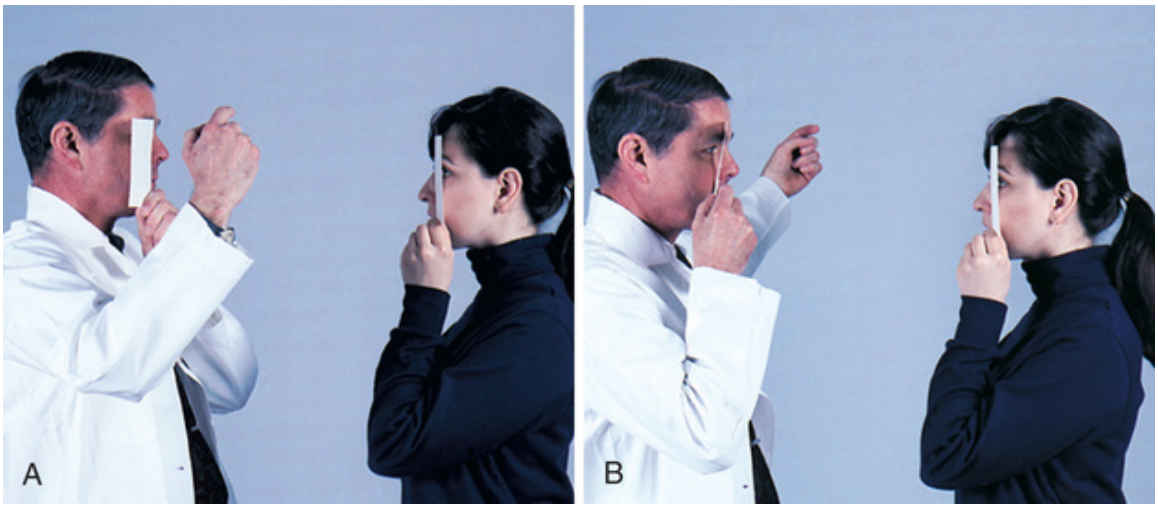


FIGURE 58-16 Assessment of visual fields by gross confrontation. In gross confrontation, the target is moved in a flat plane between the nurse and the patient. The nurse's own monocular field is compared with that of that patient.

To test visual acuity, the patient reads a Snellen chart from 6 metres away. The nurse records the number of the lowest line that the patient can read accurately. The patient who wears glasses should wear them during testing, unless they are used only for reading. The eyes should be tested individually and together. If a Snellen chart is not available, the patient should be asked to read newsprint for a gross assessment of acuity. The distance from the patient to the newsprint required for accurate reading should be recorded. Acuity may not be testable by these means if the patient does not read English or has aphasia (a language disorder).

Funduscopy reveals the physical condition of the optic disc (head of the optic nerve), as well as that of the retina and the blood vessels. This procedure is routinely performed when the optic nerve is tested. Optic nerve atrophy and papilledema can be detected by this method.

Oculomotor, Trochlear, and Abducens Nerves.

Because the oculomotor (CN III), trochlear (CN IV), and abducens (CN VI) nerves all help move the eye, they are tested together for what are termed *extraocular movements* (EOMs). The patient is asked to keep the head steady and to follow the nurse's finger only with the eyes. The nurse should keep the finger back about 30 cm so that the patient can focus on it comfortably. The nurse moves the finger to each of the six positions (right and up, right, right and down, left and up, left, left and down), holds it momentarily, and then moves back to the centre (Figure 58-17). A normal response is parallel tracking of the object with both eyes. If weakness or paralysis is

present in one of the eye muscles, the eyes do not move together, and the patient has a *disconjugate gaze.* The presence and direction of *nystagmus* (fine, rapid jerking movements of the eyes) are observed at this time, even though this condition most often indicates vestibulo-cerebellar problems.

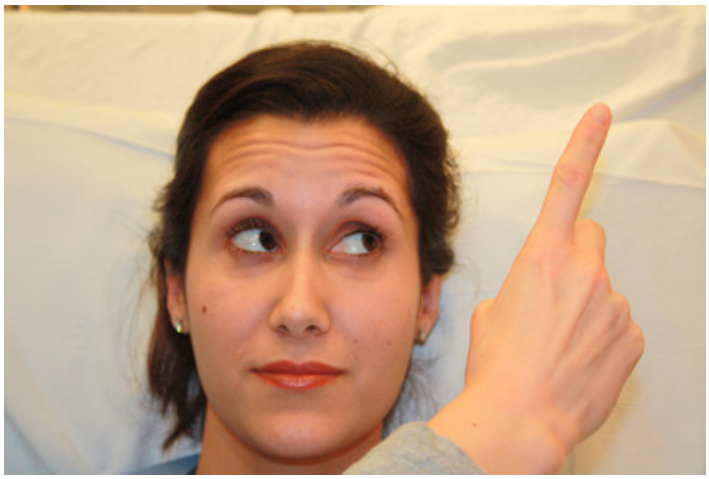

FIGURE 58-17 Nurse checking extraocular movement. Normally, both eyes move together. Eye movements should be smooth and coordinated.

Other functions of the oculomotor nerve are tested by checking for pupillary constriction and for *convergence* (eyes turning inward) and *accommodation* (pupils constricting with near vision). To test pupillary constriction, the nurse shines a light into the pupil of one eye and looks for ipsilateral (same side) constriction of the same pupil and contralateral (consensual) constriction of the opposite eye. The size and shape of the pupils are also noted. For this reflex to occur, the optic nerve must be intact. Testing for papillary constriction is an important component of the neurological assessment of patients at risk for herniation (see Chapter 59). Because the oculomotor nerve exits at the top of the brain stem at the tentorial notch, it can be easily compressed by expanding mass lesions in the cerebral hemispheres. The result is that the pupil does not constrict in response to light; it may become dilated because the sympathetic input to the pupil acts unopposed. To test convergence and accommodation, the patient focuses on the nurse's finger as it moves toward the patient's nose. Another function of the oculomotor nerve is to keep the eyelid open. Damage to the nerve can cause *ptosis* (drooping eyelid), pupillary abnormalities, and eye muscle weakness.

Trigeminal Nerve.

To test the sensory component of the trigeminal nerve (CN V), the patient is asked to identify light touch (cotton) and pinprick in each of the three divisions (ophthalmic, maxillary, and mandibular) of the nerve on both sides of the face. The patient's eyes should be closed during this part of the examination. To test the motor component, the patient clenches the teeth, and the masseter muscles, just above the mandibular angle, are palpated. The corneal reflex test, in which CN V and CN VII are evaluated simultaneously, involves applying a cotton wisp strand to the cornea. The sensory component of this reflex (corneal sensation) is innervated by the ophthalmic division of CN V. The motor component (eye blink) is innervated by the facial nerve (CN VII). This reflex is not normally tested in patients who are awake and alert because other tests are used to evaluate these two nerves. However, for patients with a decreased level of consciousness, the corneal reflex test provides an opportunity to evaluate the integrity of the brain stem at the level of the pons because the fibres of CN V and CN VII have connections in this area.

Facial Nerve.

The facial nerve (CN VII) innervates the muscles of facial expression. To test its function, the patient raises the eyebrows, closes the eyes tightly, purses the lips, draws back the corners of the mouth in an exaggerated smile, and frowns. The nurse should note any asymmetry in the facial movements because this can indicate damage to the facial nerve. Although taste discrimination of salt and sugar in the anterior two-thirds of the tongue is a function of this nerve, it is not routinely tested unless a peripheral nerve lesion is suspected.

Vestibulo-cochlear Nerve.

To test the cochlear portion of the acoustic (vestibulo-cochlear) nerve (CN VIII), the patient closes the eyes and indicates when a ticking watch or the rustling of the nurse's fingertips is heard as the stimulus is brought closer to the patient's ear. Each ear is tested individually, and the distance from the patient's ear to the sound source when first heard is recorded. This test identifies only gross deficits in hearing. For more precise assessment of hearing, an audiometer (or tuning forks) can be used (see Chapter 23). The vestibular portion of this nerve is not routinely tested unless the patient complains of dizziness, vertigo, or unsteadiness or has auditory dysfunction. In a patient who is unconscious, the oculo-cephalic reflex

(movement of the eyes when the head is briskly turned to the side) may be assessed.

Glossopharyngeal and Vagus Nerves.

The glossopharyngeal and vagus nerves are tested together because both innervate the pharynx. The glossopharyngeal nerve (CN IX) is primarily sensory. In the gag reflex (bilateral contraction of the palatal muscles initiated by stroking or touching either side of the posterior pharynx or soft palate with a tongue blade), the sensory component is mediated by CN IX and the major motor component by the vagus nerve (CN X). It is important to assess the gag reflex in patients who have a decreased level of consciousness, a brain stem lesion, or a disease involving the throat musculature. If the reflex is weak or absent, the patient may be at risk of aspirating food or secretions. The strength and efficiency of swallowing are important to test in these patients for the same reason. In another test for an awake, cooperative patient, the patient phonates by saying "ah" and the nurse notes the bilateral symmetry of elevation of the soft palate. Any asymmetry can indicate weakness or paralysis. To assess swallowing, the nurse's hands are held lightly on either side of the patient's throat while the patient swallows. Any asymmetry is noted. If the patient is endotracheally intubated, the cough reflex (elicited when the suction catheter contacts the carina of the respiratory tree) is a method of assessing cranial nerve X.

Spinal Accessory Nerve.

To test the spinal accessory nerve (CN XI), the patient shrugs the shoulders against resistance and turns the head to either side against resistance. The contraction of the sternocleidomastoid and trapezius muscles should be smooth. Symmetry, atrophy, or fasciculation of the muscle should also be noted. A *fasciculation* is a small, local involuntary muscular contraction.

Hypoglossal Nerve.

To test the hypoglossal nerve (CN XII), the patient sticks out the tongue. It should protrude in the midline. The patient should also be able to push the tongue to either side against the resistance of a tongue blade. Again, any asymmetry, atrophy, or fasciculation should be noted.

Motor Function.

The motor system examination includes assessment of bulk, tone, and power of the major muscle groups of the body, as well as assessment of balance and coordination. To test strength, the patient pushes and pulls against the resistance of the nurse's arm as it opposes flexion and extension of the patient's muscle. The patient should be asked to offer resistance at the shoulders, elbows, wrists, hips, knees, and ankles. The patient's grip strength can also be tested. To test for mild weakness of the upper extremities, the patient extends both arms forward at shoulder height with palms up while the eyes are closed. Mild weakness of the arm is demonstrated by downward drifting of the arm or pronation of the palm *(pronator drift).* Any weakness or asymmetry of strength between the same muscle groups of the right and left side should be noted.

To test tone, the limbs are passively moved through their range of motion; there should be a slight resistance to these movements. Abnormal tone is described as *hypotonia* (flaccidity) or *hypertonia* (spasticity). Involuntary movements—such as tics, tremor, *myoclonus* (spasm of muscles), *athetosis* (slow, writhing, involuntary movements of extremities), *chorea* (involuntary, purposeless, rapid motions), and *dystonia* (impairment of muscle tone)—should be noted.

To test cerebellar function, balance and coordination are assessed. A good screening test for both balance and muscle strength is to observe the patient's stance (posture while standing) and gait. The nurse should note the pace and rhythm of the gait and observe the arm swing. (The arms should move symmetrically and in the opposite direction of the leg on the same side.) The patient's ability to ambulate is a key factor in determining the amount of nursing care that is needed and the risk for injury from falling. A patient with cerebellar disease may have an *ataxic* or *staggering gait*, in which the feet are placed wide apart and the steps are unsteady.

Coordination can be easily tested in several ways. In the finger-to-nose test, the patient alternately touches the nose with the index finger and then touches the nurse's finger. The nurse repositions the finger while the patient is touching the nose so that the patient must adjust to a new distance each time the nurse's finger is touched. These movements should be performed smoothly and accurately. Other tests include asking the patient to pronate and supinate both hands rapidly and to perform a shallow knee bend, first on one leg and then on the other. Dysarthria or slurred speech should be noted because it is a sign of incoordination of the speech muscles.

In the heel-to-shin test, the patient places one heel on the opposite shin below the knee and moves the heel down the shin to the ankle. This

procedure is repeated for the other leg. These movements should flow smoothly without jerking or hesitation.

Sensory Function.

Several modalities are tested in the somatic sensory examination. Each modality is carried by a specific ascending pathway in the spinal cord before it reaches the sensory cortex.

There are some general guidelines for performing the sensory examination. The patient should always have the eyes closed to avoid visual clues. The nurse should avoid giving verbal cues such as, “Is this sharp?” The sensory stimulus should be applied in such a way that the patient does not expect it; that is, the nurse should avoid rhythmic application of the stimulus. In the routine neurological examination, sensory testing of the four extremities is sufficient. However, if a disturbance in sensory function of the skin is identified, the boundaries of that dysfunction should be carefully delineated along the dermatome.

Light Touch.

The sensation of light touch is usually tested first. The nurse gently strokes each of the four extremities with a cotton wisp and asks the patient to indicate when the stimulus is felt by saying “touch.” (The sensory examination of the trigeminal nerve may be delayed until this time because the same material for testing sensation is used.)

Pain and Temperature.

Pain is tested by touching the skin with the sharp end of a safety pin. This stimulus is irregularly alternated with a simple touch stimulus with the dull end of the pin to determine whether the patient can distinguish the two stimuli.

The sensation of temperature is tested by applying tubes of warm and cold water to the skin and asking the patient to identify the stimuli with the eyes closed. If pain sensation is intact, assessment of temperature sensation may be omitted because both sensations are carried by the same ascending pathways.

Vibration Sense.

To assess vibration sense, a vibrating C128 tuning fork is applied to the patient's fingernails and the bony prominences of the hands, the legs, and the feet while the patient's eyes are closed. The nurse asks the patient whether the vibration or “buzz” is felt. The nurse then asks the patient to

indicate when the vibration ceases. The nurse stops the vibration with the hand as desired.

Position Sense.

To assess position sense, the nurse's thumb and forefinger are placed on either side of the patient's forefinger or great toe and gently move the patient's digit up or down. The patient is asked to indicate the direction in which the digit is moved.

Another test of position sense of the lower extremities is the *Romberg test*. The patient is asked to stand with the feet together and then to close his or her eyes. If the patient is able to maintain balance with the eyes open but sways or falls with the eyes closed (i.e., a positive result of the Romberg test), disease may be present in the posterior columns of the spinal cord or the cerebellum. It is important for the nurse to ensure the patient's safety during this test.

Cortical Sensory Functions.

Several tests are used to evaluate cortical integration of sensory perceptions (which occurs in the parietal lobes). The patient's eyes should remain closed during these assessments. To assess two-point discrimination, the two points of a calibrated compass are placed on the tips of the patient's fingers and toes. The minimum recognizable separation is 4 to 5 mm in the fingertips and a greater degree of separation elsewhere. This test is important in diagnosing diseases of the sensory cortex and the PNS.

To test *graphesthesia* (ability to feel writing on skin), the patient is asked to identify numbers traced on the palm of the hands. To test *stereognosis* (ability to perceive the form and nature of objects), the patient is asked to identify the size and shape of easily recognized objects (e.g., coins, keys, a safety pin) placed in the hands. To evaluate sensory extinction or inattention, the nurse touches both sides of the patient's body simultaneously. An abnormal response occurs when the patient perceives the stimulus only on one side. The other stimulus is “extinguished.”

Reflex Function.

Tendons attached to skeletal muscles have receptors that are sensitive to stretch. A reflex contraction of the skeletal muscle occurs when the tendon is stretched. A simple muscle stretch reflex is initiated by briskly tapping the tendon of a stretched muscle, usually with a reflex hammer (Figure 58-

18). The response (muscle contraction of the corresponding muscle) is measured as follows:

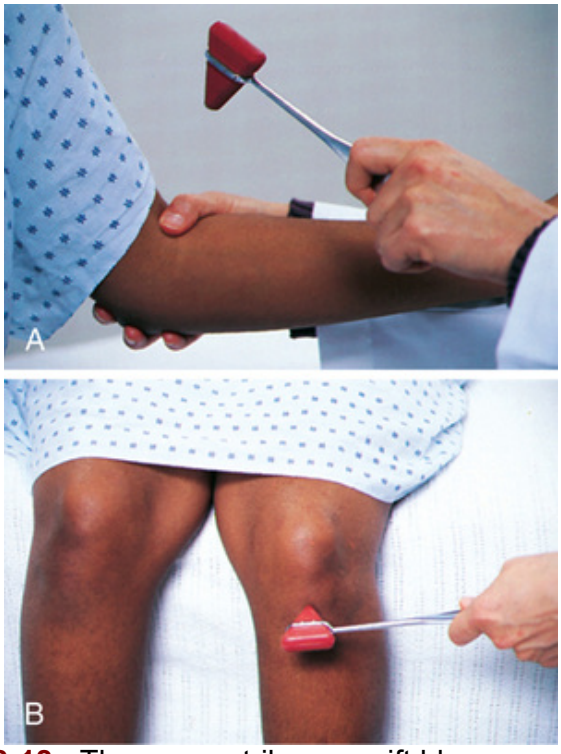

FIGURE 58-18 The nurse strikes a swift blow over a stretched tendon to elicit a stretch reflex. **A,** Biceps reflex. **B,** Patellar reflex.

0	Absence of response—always abnormal
1+	Slight but definitely present response—may or may not be normal
2+	Brisk response—normal
3+	Very brisk response—may or may not be normal
4+	Repeating reflex (clonus)—always abnormal

Clonus is a continued rhythmic contraction of the muscle with continuous application of the stimulus.

In general, the biceps, triceps, brachioradialis, and patellar and Achilles tendon reflexes are tested. The nurse elicits the biceps reflex by placing his or her thumb over the patient's biceps tendon in the antecubital space and striking the thumb with a hammer. The nurse should support the patient's forearm so that it is partially flexed at the elbow, with the palm up and relaxed. The normal response is flexion of the arm at the elbow or contraction of the biceps muscle that can be felt by the nurse's thumb.

To elicit the triceps reflex, the nurse should support the patient's upper arm (to let the arm hang limply) and then strike the patient's triceps

tendon above the elbow. The normal response is extension of the arm or visible contraction of the triceps.

To elicit the brachioradialis reflex, the nurse strikes the patient's radius 3 to 5 cm above the wrist while the patient's arm is relaxed. The normal response is flexion and supination at the elbow or visible contraction of the brachioradialis muscle.

To elicit the patellar reflex, the nurse strikes the patient's patellar tendon just below the patella. The patient can be sitting or lying as long as the leg being tested hangs freely. The normal response is extension of the leg with contraction of the quadriceps.

To elicit the Achilles tendon reflex, the nurse strikes the patient's Achilles tendon while the patient's leg is flexed at the knee and the foot is dorsiflexed at the ankle. The normal response is plantar flexion at the ankle.

A focused assessment (see Table 3-6) is used to evaluate the status or previously identified neurological problems and to monitor for signs of new problems. A focused assessment of the neurological system is presented in the "Focused Assessment" box.

Focused Assessment

Neurological System

Use this checklist to make sure the key assessment steps have been performed.

Subjective

Ask the patient about any of the following, and note responses:

Blackouts or loss of memory	Y	N
Weakness, numbness, tingling sensation in arms or legs	Y	N
Headaches, especially of new onset	Y	N
Loss of balance or coordination	Y	N
Orientation to person, place, and time	Y	N

Objective: Diagnostic

Check the following laboratory results for critical values:

Lumbar puncture	✓
CT or MRI of brain	✓
EEG	✓

Objective: Physical Examination

Inspect or observe the following:

General level of consciousness and orientation	✓
Oropharynx for gag reflex and soft palate movement	✓
Peripheral sensation of light touch and pinprick (face, hands, feet)	✓
Sense of smell with an alcohol wipe	✓
Eyes for extraocular movements, PERRLA, peripheral vision, nystagmus	✓
Gait for smoothness and coordination	✓

Palpate for the following:

Strength of neck, shoulders, arms, and legs; full and symmetrical	✓

Percuss for the following:

Reflexes	✓

CT, computed tomographic (scan); *EEG,* electroencephalogram; *MRI,* magnetic resonance imaging; *PERRLA,* pupils equal, round, and reactive to light and accommodation.

Table 58-6 is a listing of normal findings in a neurological assessment. Abnormal assessment findings of the neurological system are presented in Table 58-7.

TABLE 58-6

NORMAL PHYSICAL ASSESSMENT OF THE NERVOUS SYSTEM*

Mental Status
Alert and oriented, orderly thought processes, appropriate mood and affect
Cranial Nerves†
Sense of smell intact for soap and coffee; visual fields full to confrontation; visual acuity 20/20 in both eyes; intact extraocular movements; no nystagmus; pupils equal, round, reactive to light and accommodation; intact facial sensation for touch and pinprick; facial movements full; intact gag and swallow reflexes; symmetrical elevation of soft palate; full strength with head turning and shrugging of shoulders against resistance; midline protrusion of tongue
Motor System
Normal gait and station; normal tandem walk; negative result of Romberg test; normal and symmetrical muscle bulk, tone, strength; smooth performance of finger–nose, heel–shin movements
Sensory System
Intact sensation to light touch, position sense, vibration, pinprick, heat and cold, two-point discrimination; intact stereognosis and graphesthesia
Reflexes‡
Biceps, triceps, brachioradialis, patellar, and Achilles tendon reflexes 2+ bilaterally; downward-pointing toes with plantar stimulation

*If some portion of the neurological examination was not performed, this should be indicated (e.g., “Smell not tested”).

†May also be recorded as “CNs [cranial nerves] I to XII intact.”

‡May also be recorded as drawing of stick figure indicating reflex strength at appropriate sites.

TABLE 58-7

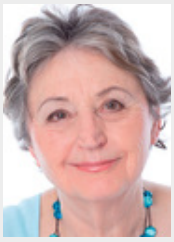
ASSESSMENT ABNORMALITIES
Nervous System

Finding	Description	Possible Etiology and Significance
Agnosia	Inability to determine meaning or significance of sensory stimulus	Cerebral cortex lesion
Altered consciousness	Inability to speak, obey commands, open eyes appropriately with verbal or painful stimulus	Intracranial lesions, metabolic disorder, psychiatric disorders
Anaesthesia	Absence of sensation	Lesions in spinal cord, thalamus, sensory cortex, or peripheral sensory nerve
Analgesia	Loss of pain sensation	Lesion in spino-thalamic tract or thalamus, lack of or damage to sensory nerve endings
Anisocoria	Unequal pupil size	Lesion, injury, or intracranial pressure in area of midbrain; can also be normal
Anosognosia	Inability to recognize bodily defect or disease	Lesions in right parietal cortex, common in right-sided brain stroke
Aphasia	Loss of language faculty (language comprehension, language expression, or both)	Cerebral cortex lesion
Apraxia	Inability to perform learned movements; defect in motor planning	Cerebral cortex lesion
Astereognosis	Inability to recognize form of object by touch	Lesions in parietal cortex
Ataxia	Lack of coordination of movement	Lesions of sensory or motor pathways, cerebellum; anticonvulsant drug, sedative, or hypnotic drug toxicity (including alcohol)
Bladder dysfunction		
• Atonic (autonomous)	Absence of muscle tone and contractility, enlarged capacity, no discomfort, overflow with large residual, inability to voluntarily empty or empty by reflex	Early stage of spinal cord injury
• Hypotonic	More ability to empty by reflex than with atonic bladder but less than normal	Interruption of afferent pathways from bladder
• Hypertonic	Increase in muscle tone, diminished capacity, reflex emptying, dribbling, incontinence	Lesions in pyramidal tracts (efferent pathways)
Diplopia	Double vision	Lesions affecting nerves of extraocular muscles, cerebellar damage
Dysarthria	Lack of coordination in articulating speech	Lesions in cerebellum or pathway of cranial nerves (including brain stem); anticonvulsant drug, sedative, or hypnotic drug toxicity (including alcohol)
Dyskinesia	Impaired power of voluntary movement, resulting in fragmentary or incomplete movements	Disorders of basal ganglia, idiosyncratic reaction to psychotropic drugs
Dysphagia	Difficulty in swallowing	Lesions involving motor pathways of cranial nerves IX and X (including lower brain stem)
Extensor plantar response (Babinski sign)	Upward-pointing toes with plantar stimulation	Suprasegmental or upper motor neuron lesion
Hemiplegia	Paralysis on one side	Stroke and other lesions involving motor cortex
Homonymous hemianopia	Loss of vision in one side of visual field	Injury or lesions in area of optic tract or its radiations to occipital cortex
Hyperaesthesia	Increase in sensation	Shingles, nerve compression, stress, or chronic pain
Hypoaesthesia	Decrease in sensation	Impingement or damage of a nerve (e.g., peripheral neuropathy in diabetes)

Finding	Description	Possible Etiology and Significance
Muscle atrophy (disuse or denervation atrophy)	Wasting away or diminution in size of muscle	Suprasegmental (upper motor neuron) lesions, segmental (lower motor neuron) lesions
Nystagmus	Jerking or bobbing of eyes as they track moving object	Lesions in cerebellum, brain stem, vestibular system; toxic effects of anticonvulsants, sedatives, hypnotics (including alcohol)
Ophthalmoplegia	Paralysis of eye muscles	Lesions in brain stem or cranial nerves III, IV, and VI
Opisthotonus	Extreme arching of back with retraction of head	Meningitis, tonic phase of grand mal seizure
Papilledema	Swelling of optic disk	Increase in intracranial pressure
Paraplegia	Paralysis of lower extremities	Spinal cord transection or mass lesion (thoracolumbar region)
Tetraplegia (quadriplegia)	Paralysis of all extremities	Spinal cord transection or mass lesion (cervical region or brain stem)

Case Study

Objective Data: Physical Examination



Source: Jeanette Dietl/Shutterstock.com.

A physical examination findings of Ms. Jones reveals the following:

- Alert, oriented, and able to answer questions appropriately but mild slowness in responding
- BP 180/110, HR 94, RR 22, T 37°C
- CNS (Canadian Neurological Scale) (see Chapter 60, Figure 60-11) score is 10
- Left-sided arm weakness (3/5) and leg weakness (4/5)

Throughout this chapter, consider diagnostic studies that may be ordered for Ms. Jones.

See pp. 1461, 1463, and 1468 for more information on Ms. Jones.

Diagnostic Studies of the Nervous System

Numerous diagnostic studies are available to assess the nervous system. Table 58-8 presents the most commonly encountered studies.

TABLE 58-8
DIAGNOSTIC STUDIES
Nervous System

Study	Description and Purpose	Nursing Responsibility
Cerebro-Spinal Fluid Analysis		
Lumbar puncture	CSF is aspirated by needle insertion in L3–4 or L4–5 interspace to assess many CNS diseases (see Table 58-9).	Help patient assume and maintain lateral recumbent position with knees flexed. Ensure maintenance of strict aseptic technique. Ensure labelling of CSF specimens in proper sequence. Encourage patient to drink fluids. Monitor neurological and VS. Administer analgesia as needed.
Radiological		
Cerebral angiography	Serial radiographic visualization of intracranial and extracranial blood vessels can help detect vascular lesions and tumours of brain. Contrast medium is used (Figure 58-19).	Assess for risk for stroke because thrombi may be dislodged during procedure. Withhold preceding meal. Explain that patient will experience hot flush of head and neck when contrast medium is injected. Explain need to be absolutely still during procedure. Monitor neurological and VS every 15–30 min for first 2 hr, every hour for next 6 hr, then every 2 hr for 24 hr. Maintain pressure dressing and ice on injection site. Maintain bed rest until patient is alert and VS are stable. Report any signs of change in neurological status.
Computed tomography (CT)	Computer-assisted radiographic views of several levels or thin cross-sections of body parts can help detect problems such as hemorrhage, space-occupying lesions, cerebral edema, brain atrophy, and other abnormalities (Figure 58-20, *A*).	Explain that procedure is noninvasive (if no contrast medium is used). Observe for allergic reaction, and note puncture site (if contrast medium is used). Explain appearance of scanner. Instruct patient to remain absolutely still during procedure.
Magnetic resonance angiography (MRA)	Differential signal characteristics of flowing blood are studied to evaluate extracranial and intracranial blood vessels. Test provides both anatomical and hemodynamic information. MRA can be used in conjunction with contrast medium (contrast-enhanced MRA [cMRA]). MRA is rapidly replacing cerebral angiography for use in diagnosing cerebro-vascular diseases.	Nursing responsibilities are similar to those for MRI.
Magnetic resonance imaging (MRI)	Imaging of brain, spinal cord, and spinal canal by means of magnetic energy helps detect infarctions, multiple sclerosis, tumours, trauma, herniation, and seizures. No invasive procedures are required (Figure 58-20, *B*).	Screen patient for joint replacements and pacemaker in body. Instruct patient to lie very still for up to 1 hr. Sedation may be necessary if patient is claustrophobic.
Positron emission tomography (PET)	Metabolic activity of brain regions is measured to assess cell death or damage. Test involves the use of radioactive material that shows up as a bright spot on the image.	Explain procedure to patient. Explain that two IV lines will be inserted. Instruct patient not to take sedatives or tranquilizers and to empty bladder before procedure. Patient may be asked to perform different activities during test.

Study	Description and Purpose	Nursing Responsibility
Single-photon emission computed tomography (SPECT)	This method of scanning is similar to PET, but more stable substances and different detectors are used. Radiolabelled compounds are injected, and their photon emissions can be detected. Images made are an accumulation of labelled compound. SPECT is used to visualize blood flow or oxygen or glucose metabolism in the brain. It is useful in diagnosing strokes, brain tumours, and seizure disorders.	Nursing responsibilities are similar to those for PET.
Skull and spine radiographs	Simple radiographs of skull and spinal column can help detect fractures, spinal misalignment, bone erosion, calcifications, or abnormal vascularity.	Explain that procedure is noninvasive. Explain positions to be assumed.
Electrographic		
Electroencephalography (EEG)	Electrical activity of brain is recorded by scalp electrodes to evaluate cerebral disease, CNS effects of systemic diseases, and brain death.	Inform patient that procedure is painless and without danger of electric shock. Withhold stimulants. Inform patient that he or she may be asked to perform various activities such as hyperventilation during test. Determine whether any medications (e.g., tranquilizers, anticonvulsant drugs) should be withheld. Resume medications after test. Assist patient in washing electrode paste out of hair.
Electromyography (EMG) and nerve conduction	Electrical activity associated with nerve and skeletal muscle is recorded by insertion of needle electrodes to detect muscle and peripheral nerve disease.	Inform patient of slight discomfort associated with insertion of needles.
Evoked potentials	Electrical activity associated with nerve conduction along sensory pathways is recorded by electrodes placed on skin and scalp. Stimulus generates the impulse. Procedure is used to diagnose disease, locate nerve damage, and monitor function intraoperatively.	Explain procedure to patient. Avoid hair spray, gel, or other hair care products and sedative drugs such as benzodiazepines and barbiturates.
Magnetoencephalography (MEG)	A sensitivity machine called a *biomagnetometer* is used to detect very small magnetic fields generated by neural activity. It can accurately pinpoint the part of the brain involved in a stroke, seizure, or other disorder or injury. Extracranial magnetic fields, as well as scalp electrical field (EEG), are measured.	MEG, a passive sensor, does not make physical contact with patient. Explain procedure to patient.
Ultrasonography		
Carotid duplex studies	Sound waves are used to determine blood flow velocity, which may indicate presence of occlusive vascular disease.	Explain procedure to patient.
Transcranial Doppler ultrasonography	Technology is the same as that for carotid duplex studies, but intracranial vessels are evaluated.	Explain procedure to patient.

CNS, central nervous system; *CSF,* cerebro-spinal fluid; *IV,* intravenous; *VS,* vital signs.

Cerebro-Spinal Fluid Analysis.

CSF analysis provides information about a variety of CNS diseases. Normal CSF fluid is clear, colourless, and free of red blood cells and contains little protein. Normal CSF values are listed in Table 58-9.

TABLE 58-9
NORMAL CEREBRO-SPINAL FLUID VALUES

Parameter	Normal Value
Appearance	Clear, colourless
Glucose	2.8–4.2 mmol/L
Microorganisms	None
pH	7.33
Pressure	9–14 mm Hg
Protein	
• Cisternal	0.15–0.25 g/L
• Lumbar	0.15–0.45 g/L
• Ventricular	0.05–0.15 g/L
RBCs	None
Specific gravity	1.007
WBCs	Adult: 0–5 × 10^9 WBCs/L

RBCs, red blood cells; *WBCs*, white blood cells.

Lumbar Puncture.

Lumbar puncture is the most common method of obtaining CSF for analysis. It is contraindicated in the presence of increased intracranial pressure or infection at the site of puncture.

Nurses often assist in this procedure because it is usually performed in the patient's room. Before the procedure, the patient should empty the bladder. The patient should lie in the lateral recumbent position, with the back as near as possible to the edge of the bed. The nurse should assist the patient in drawing up the knees to the abdomen and flexing the head to the chest. This helps separate the vertebrae so that the needle can be inserted more easily.

Using strict sterile technique, the physician inserts a long needle below the third lumbar vertebra. This may cause some local discomfort. There is no danger of injuring the spinal cord because the cord terminates between the first and second lumbar vertebrae. However, the patient may experience some pain radiating down the leg or muscle twitching if the

needle irritates the spinal root. The nurse can assure the patient that this is temporary and that the patient is not in danger of being paralyzed.

A manometer is attached to the needle, and CSF pressure is determined after the patient is asked to relax and extend the legs. If the patient does not relax and extend the legs, the pressure reading is abnormally high. Normal CSF pressure is approximately 9 to 14 mm Hg (McCance & Huether, 2014). CSF is withdrawn in a series of tubes and sent for analysis. Some examiners believe that the patient should be kept lying flat for at least a few hours after the procedure to avoid a spinal headache, which is presumably caused by loss of the cushioning effect of CSF as a result of leakage at the puncture site. The prone position may be effective in preventing CSF leakage. Other examiners do not believe that the lying position is necessary because headache seems to develop in some patients despite precautions. Meningeal irritation (nuchal rigidity) or signs and symptoms of local trauma (e.g., hematoma, pain) may develop in some patients.

Radiological Studies

Cerebral Angiography.

Cerebral angiography is indicated when vascular lesions or tumours are suspected. A catheter is inserted into the femoral (sometimes brachial) artery. It is then passed up the artery to the aortic arch and into the base of a carotid or a vertebral artery for injection of radiopaque contrast medium. Radiographs are taken in a timed sequence so that pictures of the arteries, smaller vessels, and veins can be obtained (Figure 58-19). This study can help localize and determine the presence of abscesses, aneurysms, hematomas, arteriovenous malformations, arterial spasm, and certain tumours.

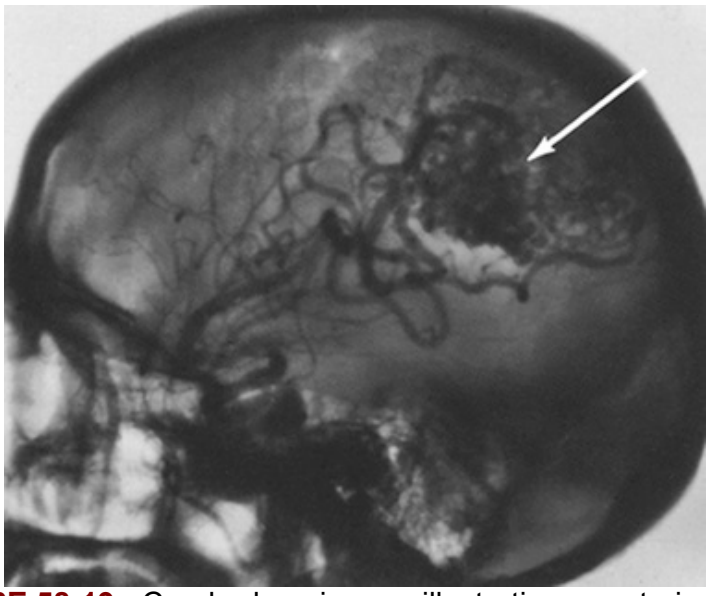


FIGURE 58-19 Cerebral angiogram illustrating an arteriovenous malformation *(arrow).* Source: From Chipps, E., Clanin, N., & Campbell, V. (1992). *Neurologic disorders.* St. Louis: Mosby.

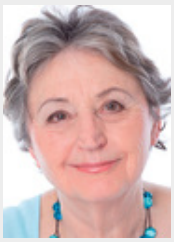
Because this is an invasive procedure, adverse reactions may occur. The patient may have an allergic (anaphylactic) reaction to the contrast medium. When this reaction occurs, it is usually immediately after injection of the contrast medium and may necessitate emergency resuscitation measures in the procedure room. The most common precaution for nurses to take in caring for the patient after the return to the room is observation for bleeding at the catheter puncture site (usually the groin). A pressure dressing and ice are usually placed on the site to promote hemostasis and prevent swelling.

Case Study

Objective Data: Diagnostic Studies



Source: Jeanette Dietl/Shutterstock.com.

The emergency department physician immediately orders a stat CT scan of the head. The CT scan rules out a hemorrhagic stroke. Stat laboratory test results include a blood glucose of 7.5 mmol/L and a PT/INR of 12.0/1.1.

This case study is continued in Chapter 60.
See pp. 1461, 1463, and 1468 for more information on Ms. Jones.

Computed Tomography.

Computed tomography (CT) is a noninvasive procedure, although intravenous injection of contrast medium may be used to enhance visualization of the blood vessels and identify disruptions in the blood–brain barrier. A number of radiographic scans of different levels of the brain are compiled with computer assistance and presented in a series of black-and-white pictures. These pictures, which illustrate "slices" of the brain (Figure 58-20, *A*), can show hemorrhages, tumours, cysts, edema, infarction, brain atrophy, and hydrocephalus. CT does not illustrate structures in the posterior fossa and the base of the brain as clearly as magnetic resonance imaging (MRI) does.

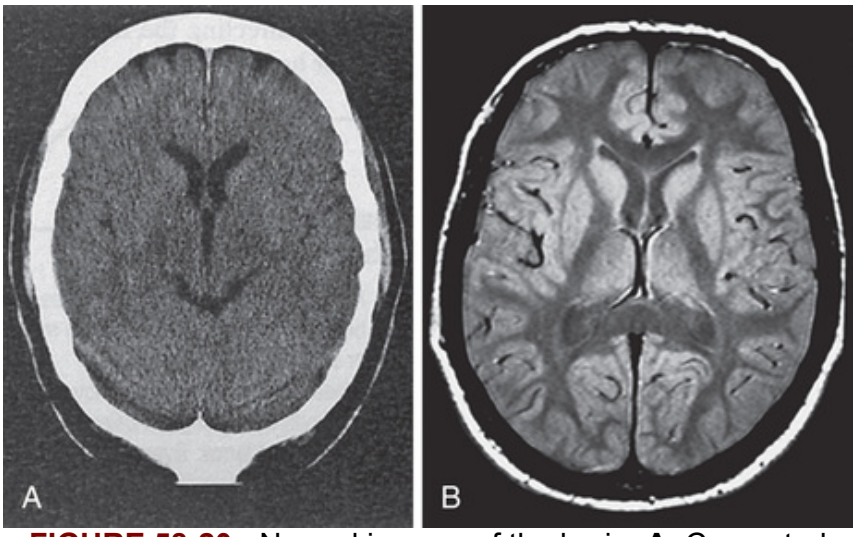


FIGURE 58-20 Normal images of the brain. **A,** Computed tomography. **B,** Magnetic resonance imaging. Source: From Fuller, G., & Manford, M. (2006). *Neurology: An illustrated colour text.* Edinburgh: Churchill Livingstone.

Magnetic Resonance Imaging.

Magnetic resonance imaging (MRI) provides greater detail than CT and improved resolution (detail) of the intracranial structures (see Figure 58-20, *B*). However, MRI requires a longer time to complete and may not be appropriate in life-threatening emergencies. Techniques of functional MRI (fMRI) provide time-related (temporal) images that can be used to evaluate how the brain responds to various stimuli.

MRI is useful in evaluating brain and spinal cord edema, hemorrhage, infarction, blood vessels, tumours, herniation, and bone lesions. It is used in the detection of early strokes and multiple sclerosis. Intravenous injection of gadolinium-containing contrast agents can enhance the images obtained with MRI. Because the images of soft tissue structures have greater contrast with MRI than with CT, MRI is the diagnostic test of choice for many neurological conditions and diseases.

Positron Emission Tomography.

Positron emission tomography (PET) is used to determine regional metabolism in the brain. PET provides a noninvasive means of determining biochemical processes that occur in the brain. PET is increasingly used to monitor patients with stroke, Alzheimer's disease, seizure disorders, epilepsy, tumours, and Parkinson's disease.

Electrographic Studies

Electroencephalography.

Electroencephalography (EEG) is the recording of the electrical activity of the surface cortical neurons of the brain, using 8 to 16 electrodes placed on specific areas of the scalp. This test is done to evaluate not only cerebral disease but also the CNS effects of many metabolic and systemic diseases and to determine brain death. Among the cerebral diseases and other conditions assessed with EEG are epilepsy, mass lesions (e.g., tumour, abscess, hematoma), cerebro-vascular lesions, and brain injury. The procedure is noninvasive. Patients sometimes have the misconception that the recording electrodes will give them an electric shock. They should be assured that this idea is not true and that the procedure is similar to electrocardiography.

Electromyography and Nerve Conduction Studies.

Electromyography (EMG) is the recording of electrical activity associated with innervation of skeletal muscle. The recording is displayed on a computer screen and may be played on a loudspeaker for simultaneous analysis. Needle electrodes are inserted into the muscle to record specific motor units because recording from the skin is not sufficient. Normal muscle at rest shows no electrical activity. Typical electrical activity occurs when the muscle contracts. This activity may be altered in diseases of muscle itself (e.g., myopathic conditions) or in disorders of muscle innervation (e.g., segmental or LMN lesions, peripheral neuropathic conditions). *Fibrillations* are spontaneous, independent contractions of individual muscle fibres that can be detected only by EMG. They appear on EMG 1 to 3 weeks after a muscle has lost its nerve supply.

In *nerve conduction studies,* a brief electrical stimulus is applied to a distal portion of a sensory or mixed nerve, and the resulting wave of depolarization is recorded at some point proximal to the stimulation. For example, a stimulus can be applied to the forefinger and a recording electrode placed over the median nerve at the wrist. The time between the onset of the stimulus and the initial wave of depolarization at the recording electrode is measured. The speed of this response is termed *nerve conduction velocity.* Damaged nerves have slower conduction velocities.

Evoked Potentials.

Evoked potentials are recordings of electrical activity associated with nerve conduction along sensory pathways. The activity is generated by a specific sensory stimulus related to the type of study (e.g., checkerboard patterns for visual evoked potentials, clicking sounds for auditory evoked potentials, mild electrical pulses for somatosensory evoked potentials). Electrodes placed on specific areas of the skin and scalp record the electrical activity, and these data are stored and averaged by a computerized instrument. A wave pattern appears on a screen and is printed on paper. Peaks in the wave pattern correspond to conduction of the stimulus through certain points along the sensory pathway (e.g., peripheral nerve, brain stem, cortical areas). Increases in the time from stimulus onset to a given peak (latency) indicate slowed nerve conduction or nerve damage. This technique is useful in diagnosing abnormalities of the visual or auditory systems because it reveals whether a sensory impulse is reaching the appropriate part of the brain. Purposes for these tests include evaluation of the optic nerve in conditions such as multiple sclerosis (optic neuritis) and the vestibulo-cochlear nerve in acoustic neuroma.

Combined Doppler and Ultrasound (Duplex) Studies

Carotid Duplex.

In a duplex study, ultrasonography and pulsed Doppler technology are combined. A technician places a probe on the patient's skin over the carotid artery and slowly moves the probe along the course of the common carotid artery to the bifurcation of the external and internal carotid arteries. The ultrasound signal emitted from the probe reflects off the moving blood cells within the vessel. The frequency of the reflected signal corresponds to the blood flow velocity. This response is amplified and is registered on a graphic record and also as sound. The graphic record registers blood flow velocity. Increases in blood flow velocity can indicate stenosis of a vessel. Duplex scanning is a noninvasive study in which the degree of stenosis of the carotid and vertebral arteries is evaluated.

Transcranial Doppler Sonography.

The same technology used in duplex studies is used in transcranial Doppler sonography, except that blood flow velocities of the intracranial blood vessels are recorded. The probe is placed on the patient's skin at various “windows” in the skull (areas in the skull that have only a thin

bony covering) to register velocities of the middle cerebral artery, anterior cerebral artery, posterior cerebral artery, terminal carotid artery, and occasionally the anterior and posterior communicating arteries. The temporal, orbital, and suboccipital sites are used. The ultrasound signal received is recorded graphically as a waveform. Peak blood flow velocities and systolic–diastolic ratios can be calculated from this information. Transcranial Doppler sonography is a noninvasive technique that is useful in assessing vasospasm associated with subarachnoid hemorrhage, altered intracranial blood flow dynamics associated with occlusive vascular disease, presence of emboli, and cerebral autoregulation.

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. In a client with a disease that affects the myelin sheath of nerves, such as multiple sclerosis, which glial cells are affected?
   a. Microglia
   b. Astrocytes
   c. Oligodendrocytes
   d. Ependymal cells
2. A state of hypoxia alters the repeated action potentials necessary for transmission of nerve impulses. Which of the following requires energy?
   a. Repolarization of the cell membrane
   b. Creation of cell membrane permeability
   c. Movement of sodium into the nerve cell
   d. Maintenance of the resting membrane potential
3. Drugs or diseases that impair the function of the extrapyramidal system may cause the loss of which of the following?
   a. Sensations of pain and temperature
   b. Regulation of the ANS
   c. Integration of somatic and special sensory inputs
   d. Automatic movements associated with skeletal muscle activity
4. Which of the following will be affected by an obstruction of the anterior cerebral arteries?
   a. Visual imaging
   b. Balance and coordination
   c. Judgement, insight, and reasoning
   d. Visual and auditory integration for language comprehension
5. Data regarding mobility, strength, coordination, and activity tolerance are important for the nurse to obtain for which of the following reasons?
   a. Many neurological diseases affect one or more of these abilities.
   b. Clients are less able to identify other neurological impairments.
   c. These are the first functions to be lost in neurological disease.

d. Aspects of movement are the most important function of the nervous system.

6. Which of the following is a result of stimulation of the parasympathetic nervous system? *(Select all that apply)*
   a. Constriction of the bronchi
   b. Increase in rate of peristalsis
   c. Increased secretion of insulin
   d. Increased blood glucose levels
   e. Relaxation of the urinary sphincters
7. Why should the muscle strength of older adults not be compared with that of younger adults?
   a. Stroke is more common in older adults.
   b. Nutritional status is better in young adults.
   c. Most young people exercise more than older adults.
   d. Aging leads to a decrease in muscle bulk and strength.
8. A lesion of which cranial nerve would cause paralysis of the lateral gaze?
   a. Cranial nerve II
   b. Cranial nerve III
   c. Cranial nerve IV
   d. Cranial nerve VI
9. During neurological testing, the client is able to perceive pain elicited by pinprick. On the basis of this finding, which of the following tests may the nurse omit?
   a. Position sense
   b. Patellar reflexes
   c. Temperature perception
   d. Heel-to-shin movements
10. A client's eyes jerk as they follow the nurse's moving finger. How would the nurse record this finding?
    a. Nystagmus
    b. Normal tracking
    c. Ophthalmoplegia

d. Ophthalmic dyskinesia

11. Which of the following are nursing responsibilities for lumbar puncture?

a. Ensuring the client has a full bladder

b. Placing the client in the lateral recumbent position

c. Straightening the client's legs just before the puncture

d. Having the client cough when the needle has been inserted

1. c; 2. d; 3. d; 4. c; 5. a; 6. a, b, c, e; 7. d; 8. d; 9. c; 10. a; 11. b.

CHAPTER 59

Nursing Management

Acute Intracranial Problems

Written by, Linda Littlejohns

Adapted by, Sarah L. Johnston

LEARNING OBJECTIVES

1. Explain the physiological mechanisms that maintain normal intracranial pressure.
2. Describe the common etiologies, clinical manifestations, and collaborative care of the patient with increased intracranial pressure.
3. Describe the collaborative care and nursing management of the patient with increased intracranial pressure.
4. Differentiate between the types of head injury by mechanism of injury and clinical manifestations.
5. Describe the collaborative care and nursing management of the patient with a head injury.
6. Explain the types, clinical manifestations, and collaborative care of brain tumours.
7. Discuss the nursing management of the patient with a brain tumour.
8. Discuss the nursing management of the patient undergoing cranial surgery.
9. Compare the primary causes, collaborative care, and nursing management of meningitis, encephalitis, and brain abscess.

KEY TERMS

brain abscess, p. 1503
cerebral edema, p. 1476
coma, p. 1477
concussion, p. 1488
contusion, p. 1489
diffuse axonal injury (DAI), p. 1488
encephalitis, p. 1502
epidural hematoma, p. 1489
Glasgow Coma Scale (GCS), p. 1483
head injury, p. 1486
intracranial pressure (ICP), p. 1475
intraparenchymal or intracerebral hematoma, p. 1490
meningitis, p. 1500
nuchal rigidity, p. 1500
subdural hematoma, p. 1489
unconsciousness, p. 1478

Acute intracranial problems include diseases and disorders that can increase intracranial pressure (ICP). This chapter discusses the mechanisms that maintain normal ICP, increased ICP, head injuries, brain tumours, and cerebral inflammatory disorders.

Intracranial Pressure

Understanding the mechanisms associated with ICP is important in caring for patients with many different neurological problems. The skull is like a closed box, with three essential components constituting its volume: brain tissue, blood, and cerebro-spinal fluid (CSF) (Figure 59-1). The brain compartment, made up of neurons, neuroglial cells, and intracellular and extracellular fluids of brain tissue, makes up approximately 78% of this volume. Blood in the arterial, the venous, and the capillary networks makes up 12% of the volume, and the remaining 10% is the volume of the CSF. Under normal conditions, the volume of these three compartments is relatively stable, maintaining ICP within normal limits. Factors that influence ICP under normal circumstances are changes in (1) blood

pressure (BP), (2) cardiac function, (3) intra-abdominal and intrathoracic pressure, (4) body position, (5) temperature, and (6) blood gases, particularly CO_2 levels. The degree to which these factors increase or decrease the ICP depends on the ability of the brain to accommodate to the changes.

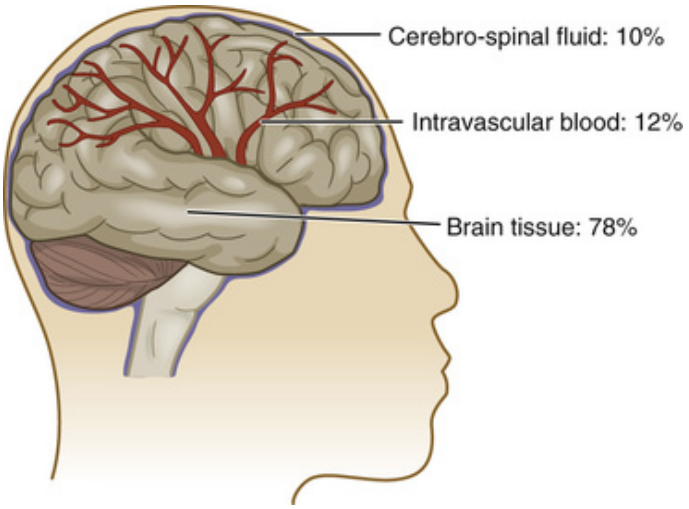

FIGURE 59-1 Components of the brain.

Primary versus secondary injury is another important concept in understanding ICP. *Primary injury* occurs at the initial time of an injury (e.g., impact of motor vehicle accident, blunt-force trauma) that results in displacement, bruising, or damage of the three components. *Secondary injury* is the resulting hypoxia, ischemia, hypotension, edema, or increased ICP that follows the primary injury. Secondary injury, which could occur several hours to days after the initial injury, is a primary concern when managing brain injury. Nursing management of the patient with an acute intracranial problem must include management of secondary injury, and thus increased ICP.

Regulation and Maintenance of Intracranial Pressure

Normal Intracranial Pressure.

Intracranial pressure (ICP) is the pressure exerted because of the combined total volume of the three components within the skull: brain tissue, blood, and CSF. The modified Monro–Kellie doctrine describes how a state of dynamic equilibrium is maintained by the volume relationship of

these three components within the rigid skull structure. If the volume in any one of the three components increases within the cranial vault and the volume from another component is displaced, the total intracranial volume will not change (Cushing, 1925). If the volume of any one of these three components increases without a corresponding decrease in another component, the result is an elevated ICP. This hypothesis is not applicable in situations in which the skull is not rigid (e.g., in neonates, in adults with unfused skull fractures).

ICP can be measured in the ventricles, subarachnoid space, subdural space, epidural space, or brain tissue, using a pressure transducer (Kawoos, McCarron, Auker, et al., 2015). Normal ICP ranges from 5 to 15 mm Hg. A sustained pressure greater than 20 mm Hg is considered abnormal and must be treated.

Normal Compensatory Adaptations.

Intrinsic compensatory mechanisms exist to resist increases in ICP. A major compensatory mechanism involves changes in the CSF volume. These changes are achieved primarily by the displacement of CSF into the spinal subarachnoid space or the basal subarachnoid cisterns and, to a lesser degree, by altering CSF production and absorption rates. Alterations in intracranial blood volume occur through the compression of cerebral veins and dural sinuses, regional cerebral vasoconstriction or dilation, and changes in venous outflow. Brain tissue volume compensates through distension of the dura or compression of brain tissue. Initially, an increase in volume produces no increase in ICP as a result of these compensatory mechanisms. However, compensatory adaptations are finite, and progressive increases in volume eventually exhaust compensatory mechanisms (Cushing, 1925). The result is increased ICP, neuronal compression, and ischemia.

Cerebral Blood Flow

Cerebral blood flow (CBF) is the amount of blood in millilitres (mL) passing through 100 grams (g) of brain tissue per minute. In adults, this equates to approximately 50 mL of blood/min/100 g of brain tissue or approximately 750 mL/min. Unlike other organs, the brain lacks the ability to store oxygen or glucose, and therefore the maintenance of adequate blood flow to the brain is critical for neuronal functioning and survival. Although the brain accounts for only about 2% of body weight, it uses 20% of the body's oxygen and 25% of its glucose.

Autoregulation of Cerebral Blood Flow.

The brain's intrinsic ability to regulate its own blood flow in response to its metabolic needs in spite of wide fluctuations in systemic arterial pressure is termed *autoregulation.* Autoregulation is the automatic alteration in the diameter of the cerebral blood vessels to maintain a constant blood flow to the brain during changes in BP. The purpose of autoregulation is to ensure adequate CBF to meet the metabolic needs of brain tissue and to maintain cerebral perfusion pressure within normal limits.

In healthy individuals, autoregulation operates within limited parameters. In cases of extreme hypotension or hypertension, autoregulation fails. If mean arterial pressure (MAP) is less than 50 mm Hg, CBF is decreased and symptoms of cerebral ischemia may occur. If MAP is greater than 150 mm Hg, the cerebral vessels are maximally constricted and further vasoconstrictor response is lost; CBF increases and intracranial hypertension may occur.

Other Factors Affecting Cerebral Blood Flow.

Carbon dioxide, oxygen, and hydrogen ion concentration affect cerebral vessel tone. The partial pressure of arterial carbon dioxide ($PaCO_2$) is a potent factor in vasoactive reactivity. An increase in $PaCO_2$ relaxes smooth muscle, dilates cerebral vessels, decreases cerebro-vascular resistance, and increases CBF. Alternately, a decrease in $PaCO_2$ reverses this process and decreases CBF. Cerebral oxygen tension (PaO_2) below 50 mm Hg results in cerebral vascular dilation. This dilation decreases cerebral vascular resistance and increases CBF. If PaO_2 is not raised, anaerobic metabolism begins, resulting in an accumulation of lactic acid. As lactic acid increases and hydrogen ions accumulate, the cerebral environment becomes more acidic. Within this acidic environment, further vasodilation occurs in a continued attempt to increase blood flow. The combination of a severely low arterial oxygen pressure (PaO_2) and an elevated hydrogen ion concentration (acidosis), which are both potent cerebral vasodilators, may produce a state wherein autoregulation is lost and compensatory mechanisms fail to meet tissue metabolic demands (Cushing, 1925).

CBF can be globally affected by cardiac or respiratory arrest, systemic hemorrhage, and other pathophysiological states (e.g., diabetic coma, encephalopathies, infections, toxicities). Regional CBF can also be affected by trauma, tumours, cerebral hemorrhage, or stroke. When regional or global autoregulation is lost, CBF is no longer maintained at a constant level but is directly influenced by changes in systemic BP, $PaCO_2$ levels, or

catecholamine levels. CBF can be indirectly reflected by calculating *cerebral perfusion pressure* (CPP). CPP is the pressure needed to ensure adequate brain tissue perfusion. CPP is equal to the MAP minus the ICP (CPP = MAP − ICP) (see example in Table 59-1). If CPP is inadequate, brain perfusion can be improved by either decreasing ICP or increasing MAP.

TABLE 59-1

CALCULATION OF CEREBRAL PERFUSION PRESSURE

CPP = MAP − ICP
$MAP = DBP + \frac{1}{3}(SBP - DBP)$ or $\frac{SBP + 2(DBP)}{3}$
Example: Systemic blood pressure = 122/84 mm Hg
MAP = 97 mm Hg
ICP = 12 mm Hg
CPP = 85 mm Hg

CPP, cerebral perfusion pressure; *DBP,* diastolic blood pressure; *ICP,* intracranial pressure; *MAP,* mean arterial pressure; *SBP,* systolic blood pressure.

As the CPP decreases, autoregulation fails and CBF decreases. Normal CPP is 70 to 100 mm Hg, and a minimum of 50 to 60 mm Hg is necessary for adequate cerebral perfusion. CPP less than 50 mm Hg is associated with cerebral ischemia. A CPP below 30 mm Hg results in cellular ischemia and is incompatible with life. Under normal circumstances, autoregulation maintains an adequate CBF and perfusion pressure primarily by cerebral vasoreactivity and metabolic adjustments that affect ICP. It is of paramount importance to maintain MAP when ICP is elevated. It should be remembered that CPP does not reflect perfusion pressure in all parts of the brain. There may be local areas of swelling and compression limiting regional perfusion pressure. Thus, for patients with these symptoms, a higher CPP may be needed to prevent localized tissue damage.

Pressure Changes.

The relationship of pressure to volume is depicted in the pressure–volume curve (Figure 59-2). The curve is affected by the brain's compliance. *Compliance* is the expandability of the brain. It is represented as the volume increase for each unit increase in pressure. With low compliance, small increases in volume result in greater increases in pressure.

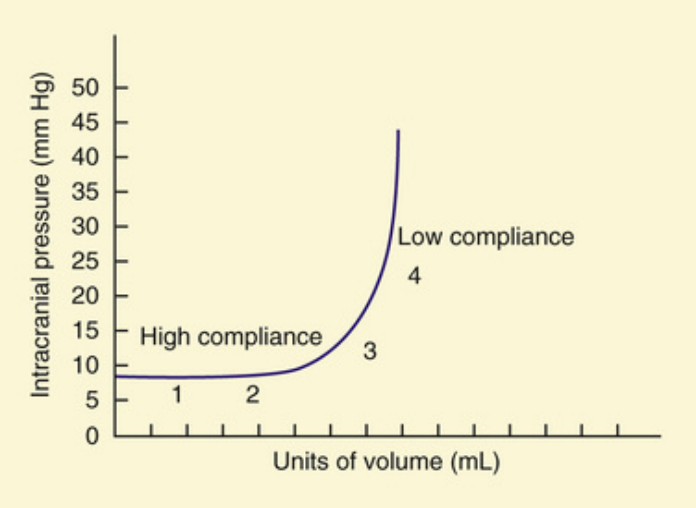

FIGURE 59-2 Intracranial pressure–volume curve. (See text for descriptions of *1*, *2*, *3*, and *4*.)

The pressure–volume curve can be used to represent the stages of increased ICP (see Figure 59-2). At stage 1 on the curve, there is high compliance. The brain is in total compensation, with accommodation and autoregulation intact. An increase in volume (in brain tissue, blood, or CSF) does not increase the ICP. At stage 2, the compliance is lessening, and an increase in volume places the patient at risk for increased ICP. At stage 3, there is low compliance as compensatory mechanisms are becoming exhausted. Any small addition of volume causes a great increase in ICP. As compensatory mechanisms fail, there is a loss of autoregulation, and the patient may exhibit symptoms indicating increased ICP, such as headache, changes in level of consciousness, or pupil responsiveness.

As the patient enters stage 4, the ICP rises to lethal levels with even slight increases in volume. Here the patient is at significant risk for hypoperfusion and brain herniation and death. *Herniation* occurs as the brain tissue is forcibly shifted from the compartment of greater pressure to a compartment of lesser pressure. In this situation, intense pressure is placed on the brain stem, and if herniation continues, brain stem death is imminent.

Increased Intracranial Pressure

Increased ICP is a life-threatening situation resulting from an increase in any or all of the three components (brain tissue, blood, CSF) of the skull. Elevated ICP (above the threshold of 20 mm Hg) is clinically significant because it diminishes CPP, increasing risk for brain ischemia and infarction, and is associated with a poor prognosis (Kawoos et al., 2015).

Mechanisms of Increased Intracranial Pressure

The brain tissue component of ICP can be increased by cerebral neoplasm, contusion, abscess, or cerebral edema. Conditions that increase the cerebral blood volume include intracranial hematomas or hemorrhages, metabolic and physiological factors (e.g., CO_2, O_2, fever, pain), and vascular anomalies. Increases in the CSF volume can result from CSF-secreting tumours or hydrocephalus. These cerebral insults may result in hypercapnia, cerebral acidosis, impaired autoregulation, and systemic hypertension, which promote the formation and spread of cerebral edema. This edema distorts brain tissue, further increasing the ICP, which leads to even more tissue hypoxia and acidosis. Figure 59-3 illustrates the progression of increased ICP.

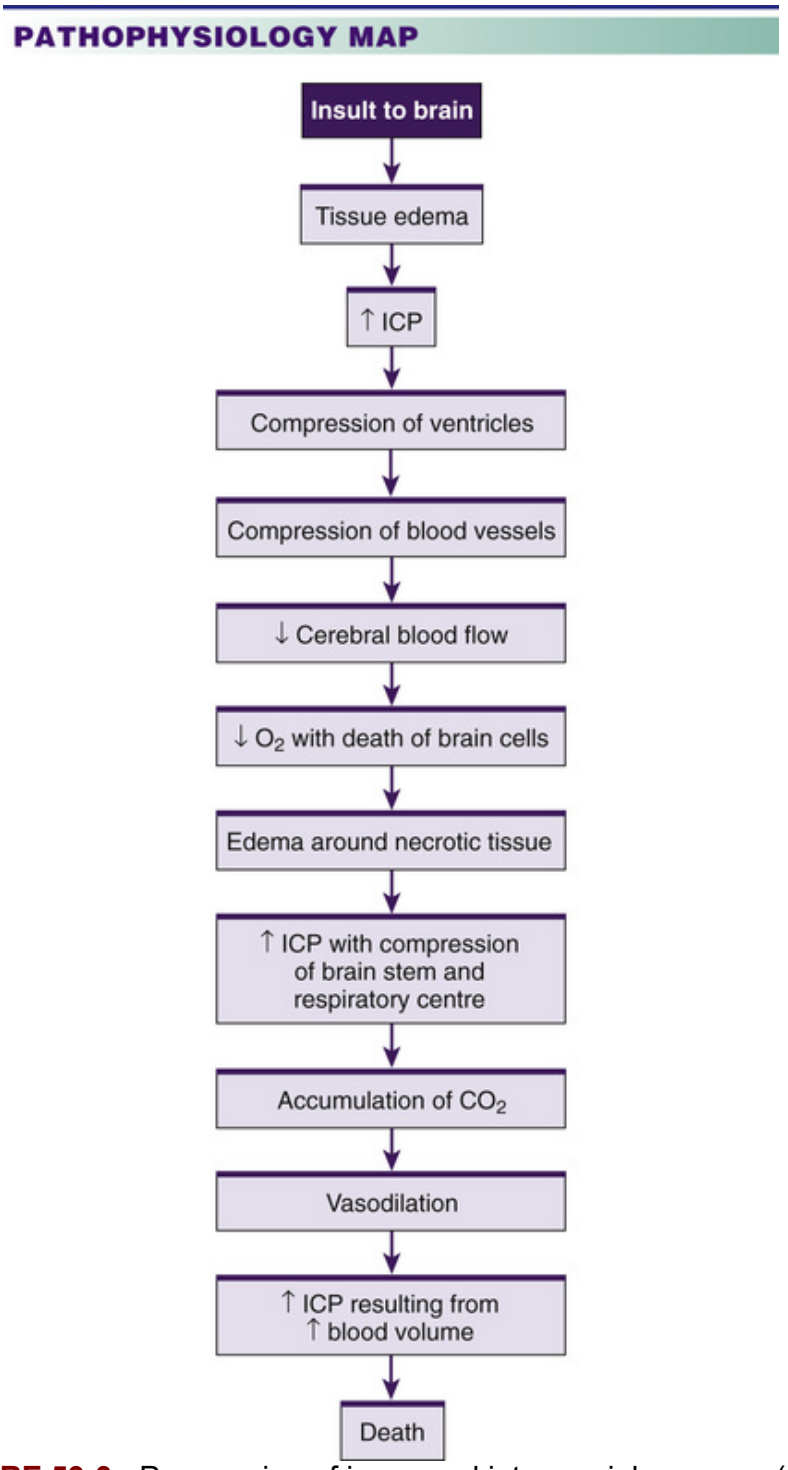

FIGURE 59-3 Progression of increased intracranial pressure (ICP).

Crucial to preservation of tissue is maintenance of CBF. Elevations in pressure that are more evenly distributed throughout the brain or slow increases in ICP (e.g., an enlarging brain lesion) preserve blood flow better than a rapid increase, as in primary brain injury. Sustained increases in

ICP result in brain stem compression and herniation of the brain from one compartment to another.

Displacement and herniation of brain tissue cause a potentially reversible pathophysiological process to become irreversible. Ischemia and edema are further increased, compounding the pre-existing problem. Herniations force the cerebellum and the brain stem downward through the foramen magnum. If compression of the brain stem is unrelieved, respiratory arrest may occur. Compression of brain tissue, brain stem structures, cranial nerves, and vessels may be fatal. Figure 59-4 illustrates herniation. (Herniation is further described in the later section of this chapter on complications of ICP.)

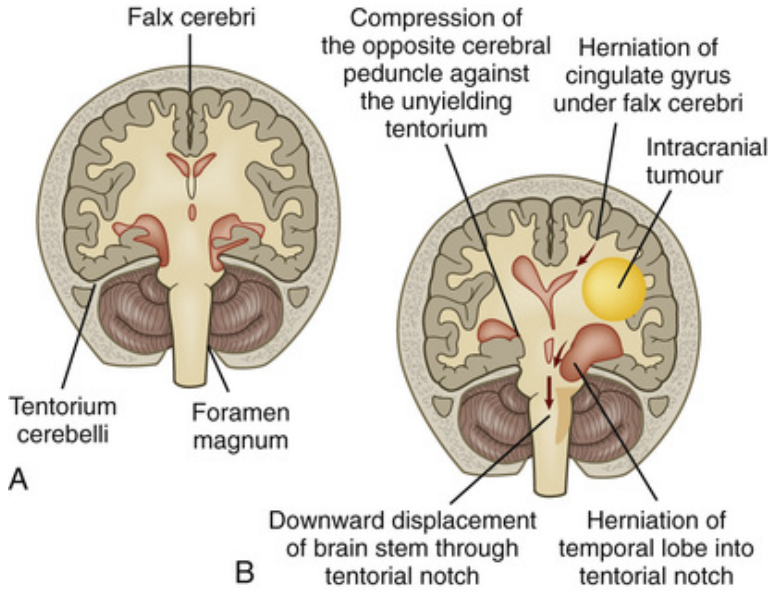

FIGURE 59-4 Herniation. **A,** Normal relationship of intracranial structures. **B,** Shift of intracranial structures. Source: Adapted from McCance, K. L., & Huether, S. E. (2010). *Pathophysiology: The biologic basis for disease in adults and children* (6th ed., p. 558, Figure 16-16). St. Louis: Mosby.

Cerebral Edema

As shown in Table 59-2, there are a variety of causes of **cerebral edema** (increased accumulation of fluid in the extravascular spaces of brain tissue). Regardless of the cause, cerebral edema results in an increase in tissue volume that carries the potential for increased ICP. Factors that contribute to the degree of cerebral edema are the extent and the severity

of the original insult as well as the cascade of secondary cellular events that occur in the hours and days following insult or injury.

TABLE 59-2
CAUSES OF CEREBRAL EDEMA

- Mass lesions
  - Brain abscess
  - Brain tumour (primary or metastatic)
  - Hematoma (intracerebral, subdural, epidural)
  - Hemorrhage (intracerebral, cerebellar, brain stem)
- Head injuries
  - Contusion
  - Diffuse axonal injury
  - Hemorrhage
  - Post-traumatic brain swelling
- Brain surgery
- Cerebral infections
  - Meningitis
  - Encephalitis
- Vascular insult
  - Anoxic and ischemic episodes
  - Cerebral infarction (thrombotic or embolic)
  - Venous sinus thrombosis
- Toxic or metabolic encephalopathic conditions
  - Hepatic encephalopathy
  - Lead or arsenic intoxication
  - Uremia

Three types of cerebral edema have been distinguished: vasogenic, cytotoxic, and interstitial. More than one type may result from a single insult in the same patient. Regardless of the cause of cerebral edema, manifestations of increased ICP result, unless compensation is adequate.

Vasogenic Cerebral Edema.

Vasogenic cerebral edema, the most common type of edema, occurs mainly in the white matter and is attributed to changes in the endothelial lining of cerebral capillaries. These changes allow leakage of macromolecules from the capillaries into the surrounding extracellular space, resulting in an osmotic gradient that favours the flow of water from the intravascular to the extravascular space. A variety of insults, such as brain tumours, head trauma, abscesses, and ingested toxins, may cause an increase in the permeability of the blood–brain barrier and produce an increase in the extracellular fluid volume. The speed and extent of the spread of the edema fluid are influenced by the systemic BP, the site of the brain injury, and the extent of the blood–brain barrier defect. This edema may produce a continuum of symptoms, ranging from headache and focal neurological deficits to disturbances in consciousness, including **coma** (profound state

of unconsciousness). It is important to recognize that although a headache may seem to be a benign symptom, in cases of cerebral edema it can quickly progress to coma and death; therefore vigilant assessment is key.

Cytotoxic Cerebral Edema.

Cytotoxic cerebral edema results from local disruption of the functional or morphological integrity of cell membranes and occurs most often in the grey matter. It develops from destructive lesions or trauma to brain tissue that lead to cerebral hypoxia or anoxia, sodium depletion, and syndrome of inappropriate antidiuretic hormone (SIADH). Cerebral edema results as fluid and protein shift from the extracellular space directly into the cells, with subsequent swelling and loss of cellular function.

Interstitial Cerebral Edema.

Interstitial cerebral edema is the result of periventricular diffusion of ventricular CSF in a patient with uncontrolled hydrocephalus. It can also be caused by enlargement of the extracellular space as a result of systemic water excess (hyponatremia). Fluid moves into the cells to equilibrate with the hypo-osmotic interstitial fluid.

Clinical Manifestations

The clinical manifestations of increased ICP can take many forms, depending on the cause, the location, and the rate at which the pressure increase occurs (Figure 59-5). The earlier the condition is recognized and treated, the better the prognosis.

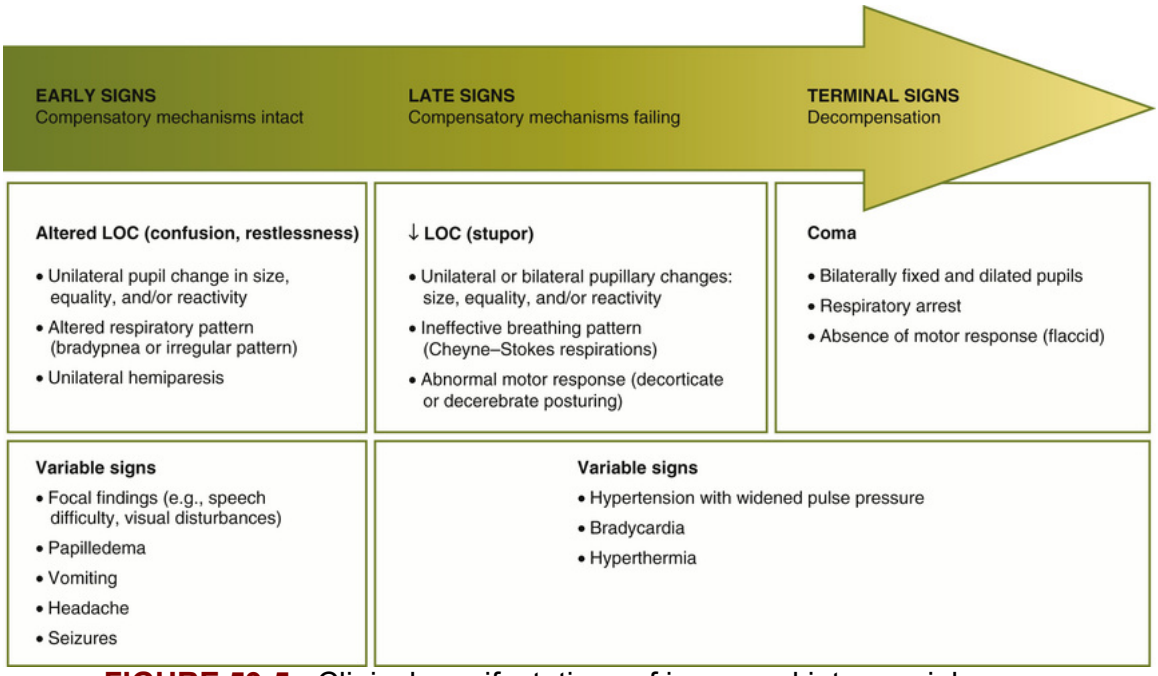

FIGURE 59-5 Clinical manifestations of increased intracranial pressure. *LOC,* level of consciousness.

Change in Level of Consciousness.

Level of consciousness (LOC) is a sensitive and early indicator of the patient's neurological status. Changes in LOC are a result of impaired CBF, which deprives the cells of the cerebral cortex and the reticular activating system (RAS) of oxygen. The RAS is located in the brain stem, with neural connections to many parts of the nervous system. An intact RAS can maintain a state of wakefulness even in the absence of a functioning cerebral cortex. Interruptions of impulses from the RAS or alteration of the functioning of the cerebral hemispheres can cause **unconsciousness** (an abnormal state of complete or partial unawareness of self or environment).

The patient's state of consciousness is defined by both the behaviour and the pattern of brain activity recorded by an electroencephalogram (EEG). The change in consciousness may be subtle, such as a flattening of affect, confusion, or decrease in level of attention. A decrease in consciousness may be dramatic, as in coma—the deepest state of unconsciousness, when the patient does not respond to sensory stimuli. The EEG pattern demonstrates decreased neuronal activity.

Changes in Vital Signs.

Changes in vital signs are caused by increasing pressure on the thalamus, the hypothalamus, the pons, and the medulla. Manifestations such as

Cushing's triad, consisting of increasing systolic pressure (widening pulse pressure), bradycardia with a full and bounding pulse, and irregular respiratory pattern, may be present but often do not appear until ICP has been increased for some time or suddenly and markedly increases (e.g., head trauma). (Pulse pressure is discussed in Chapter 34.) Always recognize Cushing's triad as a medical emergency, since this is a sign of brain stem compression and impending death. A change in body temperature may also be noted and is caused by associated pressure on the hypothalamus.

Ocular Signs.

Compression of the oculomotor nerve (cranial nerve [CN] III) results in dilation of the pupil *ipsilateral* to (same side as) the mass or lesion, sluggish or no response to light, inability to move the eye upward, and ptosis of the eyelid. These signs can be the result of a shifting of the brain from the midline, a process that compresses the trunk of CN III, paralyzing the pupil sphincter. A fixed (unresponsive), unilaterally dilated pupil is a neurological emergency that indicates herniation of the brain.

Other cranial nerves may also be affected, such as the optic (CN II), trochlear (CN IV), and abducens (CN VI) nerves. Signs of dysfunction of these cranial nerves include blurred vision, diplopia, and changes in extraocular eye movements. Central herniation may initially manifest as sluggish but equal pupil responses. Lateral herniation of the uncus, the innermost part of the temporal lobe, may cause a dilated unilateral pupil. *Papilledema,* an edematous optic disc seen on retinal examination, is also noted and is a nonspecific sign associated with swelling of the optic nerve related to increased ICP.

Decrease in Motor Function.

As the ICP continues to rise, the patient manifests changes in motor ability. A *contralateral* (opposite side of the mass lesion) hemiparesis or hemiplegia may be seen, depending on the location of the source of the increased ICP. If painful stimuli are used to elicit a motor response, the patient may exhibit localization to the stimuli or a withdrawal from the stimuli. Decorticate (flexor) and decerebrate (extensor) posturing may also be elicited by noxious stimuli (Figure 59-6). *Decorticate posture* consists of internal rotation and adduction of the arms, with flexion of elbows, wrists, and fingers as a result of interruption of voluntary motor tracts. Extension of the legs may also be seen. A *decerebrate posture* may indicate more serious damage and results from disruption of motor fibres in the

midbrain and brain stem. In this position, the arms are stiffly extended, adducted, and hyperpronated. There is also hyperextension of the legs, with plantar flexion of the feet.

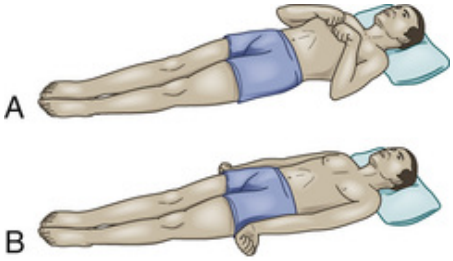

FIGURE 59-6 Decorticate and decerebrate posturing. **A,** Decorticate response. Flexion of arms, wrists, and fingers with adduction in upper extremities. Extension, internal rotation, and plantar flexion in lower extremities. **B,** Decerebrate response. All four extremities in rigid extension, with hyperpronation of forearms and plantar flexion of feet.

Headache.

Although the brain itself is insensitive to pain, compression of other intracranial structures, such as the walls of arteries and veins and the cranial nerves, can produce headache. Headaches associated with increased ICP are often continuous. Straining, agitation, or movement may accentuate the pain.

Vomiting.

Vomiting, usually not preceded by nausea, is often a nonspecific sign of increased ICP. This is related to direct pressure on the vomiting centre, located on the floor of the fourth ventricle in the medulla. Vomiting associated with increased ICP is often described as *projectile,* owing to the force of vomitus ejection.

Complications

The major complications of uncontrolled, increased ICP are inadequate cerebral perfusion and cerebral herniation (see Figure 59-4). To better understand cerebral herniation, three important structures in the brain must be described. The *falx cerebri* is a thin wall of dura that folds down between the cortex separating the two cerebral hemispheres. The *tentorium cerebelli* is a rigid fold of dura that separates the cerebral hemispheres from

the cerebellum (see Figure 59-4). There is a central opening in the tentorium cerebelli called the *tentorial incisura,* from which the brain stem emerges. This is a common site of herniation related to increased ICP.

Cingulate herniation occurs when there is lateral displacement of brain tissue beneath the falx cerebri. *Tentorial herniation* occurs when a mass lesion in the cerebrum forces the brain to herniate downward through the tentorial incisura. *Cerebellar tonsillar herniation* occurs when there is lateral and downward herniation of the cerebellar tonsils through the foramen magnum. This herniation results in medullary compression and is often fatal.

Diagnostic Studies

Diagnostic studies can identify the underlying cause of increased ICP (Table 59-3). Magnetic resonance imaging (MRI) and computed tomography (CT) have revolutionized the diagnosis of acute intracranial events. Significant technological advancement in these modalities now offers enhanced evaluation of the brain's vasculature utilizing magnetic resonance angiography (MRA) and computed tomographic angiography (CTA). All of these tests are used to differentiate the many conditions that can cause increased ICP and to evaluate therapeutic options. Other diagnostic tests that may be used include conventional cerebral angiography, EEG, ICP measurement, brain tissue oxygenation measurement via the Licox catheter (described later in this chapter), transcranial Doppler studies, and evoked potential studies. Positron emission tomography (PET) can also be used to diagnose the cause of increased ICP. In general, a lumbar puncture is not performed when increased ICP is suspected because of the possibility of cerebral herniation from the sudden release of the pressure in the skull from the area above the lumbar puncture.

TABLE 59-3

COLLABORATIVE CARE
Increased Intracranial Pressure

Diagnostic Tests and Neuromonitoring
• History and physical examination • Cerebral oxygenation monitoring (Licox catheter, $SjvO_2$) • ECG • Infrascanner • Laboratory studies, including CBC; coagulation profile; electrolytes; creatinine; BUN; ABGs; ammonia level; general drug and toxicology screen; CSF analysis for protein, cells, glucose* • MRI, CT scan, MRA, CTA, EEG, angiography, EP studies, PET • Skull and facial radiographic studies • Transcranial Doppler studies • Vital signs, neurological assessments, ICP measurements
Collaborative Therapy

• Cerebral oxygenation monitoring ($PbtO_2$, $SjvO_2$)
• Drug therapy
  • Anticonvulsant drugs (e.g., phenytoin [Dilantin])
  • Antipyretics
  • Corticosteroids (dexamethasone) (for brain tumours, bacterial meningitis)
  • Histamine H_2-receptor antagonist (e.g., ranitidine [Zantac]) or proton pump inhibitor (e.g., pantoprazole [Pantoloc]) to prevent gastro-intestinal ulcers and bleeding
  • Hypertonic saline
  • Nutritional support
  • Osmotic diuretics (mannitol)
  • Stool softeners
• Elevation of head of bed to 30 degrees with head in a neutral position
• ICP monitoring
• Intubation and mechanical ventilation
• Maintenance of CPP >60 mm Hg
• Maintenance of fluid balance and assessment of osmolality
• Maintenance of PaO_2 at ≥100 mm Hg
• Maintenance of systolic arterial pressure between 100 and 160 mm Hg
• Reduction of cerebral metabolism (e.g., high-dose barbiturates)

*CSF sampling via lumbar puncture is contraindicated if there is suspected raised ICP because there is a possibility of cerebral herniation and death.

*ABG*s, arterial blood gases; *BUN,* blood urea nitrogen; *CBC,* complete blood count; *CPP,* cerebral perfusion pressure; *CSF,* cerebro-spinal fluid; *CT,* computed tomography; *CTA,* computed tomography angiography; *ECG,* electrocardiogram; *EEG,* electroencephalogram; *EP,* evoked potential; *ICP,* intracranial pressure; *MAP,* mean arterial pressure; *MRA,* magnetic resonance angiography; *MRI,* magnetic resonance imaging; *PaO_2,* partial pressure of arterial oxygen; *$PbtO_2$,* pressure of oxygen in brain tissue*; $SjvO_2$,* jugular venous oxygen saturation.

A hand-held device called an Infrascanner can be used to detect life-threatening intracranial bleeding. The scanner directs a wavelength of light that can penetrate tissue and bone. Blood from intracranial hematomas absorbs the light differently from other areas of the brain.

Neuromonitoring

Measurement of Intracranial Pressure.

ICP may become elevated because of head trauma, stroke, subarachnoid hemorrhage, brain tumour, inflammation or infection, hydrocephalus, or brain tissue damage from other causes. Patients with or at risk for elevated ICP usually receive invasive ICP monitoring in an intensive care unit (ICU), except those with irreversible problems or advanced neurological disease. Goals for nursing management of elevated ICP include preservation of cerebral oxygenation and perfusion, early identification of neurological changes, and prevention of complications secondary to intracranial hypertension.

ICP monitoring is used to guide clinical care when the patient is at risk for or has elevations in ICP. ICP should be monitored in patients admitted with a Glasgow Coma Scale (GCS) score of 8 or less and an abnormal CT scan or MRI (hematomas, contusion, edema). (The GCS is presented in Table 59-5.) Multiple methods and devices are available to monitor ICP (Figure 59-7).

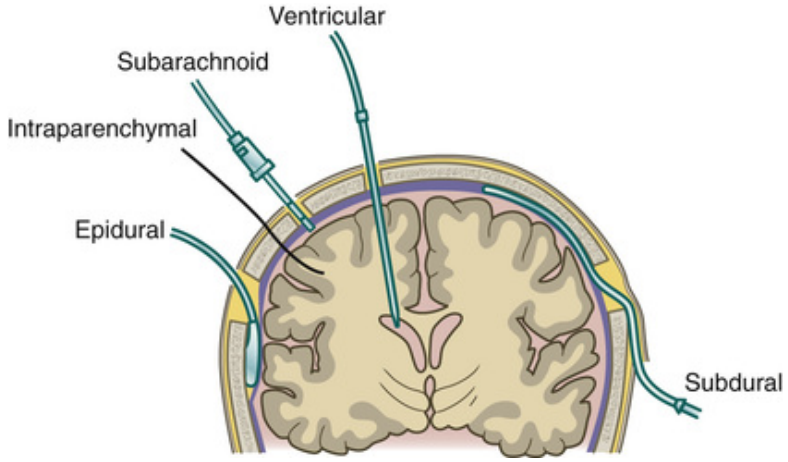

FIGURE 59-7 Coronal section of the brain shows potential sites for placement of intracranial pressure monitoring devices.

The "gold standard" for monitoring ICP is the *ventriculostomy,* whereby a catheter is inserted into the lateral ventricle and coupled to an external transducer. This technique directly measures the pressure within the ventricles and facilitates removal or sampling (or both) of CSF. Significant consideration in caring for a patient with a ventriculostomy is the constant positioning of the external transducer relative to the position of the

patient's head to maintain consistent measurements. The transducer should be level with the foramen of Monro (intraventricular foramen); the reference point for this on the patient is the tragus of the ear (Figure 59-8, *A*). When repositioning a patient with a ventriculostomy, the system may need to be rezeroed to maintain the level of the transducer. Another device used for monitoring ICP is the *fibre-optic catheter,* the tip of which is placed directly into the ventricle or the brain tissue. A sensor transducer located in the catheter tip provides measurement of the pressure in the brain. Lastly, the *subarachnoid bolt* or *screw* may be placed through the skull between the arachnoid membrane and the cerebral cortex to measure ICP; this method does not allow for drainage of CSF but can be converted into a ventriculostomy if the patient's clinical condition changes to require that intervention.

FIGURE 59-8 **A,** Levelling a ventriculostomy. **B,** Cerebro-spinal fluid is drained into a drainage system. Source: Courtesy Meg Zomorodi.

Infection is a serious consideration with ICP monitoring. Prophylactic systemic antibiotics may be administered to reduce the chances of infection. Factors that contribute to the development of infection include ICP monitoring for longer than 5 days, use of a ventriculostomy, the presence of a CSF leak, a concurrent systemic infection, and improper aseptic technique during manipulation by health care team members. Routine care may include regular diagnostic testing for CSF organism growth.

The ICP waveform is derived from the arterial pulsations of the choroids plexus in the lateral ventricles. A normal ICP waveform has a diastolic and a systolic component and correlates with the cardiac cycle. When the waveform is monitored so that components in synchrony with the cardiac cycle can be visualized, the normal ICP waveform has three phases (Table 59-4).

TABLE 59-4

NORMAL INTRACRANIAL PRESSURE WAVEFORMS*

Waveform	Meaning
P1 Percussion wave	Represents arterial pulsations; normally the highest of the three waveforms
P2 Rebound wave	Reflects intracranial compliance or relative brain volume. When P2 is higher than P1, intracranial compliance is compromised
P3 Dicrotic wave	Follows dicrotic notch; represents venous pulsations; normally, the lowest waveform

*See Figure 59-9.

It is important to monitor the ICP waveform and the CPP (Figure 59-9). It has been noted that, when the height of P2 is higher than P1, this represents low *compliance* and the patient is at risk for development of elevated ICP. It is important to consider both the rate at which changes occur and the patient's clinical condition. Neurological deterioration might not occur until ICP elevation is pronounced and sustained. Any indication of ICP elevation, either as a mean increase in pressure or as an abnormal waveform configuration, should be reported to the physician immediately.

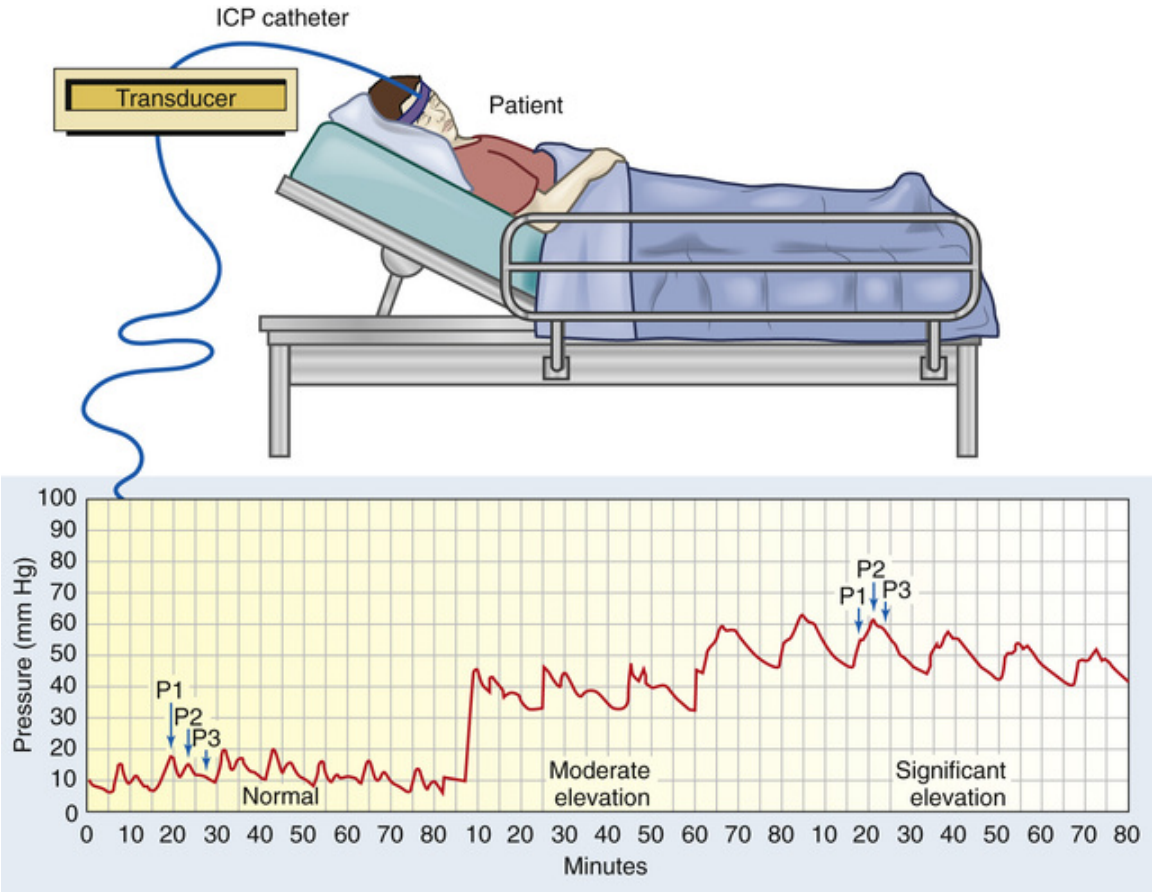

FIGURE 59-9 Intracranial pressure (ICP) monitoring can be used to continuously measure ICP. The ICP tracing shows normal, elevated, and plateau waves. At high ICP, the P2 peak is higher than the P1 peak, and the peaks become less distinct and plateau. Source: Copstead-Kirkhorn, L. C., & Banasik, J. L. (2010). *Pathophysiology* (4th ed., p. 1043, Figure 44-7). St Louis: Mosby.

Inaccurate ICP readings can be caused by CSF leaks around the monitoring device, obstruction of the intraventricular catheter or bolt (from tissue or blood clot), a difference between the height of the bolt and the transducer, kinks in the tubing, and incorrect height of the drainage system relative to the patient's reference point. Bubbles or air in the tubing can also dampen the waveform.

Cerebro-Spinal Fluid Drainage.

With the ventricular catheter and certain fibre-optic systems, it is possible to control elevations in ICP by removing CSF. Using a closed system (Figure 59-10), CSF is removed by gravity drainage and by adjusting the height of the drip chamber and drainage bag relative to the patient's ventricular reference point. Typically, a point 15 cm above the ear is

selected (see Figure 59-8, *B*). Raising the system diminishes drainage, whereas lowering the system increases drainage volume. The physician orders the level of the ICP indicating that drainage should be initiated, the amount of fluid to be drained, the height of the system, and the frequency of drainage (intermittent or continuous).

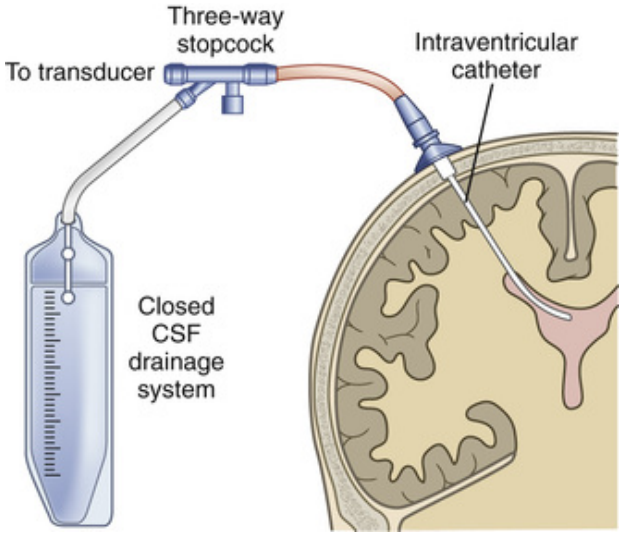

FIGURE 59-10 Intermittent drainage system. Cerebro-spinal fluid (CSF) is drained via a ventriculostomy when intracranial pressure (ICP) exceeds the upper pressure parameter set by the physician. Intermittent drainage involves opening the three-way stopcock to allow CSF to flow into the draining bag for brief periods (≤5 min) until the pressure is below the upper pressure parameters.

The two options for CSF drainage are intermittent and continuous. If intermittent drainage is ordered, the ventriculostomy system is opened at the indicated ICP and CSF is allowed to drain for 2 to 3 minutes. Then the stopcock is closed to return the ventriculostomy to a closed system. If continuous ICP drainage is ordered, careful monitoring of the volume of CSF drained is essential, keeping in mind that normal CSF production is about 20 to 30 mL/hr, with a total CSF volume of 90 to 150 mL within the ventricles and subarachnoid space.

Prevention of infection is imperative by use of strict aseptic technique during dressing changes or sampling of CSF. The system must remain intact to ensure that the ICP readings are accurate because treatment is initiated and evaluated on the basis of the readings. It is also recommended that a sign be posted above the patient's bed to notify anyone before turning, moving, or suctioning the patient to prevent the

removal of too much CSF, which can result in complications such as ventricular collapse, herniation, or subdural hematoma from rapid decompression. Although it is generally recognized that CSF removal decreases ICP and improves CPP, guidelines for CSF removal are not universally accepted but are typically based on institution or physician preference.

Cerebral Oxygenation Monitoring.

Failure to adequately deliver oxygenated blood to an injured brain is a major contributor to poor outcomes. Technology is available to measure cerebral oxygenation and cerebral perfusion. Two such devices are currently being used in intensive care settings: the *Licox brain tissue oxygenation catheter* and the *jugular venous bulb catheter.* The Licox catheter is placed in the healthy white matter of the brain and provides continuous monitoring of the pressure of oxygen in brain tissue ($PbtO_2$); the normal range for $PbtO_2$ is 20 to 40 mm Hg. A lower-than-normal $PbtO_2$ level is indicative of ischemia.

The jugular venous bulb catheter is placed in the internal jugular vein and positioned so that the catheter tip is located in the jugular bulb; placement is confirmed by radiographic study. This catheter provides a measurement of jugular venous oxygen saturation ($SjvO_2$), which indicates total venous brain tissue extraction of oxygen as a measure of cerebral oxygen supply and demand. The normal $SjvO_2$ range is 55% to 75%. Values less than 50% demonstrate impaired cerebral oxygenation. With the use of either device, interventions can be specifically focused to improve brain tissue oxygen levels. The Licox catheter has the ability to also measure brain temperature; neither device has the capability of monitoring ICP, and therefore, an ICP monitoring device may be placed for this purpose.

Collaborative Care

The goals of collaborative care (see Table 59-3) are to identify and treat the underlying cause of increased ICP and to support brain function. A careful history is an important diagnostic aid that can direct the search for the underlying cause of increased ICP (usually an increase in blood [hemorrhage], brain tissue [tumour or edema], or CSF [hydrocephalus] in the brain).

Ensuring adequate oxygenation to support brain function is the first step in the management of increased ICP. An endotracheal tube or

tracheostomy may be necessary to maintain adequate ventilation. Arterial blood gas (ABG) analysis guides the oxygen therapy. The goal is to maintain the PaO_2 at 100 mm Hg or greater. It may be necessary to maintain the patient on a mechanical ventilator to ensure adequate oxygenation.

If the condition is caused by a mass lesion, such as a tumour or hematoma, surgical removal of the mass is the best management (see the Brain Tumours and Cranial Surgery sections, later in this chapter). Nonsurgical intervention for the reduction of tissue volume related to cerebral tissue swelling and cerebral edema includes the use of osmotic diuretics, hypertonic saline, and corticosteroids.

Drug Therapy.

Drug therapy plays an important role in the management of increased ICP. Frequently, mannitol (Osmitrol), an osmotic diuretic given intravenously, is used to decrease the ICP in acute situations. Mannitol acts to decrease ICP in two ways: plasma expansion and osmotic effect. There is an immediate plasma-expanding effect that reduces the hematocrit and blood viscosity, thereby increasing CBF and cerebral oxygen delivery. A vascular osmotic gradient is created by mannitol. Thus, fluid moves from the tissues into the blood vessels. ICP is reduced by the decrease in the total brain fluid content. Fluid and electrolyte status must be closely monitored when osmotic diuretics are used as multiple administrations can increase serum sodium levels and osmolality (Shawkat, Westwood, & Mortimer, 2012).

Drug Alert

Mannitol (Osmitrol)

- Careful monitoring of patients is required due to the adverse effect of fluid shift and the potential for fluid overload and pulmonary congestion.
- Mannitol may crystallize at lower temperatures; administer intravenously using a filter.

Hypertonic saline is another drug therapy used to manage increased ICP. It reduces swelling and improves CBF, drawing water out of the brain

tissue. A patient receiving hypertonic saline infusion must also be monitored closely; blood pressure and serum sodium levels can be affected by intravascular fluid volume excess as a result of treatment. Hypertonic saline offers effective first-line treatment for elevated ICP when compared with mannitol (Kamel, Navi, Nakagawa, et al., 2011).

Corticosteroids (e.g., dexamethasone) are used to treat vasogenic edema surrounding tumours and abscesses but appear to have limited value in the management of patients with head injuries and are not recommended for those patients. Corticosteroids act by stabilizing the cell membrane and inhibiting the synthesis of prostaglandins (see Chapter 14), thus preventing the formation of proinflammatory mediators. Corticosteroids are also thought to improve neuronal function by improving CBF and restoring autoregulation.

Complications associated with the use of corticosteroids include hyperglycemia, increased incidence of infections, gastro-intestinal (GI) bleeding, and hyponatremia. Fluid intake and sodium and glucose levels should be monitored regularly. Patients receiving corticosteroids should concurrently be given antacids or histamine (H_2)-receptor blockers (e.g., ranitidine [Zantac]) or proton pump inhibitors (e.g., omeprazole [Losec], pantoprazole [Pantoloc]) to prevent GI ulcers and bleeding.

Drug therapy for reducing cerebral metabolism may be an effective strategy to control ICP. Sedation with propofol [Diprivan] and analgesia, along with the treatments described above, can be used to manage elevated ICP (Oddo, Crippa, Mehta, et al., 2016). (The discussion of drug therapy used in the management of patients with increased ICP is continued on pages 1482–1483 of this chapter.) The decision may be made to use high-dose barbiturates (e.g., pentobarbital sodium [Somnotol]) in patients with increased ICP that is refractory to all other treatments (Dinsmore, 2013). Barbiturates dampen the effects of environmental stimuli on patients, thereby decreasing cerebral metabolism and subsequently ICP. Capabilities to monitor the patient's ICP, blood flow, EEG, and metabolism should be available when this treatment is used; hypotension as a result of treatment is a concern. There is not sufficient evidence to suggest that outcomes for patients with acute traumatic brain injuries are improved with this treatment (Roberts & Sydenham, 2012). Anticonvulsant drugs such as phenytoin (Dilantin) may be used because seizures can further increase ICP (seizures are discussed in greater detail in Chapter 61).

Nutritional Therapy.

All patients must have their nutritional needs met, regardless of their state of consciousness or health. The patient with increased ICP is in a hypermetabolic and hypercatabolic state that increases the need for glucose to provide the necessary fuel for metabolism of the injured brain. If the patient cannot maintain an adequate oral intake, other means of meeting the nutritional requirements, such as enteral feedings or parenteral nutrition, should be initiated. Early feeding after brain injury may improve outcomes (Wang, Dong, Han, et al., 2013). Because malnutrition promotes continued cerebral edema, maintenance of optimal nutrition is imperative. (Nutritional therapy is discussed in Chapter 42.) Feedings or supplements should be guided by the patient's fluid and electrolyte status as well as the patient's metabolic needs.

Therapy is directed at keeping patients normovolemic. Intravenous (IV) 0.9% sodium chloride is the preferred solution for administration of piggyback medications because a lowering of serum osmolarity and an increase in cerebral edema occur if 5% dextrose in water is used.

Supportive Therapy.

Metabolic demands such as fever (38°C), agitation or shivering, pain, and seizures can also increase ICP. The health care team should plan to reduce these metabolic demands to lower the ICP in patients who are at risk. Patients should be monitored for seizure activity. Fever should be well controlled to maintain a temperature of 36° to 37°C by using antipyretics (e.g., acetaminophen [Tylenol]), cool baths, cooling blankets, ice packs, or intravascular cooling devices, as necessary. However, patients should be kept from shivering or shaking, since this increases the metabolic workload on the brain. If shivering or shaking occurs, sedatives may be needed or a different cooling method selected.

Pain should be managed while being careful not to oversedate or overmedicate. Finally, the patient should remain in a quiet, calm environment with minimal noise and interruptions. The patient should be observed for signs of agitation, irritation, or frustration. Also the caregiver and the family should be taught about decreasing stimulation, and the health care team should coordinate to minimize procedures that may produce agitation.

Nursing Management Increased Intracranial Pressure

Nursing Assessment

Subjective data about the patient with increased ICP can be obtained from the patient or family members or other persons who are familiar with the patient. The nurse must learn appropriate assessment techniques and describe the LOC by noting the specific behaviours observed. When a deviation from the normal state of consciousness occurs, a more structured method of observation should be initiated. Adequate circulation and respiration are the most vital body functions and should always be the first ones assessed.

Glasgow Coma Scale.

The **Glasgow Coma Scale (GCS)**, developed in 1974, is a quick, practical, and standardized system for assessing the degree to which consciousness is impaired. It provides a universal language for describing altered states of consciousness. The three areas assessed in the GCS correspond to the definition of coma as the inability of a patient to speak, obey commands, or open the eyes when a verbal or painful stimulus is applied (Jennett & Teasdale, 1977). Specific assessments evaluate the patient's response to varying degrees of stimuli. Three indicators of response are evaluated: (1) eye opening, (2) best verbal response, and (3) best motor response (see Table 59-5). Specific behaviours that are seen as responses to the testing stimulus in each of these three areas are given a numeric value and can be plotted on a graph. The nurse's responsibility is to elicit the best response on each of the scales; the higher the scores, the higher the level of brain functioning. A graph can be used to determine whether the patient's condition is stable, improving, or deteriorating. The subscale scores are particularly important if a patient is untestable in one area. For example, severe periorbital edema may make eye opening impossible. The total GCS score is a sum of the numeric values assigned to each of the three areas evaluated. The highest GCS score is 15 for a fully alert person, and the lowest possible score is 3. A GCS score of 8 or less is generally indicative of coma (Teasdale & Jennett, 1974).

TABLE 59-5
GLASGOW COMA SCALE

Appropriate Stimulus	Response	Score
Eyes Open		
Approach to bedside	Spontaneous response	4
Verbal command	Opening of eyes to name or command	3
Pain	Lack of opening of eyes to previous stimuli but opening to pain	2
	Lack of opening of eyes to any stimulus	1
	Untestable* (e.g., swollen)	U
Best Verbal Response		
Verbal questioning with maximum arousal	Appropriate orientation, conversant; correct identification of self, place, year, and month	5
	Confusion; conversant, but disorientation in one or more spheres	4
	Inappropriate or disorganized use of words (e.g., cursing), lack of sustained conversation	3
	Incomprehensible words, sounds (e.g., moaning)	2
	Lack of sound, even with painful stimuli	1
	Untestable* (e.g., endotracheal tube)	U
Best Motor Response		
Verbal command (e.g., "raise your arm, hold up two fingers")	Obedience of command	6
Pain applied centrally (e.g., sternal rub, pinching of upper third of trapezius, or supraorbital pressure)	Localization of pain, lack of obedience but presence of attempts to remove offending stimulus—purposeful movement	5
	Flexion withdrawal, flexion of arm in response to pain without abnormal flexion posture—nonpurposeful movement	4
	Abnormal flexion, flexing of arm at elbow and pronation, making a fist	3
	Abnormal extension, extension of arm at elbow usually with adduction and internal rotation of arm at shoulder	2
	Lack of response	1
	Untestable*	U

*Added to the original scale by many centres.

The GCS offers several advantages in the assessment of the unconscious patient. It is specific and structured, allowing different health care providers to arrive at the same conclusion regarding the patient's status. It saves time for the assessor because the ratings are done with numbers rather than with lengthy descriptions.

The GCS is also specific enough to discriminate between different or changing states. It is used to assess the arousal aspect of consciousness. Other components of the neurological assessment include pupillary checks, extremity strength testing, vital signs, and if appropriate, testing of the function of specific cranial nerves.

Neurological Assessment.

The pupils are compared with one another for size, movement, and response (Figure 59-11). If the oculomotor nerve is compressed, the pupil on the affected side (ipsilateral) becomes larger until it fully dilates. If ICP continues to increase, both pupils dilate. Pupil size is measured in millimetres before assessing the pupil response to light.

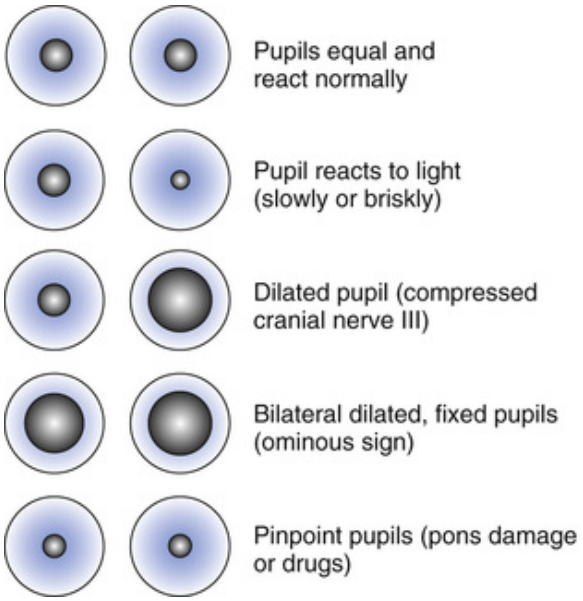

FIGURE 59-11 Pupillary check for size and response.

Pupillary reaction is tested with a penlight. The normal reaction is brisk constriction when the light is shone directly into the eye. A consensual response (a slight constriction in the opposite pupil) should also be noted at the same time. A sluggish reaction can indicate early pressure on CN III. A fixed pupil shows no response to light stimulus, which usually indicates increased ICP. However, there are other causes of a fixed pupil, including direct injury to CN III, previous eye surgery, administration of atropine, and use of mydriatic eye drops.

Evaluation of other cranial nerves can be included in the neurological assessment. Eye movements controlled by CNs III, IV, and VI can be examined in the patient who is awake and can be used to assess the function of the brain stem. In patients who are unconscious, eye movements can be elicited by reflex with the use of head movements (oculo-cephalic) and caloric stimulation (oculo-vestibular). (Chapters 23 and 24 discuss assessment and problems of the eye and ear.) Testing the corneal reflex provides clinical information regarding the function of CNs

V and VII. If corneal reflexes are absent, routine eye care should be initiated to prevent corneal abrasion.

For the patient who is awake, motor strength is tested by asking the patient to squeeze the nurse's hands to compare strength in the hands. The palmar (or pronator) drift test is an excellent measure of strength in the upper extremities. With eyes closed, the patient raises the arms in front of the body with the palmar surface facing upward. If there is any weakness in the upper extremity, the palmar surface rotates inward and the arm may drift downward. The patient keeps the eyes closed to prevent being able to see the palmar drift and trying to correct the rotating hand position. Detection of a palmar drift is an early indicator of cortico-spinal tract compression and possible increased ICP. Asking the patient to raise the foot from the bed or to bend the knees up in bed is a good assessment of lower extremity strength. All four extremities should be tested for strength and evaluated for any asymmetry in strength or movement.

For patients who are unconscious or uncooperative, motor strength can be assessed by observation of their spontaneous movement. If no spontaneous movement is possible, a pain stimulus should be applied to the patient, and the response should be noted. Resistance to movement during passive range of motion exercises is another measure of strength.

Vital signs, including BP, pulse, respiratory rate, and temperature, should also be systematically recorded. Cushing's triad is a triad of changes to vital signs (increased BP with a widening pulse pressure, bradycardia, and irregular respiratory pattern). This triad indicates severe increased ICP and impending cerebral herniation. Specific respiratory patterns are associated with severely increased ICP (Figure 59-12).

Pattern	Location of Lesion	Description
1. Cheyne–Stokes 	Bilateral hemispheric disease or metabolic brain dysfunction	Cycles of hyperventilation and apnea
2. Central neurogenic hyperventilation 	Brain stem between lower midbrain and upper pons	Sustained, regular rapid and deep breathing
3. Apneustic breathing 	Mid or lower pons	Prolonged inspiratory phase or pauses alternating with expiratory pauses
4. Cluster breathing 	Medulla or lower pons	Clusters of breaths follow each other with irregular pauses between
5. Ataxic breathing 	Reticular formation of the medulla	Completely irregular with some breaths deep and some shallow. Random, irregular pauses, slow rate

FIGURE 59-12 Common abnormal respiratory patterns associated with coma.

Nursing Diagnoses

Nursing diagnoses for the patient with increased ICP include, but are not limited to, the following:

- *Decreased intracranial adaptive capacity* (related to decreased cerebral perfusion or increased ICP)
- *Risk for ineffective cerebral tissue perfusion* as evidenced by *brain injury, brain neoplasm, cerebral aneurysm*
- *Risk for disuse syndrome* as evidenced by *alteration in level of consciousness, mechanical immobility, paralysis*

Additional information on nursing diagnoses for patients with increased ICP is presented in Nursing Care Plan (NCP) 59-1, available on the Evolve website.

Planning

The overall goals are that the patient with increased ICP will (1) maintain a patent airway, (2) have ICP within normal limits, (3) have normal fluid and electrolyte balance, and (4) have no complications secondary to immobility and decreased LOC.

Nursing Implementation

Acute Intervention

Respiratory Function.

Maintenance of a patent airway is critical in the patient with increased ICP and is a primary nursing responsibility. As the LOC decreases, the patient is at increased risk for airway obstruction from the tongue dropping back and occluding the airway or from accumulation of secretions. Altered breathing patterns may become evident. Airway patency can be aided by keeping the patient lying on one side, with frequent position changes.

Safety Alert

- Be alert to altered breathing patterns.
- Snoring sounds indicate obstruction and require immediate intervention.

Accumulated secretions should be removed by suctioning, as needed. An oral airway facilitates breathing and provides an easier suctioning route in the patient who is comatose. Any patient with altered LOC who is unable to maintain a patent airway or effective ventilation requires intubation and mechanical ventilation.

The nurse must use measures to prevent hypoxia and hypercapnia. Proper positioning of the head is important. Elevation of the head of the bed by 30 degrees enhances respiratory exchange and aids in decreasing cerebral edema. Suctioning and coughing can cause transient decreases in

the PaO_2 and increases in the ICP. Suctioning should be less than 10 seconds in duration, with administration of 100% oxygen before and after to prevent decreases in the PaO_2. To avoid cumulative increases in the ICP, suctioning should be limited to two passes per suction procedure. Patients with elevated ICP are at risk for lower CPP during suctioning. Abdominal distension can interfere with respiratory function and should be prevented. Increased intra-abdominal or intrathoracic pressures can contribute to elevated ICP by impeding cerebral venous drainage. Insertion of a nasogastric tube to aspirate the stomach contents can prevent distension, vomiting, and possible aspiration. However, in patients with facial and skull fractures, a nasogastric tube is contraindicated, and oral insertion of a gastric tube is preferred.

Pain, anxiety, and fear from the initial injury, therapeutic procedures, or noxious stimuli can increase ICP and BP, complicating the management and the recovery of the patient with a brain injury. The appropriate choice or combination of sedatives, paralytics, and analgesics for symptom management presents a challenge to the ICU team. Administration of these agents may alter the neurological state, masking true neurological changes. It may be necessary to temporarily suspend pharmacological therapy to appropriately assess neurological status. The choice, the dosage, and the combination of agents may vary depending on the patient's history, neurological state, and overall clinical presentation.

The IV anaesthetic sedative propofol (Diprivan) has gained popularity in the management of pain and anxiety in the ICU because of its rapid onset, short half-life, and oxygen-saving properties. It has been shown to depress cerebral metabolism and oxygen consumption, offering neuroprotective benefits, and is a drug of choice for sedation and elevated ICP in the ICU setting (Oddo et al., 2016).

Dexmedetomidine (Precedex), an α_2-adrenergic agonist, is used for continuous IV sedation of patients who are intubated and mechanically ventilated in the ICU setting for up to 24 hours. It is another ideal agent for patients with neurological conditions because of the ease in obtaining a neurological assessment without altering the dose because of its anxiolytic properties. The benzodiazepine midazolam can be used for sedation and management of ICP as well (Oddo et al., 2016). When using continuous IV sedatives, be aware of the adverse effects of these drugs, especially hypotension, since this can result in a lower CPP value.

Non-depolarizing neuromuscular blocking agents (e.g., cisatracurium) are useful for ventilatory management and treatment of refractory intracranial hypertension. Because these agents paralyze muscles without

blocking pain or noxious stimuli, they are used in combination with sedatives, analgesics, or benzodiazepines. Opioids, such as morphine sulphate and fentanyl, are rapid-onset analgesics with minimal effect on CBF or oxygen metabolism.

ABGs should be measured and evaluated regularly (see Chapter 28). The nurse should frequently monitor the ABG values and maintain the levels within prescribed or acceptable parameters. The appropriate ventilatory support can be ordered on the basis of the PaO_2 and $PaCO_2$ values.

Fluid and Electrolyte Balance.

Fluid and electrolyte disturbances can have an adverse effect on ICP. IV fluids should be closely monitored with the use of a limited-volume device or a volume-control apparatus for accuracy. Intake and output, with insensible losses and daily weights taken into account, are important parameters in the assessment of fluid balance.

Electrolyte determinations should be made daily, and any abnormal values should be discussed with the physician. It is especially important to monitor serum glucose, sodium, potassium, and osmolality. Urinary output is monitored to detect problems related to *diabetes insipidus* (DI) (e.g., increased urinary output related to a decrease in antidiuretic hormone secretion); SIADH, which results in decreased urinary output; and cerebral salt wasting, a form of hyponatremia caused by excessive renal sodium excretion associated with cerebral insult. Besides urinary output, the serum and urine sodium and osmolality are also used to diagnose DI, SIADH, and cerebral salt wasting. DI may result in severe dehydration unless treated. The usual treatment is fluid replacement, vasopressin, or desmopressin acetate (DDAVP). SIADH results in a dilutional hyponatremia that may produce cerebral edema, changes in LOC, seizures, and coma. (Treatment of SIADH is described in Chapter 51.) Treatment of cerebral salt wasting consists of aggressive sodium (Na^+) and volume replacement.

Monitoring Intracranial Pressure.

ICP monitoring is used in combination with other physiological parameters to guide the care of the patient and assess the patient's response to routine care. The Valsalva manoeuvre, coughing, sneezing, hypoxemia, pain, fever, and environmental stimuli are factors that can increase ICP. Nurses should be alert to these factors and should attempt to keep them to a minimum.

Body Position.

The patient with increased ICP should be maintained in the head-up position. The nurse must take care to prevent extreme neck flexion, which can cause venous obstruction and contribute to elevated ICP. The body position should be adjusted to decrease the ICP as much as possible and to improve the CPP. Traditional practice has been to elevate the head of the bed to 30 degrees, unless a concurrent cervical neck injury has been identified, in which case a reverse Trendelenburg position may be indicated to elevate the head while keeping the spine aligned. Elevation of the head of the bed reduces sagittal sinus pressure, promotes venous drainage from the head via the valveless jugular system, and decreases the vascular congestion that can produce cerebral edema. However, raising the head of the bed above 30 degrees may decrease the CPP. Careful evaluation of the effects of elevation of the head of the bed on both the ICP and the CPP is required—the bed should be positioned so that it lowers the ICP while maintaining the CPP and other indices of cerebral oxygenation.

Care should be taken to turn the patient with slow, gentle movements because rapid changes in position may increase the ICP. Caution should be used to prevent discomfort in turning and positioning the patient because pain or agitation also increases ICP. Increased intra-abdominal and intrathoracic pressure contribute to increased ICP by impeding the venous return. Thus, coughing, straining, and the Valsalva manoeuvre should be avoided. Extreme hip flexion should be prevented to decrease the risk of raising the intra-abdominal pressure. The patient should be turned at least every 2 hours.

Decorticate or decerebrate posturing is a reflex response in some patients with increased ICP (see Figure 59-6). Turning, skin care, and even passive range of motion can elicit the posturing reflexes. Attempts should be made to provide needed physical care activities to minimize complications of immobility, such as atelectasis and contractures. In cases of severe posturing reflexes, these activities may have to be done less frequently because posturing can cause increases in ICP.

Protection From Injury.

The patient with increased ICP and a decreased LOC needs protection from self-injury. Confusion, agitation, and the possibility of seizures can put the patient at risk for injury. In these cases, environmental, chemical, or physical restraints may be considered to protect the patient from harm (e.g., removing tubes, wandering). A least-restraint approach should be

used and considered only after all possible alternative interventions are exhausted. Specific employer policies and procedures should help guide restraint practice. The need for restraints should be reassessed daily. If restraints are necessary, they should be secure enough to be effective, and the area under the restraints should be observed regularly for skin irritation and adequate blood circulation. Restrained extremities should be assessed at least every 2 hours for colour, warmth, sensation, and movement. Agitation may increase with the use of restraints, which indicates the need for other measures to protect the patient from injury. Light sedation with agents such as haloperidol (Haldol) or lorazepam (Ativan) may be needed. Patient history and clinical presentation may be used to guide drug choice. Having a family member stay with the patient may have a calming effect. For the patient with seizures or the patient at risk for seizure activity, seizure precautions should be instituted. These include padded side rails, an airway at the bedside, accurate and timely administration of anticonvulsant drugs, and close observation (see Chapter 61). The patient can benefit from a quiet, nonstimulating environment. The nurse should always use a calm, reassuring approach. Touching and talking to the patient, even one who is in a coma, is always appropriate care. The nurse must create a balance between sensory deprivation and overload for the patient with increased ICP.

Psychological Considerations.

In addition to providing carefully planned physical care to patients with increased ICP, the nurse must also be aware of the psychological well-being of patients and their families. Anxiety over the diagnosis and the prognosis for patients with neurological problems can be distressing to patients and their families. The nurse's competent and assured manner in performing the care patients need is reassuring to everyone involved. Short, simple explanations are appropriate and allow patients and their families to acquire the amount of information they desire. There is a need for support, information, and education of patients, families, and caregivers. The nurse should assess the family members' desire to assist in providing care for the patient and allow for their participation as appropriate. Encourage interdisciplinary management (social work, chaplain, etc.) of the patient and family in decision making as much as possible.

Evaluation

The expected outcomes for the patient with ICP are addressed in NCP 59-1, available on the Evolve website.

Head Injury

Head injury includes any trauma to the scalp, the skull, or the brain. The term *head trauma* is used primarily to signify cranio-cerebral trauma, which includes an alteration in consciousness, no matter how brief.

Statistics for head injuries are incomplete because many victims die at the scene of the accident or because the condition is considered minor and health care services are not sought. Approximately 160 000 Canadians sustain a head injury annually, and over 1 million live with the effects of an acquired brain injury (Brain Injury Association of Canada, n.d.). Traumatic brain injury (TBI) continues to be one of the leading causes of death and the leading cause of disability after trauma. In Canada, the most common causes of TBI requiring hospitalizations are motor vehicle accidents and falls (Fu, Jing, McFaull, et al., 2015). Other causes include assaults, sports-related injuries, and recreational accidents.

Head trauma has a high potential for poor outcome. Death from head trauma occurs at three time periods following an injury: immediately after the injury, within 2 hours after the injury, and approximately 3 weeks after injury. Factors associated with a poor outcome include the increasing age of the patient, lower Glasgow Coma Scale (GCS) scores, impaired or absent eye movements or pupil light reflexes, hypoxemia, intracranial edema and intraventricular hemorrhage, and ICP levels higher than 20 mm Hg (Badri, Chen, Barber, et al., 2012). The majority of deaths after a head injury occur immediately after the injury, either from the direct head trauma or from massive hemorrhage and shock. Deaths occurring within a few hours of the trauma are caused by progressive worsening of the head injury or from internal bleeding. An immediate note of changes in neurological status and surgical intervention are critical in the prevention of deaths at this point. Deaths occurring 3 weeks or longer after injury result from multisystem failure. Expert nursing care in the weeks following the injury is crucial in decreasing mortality and optimizing patient outcomes.
