ECF volume deficit (hypovolemia) and ECF volume excess (hypervolemia) are commonly occurring clinical conditions (Table 19-4). ECF volume imbalances are typically accompanied by one or more electrolyte imbalances. As previously discussed, volume imbalances are often associated with changes in the serum sodium level. Fluid volume deficit can occur with abnormal loss of body fluids (e.g., through diarrhea, fistula drainage, hemorrhage, polyuria), decreased intake, or a plasma–to–

interstitial fluid shift. Although the terms are often used interchangeably, fluid volume deficit and dehydration are not the same; *dehydration* refers to loss of pure water alone without a corresponding loss of sodium. Fluid volume excess may result from excessive intake of fluids, abnormal retention of fluids (e.g., heart failure, renal failure), or interstitial–to–plasma fluid shift. Although shifts in fluid between the plasma and the interstitium do not alter the overall volume of the ECF, these shifts do result in changes in the clinically important intravascular volume.

TABLE 19-4
CAUSES OF ECF VOLUME IMBALANCES

ECF Volume Deficit	ECF Volume Excess
Increased loss • Vomiting • Diarrhea • Fistula drainage • GI tract suction • Excessive sweating • Third-space fluid shifts (e.g., burns, intestinal obstruction) • Overuse of diuretics • Hemorrhage	Increased retention • Heart failure • Cushing's syndrome • Chronic liver disease with portal hypertension • Long-term use of corticosteroids • Renal failure
Decreased intake • Nausea • Anorexia • Inability to drink • Inability to obtain water	Increased intake • Rare when renal function is adequate • Excessive IV administration of fluids

ECF, extracellular fluid; *GI*, gastro-intestinal; *IV*, intravenous.

Collaborative Care.

The goal of treatment for fluid volume deficit is to correct the underlying cause and to replace both water and electrolytes. Balanced IV solutions, such as lactated Ringer's solution, are usually given. Isotonic NaCl is used when rapid volume replacement is indicated. Blood is administered when volume loss is caused by blood loss.

The goal of treatment for fluid volume excess is removal of sodium and water without producing abnormal changes in the electrolyte composition or osmolality of ECF. The primary cause must be identified and treated. IV therapy is usually not indicated for this type of fluid imbalance. Diuretics and fluid restriction are the primary forms of therapy. Restriction of sodium intake may also be indicated. If the fluid excess leads to ascites or pleural effusion, an abdominal paracentesis or thoracentesis may be necessary.

Nursing Management Sodium and Volume Imbalances

Nursing Diagnoses

Nursing diagnoses and collaborative problems for patients with various fluid and sodium imbalances include, but are not limited to, the following:

ECF volume excess:

- *Excess fluid volume* related to *excessive sodium intake*
- *Ineffective airway clearance* related to *retained secretions*
- *Risk for impaired skin integrity* as evidenced by *alteration in fluid volume* (edema)
- *Disturbed body image* related to *alteration in self-perception*
- Potential complications: pulmonary edema, ascites

ECF volume deficit:

- *Deficient fluid volume* related to *insufficient fluid intake*
- *Decreased cardiac output* (related to excessive ECF losses or decreased fluid intake)
- Potential complication: hypovolemic shock

Hypernatremia:

- *Risk for injury* as evidenced by *alteration in cognitive functioning* (seizures)

Hyponatremia:

- *Risk for injury* as evidenced by *alteration in cognitive functioning* (decreased level of consciousness)

Nursing Implementation

Intake and Output.

The 24-hour records of intake and output contain valuable information regarding fluid and electrolyte problems. Sources of excessive intake or fluid losses can be identified on a properly recorded intake-and-output flow sheet. Intake should include oral, IV, and tube feedings and retained irrigants. Fluid output includes urine, excess perspiration, wound or tube drainage, vomitus, and diarrhea. Fluid loss from wounds and perspiration should be estimated. Urine specific gravity can be measured. Readings

higher than 1.030 indicate that the urine is concentrated, whereas those lower than 1.005 indicate that the urine is diluted.

Cardiovascular Changes.

Monitoring patients for cardiovascular changes is necessary to prevent or detect complications from sodium and volume imbalances. Signs and symptoms of ECF volume excess and deficit are reflected in changes in blood pressure, pulse force, and jugular venous visibility. In fluid volume excess, the pulse is full and bounding. Because of the expanded intravascular volume, the pulse is not easily obliterated by the pressure cuff. Increased volume causes distension of neck veins (jugular venous distension) and increased blood pressure.

In mild to moderate fluid volume deficit, compensatory mechanisms include sympathetic nervous system stimulation of the heart and peripheral vasoconstriction. Stimulation of the heart increases heart rate and, in combination with vasoconstriction, maintains blood pressure within normal limits. A change in position from lying to sitting or standing may elicit a further increase in heart rate or a decrease in blood pressure (orthostatic hypotension). If vasoconstriction and tachycardia provide inadequate compensation, hypotension occurs when the patient is recumbent. Severe fluid volume deficit can cause a weak, thready pulse that is easily obliterated and flattened neck veins. Severe, untreated fluid deficit results in shock.

Respiratory Changes.

Both fluid excess and fluid deficit affect respiratory status. Fluid excess results in pulmonary congestion and pulmonary edema as increased hydrostatic pressure in the pulmonary vessels forces fluid into the alveoli. Affected patients exhibit shortness of breath, irritative cough, and moist crackles on auscultation. Patients with fluid deficit demonstrate an increased respiratory rate because of decreased tissue perfusion and resultant hypoxia.

Neurological Changes.

Changes in neurological function may occur with sodium and water imbalances. With increased water volume and hyponatremia, water moves by osmosis into the brain cells. Alternatively, decreased water volume and hypernatremia cause water to shift out of the brain cells, with resultant shrinkage. In addition, profound volume depletion may cause an alteration in sensorium secondary to reduced cerebral tissue perfusion.

Assessment of neurological function includes evaluation of (1) the level of consciousness, which includes responses to verbal and painful stimuli and the determination of a person's orientation to time, place, and person; (2) pupillary response to light and equality of pupil size; and (3) voluntary movement of the extremities, degree of muscle strength, and reflexes. Nursing care focuses on maintaining patient safety.

Daily Weight Measurements.

Accurate daily weight measurements are the easiest way to estimate volume status. An increase of 1 kg is equal to 1000 mL (1 L) of fluid retention (provided that the person has maintained usual dietary intake or has not been on nothing-by-mouth [NPO] status). However, weight changes can be relied on only if obtained under standardized conditions. Obtaining an accurate weight depends on the patient's being weighed at the same time every day, with the same garments on, and on the same carefully calibrated scale. Excess bedding should be removed, and all drainage bags should be emptied before the weighing. If bulky dressings or tubes are present, which may not necessarily be used every day, a notation regarding these variables should be recorded on the flow sheet or nursing notes.

Skin Assessment and Care.

Clues to fluid volume deficit and excess can be detected by inspection of the skin. Skin should be examined for turgor and mobility. Normally, a fold of skin, when pinched, moves readily and, on release, rapidly returns to its former position. Skin areas over the sternum, the abdomen, and the anterior forearm are the usual sites for evaluation of tissue turgor (Figure 19-13). In older people, decreased skin turgor is less predictive of fluid deficit because of the loss of tissue elasticity (Hooper, Bunn, Jimoh, et al., 2014).

FIGURE 19-13 Assessment of skin turgor. When normal skin is pinched, it resumes shape in seconds. If the skin remains wrinkled for 20 to 30 seconds, the patient has poor skin turgor. Source: de Vries Feyens, C., & de Jager, C. P. C. (2011, January). Images in medicine: Decreased skin turgor. Dr. P. Marazzi/Science Source.

In ECF volume deficit, skin turgor is diminished; there is a lag in the pinched skinfold's return to its original state (referred to as *tenting*). In mild fluid deficits, the skin may appear warm, dry, and wrinkled. These signs may be difficult to evaluate in an older adult because the patient's skin may be normally dry, wrinkled, and nonelastic. In more severe deficits, the skin may be cool and moist if there is vasoconstriction to compensate for the decreased fluid volume. Oral mucous membranes are dry, the tongue may be furrowed, and many affected individuals complain of thirst. Routine oral care is critical for the comfort of a patient who is dehydrated or has a fluid restriction order.

Edematous skin may feel cool because of fluid accumulation and a decrease in blood flow secondary to the pressure of the fluid. The fluid can stretch the skin, causing it to feel taut and hard. The nurse assesses edema by pressing with a thumb or forefinger over the edematous area. A grading scale (ranging from 1+ [slight edema; 2-mm indentation] to 4+ [pitting edema; 8-mm indentation]) is used to standardize the description if an indentation remains when pressure is released. The nurse must evaluate for edema in areas where soft tissues overlie a bone, particularly the tibia, fibula, and sacrum.

Good skin care for the person with fluid volume excess or deficit is important. Edematous tissues must be protected from extremes of heat and cold, prolonged pressure, and trauma. Frequent skin care and changes

in position protect the patient from skin breakdown. Elevation of edematous extremities helps promote venous return and fluid reabsorption. Dehydrated skin needs frequent care without the use of soap. The application of moisturizing creams or oils increases moisture retention and stimulates circulation.

Other Nursing Measures.

The nurse should administer IV fluids as ordered and carefully monitor the rates of infusion of IV fluid solutions, especially when large volumes of fluid are being given. This is especially true in patients with cardiac, renal, or neurological problems. Patients receiving tube feedings need supplementary water added to their enteral formula. The amount of water depends on the osmolarity of the feeding and the patient's condition.

Patients with nasogastric suction should not be allowed to drink water because it will increase the loss of electrolytes. On occasion, such patients may be given small amounts of ice chips to suck. A nasogastric tube should always be irrigated with isotonic saline solution and not with water. Water causes diffusion of electrolytes into the gastric lumen from mucosal cells; the electrolytes are then suctioned away.

Nurses in hospital and community settings should encourage and often assist older or debilitated patients in maintaining an adequate oral intake. This may be accomplished by giving patients a drink as part of the morning care, encouraging extra sips of fluid with medications, and including a drink of fluids as part of one-on-one conversations.

Potassium Imbalances

Potassium is the major ICF cation; 98% of the body potassium is intracellular. For example, potassium concentration within muscle cells is approximately 140 mmol; potassium concentration in the ECF is 3.5 to 5.0 mmol. The sodium–potassium pump in cell membranes maintains this concentration difference by pumping potassium into the cell and sodium out, a process fuelled by the breakdown of ATP. The ratio of ECF potassium to ICF potassium is the major factor in the resting neuron's membrane potential. Many of the symptoms related to potassium imbalance are caused by changes in the ratio of ECF potassium to ICF potassium (increased or decreased ECF potassium; McCance & Huether, 2014).

Potassium is critical for many cellular and metabolic functions. It is necessary for the transmission and conduction of nerve impulses,

maintenance of normal cardiac rhythms, and skeletal and smooth muscle contraction. As the major intracellular cation, potassium regulates intracellular osmolality and promotes cellular growth. Potassium moves into cells during the formation of new tissues and leaves the cell during tissue breakdown (McCance & Huether, 2014). Potassium also plays a role in acid–base balance, which is discussed with acid–base regulation later in this chapter.

Diet is the source of potassium. The typical Western diet contains approximately 50 to 100 mEq of potassium daily, mainly from fruits, dried fruits, and vegetables. Many salt substitutes contain substantial potassium. Patients may receive potassium from parenteral sources, including IV fluids, stored transfused blood, and potassium–penicillin.

The kidneys are the primary route for potassium loss. Approximately 90% of the daily potassium intake is eliminated by the kidneys; the remainder is lost in the stool and sweat. If kidney function is significantly impaired, toxic levels of potassium may be retained. There is an inverse relationship between sodium and potassium reabsorption in the kidneys. Factors that cause sodium retention (e.g., low blood volume, increased aldosterone level) cause potassium loss in the urine. Large urine volumes can be associated with excess loss of potassium in the urine. The ability of the kidneys to conserve potassium is weak even when body stores are depleted (McCance & Huether, 2014).

Disruptions in the dynamic equilibrium between ICF and ECF potassium often cause clinical problems. Among the factors causing potassium to move from the ECF to the ICF are the following:

- Insulin
- Alkalosis
- β-Adrenergic stimulation (catecholamine release in stress, coronary ischemia, delirium tremens, or administration of β-adrenergic agonist drugs)
- Rapid cell building (administration of folic acid or cobalamin [vitamin B_{12}] to patients with megaloblastic anemia, which results in marked production of red blood cells [RBCs])

Factors that cause potassium to move from the ICF to the ECF include acidosis, trauma to cells (as in massive soft tissue damage or in tumour lysis), and exercise. Both digoxin-like drugs and β-adrenergic–blocking drugs (e.g., propranolol [Inderal]) can impair entry of potassium into cells, which results in the higher ECF potassium concentration. Causes of potassium imbalance are summarized in Table 19-5.

TABLE 19-5

POTASSIUM IMBALANCES: CAUSES AND CLINICAL MANIFESTATIONS

Hypokalemia (K^+ Level < 3.5 mmol/L)	Hyperkalemia (K^+ Level > 5.0 mmol/L)
Causes	
Potassium loss • GI losses: diarrhea, vomiting, fistulas, NG suction • Renal losses: diuretics, hyperaldosteronism, magnesium depletion • Skin losses: diaphoresis • Dialysis	Excess potassium intake • Excessive or rapid parenteral administration • Potassium-containing drugs (e.g., potassium-penicillin) • Potassium-containing salt substitute
Shift of potassium into cells • Increased insulin (e.g., IV dextrose load) • Alkalosis • Tissue repair • ↑ Epinephrine (e.g., stress)	Shift of potassium out of cells • Acidosis • Tissue catabolism (e.g., fever, sepsis, burns) • Crush injury • Tumour lysis syndrome
Lack of potassium intake • Starvation • Diet with low potassium content • Failure to include potassium in parenteral fluids if NPO status is in effect	Failure to eliminate potassium • Renal disease • Potassium-sparing diuretics • Adrenal insufficiency • ACE inhibitors
Clinical Manifestations	
Fatigue Muscle weakness Leg cramps Nausea, vomiting, ileus Soft, flabby muscles Paresthesias, decreased reflexes Weak, irregular pulse Polyuria Hyperglycemia	Irritability Anxiety Abdominal cramping, diarrhea Weakness of lower extremities Paresthesias Irregular pulse Cardiac standstill if hyperkalemia is sudden or severe
Electrocardiographic Changes	
ST segment depression Flattened T wave Presence of U wave Ventricular dysrhythmias (e.g., PVCs) Bradycardia Enhanced digitalis effect	Tall, peaked T wave Prolonged P–R interval ST depression Loss of P wave Widening QRS complex Ventricular fibrillation Ventricular standstill

ACE, angiotensin-converting enzyme; *GI,* gastro-intestinal; *IV,* intravenous; *NG,* nasogastric; *NPO,* nothing by mouth; *PVC,* premature ventricular contraction.

Hyperkalemia.

Hyperkalemia (high serum levels of potassium) may be caused by a massive intake of potassium, impaired renal excretion, shift of potassium from the ICF to the ECF, or a combination of these factors. The most common cause of hyperkalemia is renal failure. Hyperkalemia is also common in patients with massive cell destruction (e.g., burn or crush injury, tumour lysis), rapid transfusion of aged blood, and catabolic state (e.g., severe infections). Metabolic acidosis, particularly when the chloride level is normal, is associated with a shift of potassium ions from the ICF to the ECF as hydrogen ions move into the cell. Adrenal insufficiency leads to retention of potassium ions in the serum because of aldosterone deficiency. Certain drugs, such as potassium-sparing diuretics (e.g., spironolactone [Aldactone], triamterene) and angiotensin-converting enzyme (ACE) inhibitors (e.g., enalapril [Vasotec], lisinopril [Prinivil]), may contribute to the development of hyperkalemia. Both of these types of drugs reduce the kidneys' ability to secrete and therefore excrete excess potassium (see Table 19-5).

Clinical Manifestations.

Hyperkalemia causes membrane depolarization, altering cell excitability. Skeletal muscles become weak or paralyzed. The first symptom may be leg cramping. The most clinically significant problems are the disturbances in cardiac conduction. The initial finding is tall, peaked T waves. As potassium increases, cardiac depolarization decreases, leading to loss of P waves, a prolonged PR interval, ST segment depression, and a widening QRS complex (Figure 19-14). Heart block, ventricular fibrillation, or cardiac standstill may occur. Other clinical manifestations are listed in Table 19-5.

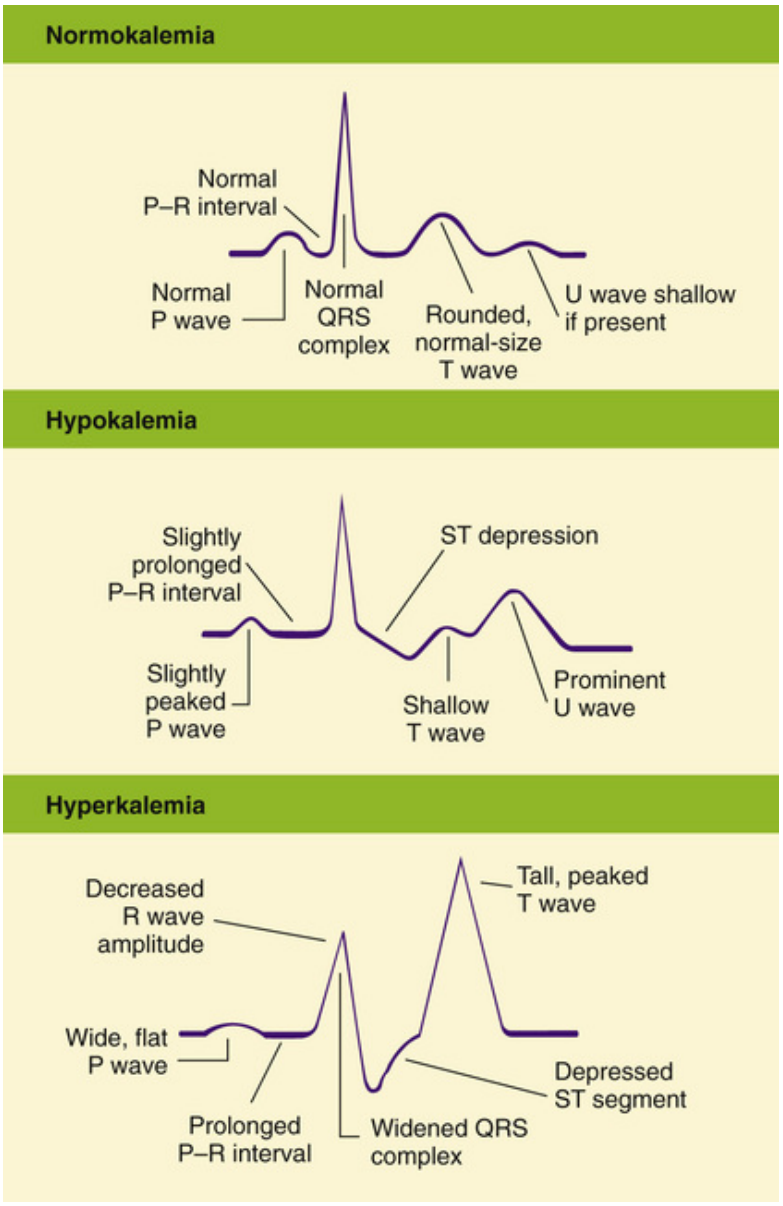

FIGURE 19-14 Electrocardiographic changes associated with alterations in potassium status. Source: Redrawn from McCance, K. L., & Huether, S. E. (2014). *Pathophysiology: The biologic basis for disease in adults and children* (7th ed., p. 117). St. Louis: Mosby.

Nursing and Collaborative Management Hyperkalemia

Nursing Diagnoses

Nursing diagnoses and collaborative problems for patients with hyperkalemia include, but are not limited to, the following:

- *Risk for injury* as evidenced by *alteration in sensation*
- Potential complication: dysrhythmias

Nursing Implementation

Treatment of hyperkalemia consists of the following (see Chapter 49, Table 49-4):

1. Eliminating oral and parenteral potassium intake.
2. Increasing elimination of potassium. This is accomplished through the use of diuretics, dialysis, and use of ion-exchange resins such as sodium polystyrene sulphonate (Kayexalate). Increased fluid intake can enhance renal potassium elimination.
3. Forcing potassium from the ECF to the ICF. This is accomplished by administration of IV insulin (along with glucose so that the patient does not become hypoglycemic) or by administration of IV sodium bicarbonate in the correction of acidosis. In rare cases, a β-adrenergic agonist (e.g., epinephrine) is administered.
4. Reversing the membrane effects of the elevated ECF potassium by administering calcium gluconate intravenously. Calcium ion can immediately reverse the effect of the depolarization on cell excitability.

In cases in which the elevation of potassium level is mild and the kidneys are functioning, it may be sufficient to withhold potassium from the diet and IV sources and increase renal elimination by administering fluids and possibly diuretics. Kayexalate, which is administered via the GI tract, binds potassium in exchange for sodium, and the resin is excreted in feces (see Chapter 49). All patients with clinically significant hyperkalemia

should be monitored electrocardiographically to detect dysrhythmias and to monitor the effects of therapy. Patients with moderate hyperkalemia should additionally receive one of the treatments to force potassium into cells, usually IV insulin and glucose. The patient experiencing dangerous cardiac dysrhythmias should receive IV calcium gluconate immediately; this serves to protect the patient while the potassium is being eliminated and forced into cells. Hemodialysis is an effective means of removing potassium from the body in patients with renal failure.

Hypokalemia.

Hypokalemia (low serum levels of potassium) can result from abnormal losses of potassium caused by a shift of potassium from ECF to ICF or, in rare cases, by deficient dietary potassium intake. The most common causes of hypokalemia are abnormal losses, via either the kidneys or the GI tract. Abnormal losses occur in patients with diuresis, particularly in patients with an elevated aldosterone level. Aldosterone is released when the circulating blood volume is low; it causes sodium retention in the kidneys but loss of potassium in the urine. Magnesium deficiency may contribute to the development of potassium depletion. Low plasma magnesium stimulates renin release and subsequently increases aldosterone levels, which results in potassium excretion. GI tract losses of potassium secondary to diarrhea, laxative abuse, vomiting, and ileostomy drainage can cause hypokalemia.

Metabolic alkalosis can cause a shift of potassium into cells in exchange for hydrogen, thus lowering the potassium level in the ECF and causing symptomatic hypokalemia. Hypokalemia is sometimes associated with the treatment of diabetic ketoacidosis because of a combination of factors, including an increased urinary potassium loss and a shift of potassium into cells with the administration of insulin and correction of acidosis. A less common cause of hypokalemia is the sudden initiation of cell formation; for example, the formation of RBCs as in treatment of anemia with cobalamin, folic acid, or erythropoietin.

Clinical Manifestations.

Hypokalemia alters resting membrane potential. It most commonly is associated with hyperpolarization, or increased negative charge within the cell. This causes excitability problems in many types of tissue. The most serious clinical problems are cardiac. The incidence of potentially lethal ventricular dysrhythmias is increased in hypokalemia. Patients should be monitored with electrocardiography for signs of hypokalemia. These

changes include impaired repolarization, which results in a flattening of the T wave and eventually in emergence of a U wave. The P wave amplitude may increase and may become peaked (see Figure 19-14). Patients taking digoxin experience increased digoxin toxicity if their serum potassium level is low. Skeletal muscle weakness and paralysis may occur with hypokalemia. As with hyperkalemia, symptoms are most often observed in the legs. Respiratory muscles and those innervated by cranial nerves are not involved. Muscle cramping and muscle cell breakdown (known as rhabdomyolysis) can be caused by hypokalemia. This can cause myoglobin to appear in the plasma and the urine, which can, in turn, lead to renal failure.

Smooth muscle function is altered by hypokalemia. Affected patients may experience decreased GI motility (e.g., paralytic ileus), altered airway responsiveness, and impaired regulation of arteriolar blood flow, all of which possibly contribute to muscle cell breakdown. Finally, hypokalemia can impair function in nonmuscle tissue. With prolonged hypokalemia, the kidneys are unable to concentrate urine, and diuresis occurs. Release of insulin is impaired, which often leads to hyperglycemia. Clinical manifestations of hypokalemia are presented in Table 19-5.

Nursing and Collaborative Management Hypokalemia

Nursing Diagnoses

Nursing diagnoses and collaborative problems for patients with hypokalemia include, but are not limited to, the following:

- *Risk for injury* as evidenced by *alteration in psychomotor functioning* (muscle weakness, hyporeflexia)
- Potential complication: dysrhythmias

Nursing Implementation.

Hypokalemia is treated by administration of potassium chloride (KCl) supplements and increasing dietary intake of potassium. KCl supplements can be given orally or intravenously. Except in severe deficiencies, KCl is never given unless the urine output is at least 0.5 mL/kg of body weight per hour. KCl supplements added to IV solutions should never exceed 60 mmol (mEq/L). The preferred level is 40 mmol. IV KCl infusion rates should not exceed 10 mEq per hour unless the patient is in a critical care setting with continuous ECG monitoring and central line access for administration (Medford-Davis & Rafique, 2014). When given intravenously, potassium may cause pain in the area of the vein where it is entering. Because KCl is irritating to the vein, assess IV sites at least hourly for phlebitis and infiltration. Infiltration can cause necrosis and sloughing of the surrounding tissue. The nurse must teach patients ways to prevent hypokalemia (Table 19-6). Patients at risk for hypokalemia should have serum potassium levels monitored regularly.

TABLE 19-6

PATIENT & CAREGIVER TEACHING GUIDE
Prevention of Hypokalemia

1. Teach the patient and caregivers the signs and symptoms of hypokalemia and to report them to the health care provider.
2. For the patient taking potassium-losing diuretics:
    - Explain the importance of increasing dietary potassium intake, especially if the patient is receiving a thiazide or loop diuretic.
    - Teach the patient which foods have high potassium content (see Chapter 49, Table 49-9).
    - Explain that salt substitutes contain approximately 50-60 mEq of potassium per teaspoon and help raise potassium if the patient is taking a potassium-losing diuretic.
3. For the patient taking potassium-sparing diuretics:
    - Explain that salt substitutes and foods with high potassium content should be avoided.
4. For the patient taking oral potassium supplements:
    - Instruct the patient to take the medication as prescribed to prevent overdosage and to take the supplement with a full glass of water to help it dissolve in the GI tract.
5. For the patient taking digitalis preparations and others at risk for hypokalemia:
    - Explain the importance of having serum potassium levels monitored regularly because a low potassium level enhances the action of digitalis.

GI, gastro-intestinal.

Safety Alert

- KCl given intravenously must always be diluted.
- Never give KCl via IV push or in concentrated amounts.
- IV bags containing KCl should be inverted several times to ensure even distribution in the bag.
- Never add KCl to a hanging IV bag, to prevent giving a bolus dose.

Calcium Imbalances

Calcium is obtained from ingested foods. However, only approximately 30% is absorbed in the GI tract. More than 99% of the body's calcium is combined with phosphorus and concentrated in the skeletal system. Bones serve as a readily available store of calcium. Thus to avoid wide variations in serum calcium levels, the movement of calcium into or out of the bone is regulated. Usually, the amounts of calcium and phosphorus found in the serum have an inverse relationship; that is, as one increases, the other decreases (McCance & Huether, 2014). The functions of calcium include transmission of nerve impulses, myocardial contractions, blood clotting, formation of teeth and bone, and muscle contractions.

Calcium is present in the serum in three forms: free or ionized; bound to protein (primarily albumin); and complexed with phosphate, citrate, or carbonate. The ionized form is the biologically active form. Approximately half of the total serum calcium is ionized.

Calcium is typically measured in millimoles per litre (mmol/L). As usually reported, serum calcium levels reflect the total calcium level (all three forms), although ionized calcium levels are sometimes reported separately. The levels listed in Table 19-7 reflect total calcium levels. Changes in serum pH alter the level of ionized calcium without altering the total calcium level. Acidosis decreases calcium binding to albumin, which leads to more ionized calcium, and alkalosis increases calcium binding, which leads to decreased ionized calcium. Alterations in serum albumin levels affect interpretation of total calcium levels. Low albumin levels result in a drop in the total calcium level, although the level of ionized calcium does not change as much.

TABLE 19-7
CALCIUM IMBALANCES: CAUSES AND CLINICAL MANIFESTATIONS

Hypocalcemia (Ca^{2+} Level <2.25 mmol/L)	Hypercalcemia (Ca^{2+} Level >2.75 mmol/L)
Causes	
Decreased total calcium • Chronic renal failure • Elevated phosphorus • Primary hypoparathyroidism • Vitamin D deficiency • Magnesium deficiency • Acute pancreatitis • Loop diuretics • Chronic alcoholism • Diarrhea • ↓ Serum albumin (patient is usually asymptomatic because of normal ionized calcium level)	Increased total calcium • Multiple myeloma • Other malignancy • Prolonged immobilization • Hyperparathyroidism • Vitamin D overdose • Thiazide diuretics • Milk–alkali syndrome
Decreased ionized calcium • Alkalosis • Excess administration of citrated blood	Increased ionized calcium • Acidosis
Clinical Manifestations	
Easy fatigability Depression, anxiety, confusion Numbness and tingling in extremities and region around mouth Hyperreflexia, muscle cramps Chvostek's sign Trousseau's sign Laryngeal spasm Tetany, seizures	Lethargy, weakness Depressed reflexes Decreased memory Confusion, personality changes, psychosis Anorexia, nausea, vomiting Bone pain, fractures Polyuria, dehydration Nephrolithiasis Stupor, coma
Electrocardiographic Changes	
Elongation of ST segment Prolonged Q–T interval Ventricular tachycardia	Shortened ST segment Shortened Q–T interval Ventricular dysrhythmias Increased digitalis effect

Calcium balance is controlled by parathyroid hormone (PTH), calcitonin, and vitamin D (McCance & Huether, 2014). PTH is produced by the parathyroid gland. Its production and release are stimulated when serum calcium levels are low. PTH increases bone resorption (movement of calcium out of bones), increases GI absorption of calcium, and increases renal tubule reabsorption of calcium.

Calcitonin is produced by the thyroid gland, and its production and release are stimulated when serum calcium levels are high. It opposes the action of PTH and thus lowers the serum calcium level by decreasing GI absorption, increasing calcium deposition into bone, and promoting renal excretion.

Vitamin D is formed through the action of ultraviolet rays on a precursor found in the skin or is ingested in the diet. Vitamin D is

important for absorption of calcium from the GI tract. Causes of calcium imbalances are listed in Table 19-7.

Hypercalcemia.

Approximately two-thirds of hypercalcemia cases are caused by hyperparathyroidism, and one-third are caused by malignancy, especially from breast cancer, lung cancer, and multiple myeloma (Wilson, Shannon, & Stang, 2011). Malignancies lead to hypercalcemia through bone destruction from tumour invasion or through tumour secretion of a parathyroid-related protein, which stimulates calcium release from bones. Hypercalcemia is also associated with vitamin D overdose. Prolonged immobilization results in bone mineral loss and increased calcium concentration. Hypercalcemia rarely occurs as a result of increased calcium intake (e.g., ingestion of antacids containing calcium, excessive administration during cardiac arrest).

Excess calcium blocks the effect of sodium in skeletal muscles, which leads to reduced excitability of both muscles and nerves (McCance & Huether, 2014). Manifestations of hypercalcemia include impaired memory, confusion, disorientation, fatigue, muscle weakness, constipation, cardiac dysrhythmias, and renal calculi (see Table 19-7).

Nursing and Collaborative Management Hypercalcemia

Nursing Diagnoses

Nursing diagnoses and collaborative problems for patients with hypercalcemia include, but are not limited to, the following:

- *Risk for injury* as evidenced by *alteration in sensation*
- Potential complication: dysrhythmias

Nursing Implementation

The basic treatment of hypercalcemia is promotion of excretion of calcium in urine by administration of a loop diuretic (e.g., furosemide [Lasix], ethacrynic acid [Edecrin]) and hydration of the patient with isotonic saline infusions. IV saline therapy necessitates careful monitoring. Fluid overload can occur in patients who cannot excrete the excess sodium because of impaired renal function.

Synthetic calcitonin can also be administered to lower serum calcium levels. A diet with low calcium content may be prescribed. Mobilization with weight-bearing activity is encouraged so as to enhance bone mineralization. In hypercalcemia associated with malignancy, the drug of choice is pamidronate (Aredia), which inhibits the activity of osteoclasts. Pamidronate is preferred because it does not have cytotoxic adverse effects and it inhibits bone resorption without inhibiting bone formation and mineralization.

Hypocalcemia.

Any condition that causes a decrease in the production of PTH may result in the development of hypocalcemia. This may occur with surgical removal of a portion of or injury to the parathyroid glands during thyroid or neck surgery. Acute pancreatitis is another potential cause of hypocalcemia. Lipolysis, a consequence of pancreatitis, produces fatty acids that combine with calcium ions, which leads to a decrease in serum calcium levels. A patient who receives multiple blood transfusions can become hypocalcemic because the citrate used to anticoagulate the blood

binds with the calcium. Sudden alkalosis may also result in symptomatic hypocalcemia despite a normal total serum calcium level. The high pH increases calcium binding to protein, decreasing the amount of ionized calcium. Hypocalcemia can occur if the diet has low calcium content or if loss of calcium is increased as a result of laxative abuse and malabsorption syndromes. (See Table 19-7 for the clinical manifestations and etiologies of hypocalcemia.)

Low calcium levels allow sodium to move into excitable cells, which increases depolarization. This results in increased nerve excitability and sustained muscle contraction that is referred to as **tetany.** Clinical signs of tetany include Trousseau's and Chvostek's signs. *Trousseau's sign* refers to carpal spasms induced by inflating a blood pressure cuff on the arm (Figure 19-15). The blood pressure cuff is inflated above the systolic pressure. Carpal spasms become evident within 3 minutes if hypocalcemia is present. *Chvostek's sign* is contraction of facial muscles in response to a tap over the facial nerve in front of the ear (see Figure 19-15). Other manifestations of tetany are laryngeal stridor, dysphagia, and numbness and tingling around the mouth or in the extremities.

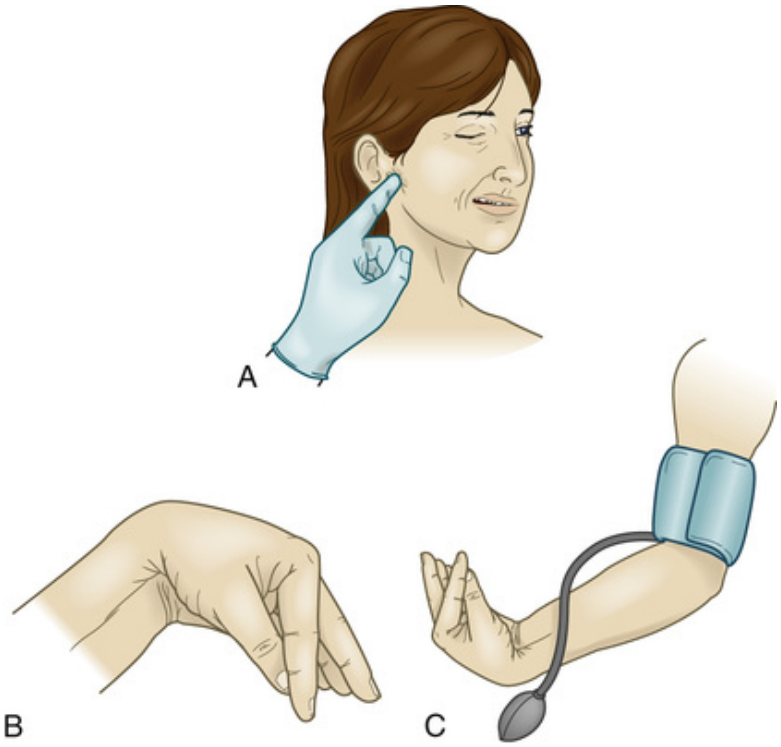

FIGURE 19-15 Tests for hypocalcemia. **A,** Chvostek's sign is contraction of facial muscles in response to a light tap over the facial nerve in front of the ear. **B,** Trousseau's sign is a carpal spasm induced by **C,** inflating a blood pressure cuff above the systolic pressure for a few minutes.

Because calcium is necessary for cardiac contractions, hypocalcemia results in decreased cardiac contractility and ECG changes. Clinical manifestations of hypocalcemia are listed in Table 19-7.

Nursing and Collaborative Management Hypocalcemia

Nursing Diagnoses

Nursing diagnoses and collaborative problems for patients with hypocalcemia include, but are not limited to, the following:

- *Risk for injury* as evidenced by *alteration in cognitive functioning* (tetany and seizures)
- Potential complications: fracture, respiratory arrest

Nursing Implementation

Treatment of hypocalcemia is aimed primarily at correcting the cause. Treating mild or asymptomatic hypocalcemia involves a diet of calcium-rich foods and calcium and vitamin D supplementation. IV preparations of calcium, such as calcium gluconate, are administered when severe symptoms of hypocalcemia are impending or present. Oral calcium supplements, such as calcium carbonate, may be used when patients are unable to consume enough calcium in the diet, such as those who do not tolerate dairy products. Pain and anxiety must be adequately treated in patients with suspected hypocalcemia because hyperventilation-induced respiratory alkalosis can precipitate hypocalcemic symptoms. Any patient who undergoes thyroid or neck surgery must be observed closely in the immediate postoperative period for manifestations of hypocalcemia because of the proximity of the surgery to the parathyroid glands.

Phosphate Imbalances

Phosphorus is a primary anion in the ICF and is essential to the function of muscle, RBCs, and the nervous system. It is deposited with calcium for bone and tooth structure. It is also involved in the acid–base buffering system, in the mitochondrial energy production of ATP, in cellular uptake and use of glucose, and as an intermediary in the metabolism of carbohydrates, proteins, and fats.

For maintenance of normal phosphate balance, renal functioning must be adequate because the kidneys are the major route of phosphate excretion. A small amount is lost in the feces. A reciprocal relationship exists between phosphorus and calcium in that a high serum phosphate level tends to cause a low calcium concentration in the serum.

Hyperphosphatemia.

The major condition that can lead to hyperphosphatemia is acute or chronic renal failure that results in an altered ability of the kidneys to excrete phosphate. Other causes include chemotherapy for certain malignancies (lymphomas), excessive ingestion of milk or phosphate-containing laxatives, and large intakes of vitamin D that increase GI absorption of phosphorus (Table 19-8).

TABLE 19-8

PHOSPHATE IMBALANCES: CAUSES AND CLINICAL MANIFESTATIONS

Hypophosphatemia (PO_4^{3-} Level <0.97 mmol/L)	Hyperphosphatemia (PO_4^{3-} Level >1.45 mmol/L)
Causes	
Malabsorption syndrome Nutritional recovery syndrome Glucose administration Total parenteral nutrition Alcohol withdrawal Phosphate-binding antacids Recovery from diabetic ketoacidosis Respiratory alkalosis	Renal failure Chemotherapeutic agents Enemas containing phosphorus (e.g., Fleet enema) Excessive ingestion (e.g., milk, phosphate-containing laxatives) Large vitamin D intake Hypoparathyroidism
Clinical Manifestations	
Central nervous system dysfunction (confusion, coma) Rhabdomyolysis Renal tubular wasting of Mg^{2+}, Ca^{2+}, HCO_3^- Cardiac problems (dysrhythmias, decreased stroke volume) Muscle weakness, including respiratory muscle weakness Osteomalacia	Hypocalcemia Muscle problems; tetany Deposition of calcium–phosphate precipitates in skin, soft tissue, corneas, viscera, blood vessels

Clinical manifestations of hyperphosphatemia (presented in Table 19-8) relate primarily to metastatic calcium–phosphate precipitates. Ordinarily, calcium and phosphate are deposited only in bone. However, an increased serum phosphate concentration along with calcium precipitates readily, and calcified deposits can develop in soft tissue such as those of the joints, arteries, skin, kidneys, and corneas (see Chapter 49). Other manifestations

of hyperphosphatemia are neuro-muscular irritability and tetany, which are related to the low serum calcium levels often associated with high serum phosphate levels.

Management of hyperphosphatemia is aimed at identifying and treating the underlying cause. Ingestion of foods and fluids with high phosphorus content (e.g., dairy products) should be restricted. Adequate hydration and correction of hypocalcemic conditions can enhance the renal excretion of phosphate. For patients with renal failure, measures to reduce serum phosphate levels include calcium supplements, phosphate-binding agents or gels, and dietary phosphate restrictions (see Chapter 49).

Hypophosphatemia.

Hypophosphatemia (low serum phosphate) is seen in patients who are malnourished or have malabsorption syndromes. Other causes include alcohol withdrawal and use of phosphate-binding antacids. Hypophosphatemia may also occur during parenteral nutrition with inadequate phosphorus replacement. Table 19-8 lists causes of phosphorus imbalances.

Most of the clinical manifestations of hypophosphatemia (presented in Table 19-8) are related to a deficiency of ATP or 2,3-diphosphoglycerate (2,3-DPG), an enzyme in RBCs. Both conditions result in impaired cellular energy resources and oxygen delivery to tissues. Hemolytic anemia may occur because of the fragility of the RBCs. Acute manifestations include CNS depression, confusion, and other mental changes. Other manifestations include muscle weakness and pain, dysrhythmias, and cardiomyopathy.

Management of a mild phosphorus deficiency may involve oral supplementation and ingestion of foods with high phosphorus content (e.g., dairy products). Severe hypophosphatemia can be serious and may necessitate IV administration of sodium phosphate or potassium phosphate. Frequent monitoring of serum phosphate levels is necessary to guide IV therapy. Sudden symptomatic hypocalcemia, secondary to increased calcium phosphorus binding, is a potential complication of IV administration of phosphorus.

Magnesium Imbalances

Magnesium, the second most abundant intracellular cation, plays an important role in essential cellular processes. It is a cofactor in many enzyme systems, including those responsible for carbohydrate

metabolism, DNA and protein synthesis, blood glucose control, and blood pressure regulation. Magnesium is required for the production and use of adenosine triphosphate (ATP), the energy source for the sodium–potassium pump. Muscle contraction and relaxation, normal neurological function, and neurotransmitter release depend on magnesium.

Approximately 50% to 60% of the body's magnesium is contained in bone. Magnesium concentration is regulated by GI absorption and renal excretion. The kidneys are able to conserve magnesium in times of need and to excrete excesses. Factors that regulate calcium balance (e.g., PTH) appear to influence magnesium balance. Manifestations of magnesium balance are often mistaken for those of calcium imbalances. Because magnesium balance is related to calcium and potassium balance, all three cations should be assessed together. Causes of magnesium imbalances are listed in Table 19-9.

TABLE 19-9

CAUSES OF MAGNESIUM IMBALANCES

Hypomagnesemia (Mg^{2+} Level <0.74 mmol/L)	Hypermagnesemia (Mg^{2+} Level >1.07 mmol/L)
Diarrhea Vomiting Chronic alcoholism Impaired GI absorption Malabsorption syndrome Prolonged malnutrition Large urine output NG suction Poorly controlled diabetes mellitus Hyperaldosteronism	Renal failure (especially if patient is given magnesium products) Excessive administration of magnesium for treatment of eclampsia Adrenal insufficiency

GI, gastro-intestinal; *NG*, nasogastric.

Hypermagnesemia.

Hypermagnesemia usually occurs only with an increase in magnesium intake accompanied by renal insufficiency or failure. In patients with chronic renal failure, ingesting products containing magnesium (e.g., Maalox, milk of magnesia) will cause excess magnesium. Magnesium excess could develop in pregnant women who receive magnesium sulphate ($MgSO_4$) for the management of eclampsia.

Excess magnesium inhibits acetylcholine release at the myoneural junction and calcium movement into cells, impairing nerve and muscle function. Initial manifestations include hypotension, facial flushing, lethargy, urinary retention, nausea, and vomiting. As the serum

magnesium level increases, deep tendon reflexes are lost, followed by muscle paralysis and coma. Respiratory and cardiac arrest can occur.

Management begins with avoiding magnesium-containing drugs and limiting diet intake of magnesium-containing foods (e.g., green vegetables, nuts, bananas, oranges, peanut butter, chocolate). If renal function is adequate, increased fluids and diuretics promote urinary excretion. In patients with impaired renal function, dialysis is required. If hypermagnesemia is symptomatic, calcium gluconate administered by IV infusion opposes the effects of the excess magnesium on cardiac muscle.

Hypomagnesemia.

Magnesium deficiency occurs in patients with limited magnesium intake or increased gastro-intestinal or renal losses. Causes of hypomagnesemia from insufficient food intake include prolonged fasting or starvation and chronic alcoholism (Table 19-9). Another potential cause is prolonged parenteral nutrition without magnesium supplementation. Fluid loss from the GI tract, inflammatory bowel disease, and proton pump inhibitors interfere with magnesium absorption. Many diuretics and osmotic diuresis from high glucose levels may cause magnesium loss through increased urinary excretion (Demssie, Patel, Kumar, et al., 2014).

Clinically, hypomagnesemia resembles hypocalcemia and may contribute to the development of hypocalcemia as a result of the decreased action of PTH. Neuro-muscular manifestations are common, such as muscle cramps, tremors, hyperactive deep tendon reflexes, Chvostek's sign, and Trousseau's sign. Neurological manifestations include confusion, vertigo, and seizures.

Magnesium deficiency can lead to cardiac dysrhythmias, such as torsades de pointes and ventricular fibrillation. Hypomagnesemia is associated with digitalis toxicity. Hypomagnesemia may also be associated with hypokalemia that does not respond well to potassium replacement. This occurs because intracellular magnesium is crucial for normal function of the sodium–potassium pump.

Mild magnesium deficiencies can be treated with oral supplements and increased dietary intake of foods with high magnesium content (e.g., green vegetables, nuts, bananas, oranges, peanut butter, chocolate). If the condition is severe, parenteral IV or intra-muscular magnesium (e.g., $MgSO_4$) should be administered. The nurse should monitor vital signs and use an infusion pump because rapid administration can lead to hypotension and cardiac or respiratory arrest.

Protein Imbalances

Plasma proteins, particularly albumin, are a significant determinant of plasma volume. Because of their large molecular size, they remain in the vascular space and contribute to the colloidal oncotic pressure. Causes of protein imbalances are listed in Table 19-10. Hypoproteinemia can occur over time. Causes related to intake are anorexia, malnutrition, starvation, fad dieting, and poorly balanced vegetarian diets. Poor absorption of protein can occur in certain GI malabsorptive diseases, such as pancreatic insufficiency and inflammatory bowel disease. Protein can shift out of the intravascular space with inflammation. Increased breakdown of proteins occurs with elevated basal metabolic rates and catabolic states, such as fever, infection, and certain malignancies. Use of protein increases with cell growth and repair after surgical wounds or burns. Hemorrhage with loss of RBCs can be a cause of protein deficit. Impaired synthesis of albumin occurs in liver failure. The kidneys can lose large amounts of protein, especially albumin, in nephrotic syndrome (see Chapter 48).

TABLE 19-10

CAUSES OF PROTEIN IMBALANCES

Hypoproteinemia (Protein Level <64 g/L)	Hyperproteinemia (Protein Level >83 g/L)
Decreased food intake Starvation Diseased liver Massive burns Loss of albumin in renal disease Major infection	Dehydration Hemoconcentration

Clinical manifestations of protein deficit include edema (caused by decreased oncotic pressure), slow healing, anorexia, fatigue, anemia, and muscle loss that results from the breakdown of body tissue to meet the body's need for protein. Intravascular fluid readily accumulates in the peritoneal cavity, which leads to ascites, when the vascular oncotic pressure is decreased in hypoproteinemia.

Management of protein deficit includes providing a high-carbohydrate, high-protein diet and dietary protein supplements. If the patient cannot meet the needs for protein orally, enteral nutrition or total parenteral nutrition may be used. (Protein-calorie malnutrition is discussed in Chapter 42.)

Hyperproteinemia is rare, but it can occur with dehydration-induced hemoconcentration.

Acid–Base Imbalances

The body normally maintains a steady balance between acids produced during metabolism and bases that neutralize and promote the excretion of the acids. Many health problems may lead to acid–base imbalances in addition to fluid and electrolyte imbalances. Patients with diabetes mellitus, chronic obstructive pulmonary disease, and kidney disease frequently develop acid–base imbalances. Vomiting and diarrhea may cause loss of acids and bases in addition to loss of fluids and electrolytes. The kidneys are an essential buffer system for acids, and in older adults, the kidneys are less able to compensate for an acid load. Older adults also have decreased respiratory function, which impairs compensation for acid–base imbalances. In addition, tissue hypoxia from any cause may alter acid–base balance. The nurse must always consider the possibility of acid–base imbalance in patients with serious illnesses.

pH and Hydrogen Ion Concentration.

The acidity or alkalinity of a solution depends on its hydrogen ion (H^+) concentration. An increase in H^+ concentration leads to acidity; a decrease leads to alkalinity. (Definitions related to acid–base balance are presented in Table 19-11.)

TABLE 19-11

TERMS IN ACID–BASE PHYSIOLOGY

Acid	Donor of hydrogen ion (H^+); separation of an acid into H^+ and its accompanying anion in solution
Acidemia	Signifying an arterial blood pH of <7.35
Acidosis	Process that adds acid or eliminates base from body fluids
Alkalemia	Signifying an arterial blood pH of >7.45
Alkalosis	Process that adds base or eliminates acid from body fluids
Anion gap	Calculation approximating normally unmeasured anions in the plasma; helpful in differential diagnosis of acidosis
Base	Acceptor of hydrogen ions; chemical combining of acid and base when hydrogen ions are added to a solution containing a base; bicarbonate (HCO_3^-) is most abundant base in body fluids
Buffer	Substance that reacts with an acid or base to prevent a large change in pH
pH	Negative logarithm of the H^+ concentration

Although acids are produced by the body daily, the H^+ concentration of body fluids is small (0.0004 mEq/L). This tiny amount is maintained within a narrow range to ensure optimal cellular function. H^+ concentration is usually expressed as a negative logarithm (symbolized as **pH**) rather than in milliequivalents. The use of the negative logarithm reveals an inverse relationship: the higher the pH, the lower the H^+ concentration. In contrast to a pH of 7, a pH of 8 represents a ten-fold decrease in H^+ concentration.

The pH of a chemical solution may range from 1 to 14. A solution with a pH of 7 is considered neutral. Acidic solutions have a pH less than 7, whereas alkaline solutions have a pH greater than 7. Blood is slightly alkaline (pH of 7.35-7.45). Medically, if a patient's blood pH drops below 7.35, the patient has **acidosis,** even though the blood may never become truly acidic. If the blood pH is greater than 7.45, the patient has **alkalosis** (Figure 19-16).

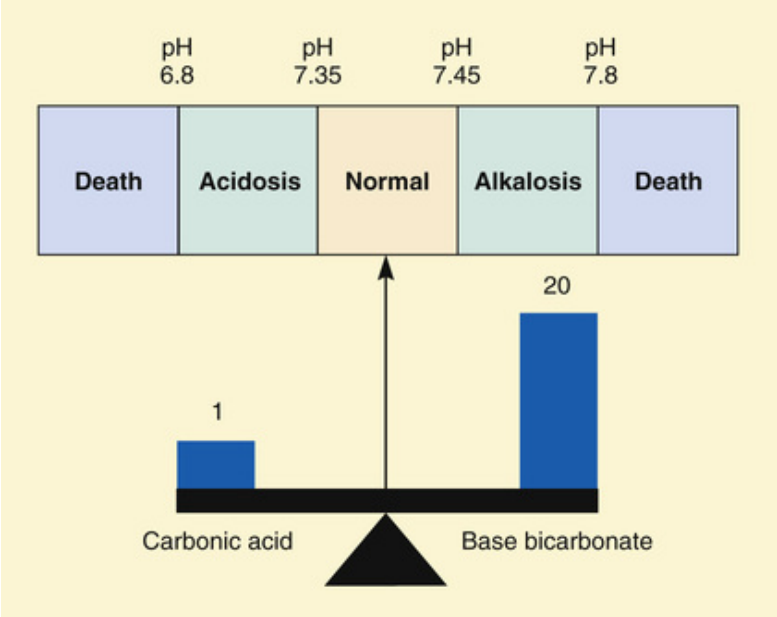

FIGURE 19-16 The normal range of plasma pH is 7.35 to 7.45. A normal pH is maintained by a ratio of 1 part carbonic acid to 20 parts bicarbonate.

Acid–Base Regulation.

The body's metabolic processes constantly produce acids. These acids must be neutralized and excreted to maintain acid–base balance. Normally, the body has three mechanisms by which it regulates acid–base balance to maintain the arterial pH between 7.35 and 7.45: the buffer systems, the respiratory system, and the renal system.

The regulatory mechanisms react at different speeds. Buffers react immediately; the respiratory system responds in minutes and reaches maximum effectiveness in hours; and the renal response takes 2 to 3 days to respond maximally, but the kidneys can maintain balance indefinitely in patients with chronic imbalances.

Buffer System.

The buffer system is the fastest-acting system and the primary regulator of acid–base balance. **Buffers** act chemically to change strong acids into weaker acids or to bind acids to neutralize their effect. All body fluids contain buffers. The major buffer system in ECF is carbonic acid–bicarbonate. Other buffers include phosphate, protein, and hemoglobin. The cell can act as a buffer by the shifting of H^+ in and out of the cell. When ECF levels of H^+ are increased, H^+ enters the cell in exchange for potassium. This may result in hyperkalemia. Conversely, with decreased H^+ levels, H^+ enters plasma in exchange for potassium. This is why alkalosis can cause hypokalemia.

A buffer consists of a weakly ionized acid or a base and its salt. Buffers function to minimize the effect of acids on blood pH until they can be excreted from the body. The carbonic acid (H_2CO_3)–bicarbonate (HCO_3^-) buffer system neutralizes hydrochloric acid (HCl) in the following manner:

$$\underset{\text{(strong acid)}}{HCl} + \underset{\text{(weak base)}}{NaHCO_3} \rightarrow \underset{\text{(salt)}}{NaCl} + \underset{\text{(weak acid)}}{H_2CO_3}$$

In this way, combining a strong acid with a base prevents the acid from causing a large decrease in pH. The carbonic acid is broken down to H_2O and CO_2. The lungs excrete CO_2, either combined with insensible H_2O as carbonic acid or alone as CO_2.

The phosphate, protein, and hemoglobin buffer systems act in the same way as the bicarbonate system. The main components of the phosphate system are monohydrogen phosphate (HPO_4^{2-}) and dihydrogen phosphate ($H_2PO_4^-$). A phosphate, combined with sodium, can neutralize a strong acid such as HCl by forming NaCl and sodium biphosphate (NaH_2PO_4), a weak acid. If a strong base, such as sodium hydroxide (NaOH), is present, sodium biphosphate (NaH_2PO_4) neutralizes it to a weaker base (Na_2HPO_4) and H_2O.

Intracellular and extracellular proteins constitute an effective buffering system throughout the body. The protein buffering system acts like the bicarbonate system. Some of the amino acids of proteins contain free acid radicals such as —COOH, which can dissociate into CO_2 and H^+. Other amino acids have basic radicals such as $—NH_3OH$, which can dissociate into NH^{3+} and OH^-; the OH^- can combine with an H^+ to form H_2O.

Using the "chloride shift" mechanism, hemoglobin regulates pH by shifting chloride in and out of RBCs in exchange for bicarbonate. This shift is regulated according to the level of oxygen in blood.

The cell can also act as a buffer by shifting hydrogen in and out of the cell. With an accumulation of H^+ in the ECF, the intracellular compartment can accept hydrogen in exchange for another cation (e.g., Na^+).

The body buffers an acid load better than it neutralizes base excess. Buffers cannot maintain pH without the adequate functioning of the respiratory and renal systems.

Respiratory System.

The lungs help maintain a normal pH by excreting CO_2 and water, which are by-products of cellular metabolism. When released into circulation, CO_2 enters RBCs and combines with H_2O to form H_2CO_3. The carbonic acid dissociates into hydrogen ions and bicarbonate. The free hydrogen is buffered by hemoglobin molecules, and the bicarbonate diffuses into the plasma. In the pulmonary capillaries, this process is reversed, and CO_2 is formed and excreted by the lungs. The overall reversible reaction is expressed as the following:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$

The amount of CO_2 in the blood directly relates to carbonic acid concentration and subsequently to H^+ concentration. With increased respirations, less CO_2 remains in the blood. This leads to less carbonic acid and fewer H^+ molecules. With decreased respirations, more CO_2 remains in the blood. This leads to increased amounts of carbonic acid and more H^+.

The rate of excretion of CO_2 is controlled by the respiratory centre in the medulla in the brainstem. If increased amounts of CO_2 or H^+ are present, the respiratory centre stimulates an increased rate and depth of breathing. Respirations are inhibited if the centre senses low H^+ or CO_2 levels.

As a compensatory mechanism, the respiratory system acts on the CO_2 + H_2O side of the reaction by altering the rate and depth of breathing to "blow off" (through hyperventilation) or "retain" (through hypoventilation) CO_2. If a respiratory problem is the cause of an acid–base

imbalance (e.g., respiratory failure), the respiratory system cannot play its usual role to correct a pH alteration.

Renal System.

Under normal conditions, the kidneys reabsorb and conserve all of the bicarbonate they filter. The kidneys can generate additional bicarbonate and eliminate excess H^+ as compensation for acidosis. The three mechanisms of acid elimination include (1) secretion of small amounts of free hydrogen into the renal tubule, (2) combination of H^+ with ammonia (NH_3) to form ammonium (NH_4^-), and (3) excretion of weak acids.

The body depends on the kidneys to excrete a portion of the acid produced by cellular metabolism. Thus the kidneys normally excrete an acidic urine (average pH is 6). As a compensatory mechanism, the pH of the urine can decrease to 4 and increase to 8. If the renal system is the cause of an acid–base imbalance (e.g., renal failure), it loses its ability to correct a pH alteration.

Alterations in Acid–Base Balance.

An acid–base imbalance is produced when the ratio of 1 : 20 between acid and base content is altered (Table 19-12; see also Figure 19-16). A primary disease or process may alter one side of the ratio (e.g., CO_2 retention in pulmonary disease). The compensatory process is an attempt to maintain the other side of the ratio (e.g., increased renal bicarbonate reabsorption). When the compensatory mechanism fails, an acid–base imbalance results. The compensatory process may be inadequate because either the pathophysiological process is overwhelming or there is insufficient time for the compensatory process to function.

TABLE 19-12
ACID–BASE IMBALANCES

Common Causes	Pathophysiology	Laboratory Findings
Respiratory Acidosis		
Chronic obstructive pulmonary disease Barbiturate or sedative overdose Chest wall abnormality (e.g., obesity) Severe pneumonia Atelectasis Respiratory muscle weakness (e.g., Guillain-Barré syndrome) Mechanical hypoventilation	CO_2 retention by lungs from hypoventilation Compensatory response to HCO_3^- retention by kidneys	↓ Plasma pH ↑ $PaCO_2$ HCO_3^- normal (uncompensated) ↑ HCO_3^- (compensated) Urine pH <6 (compensated)
Respiratory Alkalosis		
Hyperventilation (caused by hypoxia, pulmonary emboli, anxiety, fear, pain, exercise, fever) Stimulated respiratory centre caused by septicemia, encephalitis, brain injury, salicylate poisoning Mechanical hyperventilation	Increased CO_2 excretion by lungs from hyperventilation Compensatory response of HCO_3^- excretion by kidneys	↑Plasma pH ↓ $PaCO_2$ HCO_3^- normal (uncompensated) ↓ HCO_3^- (compensated) Urine pH > 6 (compensated)
Metabolic Acidosis		
Diabetic ketoacidosis Lactic acidosis Starvation Severe diarrhea Renal tubular acidosis Renal failure Gastro-intestinal fistulas Shock	Gain of fixed acid, inability to excrete acid or loss of base Compensatory response of CO_2 excretion by lungs	↓ Plasma pH $PaCO_2$ normal (uncompensated) ↓ PCO_2 (compensated) ↓ HCO_3^- Urine pH <6 (compensated)
Metabolic Alkalosis		
Severe vomiting Excess gastric suctioning Diuretic therapy* Potassium deficit Excess $NaHCO_3$ intake Excessive mineralocorticoids	Loss of strong acid or gain of base Compensatory response of CO_2 retention by lungs	↑ Plasma pH $PaCO_2$ normal (uncompensated) ↑ PCO_2 (compensated) ↑ HCO_3^- Urine pH >6 (compensated)

*Commonly used diuretics such as thiazides and furosemide are known to produce mild alkalosis by affecting tubular excretion of electrolytes and bicarbonate.

HCO_3^-, bicarbonate; *$NaHCO_3$*, sodium bicarbonate; *$PaCO_2$*, arterial partial pressure of CO_2; *PCO_2*, partial pressure of CO_2.

Acid–base imbalances are classified as respiratory or metabolic. *Respiratory imbalances* affect carbonic acid concentrations; *metabolic imbalances* affect the base bicarbonate. Therefore, acidosis can be caused by an increase in carbonic acid (respiratory acidosis) or a decrease in

bicarbonate (metabolic acidosis). Alkalosis can be caused by a decrease in carbonic acid (respiratory alkalosis) or an increase in bicarbonate (metabolic alkalosis). Imbalances may be further classified as acute or chronic. Chronic imbalances allow greater time for compensatory changes.

Respiratory Acidosis.

Respiratory acidosis (carbonic acid excess) occurs with hypoventilation (see Table 19-12). Hypoventilation results in a buildup of CO_2; subsequently, carbonic acid accumulates in the blood. Carbonic acid dissociates, causing liberation of H^-, and the pH decreases. If CO_2 is not eliminated from the blood, acidosis results from the accumulation of carbonic acid (Figure 19-17, *A*).

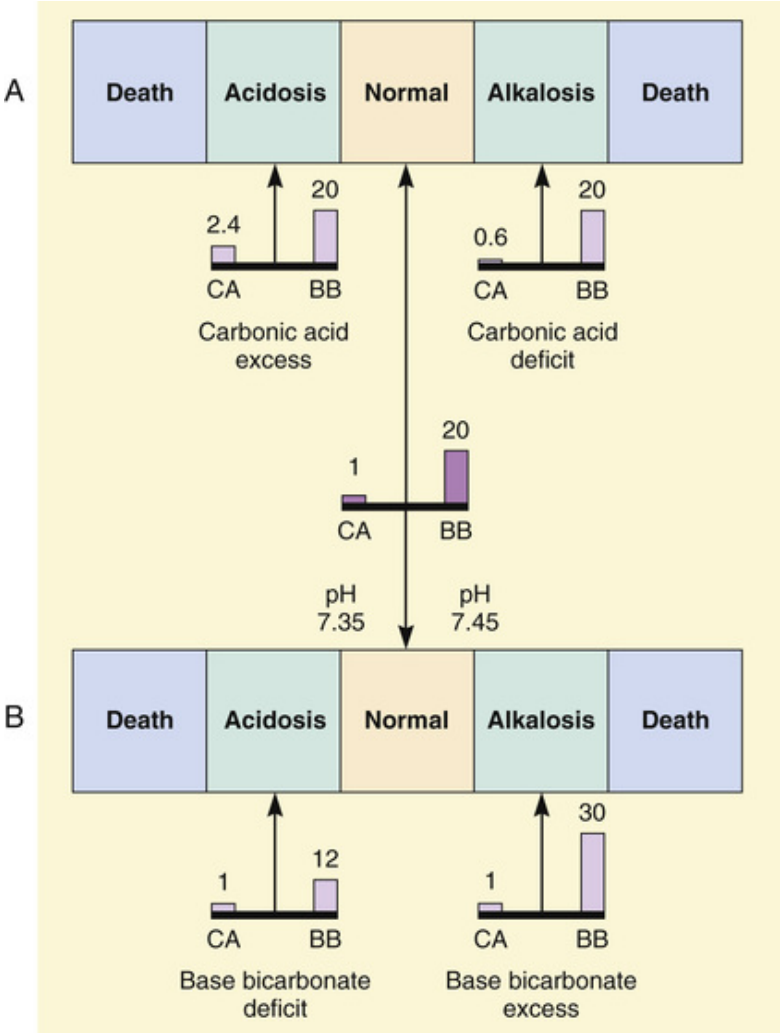

FIGURE 19-17 Kinds of acid–base imbalances. **A,** Respiratory imbalances caused by carbonic acid (CA) excess and CA deficit. *BB,* base bicarbonate. **B,** Metabolic imbalances caused by BB deficit and BB excess.

To compensate, the kidneys conserve bicarbonate and secrete increased concentrations of H^+ into the urine. In acute respiratory acidosis, the renal compensatory mechanisms begin to operate within 24 hours. Therefore, even in anticipation of the kidneys' compensating for the imbalance, the serum bicarbonate level is usually normal.

Respiratory Alkalosis.

Respiratory alkalosis (carbonic acid deficit) occurs with hyperventilation (see Table 19-12). The primary cause of respiratory alkalosis is hypoxemia from acute pulmonary disorders (e.g., pneumonia, pulmonary embolus). Hyperventilation can occur as a physiological response to metabolic

acidosis and increased metabolic demands (e.g., in a state of fever). Pain, anxiety, and some CNS disorders can cause an increase in respirations without a physiological need. The decrease in the arterial CO_2 level leads to a decrease in carbonic acid concentration in the blood and an increase in pH (see Figure 19-17, *A*).

Compensated respiratory alkalosis is uncommon unless the patient has been maintained on a ventilator or has a CNS problem. A decreased bicarbonate level differentiates compensated respiratory alkalosis from acute or uncompensated respiratory alkalosis.

Metabolic Acidosis.

Metabolic acidosis (base bicarbonate deficit) occurs when an acid other than carbonic acid accumulates in the body or when bicarbonate is lost from body fluids (see Table 19-12 and Figure 19-17, *B*). In both cases, a bicarbonate deficit results. Ketoacid accumulation in diabetic ketoacidosis and lactic acid accumulation with shock are examples of accumulation of acids. Severe diarrhea results in loss of bicarbonate. In renal disease, the kidneys lose their abilities to reabsorb bicarbonate and secrete H^+.

The compensatory response to metabolic acidosis is to increase CO_2 excretion by the lungs. Many affected patients develop Kussmaul's respiration (deep, rapid breathing). In addition, the kidneys attempt to excrete additional acid.

If metabolic acidosis is present, calculating the *anion gap* helps determine the source of the acidosis. The anion gap is the difference between the measured serum cations and anions in ECF. The anion gap is calculated according to the following formula:

$$\text{Anion gap (in mmol/L)} = Na^+ - (HCO_3^- + Cl^-)$$

A normal anion gap is 8 to 16 mmol/L. The anion gap increases in metabolic acidosis associated with acid gain (e.g., lactic acidosis, diabetic ketoacidosis) but is normal in metabolic acidosis caused by bicarbonate loss (e.g., diarrhea).

Metabolic Alkalosis.

Metabolic alkalosis (base bicarbonate excess) occurs when acid is lost (as a result of prolonged vomiting or gastric suction) or when bicarbonate increases (from ingestion of baking soda) occurs (see Table 19-12 and Figure 19-17, *B*). The compensatory mechanism is a decreased respiratory

rate to increase plasma CO_2. However, once hypoxemia occurs or plasma CO_2 reaches a certain level, stimulation of chemoreceptors increases respirations. Renal excretion of bicarbonate also occurs.

Mixed Acid–Base Disorders.

A mixed acid–base disorder occurs when two or more acid–base disturbances are present at the same time. The pH will depend on type, severity, and acuity of each of the simple disorders involved. Respiratory acidosis combined with metabolic alkalosis (e.g., chronic obstructive pulmonary disease treated with diuretic therapy) may result in a near-normal pH, whereas respiratory acidosis combined with metabolic acidosis causes a greater decrease in pH than either disorder alone. An example of a mixed acidosis appears in a patient in cardiopulmonary arrest. Hypoventilation elevates the CO_2 level, and anaerobic metabolism produces lactic acid. An example of a mixed alkalosis is the case of a patient who is hyperventilating because of postoperative pain and is also losing acid as a result of nasogastric suctioning.

Clinical Manifestations.

Clinical manifestations of acidosis and alkalosis are summarized in Tables 19-13 and 19-14. Because a normal pH is vital for all cellular reactions, the clinical manifestations of acid–base imbalances are generalized and nonspecific. The actual compensatory mechanisms also produce some clinical manifestations. For example, the deep, rapid respirations of a patient with metabolic acidosis are an example of respiratory compensation. In alkalosis, hypocalcemia may concurrently be present and accounts for many of the clinical manifestations.

TABLE 19-13
CLINICAL MANIFESTATIONS OF ACIDOSIS

Respiratory (↑ PCO_2)	Metabolic (↓ HCO_3^-)
Neurological	
Drowsiness Disorientation Dizziness Headache Coma	Drowsiness Confusion Headache Coma
Cardiovascular	
↓ Blood pressure Ventricular fibrillation (related to hyperkalemia from compensation) Warm, flushed skin (related to peripheral vasodilation)	↓ Blood pressure Dysrhythmias (related to hyperkalemia from compensation) Warm, flushed skin (related to peripheral vasodilation)
Gastro-intestinal	
No significant findings	Nausea, vomiting, diarrhea, abdominal pain
Neuro-muscular	
Seizures	No significant findings
Respiratory	
Hypoventilation with hypoxia (lungs are unable to compensate when there is a respiratory problem)	Deep, rapid respirations (compensatory action by the lungs)

HCO_3^-, bicarbonate; PCO_2, partial pressure of CO_2.

TABLE 19-14
CLINICAL MANIFESTATIONS OF ALKALOSIS

Respiratory (↓ PCO_2)	Metabolic (↑ HCO_3^-)
Neurological	
Lethargy Light-headedness Confusion	Dizziness Irritability Nervousness Confusion
Cardiovascular	
Tachycardia Dysrhythmias (related to hypokalemia from compensation)	Tachycardia Dysrhythmias (related to hypokalemia from compensation)
Gastro-intestinal	
Nausea Vomiting Epigastric pain	Anorexia Nausea Vomiting
Neuro-muscular*	
Tetany Numbness Tingling of extremities Hyperreflexia Seizures	Tremors Hypertonic muscles Muscle cramps Tetany Tingling of fingers and toes
Respiratory	
Hyperventilation (lungs are unable to compensate when there is a respiratory problem)	Hypoventilation (compensatory action by the lungs)

*Alkalosis decreases calcium binding to protein.

HCO_3^-, bicarbonate; *PCO_2*, partial pressure of CO_2.

Blood Gas Values

Arterial blood gas (ABG) values provide valuable information about a patient's acid–base status, the origin of the imbalance, an idea of the body's ability to regulate pH, and a reflection of the patient's overall oxygen status. Acid–base disturbances are diagnosed and compensatory processes identified in the following six steps:

1. Determining whether the pH is acidotic or alkalotic. A value of 7.4 is the starting point. Values less than 7.4 characterize the pH as acidotic and values greater than 7.4 characterize the pH as alkalotic. If the pH is between 7.35 and 7.45, and the CO^2, HCO_3^-, and arterial partial pressure of oxygen (PaO_2) are within normal limits, the ABG values are normal. If any value is abnormal, then step 2 follows.

2. Analyzing the arterial partial pressure of carbon dioxide ($PaCO_2$) to determine whether the patient has respiratory acidosis or alkalosis. Levels of CO_2 are controlled by the lungs, and CO_2 is thus considered the respiratory component of the ABG. Because carbonic acid forms when CO_2 is dissolved in blood, high CO_2 levels indicate acidosis, and low CO_2 levels indicate alkalosis.
3. Analyzing the HCO_3^- level to determine whether the patient has metabolic acidosis or alkalosis. Levels of HCO_3^-, the metabolic component of the ABG value, are controlled primarily by the kidneys. Because HCO_3^- is a base, high levels of HCO_3^- result in alkalosis, and low levels result in acidosis.
4. Determining whether the CO_2 or the HCO_3^- level matches the acid or base alteration of the pH. For example, if the pH is acidotic and the CO_2 level is high (respiratory acidosis) but the HCO_3^- level is high (metabolic alkalosis), the CO_2 is the parameter that matches the pH derangement. The patient's acid–base imbalance would be diagnosed as respiratory acidosis.
5. Deciding whether the body is attempting to compensate for the pH change. If the parameter that does not match the pH is moving in the opposite direction, the body is attempting to compensate. In step 4, the HCO_3^- is alkalotic; this is in the opposite direction of respiratory acidosis and is considered compensation. If compensatory mechanisms are functioning, the pH will return toward 7.4. When the pH is back to normal, the patient has *full compensation.* The body will not overcompensate for pH changes. If both parameters match the pH, it is possible that a combined respiratory or metabolic acidosis or alkalosis is present. For example, if the pH is acidotic, the CO_2 level is high (respiratory acidosis), and the HCO_3^- level is low (metabolic acidosis), the patient's underlying acid–base imbalance is combined respiratory-metabolic acidosis.
6. Assessing the PaO_2 and O_2 saturation. If these values are abnormal, hypoxemia is present.

Table 19-15 lists normal ABG values, and Table 19-16 provides a sample ABG value with interpretation. (Refer to Table 19-12 for the laboratory findings of the four major acid–base disturbances.) Table 19-17 explains the

ROME (**r**espiratory, **o**pposite, **m**etabolic, **e**quivalent) mnemonic to clarify acid–base imbalances. (Blood gases are discussed further in Chapter 28.)

TABLE 19-15

NORMAL ARTERIAL BLOOD GAS VALUES

Parameter	Arterial
pH	7.35–7.45
PCO_2	35–45 mm Hg
Bicarbonate (HCO_3^-) level	21–28 mmol/L
PO_2*	80–100 mm Hg
Base excess	0 ±2.0 mEq/L

*Decreases above sea level and with increasing age.

PCO_2, partial pressure of carbon dioxide; *PO_2,* partial pressure of oxygen.

TABLE 19-16
ARTERIAL BLOOD GAS (ABG) ANALYSIS

ABG Values
pH 7.30 $PaCO_2$ 25 mm Hg HCO_3 16 mEq/L PaO_2 90 mm Hg
Analysis
1. pH of <7.4 indicates acidosis. 2. $PaCO_2$ is low, indicating respiratory alkalosis. 3. HCO_3^- level is low, indicating metabolic acidosis. 4. Metabolic acidosis matches the pH. 5. The $PaCO_2$ level does not match but is in the opposite direction, which indicates the lungs are attempting to compensate for the metabolic acidosis. 6. The PaO_2 indicates adequate oxygenation of the blood.
Interpretation
This ABG value is interpreted as representing metabolic acidosis with partial compensation. If the pH returns to the normal range, the patient is said to have full compensation.

ABG, arterial blood gas; *HCO_3^-,* bicarbonate; *$PaCO_2$,* partial pressure of arterial CO_2; *PaO_2,* partial pressure of oxygen.

TABLE 19-17
ROME: MNEMONIC FOR ACID–BASE IMBALANCES

For acid–base imbalances, the mnemonic ROME can be used.
In **r**espiratory conditions, the pH and the $PaCO_2$ are in **o**pposite directions.

- In respiratory alkalosis, the pH is ↑ and the $PaCO_2$ is ↓.
- In respiratory acidosis, the pH is ↓ and the $PaCO_2$ is ↑.

In **m**etabolic conditions, the pH and the HCO_3^- go in the same direction (**e**qual or **e**quivalent). The $PaCO_2$ may also go in the same direction.

- In metabolic alkalosis, pH and HCO_3^- are ↑ and the $PaCO_2$ is ↑ or normal.
- In metabolic acidosis, pH and HCO_3^- are ↓ and the $PaCO_2$ is ↓ or normal.

Type of Imbalance	Respiratory: Opposite		Metabolic: Equivalent	
	pH	$PaCO_2$	pH	HCO_3^-
Acidosis	↓	↑	↓	↓
Alkalosis	↑	↓	↑	↑

HCO_3^-, bicarbonate; *$PaCO_2$*, arterial partial pressure of carbon dioxide.

Assessment of Fluid, Electrolyte, and Acid–Base Imbalances

Subjective Data

Important Health Information

Past Health History.

The patient should be questioned about any health history of past problems involving the kidneys, the heart, the GI system, or the lungs that could affect the current fluid, electrolyte, and acid–base balance. Medical information about specific diseases such as diabetes mellitus, diabetes insipidus, chronic obstructive pulmonary disease, ulcerative colitis, and Crohn's disease should be obtained from the patient. The patient should also be questioned about the incidence of a prior fluid, electrolyte, or acid–base disorder.

Medications.

The patient's current and past use of medications must be assessed. The ingredients in many drugs, especially over-the-counter drugs, are often overlooked as sources of sodium, potassium, calcium, magnesium, and other electrolytes. Many prescription drugs, including diuretics, corticosteroids, and electrolyte supplements, can cause fluid and electrolyte problems.

Surgery or Other Treatments.

The patient should be asked about previous or current renal dialysis, kidney surgery, or bowel surgery that resulted in a temporary or permanent external collecting system, such as a colostomy or nephrostomy.

Other Subjective Data.

If the patient is currently experiencing a problem related to fluid, electrolyte, and acid–base balance, a careful description of the illness, including onset, course, and treatment, should be obtained.

The nurse should ask the patient about diet and any special dietary practices. Weight reduction diets, fad diets, or any eating disorders, such

as anorexia or bulimia, can lead to fluid and electrolyte problems. If the patient is on a special diet, such as one of low sodium content or high potassium content, the nurse should assess the patient's ability to adhere to the dietary prescription.

The patient's usual bowel and bladder habits should be noted. Any deviations from the expected elimination pattern, such as diarrhea, nocturia, or polyuria, should be carefully documented.

The patient's exercise pattern is important to determine because excessive perspiration secondary to exercise could result in a fluid and electrolyte problem. Also, the patient's exposure to extremely high temperatures as a result of leisure or work activity should be determined. The patient should be asked what practices are followed to replace fluid and electrolytes lost through excessive perspiration.

The patient should be queried about any changes in sensations, such as numbness, tingling, fasciculations (uncoordinated twitching of a single muscle group), or muscle weakness, that could indicate a fluid and electrolyte problem. In addition, both the patient and the caregivers should be asked whether any changes in mentation or alertness have been noted, such as confusion, memory impairment, or lethargy.

Objective Data

Physical Examination.

There is no specific physical examination to assess fluid, electrolyte, and acid–base balance. Common abnormal assessment findings of major body systems offer clues to possible imbalances (Table 19-18).

TABLE 19-18

ASSESSMENT ABNORMALITIES
Fluid and Electrolyte Imbalances

Finding	Possible Cause
Skin	
Poor skin turgor	Fluid volume deficit
Cold, clammy skin	Na^+ deficit, shift of plasma to interstitial fluid
Pitting edema	Fluid volume excess
Flushed, dry skin	Na^+ excess
Pulse	
Bounding pulse	Fluid volume excess, shift of interstitial fluid to plasma
Rapid, weak, thready pulse	Shift of plasma to interstitial fluid, Na^+ deficit, fluid volume deficit
Weak, irregular, rapid pulse	Severe K^+ deficit
Weak, irregular, slow pulse	Severe K^+ excess
Blood Pressure	
Hypotension	Fluid volume deficit, shift of plasma to interstitial fluid, Na^+ deficit
Hypertension	Fluid volume excess, shift of interstitial fluid to plasma
Respirations	
Deep, rapid breathing	Compensation for metabolic acidosis
Shallow, slow, irregular breathing	Compensation for metabolic alkalosis
Shortness of breath	Fluid volume excess
Moist crackles	Fluid volume excess, shift of interstitial fluid to plasma
Skeletal Muscles	
Cramping of exercised muscle	Ca^{2+} deficit, Mg^{2+} deficit, alkalosis
Carpal spasm (Trousseau's sign)	Ca^{2+} deficit, Mg^{2+} deficit, alkalosis
Flabby muscles	K^+ deficit
Positive Chvostek's sign	Ca^{2+} deficit, Mg^{2+} deficit, alkalosis
Behaviour or Mental State	
Picking at bedclothes	K^+ deficit, Mg^{2+} deficit
Inappropriate indifference	Fluid volume deficit, Na^+ deficit
Apprehension	Shift of plasma to interstitial fluid
Extreme restlessness	K^+ excess, fluid volume deficit
Confusion and irritability	K^+ deficit, fluid volume excess, Ca^{2+} excess, Mg^{2+} excess, H_2O excess
Decreased level of consciousness	H_2O excess

Laboratory Values.

Assessment of serum electrolyte values is a good starting point for identifying fluid and electrolyte imbalance (see Table 19-2). However, serum electrolyte values often provide only cursory information. Each value reflects the concentration of the particular electrolyte in the ECF but does not necessarily provide information concerning the concentration of the electrolyte in the ICF. For example, the majority of the potassium in the body is intracellular. Changes in serum potassium values may be the result of a true deficit or an excess of potassium, or it may reflect the movement of potassium into or out of the cell over the course of acid–base imbalances.

An abnormal serum sodium level may reflect a sodium problem or, more possibly, a water problem. A reduced hematocrit value could indicate anemia, or it could be caused by fluid volume excess. Other laboratory tests that are helpful in evaluating the presence of or risk for fluid, electrolyte, and acid–base imbalances include serum and urine osmolality, serum glucose level, serum urea nitrogen (BUN) values, serum creatinine level, urine specific gravity, and urine electrolyte concentrations.

In addition to arterial and venous blood gas values, serum electrolyte data can provide important information concerning a patient's acid–base balance. Changes in the serum bicarbonate (often reported as total CO_2 or CO_2 content on an electrolyte panel) indicate the presence of metabolic acidosis (low bicarbonate level) or alkalosis (high bicarbonate level). Calculation of the anion gap can help determine the source of metabolic acidosis. The anion gap is increased in metabolic acidosis associated with acid gain (e.g., lactic acidosis, diabetic ketoacidosis) but remains normal in metabolic acidosis caused by bicarbonate loss (e.g., diarrhea).

Oral Fluid and Electrolyte Replacement

In all cases of fluid, electrolyte, and acid–base imbalances, the treatment is directed toward correction of the underlying cause. The specific diseases or disorders that cause these imbalances are discussed in various chapters throughout this text. Mild fluid and electrolyte deficits can be corrected with the use of oral rehydration solutions containing water, electrolytes, and glucose. Glucose not only provides calories but also promotes sodium absorption in the small intestine. Commercial oral rehydration solutions are now available in markets and pharmacies for home use.

Intravenous Fluid and Electrolyte Replacement

IV fluid and electrolyte therapy are commonly used to treat many different fluid and electrolyte imbalances. Many patients need maintenance IV fluid therapy only while they cannot take fluids orally (e.g., during and after surgery). Other patients need corrective or replacement therapy for losses that have already occurred. The amount and the type of solution are determined by the normal daily maintenance requirements and by imbalances identified by laboratory results. Table 19-19 is a list of commonly prescribed IV solutions. The available selections have remained fairly constant over the years. With IV fluid replacement therapy, local complications may occur, including phlebitis, ecchymosis, extravascular fluid infiltration, infection, thrombosis, and venous spasm. Systemic complications may also occur, such as bacteremia and sepsis, air embolism, and pulmonary edema.

TABLE 19-19

Composition and Use of Commonly Prescribed Crystalloid Solutions

Solution	Tonicity	Concentration (mmol/kg)	Glucose Content (g/L)	Indications and Considerations
Dextrose in Water				
5%	Isotonic, but physiologically hypotonic	278	50	Provides free water necessary for renal excretion of solutes Used to replace water losses and treat hypernatremia Provides 170 cal/L Does not provide any electrolytes
10%	Hypertonic	556	100	Provides free water only, no electrolytes Provides 340 cal/L
Saline (Sodium Chloride [NaCl])				
0.45%	Hypotonic	154	0	Provides free water in addition to Na^+ and Cl^- Used to replace hypotonic fluid losses Used as maintenance solution, although it does not replace daily losses of other electrolytes Provides no calories
0.9%	Isotonic	308	0	Used to expand intravascular volume and replace extracellular fluid losses Only solution that may be administered with blood products Contains Na^+ and Cl^- in excess of plasma levels Does not provide free water, calories, other electrolytes May cause intravascular overload or hyperchloremic acidosis
3.0%	Hypertonic	1026	0	Used to treat symptomatic hyponatremia Must be administered slowly and with extreme caution because it may cause dangerous intravascular volume overload and pulmonary edema
Dextrose in Saline				
5% in 0.225%	Isotonic	355	50	Provides Na^+, Cl^-, and free water Used to replace hypotonic losses and treat hypernatremia Provides 170 cal/L
5% in 0.45%	Hypertonic	432	50	Same as 0.45% NaCl except provides 170 cal/L
5% in 0.9%	Hypertonic	586	50	Same as 0.9% NaCl except provides 170 cal/L
Multiple-Electrolyte Solutions				
Ringer's solution	Isotonic	309	0	Similar in composition to plasma except that it has excess Cl^-, no Mg^{2+} and no HCO_3^- Does not provide free water or calories Used to expand the intravascular volume and replace extracellular fluid losses
Lactated Ringer's (Hartmann's) solution	Isotonic	274	0	Similar in composition to normal plasma except does not contain Mg^{2+} Used to treat losses from burns and lower GI tract May be used to treat mild metabolic acidosis but should not be used to treat lactic acidosis Does not provide free water or calories

GI, gastro-intestinal; HCO_3^-, bicarbonate.

Solutions

Hypotonic.

A hypotonic solution provides more water than electrolytes, diluting the ECF. Osmosis then produces a movement of water from the ECF to the ICF. After osmotic equilibrium has been achieved, the ICF and the ECF have the same osmolality, and both compartments have been expanded. Examples of hypotonic fluids are listed in Table 19-19. Maintenance fluids are usually hypotonic solutions (e.g., 0.45% NaCl) because normal daily losses are hypotonic. Additional electrolytes (e.g., KCl) may be added to maintain normal levels. Hypotonic solutions have the potential to cause cellular swelling, and patients should be monitored for changes in mentation, which may indicate cerebral edema (Porth, 2013).

Although 5% dextrose in water is considered an isotonic solution, the dextrose is quickly metabolized, and the net result is the administration of free water (hypotonic) with proportionately equal expansion of the ECF and ICF. One litre of a 5% dextrose solution provides 50 g of dextrose, or 170 calories. Although this amount of dextrose is not enough to meet caloric requirements, it helps prevent ketosis associated with starvation. Pure water must not be administered intravenously because it would cause hemolysis of RBCs.

Isotonic.

Administration of an isotonic solution expands only the ECF. There is no net loss or gain from the ICF. An isotonic solution is the ideal fluid replacement for a patient with an ECF volume deficit. Examples of isotonic solutions include lactated Ringer's solution and 0.9% NaCl. Lactated Ringer's solution contains sodium, potassium, chloride, calcium, and lactate (the precursor of bicarbonate) in approximately the same concentrations as those of the ECF. Its use is contraindicated in the presence of lactic acidosis because of the body's decreased ability to convert lactate to bicarbonate.

Isotonic saline (0.9% NaCl) has a sodium concentration (154 mmol/L) somewhat higher than that of plasma (135–145 mmol/L) and a chloride concentration (154 mmol/L) significantly higher than the plasma chloride

level (98–106 mmol/L or mEq/L). Therefore, excessive administration of isotonic NaCl can cause elevation of sodium and chloride levels. Isotonic saline may be used when a patient has sustained both fluid and sodium losses or as vascular fluid replacement in hypovolemic shock.

Hypertonic.

A hypertonic solution initially raises the osmolality of ECF and expands it. It is useful in treatment of hypovolemia and hyponatremia. Examples are listed in Table 19-19. In addition, the higher osmotic pressure causes water to shift out of the cells and into the ECF. Hypertonic solutions (e.g., 3% NaCl) necessitate frequent monitoring of blood pressure, lung sounds, and serum sodium levels and should be used with caution because of the risk for intravascular fluid volume excess, as well as for intracellular dehydration (Porth, 2013).

Although concentrated dextrose and water solutions (≥10% dextrose) are hypertonic solutions, once the dextrose is metabolized, the net result is the administration of water. The free water provided by these solutions ultimately causes both the ECF and the ICF to expand. The primary use of these solutions is in the provision of calories. Concentrated dextrose solutions may be combined with amino acid solutions, electrolytes, vitamins, and trace elements to provide total parenteral nutrition (see Chapter 42). Solutions containing 10% dextrose or less may be administered through a peripheral IV catheter. Solutions with greater concentrations of dextrose must be administered through a central catheter so that dilution is adequate to prevent shrinkage of RBCs.

Intravenous Additives.

Additives in basic IV solutions replace specific losses. KCl, calcium chloride (CaCl), $MgSO_4$, and HCO_3^- are common additives. The use of each was described earlier in the discussion of the specific electrolyte deficiencies. Many premixed IV solutions containing specific additives are available. Use of these solutions reduces error inasmuch as they contain the correct amount of the electrolytes in the proper volumes and types of IV solution. Recommendations for administering potassium vary, but in general, no more than 10 to 20 mEq per hour is considered safe for routine administration. Potassium can be safely diluted as 40 mEq/L of solution, with a maximum of 60 mEq/L. It must never be administered undiluted or by IV push because it can cause fatal cardiac reactions.

Plasma Expanders.

Plasma expanders stay in the vascular space and increase the osmotic pressure. Plasma expanders include colloids, dextran, and hetastarch. Colloids are protein solutions such as plasma, albumin, and commercial plasmas. Albumin is available in 5% and 25% solutions. The 5% solution has an albumin concentration similar to that of plasma and expands the intravascular fluid millilitre for millilitre. In contrast, the 25% albumin solution is hypertonic and causes additional fluid to move from the interstitium. Dextran is a complex synthetic sugar. Because dextran is metabolized slowly, it remains in the vascular system for a prolonged period but not as long as the colloids. It causes additional fluid to move into the intravascular space. (Indications for plasma volume expanders are discussed in Chapter 69.)

If the patient has lost blood, whole blood or packed RBCs are necessary. Packed RBCs have the advantage of giving the patient primarily RBCs; the blood bank can use the plasma for blood components. Whole blood, with its additional fluid volume, may cause circulatory overload. Although packed cells have a decreased plasma volume, they will increase the oncotic pressure and pull fluid into the intravascular space. Loop diuretics may be administered with blood to prevent symptoms of fluid volume excess in anemic patients who are not volume depleted. (Administration of blood is discussed in Chapter 33.)

Central Venous Access Devices

Central venous access devices (CVADs) are catheters that are placed in large blood vessels (e.g., subclavian vein, jugular vein) when access to the vascular system is needed frequently. In contrast to CVADs, the basic IV catheter is inserted into a peripheral vein in the hand, inside of the arm, or antecubital fossa and is used for short-term IV access. Central venous access can be achieved by three different methods: centrally inserted catheters, peripherally inserted central catheters (PICCs), or implanted ports. Centrally inserted catheters and implanted ports must be placed by a physician, whereas PICCs can be inserted by a nurse with specialized training.

Evidence-Informed Practice

Research Highlight

Do Heparin Flushes Decrease Occlusions in Central Venous Catheters?

Clinical Question

For patients with intermittently used central venous catheters (P), do heparin solution flushes (I) versus normal saline flushes (C) decrease catheter occlusions (O)?

Best Available Evidence

Cochrane systematic review of six studies with a total of 1 433 participants.

Critical Appraisal and Synthesis of Evidence

- Study participants were adult patients with a central venous catheter (CVC) or a peripherally inserted central catheter (PICC).
- Primary outcomes included occlusion of CVCs and duration (in days) of catheter patency.

- There were wide variations in guideline recommendations and practice surrounding the effectiveness of heparin flushing of CVCs.
- Potential harms were associated with heparin use, especially in critically ill patients.

Conclusions

- No conclusive evidence favours intermittent flushing with heparin over flushing with 0.9% normal saline with regard to safety or efficacy.
- More studies of central venous access maintenance are needed to guide evidence-informed practice.

Implications for Nursing Practice

- Maintenance of catheter patency is critical.
- Flushing devices with saline solution may be a safe and effective alternative to heparin flushes for catheter maintenance.

P, patient population of interest; *I,* intervention or area of interest; *C,* comparison of interest or comparison group; *O,* outcome(s) of interest (see Chapter 1 of this textbook).

CVADs enable frequent, continuous, rapid, or intermittent administration of fluids and medications. They allow for the administration of drugs that are potential vesicants, blood and blood products, and parenteral nutrition. They may also be used for hemodynamic monitoring and venous blood sampling. These devices are indicated for patients who have limited peripheral vascular access or who have a projected need for long-term vascular access. Table 19-20 provides examples of medical conditions in which CVADs are used.

TABLE 19-20
INDICATIONS FOR USE OF CENTRAL VENOUS ACCESS DEVICE*

Medical Condition	Indications for Use
Medication administration	
• Cancer	Chemotherapy, infusion of irritating or vesicant medications
• Infection	Long-term administration of antibiotics
• Pain	Long-term administration of pain medication
• Drugs and other substances that increase risk for phlebitis	Epoprostenol (Flolan), calcium chloride, potassium chloride, amiodarone (Cordarone)
Nutritional replacement	Infusion of parenteral nutrition
	Solutions with higher dextrose content can be infused through CVAD (versus peripheral line)
Blood samples	Multiple diagnostic blood tests over a period of time
Blood transfusions	Infusion of blood or blood products in acute situations, as well as over a period of time
Renal failure	Performing hemodialysis (especially on an acute basis) or continuous renal replacement therapy
Shock, burns	Infusion of high volumes of fluid and electrolyte replacement
Hemodynamic monitoring	Measuring CVP to assess fluid balance
Heart failure	Performing ultrafiltration
Autoimmune disorders	Performing plasmapheresis

*This list is not all-inclusive, and these are examples only.

CVAD, central venous access device; *CVP*, central venous pressure.

Advantages of CVADs include a reduced need for multiple venipunctures, decreased risk of extravasation injury, and immediate access to the central venous system. Although the incidence is decreased,

extravasation can nonetheless occur if the device being used is displaced or damaged. The major disadvantages of CVADs are an increased risk of systemic infection and the invasiveness of the insertion procedure.

Centrally Inserted Catheters

The tip of centrally inserted catheters (also called central venous catheters [CVCs]) rests in the distal end of the superior vena cava near its junction with the right atrium (Figure 19-18). The other end of the catheter exits through a separate incision on the chest or abdominal wall. Nontunnelled catheters are placed usually in the subclavian or internal jugular vein and more rarely in the femoral vein. They are best for patients with short-term needs in an acute care setting. Surgically placed tunnelled catheters (e.g., Hickman catheters) are suitable for long-term needs. Tunnelling of the catheter through subcutaneous tissue and the synthetic cuff used to anchor the catheter provide stability and decrease infection risk. Accurate placement must be verified by chest radiography before the catheter can be used. After the site heals, the catheter does not require a dressing, which makes it easier for the patient to maintain the site at home. Care requirements include injection cap change, cleansing, flushing, and dressing change.

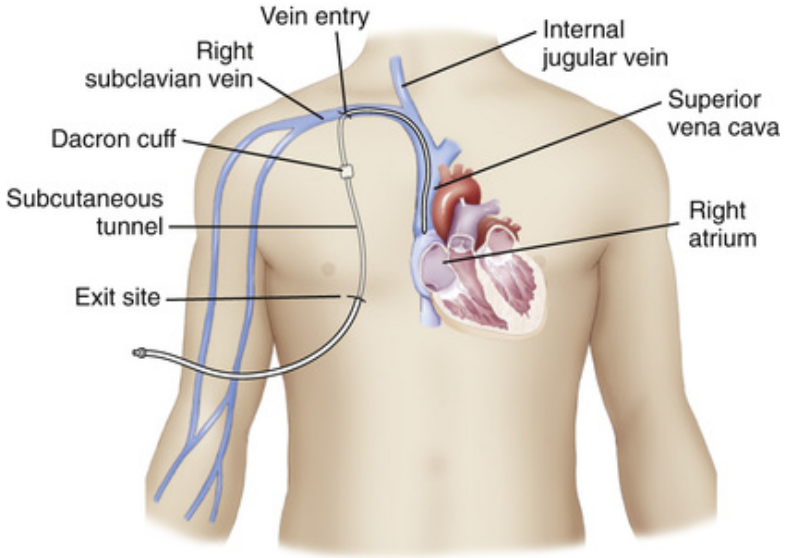

FIGURE 19-18 Tunnelled central venous catheter. Note tip of the catheter in the superior vena cava.

CVCs are available as single-, double-, triple-, or quadruple-lumen catheters. Multilumen catheters are useful in critically ill patients because each lumen can be simultaneously used to provide a different therapy. For example, incompatible drugs can be infused in separate lumens without mixing, and a third lumen can provide access for blood sampling. Specific types of long-term central catheters are Hickman catheters, for which clamps are needed to make sure the valve is closed, and Groshong catheters, which have a valve that opens as fluid is withdrawn or infused and remains closed when not in use.

Peripherally Inserted Central Catheters

PICCs are central venous catheters inserted into a vein in the arm. The basilic vein is preferred because of its large diameter. PICC lines are inserted at or just above the antecubital fossa and advanced to a position with the tip ending in the distal one third of the superior vena cava (Figure 19-19). Single-, double-, or triple-lumen PICCs are available; those with double lumens are preferred because they allow for simultaneous uses. PICCs are used with patients who need vascular access for 1 week to 6 months, but they can be in place for longer periods.

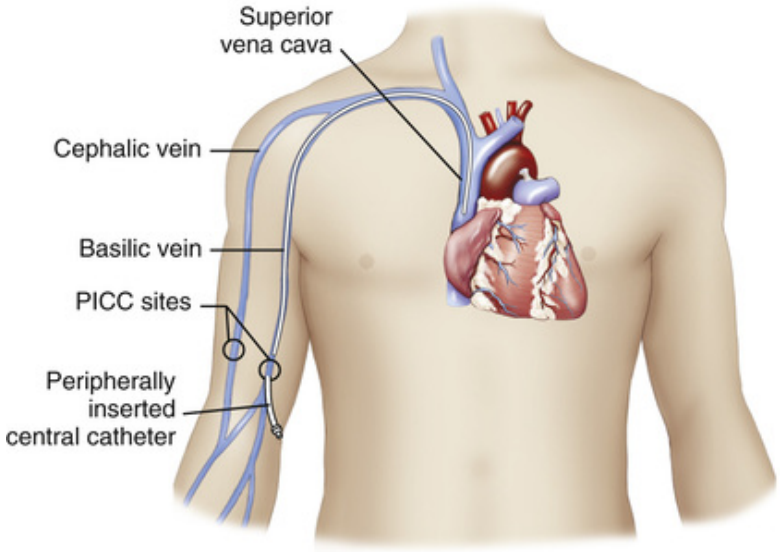

FIGURE 19-19 Peripherally inserted central catheter (PICC) can be inserted into the basilic or cephalic vein.

The technique for placement of a PICC line involves insertion of the catheter through a needle with the use of a guide wire or forceps to

advance the line. Advantages of the PICC over a CVC are lower infection rate, fewer insertion-related complications, decreased cost, and ability to be inserted at the patient's bedside or in the outpatient area.

Complications of PICC lines include catheter occlusion and phlebitis (Table 19-21). If phlebitis occurs, it usually happens within 7 to 10 days after insertion. The nurse must not use the arm with the PICC to obtain a blood pressure reading or draw blood. When the blood pressure cuff is inflated, the PICC can touch the vein wall, which increases the risk of vein damage and thrombosis.

TABLE 19-21

POTENTIAL COMPLICATIONS OF CENTRAL VENOUS ACCESS DEVICES

Possible Cause	Clinical Manifestations	Nursing and Collaborative Management
Catheter Occlusion		
Clamped or kinked catheter Tip against wall of vessel Thrombosis Precipitate buildup in lumen	Sluggish infusion or aspiration Inability to infuse or aspirate	Instructing patient to change position, raise arm, and cough Assessing for and alleviating clamping or kinking Flushing with normal saline with a 10-mL syringe; do not force flush Fluoroscopy to determine cause and site Anticoagulant or thrombolytic agents
Embolism		
Catheter breakage Dislodgement of thrombus Entry of air into circulation	Chest pain Respiratory distress (dyspnea, tachypnea, hypoxia, cyanosis) Hypotension Tachycardia	Administering oxygen Clamping catheter Placing patient on left side with head down (air emboli) Notifying physician
Catheter-Related Infection (Local or Systemic)		
Contamination during insertion or use Migration of organisms along catheter Immuno-suppression of patient	Local: redness, tenderness, purulent drainage, warmth, edema Systemic: fever, chills, malaise	Local • Culture of drainage from site • Warm, moist compresses • Catheter removal if indicated Systemic • Blood cultures • Antibiotic therapy • Antipyretic therapy • Catheter removal if indicated
Pneumothorax		
Perforation of visceral pleura during insertion	Decrease in or absence of breath sounds Respiratory distress (cyanosis, dyspnea, tachypnea) Chest pain Unilateral distension of chest	Administering oxygen Positioning in semi-Fowler's position Preparing for chest tube insertion
Catheter Migration		
Improper suturing Insertion site trauma Changes in intrathoracic pressure Forceful catheter flushing Spontaneous movement	Sluggish infusion or aspiration Edema of chest or neck during infusion Patient complaint of gurgling sound in ear Dysrhythmias Increased external catheter length	Fluoroscopy to verify position Assistance with removal and new CVAD placement

CVAD, central venous access device.

Implanted Infusion Ports

An implanted infusion port is a CVC connected to a single or double implanted subcutaneous injection port (Figure 19-20, *A*). The catheter is

placed into the desired vein, and the other end is connected to a port that is surgically implanted in a subcutaneous pocket on the chest wall. The port consists of a metal sheath with a self-sealing silicone septum. Drugs are injected through the skin into the port. After being filled, the reservoir slowly releases the medicine into the bloodstream.

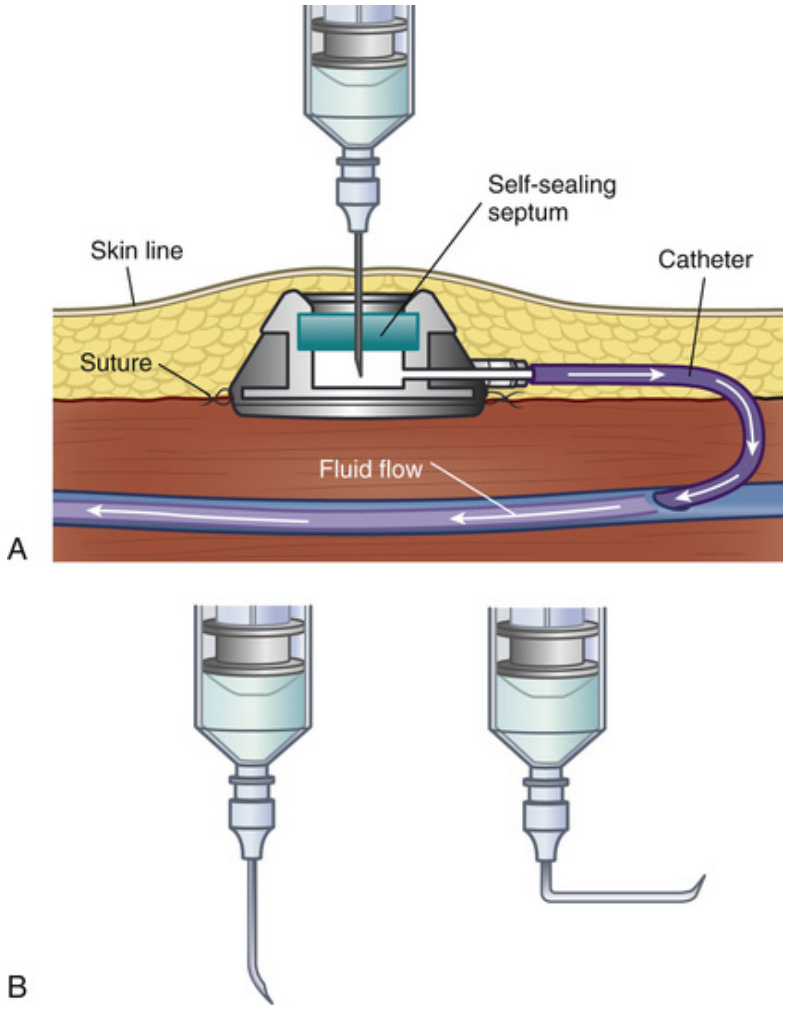

FIGURE 19-20 **A,** Cross-section of implantable port displaying access of the port with the Huber-point needle. Note the deflected point of the Huber-point needle, which prevents coring of the port's septum. **B,** Two Huber-point needles used to enter the implanted port. The 90-degree needle is used for top-entry ports for continuous infusion. Source: **A,** Courtesy Pharmaceia Deltec, Inc., St. Paul, MN.

The port is accessed via the septum by means of a special noncoring needle that has a deflected tip, which prevents damage to the septum that could render the port useless (see Figure 19-20, *B*). Implanted ports are

convenient for long-term therapy and can remain in the body for years. Because the port is hidden, it offers cosmetic advantages (Zaghal, Khalife, Mukherji, et al., 2012). Care requirements include regular flushing. Formation of "sludge" (accumulation of clotted blood and drug precipitate) may also occur within the port septum.

Complications

The potential for complications associated with CVADs is always present. Astute monitoring and assessment may assist in early identification of potential complications. Table 19-21 lists potential complications of CVADs.

Nursing Management Central Venous Access Devices

Nursing management of CVADs includes assessment, dressing change and cleansing, injection cap changes, and flushing. Although institution policies and procedures may differ for specific types of CVADs, there are some general guidelines to be followed.

Catheter and insertion site assessment includes inspecting the site for redness, edema, warmth, drainage, and tenderness or pain. Observing the catheter for misplacement or slippage is important. The nurse should perform a comprehensive pain assessment, particularly noting any complaints of chest or neck discomfort, arm pain, or pain at the insertion site. Newly placed CVADs should not be used until the tip position is verified with a chest radiograph.

Dressing change and cleansing of the catheter insertion site should be performed according to institution policies and procedures with strict sterile technique. Transparent semipermeable dressings or gauze and tape can be used. If the site is bleeding, a gauze dressing may be preferable; otherwise, transparent dressings are preferred because they allow observation of the site without having to be removed. Transparent dressings may be left in place for up to 1 week. The dressing should be changed immediately if it becomes damp, loose, or soiled.

The skin around the catheter insertion suite should be cleansed according to institution policy. A chlorhexidine-based preparation is the cleansing agent of choice. Its effects last longer than either povidone-iodine or isopropyl alcohol, offering improved killing of bacteria (Marschall, Mermel, Fakih, et al., 2014). When chlorhexidine is used, cleansing the skin with friction is critical for preventing infection (Weinstein & Hagle, 2014). When applying a new dressing, the nurse should allow the area to air-dry completely. The lumen ports are secured to the skin above the dressing site. The nurse should document the date and time of the dressing change and initial the dressing.

Injection caps must be changed at regular intervals with the use of strict sterile technique according to institution policy or when they are damaged from excessive punctures. The patient should be taught to turn the head to the opposite side of the CVAD insertion site during cap change. If the catheter cannot be clamped and is open to air, the patient should be asked to lie flat in bed and perform the Valsalva manoeuvre to prevent an air embolism.

Flushing is one of the most effective ways to maintain lumen patency and to prevent occlusion of the CVAD. It also keeps incompatible drugs or fluids from mixing. The lumen is flushed with a normal saline solution in a syringe that has a barrel capacity of 10 mL or more to avoid excess pressure on the catheter. If resistance is felt, force should not be applied; this could result in rupture of the catheter or in the creation of an embolism if a thrombus is present. Because of the risk of contamination and infection, prefilled syringes or single-dose vials are preferred over multiple-dose vials. During flushing, the push–pause method is preferred over a continual even push of saline into the catheter. The push–pause technique creates turbulence within the catheter lumen, promoting the removal of debris that adheres to the catheter lumen. This technique involves injecting the saline with a rapid alternating push–pause motion, instilling 1 to 2 mL with each push on the syringe plunger.

Removal of Central Venous Access Devices

CVADs should be removed according to institution policy and the nurse's scope of practice. In many agencies, nurses with demonstrated competency can remove PICCs and nontunnelled CVCs. The procedure involves removing any sutures and then gently withdrawing the catheter. The patient is instructed to perform the Valsalva manoeuvre as the last 5 to 10 cm of the catheter is withdrawn. The nurse immediately applies pressure to the site with sterile gauze to prevent air from entering and to control bleeding. The catheter tip is inspected to ensure that it is intact. After bleeding has stopped, an antiseptic ointment and sterile dressing are applied to the site.

Case Study

Fluid and Electrolyte Imbalance

Source: elbud/Shutterstock.com.

Patient Profile

Sarah Stern, a 73-year-old woman with lung cancer, has been receiving chemotherapy on an outpatient basis. She completed her third treatment 5 days ago and has been experiencing nausea and vomiting for 2 days even though she has been taking prochlorperazine as directed. Ms. Stern's daughter brings her to the hospital, where she is admitted to the medical unit. The admitting nurse performs a thorough assessment.

Subjective Data

- Complains of lethargy, weakness, and a dry mouth
- States she has been too nauseated to eat or drink anything for 2 days

Objective Data

- Heart rate, 110; pulse, thready
- Blood pressure, 100/65 mm Hg
- Weight loss of 2.2 kg since she received her chemotherapy treatment 5 days ago
- Dry oral mucous membranes

Discussion Questions

1. According to her clinical manifestations, what fluid imbalance does Ms. Stern have?
2. What additional assessment data should the nurse obtain?
3. What are the patient's risk factors for fluid and electrolyte imbalances?

4. The nurse draws blood for a serum chemistry evaluation. What electrolyte imbalances are likely to be found and why?
5. Ms. Stern is at risk for which acid–base imbalance? Describe the changes that would occur in Ms. Stern's ABG values with this acid–base imbalance. How would her body compensate?
6. What is the interprofessional team's priority at this time for Ms. Stern?
7. The physician orders dextrose 5% in 0.45% saline to infuse at 100 mL per hour. What type of solution is this, and how will it help Ms. Stern's fluid imbalance?
8. ***Priority Decision:*** What are the priority nursing interventions for Ms. Stern?
9. ***Evidence-Informed Practice:*** Ms. Stern has a double-lumen PICC in her left arm. One lumen is connected to the IV infusion; the other is unused. What is the recommended practice for maintaining the patency of the unused lumen?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. In which of the following fluid compartments is the majority of the body's water contained?
   a. Interstitial
   b. Intracellular
   c. Extracellular
   d. Intravascular

2. Which mechanism is involved with equalizing the fluid concentration when the blood plasma has a higher osmolality than the intracellular fluid in blood cells?
   a. Osmosis
   b. Diffusion
   c. Active transport
   d. Facilitated diffusion

3a. An older woman was admitted to the medical unit with GI bleeding and fluid volume deficit. What are the clinical manifestations of the latter problem? *(Select all that apply)*
   a. Weight loss
   b. Dry oral mucosa
   c. Full bounding pulse
   d. Engorged neck veins
   e. Decreased central venous pressure

3b. Which of the following nursing actions is required for clients with hyponatremia?
   a. Fluid restriction
   b. Administration of hypotonic intravenous fluids
   c. Administration of a cation exchange resin
   d. Increased water intake for clients on nasogastric suction

3c. Which of the following should the nurse monitor for when a client is receiving a loop diuretic?
   a. Restlessness and agitation

b. Paresthesias and irritability

c. Weak, irregular pulse and poor muscle tone

d. Increased blood pressure and muscle spasms

3d. Which of the following clients would be at greatest risk for the potential development of hypermagnesemia?

a. An 83-year-old man with lung cancer and hypertension

b. A 65-year-old woman with hypertension taking β-adrenergic blockers

c. A 42-year-old woman with systemic lupus erythematosus and renal failure

d. A 50-year-old man with benign prostatic hyperplasia and a urinary tract infection

3e. In a client who has just undergone a total thyroidectomy, it is especially important for the nurse to assess which of the following?

a. Weight gain

b. Depressed reflexes

c. Positive Chvostek's sign

d. Confusion and personality changes

3f. Care of the client experiencing hyperphosphatemia secondary to renal failure includes which of the following?

a. Calcium supplements

b. Potassium supplements

c. Magnesium supplements

d. Fluid replacement therapy

4. How do the lungs act as an acid–base buffer?

a. By increasing respiratory rate and depth when CO_2 levels in the blood are high, thereby reducing acid load

b. By increasing respiratory rate and depth when CO_2 levels in the blood are low, thereby reducing base load

c. By decreasing respiratory rate and depth when CO_2 levels in the blood are high, thereby reducing acid load

d. By decreasing respiratory rate and depth when CO_2 levels in the blood are low, thereby increasing acid load

5. A client has the following arterial blood gas results: pH, 7.52; partial pressure of carbon dioxide in the arterial blood ($PaCO_2$), 30 mm Hg; HCO_3^- level, 24 mmol/L. These results indicate the presence of which acid–base disturbance?
   a. Metabolic acidosis
   b. Metabolic alkalosis
   c. Respiratory acidosis
   d. Respiratory alkalosis
6. What is the typical fluid replacement for the client with a fluid volume deficit?
   a. Dextran
   b. 0.45% Saline
   c. Lactated Ringer's solution
   d. 5% Dextrose in 0.45% saline
7. The nurse is unable to flush a central venous access device and suspects occlusion. Which of the following would be the best nursing intervention?
   a. Apply warm moist compresses to the insertion site.
   b. Attempt to force 10 mL of normal saline into the device.
   c. Place the client on the left side with head-down position.
   d. Instruct the client to change positions, raise arm, and cough.

1. b; 2. a; 3a. a, b, e; 3b. a; 3c. c; 3d. c; 3e. c; 3f. a; 4. a; 5. d; 6. c; 7. d.

CHAPTER 20

Nursing Management

Preoperative Care

Written by, Janice A. Neil

Adapted by, Debra Clendinneng

LEARNING OBJECTIVES

1. Identify the common purposes and settings of surgery.
2. Describe the scope of practice for the perianesthesia nurse.
3. Describe the purpose and components of a preoperative nursing assessment.
4. Explain the purpose and components of informed consent for surgery.
5. Examine the nursing role in the physical, psychological, and educational preparation of the patient undergoing surgery.
6. Prioritize nursing responsibilities related to day-of-surgery preparation for the surgical patient.
7. Identify the purposes and types of preoperative medications.
8. Apply knowledge of special considerations in the preoperative preparation for the older-adult surgical patient.

KEY TERMS

ambulatory surgery, p. 385

elective surgery, p. 384

emergency surgery, p. 384

informed consent, p. 394

same-day admission, p. 385

The Canadian health care system focuses on the health and well-being of all Canadians and has a renewed commitment to support innovation in and improve health care delivery to First Nations communities (Health Canada, 2015). Despite Canadians' commitment to health promotion and illness prevention, there are patients with diseases or conditions that require surgical interventions (Health Quality Ontario, 2012). Surgery may be performed for any of the following purposes:

1. *Diagnosis:* Determination of the presence or extent of pathological abnormality (e.g., lymph node biopsy or bronchoscopy).
2. *Cure or repair:* Elimination or repair of a pathological condition (e.g., removal of a ruptured appendix or benign ovarian cyst) or repair of anatomy (e.g., fracture fixation).
3. *Palliation:* Alleviation of symptoms without cure (e.g., cutting a nerve root [rhizotomy] to remove symptoms of pain or creating a colostomy to bypass an inoperable bowel obstruction).
4. *Prevention:* For example, removal of a premalignant or partial colectomy in a patient with familial adenomatous polyposis to prevent cancer.
5. *Exploration:* Surgical examination to determine the nature or extent of a disease (e.g., laparotomy).
6. *Cosmetic improvement:* For example, repair of a burn scar or changing breast shape.

Terminology used in surgical procedures combines anatomical vocabulary with prefixes and suffixes derived primarily from Latin and Greek. The use of this language pattern allows us to determine

what operation or procedure is being done. Table 20-1 provides a sampling of suffixes that are commonly combined with an anatomical part or organ in naming surgical procedures.

TABLE 20-1
SUFFIXES DESCRIBING COMMON SURGICAL PROCEDURES

Suffix	Meaning	General Surgery	Orthopedic Surgery	Urological Surgery
-ectomy	Excision/removal	Appendectomy	Discectomy	Nephrectomy
-oscopy	Looking into	Gastroscopy	Knee arthroscopy	Cystoscopy
-ostomy	Creation of opening into	Colostomy		Ureterostomy
-otomy	Cutting into/incision	Tracheotomy	Arthrotomy	Cystotomy
-plasty	Repair/reconstruction	Mammoplasty	Total hip arthroplasty	Ureteroplasty

Surgical Settings

Surgery may be urgent **(emergency surgery)** or carefully planned **(elective surgery).** Regardless of where the surgery is performed or whether it is emergency or elective surgery, nurses are vital in preoperative patient preparation, caring for the patient during surgery, and facilitating the patient's recovery postoperatively.

Surgical Wait Times

Currently, all provinces in Canada collect and report on surgical wait times for cancer, heart, joint replacement, and sight-restoration surgery. Provincial wait times are compared using a pan-Canadian benchmark for the various categories (Canadian Institute for Health Information [CIHI], 2016). Efforts to reduce wait times for elective surgery in Canada had mixed results from 2011 to 2016. For instance, the wait time for cataract surgery increased, while the wait time for joint surgery remained stable despite the increased number of procedures performed. Wait times for urgent repair of hip fractures, which is associated with a high mortality risk in seniors, decreased significantly in those five years. Despite all the contextual variables, Canada remains committed to reducing surgical and diagnostic wait times and continues to perform well when compared internationally (CIHI, 2016).

Elective Inpatient Surgery

The most common inpatient surgeries in Canada are Caesarean section, knee replacement, fractures, coronary artery angioplasty, and hip replacement surgery (CIHI, 2015). Patients requiring hospitalization for surgery are usually admitted the day of their surgery **(same-day admission).**

Ambulatory Surgery.

In Canada, for the majority of surgeries, the patient is discharged on the same day. **Ambulatory surgery,** also called *same-day surgery,* can be conducted in emergency departments, endoscopy clinics, doctors' offices, and outpatient surgery units in hospitals. These procedures can be performed using general, regional, or local anaesthetic, usually take less than 2 hours, necessitate less than a 3- to 4-hour stay in the postanaesthesia care unit (PACU), and do not require overnight hospitalization. Sometimes patients are admitted to hospital postoperatively if they experience difficulty with pain control, nausea, or vomiting.

Several nurses are involved in the surgical patient's continuum of care through the preoperative, intraoperative, and postoperative phases. The following information gathered by the perianesthesia nurse before surgery assists these nurses in planning care:

- The disorder necessitating surgery
- Awareness of comorbidities
- Identification of the patient's response to the stress of surgery
- Assessment of results of preoperative diagnostic tests
- Consideration of bodily alterations, impact of comorbidities, risks, and potential complications associated with surgery

This preoperative assessment is communicated and documented to ensure continuity of care.

The preoperative nursing measures included in this chapter are applicable to the preparation of any patient undergoing surgery. Measures to prepare for specific surgical procedures (e.g., abdominal, thoracic, or orthopedic surgery) are covered in appropriate chapters of this text.

Preoperative Admission Assessment

The patient's initial contact for preoperative evaluation is done at the preoperative admission clinic (PAC), where the patient is interviewed by a perianesthesia nurse. The interview is done well in advance of surgery in order to ensure time to (Andrews & Cartwright, 2016):

- Obtain consults or diagnostic testing
- Ensure that the patient's emotional status and medical regimen (e.g., glycemic control) are satisfactory
- Make arrangements for family care and transportation

The purposes of the preoperative assessment are (1) to decrease surgical delays or cancellations by obtaining patient health information (e.g., physical assessment and American Society of Anesthesiologists physical status); (2) to evaluate and reduce patient anxiety by providing clear explanations, correcting misconceptions, and supporting physiological, cognitive, and psychosocial perspectives (Andrews & Cartwright, 2016); and (3) to educate and allow questions from the patient and family or caregiver regarding the preparation for surgery and anaesthetic protocols. The information provided includes:

- Protocol for taking routine medication on day of surgery
- Which medications (e.g., anticoagulants) or herbal remedies to stop prior to surgery and when to stop them
- Nothing-by-mouth (NPO) instructions

- Pain management options
- Infection prevention and wound care
- Postoperative discharge and care (see Chapter 22)

Day-of-Surgery Assessment

All surgical patients have a physical assessment completed and documented by a physician. The extent of the exam is dependent on the type of surgery and anaesthesia required.

On the day of surgery, the nurse does a focused preoperative assessment that reviews existing information, reinforces teaching, and reviews discharge plans (Odom-Forren, 2013). Each hospital or facility has a concise preoperative checklist that helps the nurse meet the following goals:

- Confirm and identify changes to patient's physical status by reviewing the physical exam, confirming preoperative consultations are complete (e.g., by a cardiology, internal medicine, physiotherapy, or wound care nurse) and communicate mobility or sensory deficits to the perioperative team.
- Determine the patient's psychological status and reinforce coping strategies.
- Establish baseline data (i.e., vital signs) for comparison in the intraoperative and postoperative period.
- Review prescription medications, over-the-counter drugs, and herbal medications that may affect the surgical outcome.
- Ensure that preoperative laboratory and diagnostic test results are documented and communicated to appropriate personnel.

- Support the patient's language, family, culture, and spiritual or religious needs that may affect the surgical experience.
- Determine whether the patient has adequate information from the surgeon to make an informed decision to have surgery, and ensure that the consent form is signed by the patient and physician.
- Ensure the patient understands the discharge plan and has postoperative support. This may involve consulting with and setting up postoperative care with rehabilitative facilities or community nursing agencies.

Subjective Data

Psychosocial Assessment.

The meaning of surgery should be explored with the patient as each person has a different perception and anxiety level regarding the procedure, anaesthesia, and postoperative pain (Odom-Forren, 2013). Stress can negatively impact surgical outcomes, such as causing a longer, more painful postoperative recovery (Pereira, Figueiredo-Braga, & Carvalho, 2015). Many factors influence the patient's susceptibility to stress, including the use of positive coping strategies, such as taking an active role, relaxation training, using distraction, and practising other pain control techniques. Past experiences, current health, socioeconomic status, and age also impact stress. Calm, confident nursing communication can help allay patients' fears (Odom-Forren, 2013). (See Chapter 8 for a discussion of stress.)

Older adults may perceive hospitalization for surgery as a physical decline or loss of mobility and independence. They may fear being placed in a long-term care facility, which some view as a

place to die. The nurse is instrumental in alleviating anxieties and restoring the self-esteem of these surgical patients (see "Age-Related Considerations" at the end of the chapter), by identifying stressors that can negatively affect them (Table 20-2). Children and their caregivers also experience anxiety related to surgery despite increased knowledge of perioperative events (Tourigny, Clendinneng, Chartrand, et al., 2011). Nurses reassure anxious parents and reduce children's emotional distress by correcting erroneous ideas and providing timely information in the perioperative period. The nurse uses language that is familiar to the child or youth and caregivers in order to increase their understanding of surgical consent and of perioperative processes. If the patient and caregivers do not speak English, it is ideal to have an interpreter to disseminate information. Not all hospitals can provide an interpreter, so families may bring an English-speaking representative with them to the preoperative interview. (The use of interpreters is discussed in Chapter 2.)

TABLE 20-2

PSYCHOSOCIAL ASSESSMENT OF THE PATIENT BEFORE SURGERY

Situational Changes
• Determine support systems, including family, other caregivers, significant others, and religious or spiritual orientation. • Define degree of personal control, decision making, and independence. • Consider the impact of surgery and hospitalization on family and dependents and financial impacts related to recovery time and medical expenses. • Identify the presence of hope and anticipation of positive results.
Concerns With the Unknown
• Identify specific areas and depth of anxiety and fears. • Identify expectations of surgery, changes in current health status, and effects on daily living.
Concerns With Body Image
• Identify current roles or relationships and view of self. • Determine perceived or potential changes in role or relationships and their impact on body image.
Past Experiences
• Review previous surgical experiences, hospitalizations, and treatments. • Determine responses to those experiences (positive and negative). • Identify current perceptions of surgical procedure in relation to the above and information from others (e.g., a neighbour's view of a personal surgical experience).
Knowledge Deficit
• Identify what preoperative information this specific patient wants to receive. • Assess understanding of the surgical procedure, including preparation, care, interventions, preoperative activities, restrictions, and expected outcomes. • Identify the accuracy of information the patient has received from others, including the health care team, family, friends, and the media.

Anxiety.

Patients may be anxious when facing surgery because of lack of knowledge, for example, not knowing what to expect during the surgical experience or having uncertainty about the outcome of surgery and the potential findings of diagnostic procedures. Some may worry about allowing strangers to take control of their life or even have concerns about not waking from anaesthesia. Studies have shown that preoperative education that includes information about perianesthesia helps decrease anxiety and allay fears (Campbell, 2015). Further, Pereira, Figueiredo-Braga, and Carvalho (2015) demonstrated that nurses' using an empathic, patient-centred approach during the preoperative interview results in improved patient satisfaction, lower pain levels, and faster wound healing.

Patients may be concerned when surgical or anaesthetic interventions, for example, blood transfusions, are in conflict with

religious or cultural beliefs. The requesting physician should discuss the need for blood replacement with the patient and obtain an informed consent, noting patient consent or refusal for transfusion on the patient's chart. This discussion presents an opportunity to provide information to patients about autologous blood donation if they are undergoing surgeries with a higher likelihood of requiring a transfusion (Ontario Regional Blood Coordinating Network, 2013).

Common Fears.

The primary reasons patients fear surgery are the fear of dying under anaesthesia, permanent disability resulting from the operation, pain, change in body image, or receiving a poor prognosis during a diagnostic procedure (e.g., breast biopsy). Patients can become fearful after independently hearing or reading about the risks of surgery and during the informed-consent process when the surgeon explains all aspects of the operation to the patient.

Fear of death can be extremely stressful for the patient. If the nurse identifies that a patient has a fear of death, this information must be communicated to the surgeon immediately. It is important that the surgeon talk with the patient in order to understand where the fear originates and to assuage anxiety. *Fear of pain and discomfort* during and after surgery is common. If the fear appears extreme, the nurse should notify the anaesthesiologist so that appropriate preoperative medication (such as an antianxiety medication) can be ordered. The patient should be reassured that medications are available to minimize or eliminate pain during and after surgery. Drugs can be given that provide an amnesic effect so that the patient will not remember what occurs during the surgical episode. These medications can cause temporary cognitive deficits following surgery that the patient must be informed of. The nurse should stress that the patient should ask for pain medications as needed following surgery and that taking these medications will not contribute to an addiction but may assist with postoperative recovery. (Pain is discussed in Chapter 10.)

Fear of mutilation or alteration in body image can occur whether the surgery is minor or radical, such as amputation. Even the presence of just a small scar on the body can be bothersome to some patients.

The nurse assesses these concerns with an open, nonjudgemental attitude.

Fear of anaesthesia may arise from fear of the unknown, from tales of others' bad experiences, or from previous personal experience. Some patients are concerned about information provided about hazards or complications (e.g., brain damage, paralysis, family history of malignant hyperthermia). Other patients have a fear of losing control while under the influence of anaesthesia. If these fears or questions are identified, the nurse should inform the anaesthesiologist immediately so that he or she can reassure the patient and confirm that a nurse and the anaesthesiologist will be present at all times during surgery.

Fear of disruption of life functioning or patterns can present in varying degrees. A patient may fear permanent disability or loss of life or have concerns about physical limitations after surgery. Also common are concerns about separation from family and worry about how a spouse or children will manage. Financial concerns may surface as a result of an anticipated loss of income because of missed work. If the nurse identifies any of these fears, consultation with a social worker, a spiritual or cultural advisor, a psychologist, or family members may provide valuable assistance to the patient.

Coping With Surgery.

The way patients transition through the perioperative period can impact their postoperative recovery. Many draw on their spirituality, seeking inner peace and sources of hope. As patients, especially outpatients, move through the surgical experience in an accelerated fashion, the perioperative team must be responsive to the patient's health goals, hopes, and fears in order to provide the necessary support. Perioperative caregivers who listen to the patient's story may be perceived as a “person who offers spiritual care during a point of vulnerability and need” (Griffin, 2013, p. 251). Griffin also advises health care providers to engage in meaningful relationships with the perioperative patient before surgery and to mitigate feelings of vulnerability in the intimidating operating room (OR) environment.

Health History.

During the preoperative interview, the nurse should ask about the patient's diagnosed medical conditions and current health issues. An organized approach using hospital guidelines and subjective questioning elicits good information regarding the patient's health history. Initially, the nurse should determine whether the patient understands the reason for surgery. For example, the patient scheduled for a total knee replacement may indicate that the reason for surgery is increasing pain and mobility problems. Detailed information on past hospitalizations, previous surgeries, dates of the surgeries, and any adverse reactions or problems with surgery or anaesthetics is documented. As an example, the patient may have experienced a bad wound infection or a reaction to an analgesic following a prior surgery.

Women should be asked about their menstrual and obstetrical history, including the date of their last menstrual period and the number of pregnancies and deliveries they have had. If the patient states that she might be pregnant, this information should be immediately communicated to the surgeon to avoid maternal and subsequent fetal exposure to anaesthetics during the first trimester. Questioning an adolescent regarding her reproductive functioning may be embarrassing for her and should be done in privacy with parents or guardians out of the room.

The nurse may identify inherited conditions by asking about the patient's family health history. A family history of cardiac and endocrine disease should be recorded. If a patient reports a mother or father with hypertension, sudden cardiac death, myocardial infarction, or coronary artery disease, the nurse should be alerted to the possibility that the patient may have a similar predisposition or condition. A family history of diabetes should be investigated because of the familial predisposition to both type 1 and type 2 diabetes mellitus. Tendencies toward these conditions may be exacerbated during surgery and affect physiological function during and after surgery. Since inherited traits, such as sickle cell trait, contribute to the choice of anaesthesia and impact surgical outcomes, they must be considered in family histories (Odom-Forren, 2013).

Anaesthesia care providers obtain the patient's and family's anaesthetic history, particularly adverse reactions to or problems with anaesthesia, such as malignant hyperthermia. This rare metabolic disease is characterized by hyperthermia with rigidity of skeletal muscles and can result in death. The genetic predisposition for malignant hyperthermia susceptibility is well documented, and anaesthetic care plans are preventive (Rothrock, 2015). (Malignant hyperthermia is discussed in Chapter 21.)

Medications.

As part of the preoperative interview, the nurse documents the patient's current medication use, including the use of over-the-counter (OTC) drugs and herbal products. Patients may be asked to bring their medication bottles when attending the PAC so that the nurse can accurately chart the names and dosages because patients who use a variety of medications may not remember specific details. At this time, it is important also to investigate whether the patient is taking the medication as ordered or has stopped taking it because of cost, adverse effects, or the belief that ongoing therapy is no longer needed.

Medications and herbal products may interact with anaesthetics, often increasing or decreasing potency and effectiveness, or they may be needed during surgery to maintain physiological function. It is important to consider the effects of medications used for heart disease, hypertension, immuno-suppression, seizure control, anticoagulation, and endocrine replacement. Insulin or oral hypoglycemic agents may require dosage or agent adjustments during the perioperative period because of increased body metabolism, decreased caloric intake, stress, and anaesthesia. Many patients use OTC acetylsalicylic acid (Aspirin) or are on anticoagulant therapy such as warfarin sodium (Coumadin), heparin, clopidogrel (Plavix), or others that inhibit platelet aggregation and may contribute to postoperative bleeding complications. Surgeons often require that patients stop taking acetylsalicylic acid (Aspirin) for at least 2 weeks before surgery. It is also important to stress that stopping some medications abruptly can

cause complications. The preoperative nurse should check with an anaesthesiologist to ensure which medications should be stopped and which should be taken the day of surgery.

The use of herbal therapy and dietary supplements is common, but many patients do not disclose to health care providers that they take these supplements unless specifically asked (Larner, 2015). Therefore, it is essential for the nurse to ask about the use of vitamins, herbal supplements, and other alternative substances (see Chapter 12, Table 12-7). These products may interfere with anaesthesia and potentially cause complications during surgery, such as effects on blood pressure, increased sedation, cardiac effects, electrolyte alterations, and inhibition of platelet aggregation. In patients taking anticoagulants or platelet aggregation inhibitors, the use of specific herbal products can cause excessive postoperative bleeding that may necessitate a return to the OR. These types of supplements must be discontinued before surgery, as ordered by the physician (Larner, 2015). Some effects of specific herbs that can be of concern during the perioperative period are identified in the "Complementary & Alternative Therapy" box.

Complementary & Alternative Therapies

Effects of Herbs and Supplements During the Perioperative Period

Herb	Perioperative Considerations
Echinacea	May cause immune suppression if taken over long term. Use to be discontinued as far in advance of surgery as possible.
Ephedra	Stimulant, decongestant, bronchodilator, taken for weight loss. Multiple cardiovascular and GI adverse effects. Use to be discontinued at least 24 hours preoperatively.
Feverfew	May increase clotting time. Preoperative use to be avoided.
Garlic	May increase clotting time and potentiate effects of anticoagulants. Use to be discontinued at least 7 days preoperatively.
Ginger	May increase bleeding, especially in patients taking anticoagulants. To be avoided preoperatively.
Ginkgo biloba	May increase bleeding, especially in patients taking anticoagulants. Use to be discontinued at least 36 hours preoperatively.
Ginseng	May falsely elevate digoxin levels and potentiate MAOIs. Contraindicated for cardiac disorders, hypertension, and hypoglycemia. Use to be discontinued 7 days preoperatively.
Goldenseal	May cause hypotension; may increase edema and potentiate effect of insulin. Preoperative use to be avoided.
Kava	May prolong the effects of certain anaesthetics and have adverse effect on motor reflexes. Use to be discontinued at least 24 hours preoperatively.
Licorice	Certain preparations may cause elevated BP or electrolyte imbalance. Not to be used for more than 7 days preoperatively.
Saw palmetto	May have additive effects with other hormone therapies.
St. John's wort	May prolong the effects of anaesthetic agents, potentiate opioids, and cause electrolyte imbalance.
Valerian	Potentiates sedative–hypnotics; may prolong anaesthesia recovery time. Dose to be tapered for 1–2 weeks preoperatively.
Vitamin E	May increase bleeding and may increase heart rate.

BP, blood pressure; *GI*, gastro-intestinal; *MAOI*, monoamine oxidase inhibitor.

Sources: American Society of Anesthesiologists. (2003). *What you should know about herbal and dietary supplement use and anesthesia.* Park Ridge, IL: Author; Rothrock, J. C. (Ed.). (2015). *Alexander's care of the patient in surgery* (15th ed., pp. 1171–1172). St. Louis: Elsevier.

In the preoperative interview, the nurse should ask the patient about recreational drug use and any substance use disorder. Substances most likely to be abused include tobacco, alcohol, opioids, marihuana, and cocaine. Questions should be asked matter-of-factly and information given that recreational drug use may affect the type and amount of anaesthesia required. When patients are aware of the potential interactions of these drugs with anaesthetics, most will respond honestly about their drug use. Chronic alcohol use may place the patient undergoing surgery at risk because of lung, gastro-intestinal, or liver damage. When liver function is decreased, metabolism of anaesthetic agents is prolonged, nutritional status is altered, and the potential for postoperative

complications is increased. Alcohol withdrawal can also occur during lengthy surgery or in the postoperative period but can be avoided with appropriate planning and management (see Chapter 11).

When assessing medication use, drug intolerance and drug allergies should be considered. Drug intolerance usually results in adverse effects that are uncomfortable or unpleasant for the patient but not life-threatening. These effects can include nausea, constipation, diarrhea, or *idiosyncratic* (opposite from expected) reactions. A true drug allergy produces hives, an anaphylactic reaction, or both, causing cardiopulmonary compromise, including hypotension, tachycardia, bronchospasm, and possibly pulmonary edema. Awareness of drug intolerance and drug allergies, however, makes it possible to maintain patient comfort, safety, and stability. For example, some anaesthetic drugs contain sulphur, so the anaesthesiologist should be notified of a history of allergy to sulphur. Any drug intolerance or drug allergy identified must be documented and flagged on the patient's chart, and, on the day of surgery, an allergy wristband is put on the patient. Depending on institutional protocol, the nurse may be responsible for entering the identified allergy in the electronic medical record so that all health care providers and the pharmacy have knowledge of any medication or related allergy.

All findings of the medication history are documented and communicated to the intraoperative and postoperative teams. Although the anaesthesiologist will determine the appropriate schedule and dose of the patient's routine medications before and after surgery based on the medication history, the nurse must ensure that all of the patient's medications are identified, administer the medications as ordered, and monitor the patient for potential interactions and complications.

Allergies.

The nurse should inquire about nonpharmaceutical allergies to foods, metals, chemicals, tape, and pollen. The patient with a history of any allergic response has a greater potential for demonstrating

hypersensitivity reactions to drugs administered during anaesthesia. Patients should also be screened for possible latex allergies (Operating Room Nurses Association of Canada, 2015) (see Chapters 16 and 21). Centimole (2013) recommends that patients who report the following be considered at risk for latex allergy:

- History of contact dermatitis and atopic immunological reactions
- Allergies to nuts, bananas, avocados, figs, chestnuts, papayas
- Neural tube defects
- Multiple operations
- Repeated bladder catheterizations

High-risk groups for latex allergy also include health care providers. Latex allergies produce reactions ranging from mild skin redness to anaphylaxis (Centimole, 2013).

Review of Systems.

A thorough body systems review is performed and documented before surgery by members of the perioperative team. This review of systems is described in detail in Chapter 3. The surgeon does a preoperative physical examination (PE) and patient history and orders appropriate preoperative laboratory tests and consultations before the day of surgery. In the immediate preoperative period, there is seldom time for the nurse to do a full physical assessment, so nurses rely on the chart documentation. The following are important points for the nurse to assess immediately before surgery to ensure a seamless, safe experience for the patient.

Nervous System.

Preoperative evaluation of neurological functioning includes assessing the patient's ability to respond to questions, follow commands, and maintain orderly thought patterns. Alterations in

the patient's hearing (e.g., requiring hearing aids) and vision (e.g., requiring glasses, development of glaucoma) may affect responses and ability to follow directions. A person's ability to pay attention, concentrate, and respond appropriately is documented to use as the baseline for postoperative comparison.

Impaired cognitive function may affect the patient's ability to prepare for surgery, and the nurse must determine whether all preoperative procedures were carried out—for example, bowel preparations. If confusion is noted and persistent, it is important to determine whether there are appropriate resources and support to assist the patient after surgery.

Cognitive function is of major importance in the assessment of older-adult patients. Although major surgery is a predisposing factor for delirium, other predictive conditions for delirium are dehydration, malnutrition, immobility, urinary catheters, medications, and infection (Rothrock, 2015). Nonverbal older patients and those with chronic conditions such as Alzheimer's disease must be assessed for their interpretation of pain before surgery so that postoperative pain scales can be used effectively. It has been demonstrated that older adults are at risk for undetected pain due to beliefs that pain must be endured and that they should not disturb nurses with complaints of pain (Rothrock, 2015). These preoperative findings are extremely important for postoperative comparison.

Cardiovascular System.

The purpose of evaluating cardiovascular function is to determine the presence of pre-existing disease or existing problems so that the patient's condition can be effectively monitored during the surgical and recovery periods. If there is a history of cardiac problems, including hypertension, angina, dysrhythmias, heart failure, or myocardial infarction, or use of pacemakers or implanted cardiac devices, the patient may need a cardiology and anaesthesia consult before surgery.

If pertinent, clotting and bleeding times and other relevant laboratory results must also be on the chart before surgery. For example, for the patient who receives digitalis therapy, serum

potassium levels must be documented. If the patient has a history of congenital, rheumatic, or valvular heart disease, antibiotic prophylaxis before surgery may be given to decrease the risk for bacterial endocarditis. Further, the nurse should confirm that the patient has not taken anticoagulants, as an international normalized ratio (INR) may need to be drawn before surgery.

Respiratory System.

The patient should be asked about any recent or chronic upper respiratory infections. The presence of an upper airway infection may result in the cancellation or postponement of elective surgery because the patient has an increased anaesthetic risk. If the patient has a history of respiratory problems, he or she will have an anaesthetic consult before surgery and an appropriate workup.

If a patient has asthma, the nurse should inquire about the patient's recent use of inhaled or oral corticosteroids and bronchodilators. The patient with a severe active airway infection, chronic obstructive pulmonary disease, or asthma is at risk for pulmonary complications, including bronchospasm, laryngospasm, hypoxemia, and atelectasis.

The patient who smokes should be encouraged to stop at least 6 weeks before surgery to decrease the risk for intraoperative and postoperative respiratory complications. Many patients may find this difficult given the added stress of impending surgery (Registered Nurses' Association of Ontario, 2015). The greater the patient's pack-years of smoking, the greater the patient's risk for pulmonary complications.

Obesity; spinal, chest, or airway deformities; and sleep apnea can compromise respiratory function. Depending on the patient's history and PE findings, baseline pulmonary function tests and arterial blood gas tests may be ordered before surgery.

Urinary System.

Before surgery, the patient's urinary system status should be documented. Results of any renal function tests, such as serum creatinine and blood urea nitrogen (serum urea [nitrogen]), ordered before surgery should be available on the patient's chart.

Male patients who have problems voiding may have an enlarged prostate, which would hinder the insertion of a urinary catheter during surgery and also impair voiding in the postoperative period. This information is documented for the perioperative team. The nurse should inform patients if they will have a catheter after surgery.

Integumentary System.

Any skin rashes, boils, ulcers, or other dermatological conditions should be noted. A history of pressure injuries may necessitate extra padding during surgery, and skin problems may affect postoperative healing.

Musculo-Skeletal System.

The nurse should note mobility problems in any affected joints, as these restrictions influence intraoperative and postoperative positioning and can affect ambulation. Spinal anaesthesia may be difficult if the patient cannot flex her or his lumbar spine adequately to allow easy needle insertion. If the neck is affected, intubation and airway management may be difficult.

Endocrine System.

Diabetes mellitus is a risk factor for both anaesthesia and surgery. The patient with diabetes is at risk for the development of hypoglycemia, hyperglycemia, ketosis, cardiovascular alterations, delayed wound healing, and infection. Preoperative capillary blood glucose tests should be done to determine baseline levels. It is important to clarify with the patient's surgeon or anaesthesiologist whether the patient should take the usual dose of insulin on the day of surgery. Some practitioners prefer that the patient take only half of the usual dose; others ask that the patient take either the usual dose or no insulin at all. Regardless of the preoperative insulin orders, the patient's capillary blood glucose will be determined periodically and managed, if necessary, with regular (short-acting, rapid-onset) insulin.

It should also be determined whether the patient has a history of thyroid dysfunction. Either hyperthyroidism or hypothyroidism can

place the patient at surgical risk because of alterations in metabolic rate. If the patient takes a thyroid replacement drug, the nurse should check with the anaesthesiologist about administration of the drug the day of surgery. If the patient has a history of thyroid dysfunction, laboratory tests may be ordered to determine current levels of thyroid function.

Immune System.

Patients with active chronic infections, such as hepatitis, acquired immune deficiency syndrome, or tuberculosis, may be suitable for surgery; however, if the patient has a history of immuno-suppression or takes immuno-suppressive drugs, this will be noted in the patient chart. Impairment of the immune system can lead to delayed wound healing and postoperative infections. If the patient has an acute infection (e.g., active skin rash, acute sinusitis, flu, etc.), elective surgery is frequently cancelled. (Infection control guidelines are discussed in Chapter 17.)

Fluid and Electrolyte Status.

The patient should be questioned about vomiting, diarrhea, or difficulty swallowing. Drugs that the patient takes that alter fluid and electrolyte status, such as diuretics, should also be identified because serum electrolyte levels may need to be evaluated before surgery. Most patients have restricted fluids because of NPO status before surgery; it is the responsibility of the anaesthesiologist to administer intravenous (IV) fluids and electrolyte therapy to maintain proper hydration.

Nutritional Status.

Nutritional extremes in patients require consideration in the perioperative period. For example, if the patient is extremely obese, having notification before surgery allows the perioperative nurse time to prepare the necessary equipment and instrumentation. Obesity stresses the cardiac and pulmonary systems and predisposes the patient to obstructive sleep apnea, which in turn can indicate difficult intubation and post-extubation complications. Ventricular

arrhythmias and hypertension are other potential complications (Clifford, 2013).

Malnutrition is a result of inadequate intake of protein or calories. It can cause poor tolerance for anaesthetic drugs, altered wound healing, and susceptibility to infections and cause an increased risk for morbidity and mortality (Jackson, 2015). Many older adults are at risk for malnutrition and fluid volume deficits. If the patient is very thin, the perioperative team should be notified so as to have adequate pressure-reducing positioning devices (pressure points on all patients are protected routinely) on the operating bed. Pressure reduction helps prevent pressure injuries, especially during lengthy procedures. Nutritional deficiencies impair the ability to recover from surgery, so if the nutritional problem is severe, surgery may be postponed until the patient's weight and nutritional deficiencies are corrected.

Impaired nutritional status may affect postoperative recovery and should be identified if the patient will remain in the hospital after surgery. This is particularly true of the undernourished geriatric patient who is at high risk for postoperative morbidity and mortality (Papanier Wells & Flanagan, 2015).

Nursing Assessment: Patient About to Undergo Surgery.

The review of the patient's health provides valuable data about the patient's physical and psychological status as well as cultural values and beliefs related to his or her health care. Questions to ask a patient about to undergo surgery are listed in Table 20-3.

TABLE 20-3

HEALTH HISTORY
Patient About to Undergo Surgery

Subjective Data
Past Health History
• Have you had surgeries in the past?* Which ones?* Did you have any complications?* • Have you or any family members ever experienced any problems with anaesthesia?* • Do you have any past hospitalizations?* • Do you have any chronic health conditions? • Do you have a history of high blood pressure or cardiac disease?* • Do you have any history of dyspnea, coughing, hemoptysis, COPD, or asthma?*
Current Health History
• What is your usual or present height and weight? Have you had a recent weight gain or loss?* • Do you at present have an upper respiratory infection?* • Do you wear glasses, contact lenses, or a hearing aid?* • Do you smoke?* If yes, how many packs daily? For how many years? • What is your usual use of alcohol? • Do you have any problems healing?* • Do you have any musculo-skeletal problems that might affect positioning during surgery or activity level after surgery?* • Do you have any limitation in mobility of your neck?* (Might affect intubation for surgery) • Do you require any special equipment for ambulation?* • How would you describe your pain tolerance? What methods have you found effective for pain relief? • Do you have anxiety related to the surgery? • Will you have the support you feel you need following discharge?
Medications
• Are you currently taking any prescribed medications, over-the-counter medications, or herbal or vitamin supplements?* • Do you have any allergies or sensitivities to any foods or medications?*

*If yes, describe.

COPD, chronic obstructive pulmonary disease.

Objective Data

Physical Examination.

In Canada, the health authority in each province or territory may have its own policies on preoperative health assessments, but it is important to have a PE documented on the chart in case surgical complications arise. This examination may be done in advance of surgery or on the day of surgery.

Findings from the patient's history and PE will enable the anaesthesiologist to assign the patient a physical status rating for anaesthesia administration reference. The classification system

commonly used was developed by the American Society of Anesthesiologists as a way to provide a standardized way to assess the expected anaesthesia outcome for the surgical patient and provide health care providers consistent communication about the patient's physical status and fitness for surgery (Marley, Calabrese, & Thompson, 2014) (Table 20-4). Many physiological stressors may put the patient at risk for surgical complications, whether the surgery is an elective or an emergency procedure. A physiological assessment of the patient who is about to undergo surgery is presented in Table 20-5. If the PE is done immediately before surgery, it will be a more focused assessment because of the impending procedures that must be completed before surgery. The nurse should review the documentation already present on the patient's chart, including the review of systems and the physician's PE report. All findings must be documented, with any relevant findings immediately communicated to members of the perioperative team.

TABLE 20-4

ASA PHYSICAL STATUS CLASSIFICATION SYSTEM

Rating	Examples
ASA I: Healthy normal patient	Healthy, nonsmoking, no or minimal alcohol intake
ASA II: Patient with mild systemic disease	Mild disease, minimal functional limitations (e.g., currently smoking, social alcohol intake, pregnancy, obesity, controlled diabetes, controlled hypertension, mild lung disease)
ASA III: Patient with severe systemic disease	Substantial functional limitations with one or more moderate to severe diseases (e.g., poorly controlled diabetes, hypertension, COPD, active hepatitis, premature infant, myocardial ischemia, CVA)
ASA IV: Patient with severe systemic disease that is a constant threat to life	*Examples:* Recent (<3 months) myocardial infarction, CVA, ongoing cardiac ischemia, sepsis, acute respiratory disease, DIC
ASA V: Moribund patient not expected to survive without surgery	*Examples:* Ruptured abdominal/thoracic aneurysm, massive trauma, massive intracranial bleed, ischemic bowel plus cardiac or multiple organ failure
ASA VI: Brain-dead patient	Organs being removed for donation

COPD, chronic obstructive pulmonary disease; *CVA,* cerebro-vascular accident; *DIC,* disseminated intravascular coagulation.

Source: Based on ASA physical status classification system, 2014, of the American Society of Anesthesiologists. A copy of the full text can be obtained from ASA, 1061 American Lane, Schaumburg, Illinois 60173-4973 or online at *www.asahq.org*.

TABLE 20-5

PHYSIOLOGICAL ASSESSMENT OF THE PATIENT BEFORE SURGERY*

Neurological System
• Determine orientation to time, place, and person. • Identify presence of confusion, disorderly thinking, or inability to follow commands. • Identify past history of strokes, TIAs, or diseases of the central nervous system such as Parkinson's disease or multiple sclerosis. • Identify history of headaches or issues with vision or hearing.
Cardiovascular System
• Identify acute or chronic problems; focus on the presence of angina, hypertension, heart failure, and recent history of myocardial infarction. • Palpate baseline radial pulse for rate and characteristics. • Inspect for edema, noting location and severity. • Take baseline blood pressure. • Identify any medication or herbal product that may affect coagulation (e.g., acetylsalicylic acid, ginkgo biloba, ginger). • Review laboratory and diagnostic tests for cardiovascular function when indicated.
Respiratory System
• Identify acute or chronic problems; note the presence of infection or COPD. • Assess history of smoking and encourage the patient to stop before surgery by educating him or her about the increased risk for complications. • Determine baseline respiratory rate and rhythm, regularity of pattern, and pulse oximetry. • Observe for cough, dyspnea, use of accessory muscles of respiration, and cyanosis.
Urinary System
• Identify any pre-existing disease and ability of the patient to void. Prostate enlargement may affect catheterization during surgery and ability to void after surgery. • Review laboratory and diagnostic tests for renal function when indicated.
Hepatic System
• Review any history of substance abuse, especially alcohol and intravenous drug use. • Review laboratory and diagnostic tests for liver when indicated.
Endocrine and Hematological Systems
• Identify pre-existing problems with bleeding or hematological and endocrine disorders.
Integumentary System
• Assess mucous membranes for dryness and intactness. • Determine skin status; note drying, bruising, or breaks in integrity of surface. • Inspect skin for rashes, boils, or infection, especially around the planned surgical site. • Assess skin moisture and temperature. • Inspect the mucous membranes and skin turgor for presence of dehydration. • Identify any history of problems with wound healing.
Musculo-Skeletal System
• Examine skin–bone pressure points and pressure injuries. • Assess for limitations in joint pain, range of motion, and muscle weakness. • Assess mobility, gait, and balance.
Gastro-Intestinal–Nutritional System
• Identify history of gastro-intestinal disorders or problems with elimination. • Determine food and fluid intake patterns and any recent weight loss. • Weigh patient. • Assess for the presence of dentures and bridges (loose dentures or teeth may be dislodged during intubation).

*See related body system chapters for more specific assessments and related laboratory studies.

COPD, chronic obstructive pulmonary disease; *TIA,* transient ischemic attack.

Laboratory and Diagnostic Testing.

Preoperative laboratory and electrocardiogram testing is obtained based on the patient's history in order to determine their surgical and anaesthetic risk. Diagnostic tests must be ordered judiciously according to hospital protocol in order to reduce unnecessary testing (Marley, Calabrese, & Thompson, 2014). For example, if the patient is taking an anticoagulant (including Aspirin), a coagulation profile may be done; a patient on diuretic or digoxin therapy may need to have a potassium level obtained; a patient taking medications for dysrhythmias will have a preoperative electrocardiogram. Blood glucose monitoring should be done for patients with diabetes. Findings may necessitate dosage or drug adjustments during the perioperative period because of increased body metabolism, decreased caloric intake, stress, and anaesthesia. Regulation of the stability of the blood glucose levels during surgery will promote a more positive outcome. Commonly ordered preoperative laboratory tests can be found in Table 20-6.

TABLE 20-6

COMMON PREOPERATIVE LABORATORY TESTS

Test	Area Assessed
ABGs, oximetry	Pulmonary and metabolic function
Blood glucose	Metabolic status, diabetes mellitus
Blood studies: RBC, Hb, Hct, platelets, WBC, WBC differential	Anemia, immune status, infection
Blood type, screen, and crossmatch	Blood availability for replacement (elective surgery patients may have own blood available—autologous)
Blood urea nitrogen*	Renal function
Chest radiograph	Pulmonary disorders, cardiac enlargement
Creatinine	Renal function
Electrocardiogram	Cardiac disease, electrolyte abnormalities
Electrolytes	Metabolic status, renal function, diuretic adverse effects
Liver function tests	Liver function
Pregnancy	Reproductive status
Prothrombin (INR) or partial thromboplastin time	Bleeding tendencies
Pulmonary function studies	Pulmonary status
Urinalysis	Renal status, hydration, urinary tract infection and disease

*Serum urea (nitrogen).

ABGs, arterial blood gases; *Hct*, hematocrit; *Hb*, hemoglobin; *INR*, international normalized ratio; *RBC*, red blood cell; *WBC*, white blood cell.

Offices and PACs may do the preoperative tests days before surgery. Thus, the nurse must ensure that all laboratory reports are on the chart. Lack of these reports may result in a delay or cancellation of the surgery.

Nursing Management Patient About to Undergo Surgery

Preoperative nursing interventions are derived from the nursing assessment and must reflect each individual patient's specific needs. Physical preparations will be determined by the pending surgery and the routines of the surgery setting. Psychological preparations should be tailored to each patient's needs. Preoperative teaching may be minimal or extensive. General information for surgery should be given.

Preoperative Education

Preoperative education empowers the patient to make informed health decisions and to participate effectively during the surgical experience. Preoperative teaching increases patient compliance with instructions and satisfaction and may reduce fear, anxiety, stress, the duration of hospitalization, and recovery time following discharge. In our multicultural Canadian society, challenges nurses may encounter in perianesthesia teaching include language barriers; cultural perceptions of health, hospitals, and surgery; and the individualized time required to allay the patient's concerns and anxiety level.

In most surgical settings, patients attend the PAC within a month of their scheduled surgery. However, even in unplanned surgery, there is time for the nurse to present information to the patient about the surgery and the postoperative period. The only time patients may not receive any information about their surgery is in an emergency situation where there is no time for teaching. In the PAC, information is presented to the patient in verbal, video, and written forms, which patients and caregivers can review at their leisure.

In preparing the patient for surgery, the nurse identifies the patient's educational needs by determining age, language, reading level, emotional status, and motivation to understand surgery and the perianesthesia process. Preoperative teaching concerns three types of information: sensory, process, and procedural. Different patients, with varying cultures, backgrounds, and experience, may

want different types of information. Patients wanting *sensory information* want to know what they will see, hear, smell, and feel during the surgery. The nurse may tell them that the OR will be cold, but they can ask the perioperative nurse for a warm blanket; the lights in the OR are very bright; or there will be lots of sounds that are unfamiliar and specific smells. Patients wanting *process information* may not want specific details but desire the general flow of what is going to happen. Patients can be advised that a nurse and anaesthesiologist will speak with them in the preoperative unit; then they will go to the OR, and, when they wake up, they will be in the PACU. After this, they will be transferred back to their postoperative room or home. With *procedural information*, desired details are more specific: for example, an IV line will be started while patients are in the holding area, and, in the OR, patients will be asked to move onto the narrow bed, and a safety strap will be put over their thighs.

Preoperative patient teaching is a perianesthesia nursing team effort; PAC nurses initiate teaching, perioperative nurses continue it, and the postoperative and discharge nurses reinforce and supplement it. Community nurses who visit the patient at home, in the community, or in extended-care facilities after surgery must also be cognizant of the surgical teaching plan. All teaching should be documented in the patient's medical record. A patient and caregiver teaching guide for preoperative preparation is presented in Table 20-7. Additional information related to patient teaching may be found in Chapter 4.

TABLE 20-7

PATIENT & CAREGIVER TEACHING GUIDE
Preoperative Preparation

Sensory Information
• Holding area is often noisy. • Drugs and cleaning solutions may cause chemical odours. • Operating room can be cold; warming blankets are available. • Talking may be heard in the OR but will be distorted because of masks. Questions should be asked if something is not understood. • OR bed will be narrow. A safety strap will be applied over the thighs. • Lights in the OR can be very bright. • Machines (making ticking and pinging noises) may be heard when awake. Their purpose is to monitor and ensure safety.
Procedural Information
• What to bring and what type of clothing to wear on the day of surgery. • Any changes in time of surgery. • Fluid and food restrictions—fasting guidelines. • Physical preparation required (e.g., bowel or skin preparation with antibacterial cleanser). • Purpose of frequent vital signs assessment. • Pain control and other comfort measures (including any pain scales that a specific hospital might use to assess pain). • Coughing and deep-breathing practice (possibly using incentive spirometry). • How to use a pillow to assist with splinting after surgery. • Insertion of intravenous lines. • Procedure for anaesthesia administration. • Importance of transferring, turning, mobilizing pain management, and postoperative exercises. • Expected procedure for discharge and postoperative support.
Process Information
Information About General Flow of Surgery
• Admission area. • Preoperative holding area, OR, and PACU (recovery area). • Families can usually stay in holding area until surgery. • Families may be able to enter recovery area as soon as patient is awake. • Identification of any technology that may be present on awakening, such as monitors and central lines.
Where Families Can Wait During Surgery and Postoperative Roles
• Patient and family members need to be encouraged to verbalize concerns. • OR staff will notify family when surgery is completed. • Surgeon will usually talk with family following surgery. • A competent adult must accompany the patient upon discharge and continue monitoring the patient at home as per the discharge instructions. • Caregivers have requisite information to contact a health care provider with concerns and questions after discharge.

OR, operating room.

General Surgery Information.

The nurse also provides information specific to the operation being performed and the educational needs of the patient (Table 20-8). All

patients should receive instruction about deep breathing, incentive spirometry, coughing, and mobilizing after surgery. This education is essential because patients may not want to do these activities after surgery unless they are taught the rationale for them and practise them before surgery. Patients and caregivers should be told whether there will be tubes, drains, monitoring devices, or special equipment after surgery and that these devices enable the nurse to safely care for the patient.

TABLE 20-8
SUMMARY OF PREOPERATIVE TEACHING

Topic	What to Teach the Patient	Rationale
Nutrition	• NPO guidelines • Diet increased slowly • Nausea is common—there are medications to help with this	• NPO guidelines help keep the stomach empty, reducing the potential for aspiration during anaesthesia induction. • Diet is increased slowly to prevent gastric overfilling and prevent nausea.
Ambulation	• Ambulate early • May have immobilizers, have to use assistive devices • Leg exercises • May have to wear antiembolism stockings after surgery	• Early ambulation increases circulation, ventilation, muscle tone, and vital capacity; improves gastro-intestinal and urinary function; reduces pain; and supports healing. • Antiembolic stockings reduce the incidence of postoperative formation of deep vein thrombosis.
Breathing	• To perform deep breathing and coughing exercises • Splinting • Use of incentive spirometer	• Postoperative patients are at risk for pulmonary complications (e.g., pneumonia) due to increased respiratory secretions, decreased lung expansion, and depression of the respiratory centre that occurs during general anaesthesia.
Grooming	• Take a bath or shower morning of surgery—may be required to bathe using chlorhexidine • Remove nail polish, artificial fingernails, hair clips, and jewellery (including from piercings) before surgery • Remove dentures and eyeglasses (stored during surgery) • Remove external prosthetics • Remove contact lenses	• Showers remove soil and reduce the number of transient bacteria on the skin. • Nail polish prevents accurate assessment of nail beds and interferes with pulse oximetry. • Jewellery can interfere with patient positioning, cause pressure points, and get caught on equipment. • Dentures and glasses interfere with administering general anaesthesia. • External prosthetics may impair patient transfer and positioning and interfere with intraoperative equipment. • Contact lenses can cause corneal abrasions if left in during surgery.
Medications	• Take preoperative medication as ordered • Consult physician, anaesthesiologist, or surgeon regarding when and what prescribed medications, OTC medications, and herbal remedies should be stopped preoperatively	• Medication is used preoperatively to: Assist with reducing anxiety and sedating the patient Reduce oral secretions Reduce risk of aspiration of gastric contents Reduce nausea and vomiting • Prescribed and OTC medications and herbal remedies may cause surgical complications (e.g., increased bleeding, hypertension, arrhythmias) and may need to be discontinued prior to surgery
Pain control	• Ask for pain medication as needed • Types of pain control (epidural, PCA)	• Early and effective analgesia reduces postoperative problems such as: Decreased lung compliance; risk of atelectasis Decreased mobility; risk of thrombo-embolism Increased risk of myocardial ischemia Impaired immune system Delayed return of bowel and gastric function

Topic	What to Teach the Patient	Rationale
Drains, dressings, and tubings	• Drains (e.g., Jackson-Pratt, Hemovac) • Dressings (staples, sutures) to be expected • Tubing: IV, NG, or epidural tubing	• Preoperative patient and family teaching prepares them for the presence of postoperative drains and tubes. • Patient instruction and postoperative follow-up regarding routine practices for infection control and wound management can reduce the incidence of SSI.
Safety	• Patient identification and allergy wrist band (if appropriate) in place • Instructed to call for assistance to get out of bed • Use of call bell • Instructed not to climb over the side rails	• Identification and allergy wrist bands are important so that all health care providers can identify the patient and immediately be alerted to any allergies. • Patient injury such as rail entrapment and falls can occur if patients try to climb over bed rails.
Preoperative information	• Parking • Time to be at hospital and time of surgery • Waiting areas for family • Length of expected stay	• Preoperative information provides patients and family with guidelines and can mitigate stress on the day of surgery.

IV, intravenous; *NG,* nasogastric; *NPO,* nothing by mouth; *OTC,* over-the-counter; *PCA,* patient-controlled analgesia; *SSI,* surgical site infection.

Examples of individualized teaching may include how to use incentive spirometers or postoperative, patient-controlled analgesia pumps. Examples of surgery-specific information include having an immobilizer (for a patient undergoing a total joint replacement), having an epidural catheter for postoperative pain control, or waking up in the intensive care unit (for a patient requiring extensive surgery).

Ambulatory Surgery Information.

The ambulatory surgery patient or the patient admitted to hospital the day of surgery will need to receive information before admission. The teaching is generally done in the surgeon's office or PAC and reinforced on the day of surgery. Some ambulatory surgical centres have the staff telephone the patient the evening before surgery to answer last-minute questions and to reinforce teaching.

Information provided includes the need for preoperative shower, bowel prep, or medication; arrival time at the hospital; and the time of surgery. Arrival time is usually a minimum of 2 hours before the scheduled time of surgery to allow for the completion of the preoperative assessment and paperwork. Information given can also

include the day-of-surgery events such as patient registration, parking, what to wear, what to bring, and the need to have a responsible adult present for transportation home after surgery.

Restriction of fluids and food is necessary preoperatively to minimize the risk for aspiration when administering general anaesthesia and to decrease the risk for postoperative nausea and vomiting. Fasting, however, is associated with dehydration, hypoglycemia, electrolyte imbalance, and patient discomfort; therefore, the patient must follow guidelines accurately (Falconer, Skouras, Carter, et al., 2014). Dobson, Chong, Chow, and colleagues (2017) recommend instituting guidelines that vary according to patient age and pre-existing medical conditions. Guidelines apply to all forms of anaesthesia, including local and monitored anaesthesia care. Patients undergoing emergency surgery must be assessed to determine the risk of delaying surgery versus the risk for gastric content aspiration. The type and amount of food ingested is considered when determining the duration of fasting, and adults and children should be encouraged to drink clear fluids up to 2 hours before surgery (see Table 20-9). Educating the patient regarding the rationale for adhering to NPO orders improves patient compliance and leads to a decrease in surgical delays and cancellations.

TABLE 20-9

PREOPERATIVE FASTING RECOMMENDATIONS OF THE CANADIAN ANESTHESIOLOGISTS' SOCIETY

Liquid and Food Intake	Minimum Fasting Period (hr)
After drinking clear liquids (e.g., water, clear tea, black coffee, carbonated beverages, and fruit juice without pulp)	2
After ingesting breast milk	4
After light meal (e.g., toast and clear liquids) or after drinking infant formula or nonhuman milk	6
After meal including meat, fried or fatty food	8

Evidence-Informed Practice

Translating Research Into Practice

Gurden Kaur is a 57-year-old woman scheduled for a knee replacement. She has been NPO since midnight and was scheduled to be the third surgical case of the day. Unfortunately, several emergency surgeries have resulted in delays, and she is not expected to leave for surgery for another 4 hours. She tells the nurse that she has a "headache" from missing her "morning coffee." She says she is hungry and thirsty, and, since surgery has been delayed, she would like a cup of coffee.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
For healthy adults, the minimum fasting period for clear liquids before surgery is 2 hours.	NPO restrictions are meant to prevent aspiration and vomiting during surgery. Patients who are NPO from midnight frequently complain of hunger and thirst while waiting for surgery. Patients who regularly drink caffeine in the morning often experience a "caffeine withdrawal" headache when fasting. Clear liquids consist of water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee.	Patient is requesting something to drink given the extended period of fast due to the delay in surgery.

NPO, nothing by mouth.

Decision and Action

The nurse knows that the current protocol of keeping all patients NPO after midnight for surgery does not reflect the best available evidence and that a multidisciplinary task force is working to review and revise the protocol. The nurse decides to call the anaesthesia care provider to discuss Ms. Kaur's situation and request that clear liquids be ordered for her.

Legal Preparation for Surgery

Legal preparation for surgery consists of checking that all required forms have been correctly signed and are present in the chart and that the patient and family clearly understand what is going to happen. The most important of these forms are the signed consent form for the surgical procedure on the correct side (right or left), with no abbreviations, and specific consents for anaesthesia interventions and for blood transfusion. Other forms can include those that have been completed for advance directives and powers of attorney (see Chapter 13).

Consent for Surgery.

It is critical that nurses, as patient advocates, understand the ethical and legal tenets of informed consent. From an ethical perspective, the patient, at all times, has the right to autonomously make his or her own health decisions regarding medical, surgical, or diagnostic treatment.

Before nonemergency surgery can be legally performed, the patient must voluntarily sign an **informed consent** in the presence of a witness. Informed surgical consent is an active process between the surgeon and the patient that allows the patient to assess information and make an informed decision. Legally, a written, signed, and witnessed surgical consent helps protect the patient, surgeon, hospital, and health care team. Surgical consent forms may vary

among facilities; nurses must be familiar with the form and process of obtaining consent in their institution.

According to the Canadian Medical Protective Association (CMPA; 2016), three key elements are required for a consent to be considered valid:

1. It must be voluntary.
2. The patient must have the mental capacity to consent.
3. The patient must be properly informed.

Voluntary Consent.

Patients must be free either to consent to or to refuse treatment without duress, fraud, or coercion. It is considered prudent to have the surgical consent signed by the patient before giving any preoperative drugs that may interfere with patient comprehension. It is the physician's legal responsibility to obtain consent; however, in most institutions, the nurse may witness the patient's signature on the consent form. Preoperatively, the nurse can be a patient advocate, by verifying that the patient voluntarily signed the consent and understands the consent and its implications. If the patient is unclear about operative plans, the nurse may need to contact the surgeon to offer additional information. The patient must be informed that permission for treatment may be withdrawn at any time, even after the consent has been signed.

Documentation of the consent discussion should be made in the patient chart, and, in many Canadian jurisdictions, a signed consent form is a legal requirement before surgery (CMPA, 2016).

Capacity to Consent.

Patient understanding is complex. However, the physician must ensure the patient comprehends the consent discussion, taking into consideration such things as emotional state and language difficulties. A patient has the capacity to consent if he or she understands the nature and effects of the proposed treatment, the consequences of refusing the treatment, and any alternatives to the treatment. Capable patients have a right to refuse to consent.

In all provinces and territories except Quebec, there is no chronological age of consent; capacity to consent is determined by maturity. This means children and youth are considered capable of consenting to or of refusing treatment if their physical, mental, and emotional development allow them to fully appreciate the consequences of their decisions. Additionally, capable minors must give permission (consent) to the physician to have their parents involved in health care decisions. In Quebec, people 14 years and older can give consent (CMPA, 2016).

The patient who is unconscious or who has diminished capacity may have the consent form signed by a responsible family member or legally appointed representative. Hospital policies should be consulted for clarification.

Life-Threatening Situations.

If the patient's life or limb is at risk, the patient is unable to consent, and the substitute decision maker is not available, the doctor does what is immediately necessary based on any known wishes of the patient and then obtains consent as soon as possible.

Properly Informing the Patient.

The physician relates the diagnosis, also explaining any uncertainty about the diagnosis, the proposed treatment, the risks and consequences, the probability of a successful outcome, and the consequences of leaving the medical condition untreated. The patient must know the availability, benefits, and risks of alternative treatments (see the "Ethical Dilemmas" box). Depending on the patient's unique condition, the physician may need to discuss uncommon risks, such as permanent disability or death.

Ethical Dilemmas

Informed Consent

Situation

The nurse discusses with a patient his impending surgery in the preoperative holding area. It becomes obvious that this competent adult patient was not fully informed of the alternatives to this surgery, although he has signed the consent form.

Important Points for Consideration

- Informed consent requires that patients have complete information about the proposed treatment and its possible consequences as well as alternative treatments and possible consequences.
- Risks and benefits of each treatment option must also be explained in order for patients to weigh treatment options.
- It is the surgeon's responsibility to provide this information.
- An important element of informed consent is the opportunity to have questions answered about the various treatment options and their possible outcomes.
- Health care providers must not decide what is best for patients.
- As patient advocate, the nurse must ensure that the patient is not rushed into making an informed decision.

Clinical Decision-Making Questions

1. What should the nurse do?
2. What is the nurse's role as patient advocate in the informed-consent process?

Day-of-Surgery Preparation

Nursing Role

Communication is a major consideration in the patient's surgical experience. Nurses can help patients understand the questions posed preoperatively by taking a "teach-back" approach to verify that patients understand the information they are given and that, if necessary, culturally appropriate translators are available (Health Quality Ontario, 2012).

Surgery preparation will vary depending on whether the patient is an inpatient or an outpatient. The nurse prepares inpatients for surgery, but in the case of outpatient procedures, the patient or a family member may have the responsibility of preoperative preparation.

Nurses, however, must ensure the following are complete before surgery: final preoperative teaching, readiness assessment, and communication of pertinent findings from diagnostic procedures and consults to appropriate health care providers. This can be challenging for investigations done outside the hospital, as in many provinces there is poor data sharing. For instance, in Ontario, only 21% of hospitals, health care organizations, and health care providers can send electronic referrals (Health Quality Ontario, 2012). The chart should include a patient history, physical examination, lab results, baseline vitals, informed consent, and nurses' notes. All critical documentation must accompany the patient or be accessible electronically in the OR.

Most institutions require that a patient has showered or bathed before surgery and is dressed in a hospital gown; underclothes may or may not be permitted. The patient should not wear cosmetics because observation of skin colour will be important. Nail polish is removed because it may skew the results of the pulse oximeter placed on the patient's fingertip and used to monitor oxygenation. An identification band, and, if applicable, an allergy band, is put on the patient. The band(s) must remain on the patient as a means of communicating important information to health care providers

(Figure 20-1). If the patient has been typed and screened for possible blood transfusion, a blood band also may be applied to the patient's wrist. All patient valuables are returned to a family member or locked up according to institutional protocol. If the patient prefers not to remove a wedding ring, in most circumstances, the ring can be taped securely to the finger to prevent loss. All other jewellery (including body piercings) and prostheses such as dentures, contact lenses, and glasses, are generally removed to prevent loss or damage. Hearing aids are usually left in place to allow the patient to better follow instructions. Glasses and hearing aids, if removed, must be returned to the patient as soon as possible following surgery.

FIGURE 20-1 As part of the preoperative preparations, the nurse performs a safety check by verifying that the patient has an identification band (wristband) before going to surgery. Source: Courtesy Susan R. Volk, MSN, RN, CCRN, CPAN, Staff Development Specialist, Christiana Care Health System, Newark, DE.

The patient must void shortly before surgery to prevent involuntary elimination under anaesthesia and reduce the possibility

of urinary retention during early postoperative recovery. The patient should void before administration of any preoperative medication since many preoperative medications can interfere with balance and possibly lead to a fall when the patient is in the bathroom. Voiding should be documented on the patient record. The nurse should determine that all preoperative preparations have been completed and that the signed consent for surgery is present before giving any preoperative medications.

Safety Alert

Use a preoperative checklist (Figure 20-2) to ensure that all preoperative preparations have been completed before the patient is given any sedating medications.

Preoperative Medications.

Preoperative medications are used for a variety of reasons, and patients may receive a single drug or a combination of drugs. The following are examples of preoperative medications:

- *Benzodiazepines* such as midazolam, diazepam (Valium), and lorazepam (Ativan) and *barbiturates* reduce anxiety and are used for their sedative and amnesic properties.

• *Anticholinergics* such as atropine and glycopyrrolate may be given to reduce respiratory and oral secretions.
• *Opioids* such as morphine, meperidine (Demerol), and fentanyl may be given to decrease intraoperative anaesthetic requirements and to decrease pain.
• *Antiemetics* such as metoclopramide may be given to decrease nausea and vomiting after surgery.
• *Antacids* such as sodium citrate increase gastric pH, as do the following histamine H_2-receptor antagonists, in addition to decreasing gastric volume: cimetidine, famotidine (Pepcid), and ranitidine (Zantac).
• *Antibiotics* are routinely given intravenously before surgery or in the OR, with optimal initiation 30 minutes before the incision time. (Some provinces require reporting of prophylactic antibiotic use rates for specific surgical interventions to monitor surgical site infections.)
• *Eye drops* are commonly ordered and administered for the patient undergoing cataract and other eye surgery. The patient may require multiple sets of eye drops to be administered at 5-minute intervals to adequately prepare the eye for surgery.

There is no standard protocol for routine preoperative medications. In order to facilitate patient teaching and eliminate confusion, written preoperative orders clarify which medications should and should not be taken on the day of surgery. If there is any question, the nurse should clarify the orders with the anaesthesiologist. Most patients will be advised to take routine cardiac, antihypertensive, and asthma medications on the day of surgery. In the case of insulin, it is important to clarify the time and amount of the last dose before surgery.

Premedications may be administered by oral, IV, subcutaneous, or intramuscular routes. Oral medications should be given 60 to 90 minutes before the patient goes to the OR. Because patients are fluid restricted before surgery, the patient should swallow these medications with a minimal amount of water. Intramuscular and subcutaneous injections should be given 30 to 60 minutes before arrival at the OR (minimally 20 minutes). IV medications are usually administered to the patient after arrival in the preoperative holding area or OR. The medication administration must be charted immediately. The patient should be told the effects of the medications, such as relaxation, drowsiness, and dry mouth.

Informatics in Practice

Bar-Coding in Medication Administration

- According to Institute for Safe Medication Practices (ISMP) Canada (2013), 38% of medication misadventures occur in the dose administration.
- A surgical patient who receives the appropriate preoperative antibiotic within 60 minutes of the incision being made has a decreased risk of developing a surgical site infection (Canadian Patient Safety Institute, 2014).
- Software systems that bar-code patients and medications can be used to monitor accurate dosage and time of medication administration.

- Data are tracked on a computer-based system.
- Retrospective chart reviews allow health care providers to review the data, see the time patients received antibiotics, and compare the rate of wound infections for those who did and did not receive timely treatment.

Transportation to the Operating Room

If the patient is an inpatient, transport personnel go to the patient's room with a stretcher to transport the patient to surgery. The nurse assists the patient in transferring from the hospital bed to the OR stretcher, and the side rails of the stretcher are raised and secured. The nurse should ensure that the completed chart goes with the patient.

If the patient is an outpatient, the patient may be transported to the OR by stretcher or wheelchair, or, in the absence of premedication, the patient may walk, accompanied, to the OR. The method of transportation must be safe and documented by the nurse responsible for the transfer.

The family or caregivers are instructed where to wait for the patient during surgery. Many hospitals have a surgical waiting room where OR personnel communicate the status of the patient to the family. It is in this waiting room that the surgeon can locate the family after surgery and where families can be notified when surgery is complete. Some hospitals provide pagers to waiting family members so that they may eat or run errands during the surgery.

While the patient is in surgery, the patient's room is prepared to accommodate the patient's needs after surgery, the bed is made and raised to stretcher height, and, if necessary, disposable pads are placed for any anticipated drainage. There should be a basin, soap, towels, and clean gown available in the patient's room. Necessary equipment, including those for vital signs, IV administration, oxygen, suction, kidney basin, and additional pillows for positioning, should also be placed in the room and organized to facilitate entry of the stretcher or hospital bed. Having the room

ready and equipped makes the patient transfer from the PACU smooth.

Culturally Competent Care

Patient About to Undergo Surgery

In Canada, health care providers must be aware and supportive of cultural perceptions and beliefs of patients when preparing them for surgery. Decisions made because of cultural variations must be respected and valued. For example, Makokis and Makokis (2015) detail the experience of one of the authors, a 51-year-old Cree woman faced with undergoing a total hysterectomy in the Western medical system. Makokis felt the need to respect and give thanks to her uterus and ovaries, which had given her the gift of two children. She wanted to bring her body parts home from the hospital, wrapped in sage and broadcloth (both have spiritual significance), provide a ceremony for them, and commit them to Mother Earth. Makokis's preparation involved planning ahead with her gynecologist and a First Nations liaison worker. After the surgery, which was uneventful, Makokis was able to carry out her burial ceremony and felt that she had been treated with respect by the health care team.

Age-Related Considerations

Older-Adult Patient About to Undergo Surgery

Many surgical procedures are performed on patients older than 65 years of age, and surgery can be safely performed even on those in their 90s. Frequently performed procedures in older adults include cataract extraction, coronary and vascular procedures, prostate surgery, herniorrhaphy, cholecystectomy, total knee and hip replacements, and repair of fractured hips.

The nurse must be particularly alert when assessing and caring for the older-adult patient undergoing surgery. An event that has little effect on a younger patient may be overwhelming to the older patient. As well, the risks associated with anaesthesia and surgery increase in the older patient. As a whole, the older the patient, the greater the risk for complications after surgery (Rothrock, 2015). However, assessment and consideration of the physiological status of older adults, and not simply their chronological age, are essential when planning surgery and assessing risks. A 75-year-old woman may be biologically healthy and more like a 60-year-old in physiological responses. Conversely, a 55-year-old with multiple chronic health problems may biologically resemble a 75-year-old. The risk for surgical complications in the older adult relates to physiological aging (frailty can be predictive of postoperative outcomes) and changes that compromise organ function, reduce reserve capacity, and limit the body's ability to adapt to stress.

When preparing patients for surgery, a detailed history and complete physical examination are obtained. Preoperative laboratory tests and results, an electrocardiogram, and chest radiograph help plan the choice of and technique for anaesthesia. More than one physician may be involved in geriatric care, so the nurse coordinates the care and the physicians' orders for the patient.

Knowledge of family support is important when considering the continuity of care for the older adult, especially for same-day surgical patients who may be discharged to a family caregiver.

The nurse must remember that many older adults have sensory deficits. Vision and hearing may be diminished, and bright lights may bother those with eye problems. Physical reactions are often slowed as a result of mobility and balance problems, so more time should be allowed for the older adult to complete preoperative testing. Since thought processes and cognitive abilities also may be slowed or impaired, these patients may need extra time to understand preoperative instructions. Remember, however, that not every older person has cognitive deficits. Sensory function and cognition must be assessed and documented (Rothrock, 2015). If, for any reason, the patient cannot sign the consent form for himself or herself, a legal representative of the patient must be present to provide consent for surgery.

Some older adults live in long-term care facilities. Transportation from these agencies must be coordinated so that the arrival time allows for surgery preparation. If a long-term care patient is cognitively impaired, a falls-risk assessment should be completed.

Adding to the stress of the surgical procedure, even a minimally invasive one, the perceived situational change and loss may be overwhelming to the older adult. The threat to independence, lifestyle, and self-esteem may result in ineffective coping. The nurse must be particularly supportive and help the older adult cope with the surgical experience.

Case Study

Patient About to Undergo Surgery

Source: Sergei Bachlakov/Shutterstock.com.

Patient Profile

Mrs. Mary Goodswimmer, an 82-year-old First Nations retired librarian, is admitted to the hospital with compromised circulation of the right lower leg and a necrotic right foot. She was diagnosed with diabetes 40 years ago and takes insulin to maintain appropriate blood glucose levels. She is scheduled for surgery today for a below-knee amputation under spinal anaesthesia. She had a light breakfast at 0600 hours and a glass of apple juice at 1000 hours but has not had anything since. It is now 1300 hours on the day of surgery.

Subjective Data

- History of type 2 diabetes mellitus for 40 years
- History of renal problems
- History of vision problems
- Surgical history that includes a Caesarean section at age 30 and a cholecystectomy at age 65; did not heal well following the last surgery
- Blood glucose has not been well controlled
- Pension cheques barely cover the cost of living and medications
- Lives alone but has family who want her to move in with them following surgery
- Uses herbs to control diabetes and frequently refuses to take insulin

Objective Data

Physical Examination

- Alert, cognitively intact, anxious, older woman with complaints of numbness and lack of feeling in right leg
- Weight, 65 kg; height, 160 cm
- Wears glasses
- Has macular degeneration in her right eye

Diagnostic Studies

- Admission laboratory blood glucose level was 29.8 mmol/L
- Morning finger-stick blood glucose level was 5.3 mmol/L
- Doppler pulses for lower right leg very weak; absent in right foot
- Doppler pulses in left leg present, weak in left foot
- Serum creatinine 221 mmol/L

Collaborative Care

- Scheduled for a below-the-knee amputation of the right leg as the last case of the day

Discussion Questions

1. What factors may influence Mrs. Goodswimmer's response to hospitalization and surgery?
2. ***Priority decision:*** Given Mrs. Goodswimmer's history, what preoperative nursing assessments should be completed and why?
3. What potential perioperative complications might be expected for Mrs. Goodswimmer?
4. ***Priority decision:*** What priority topics should be included in Mrs. Goodswimmer's preoperative teaching plan?
5. ***Priority decision:*** Based on the assessment data presented, identify the priority nursing diagnoses and related interventions. Are there any collaborative problems?

6. ***Evidence-informed practice:*** Mrs. Goodswimmer asks why she received insulin this morning when she has not eaten anything since midnight. How should the nurse respond to her?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Which of the following surgical procedures involves removal of a body organ?
   a. Colostomy
   b. Laparotomy
   c. Mammoplasty
   d. Cholecystectomy
2. Which of the following is one of the most important goals of the preoperative assessment by the nurse?
   a. Determine whether the client's psychological stress is too high to undergo surgery.
   b. Identify what information the client needs to understand before surgery.
   c. Establish baseline data for comparison of the client's status in the intraoperative and postoperative periods.
   d. Determine whether the client's surgery should be done on an inpatient, an outpatient, or a same-day admission basis.
3. A client who is scheduled for a hysterectomy reports using ginkgo biloba to improve her memory. Which of the following questions is the most important for the perioperative nurse to ask the client?
   a. “How long have you used ginkgo biloba?”
   b. “How have you been able to tell if this herb is effective?”
   c. “Have you been taking this herb during the last several weeks?”
   d. “Have you experienced any adverse effects of taking this herbal product?”
4. What is the nurse's role when assisting a client with informed consent before an operative procedure?
   a. Obtains the consent when a surgeon cannot

b. Asks the client to explain what surgical procedure she or he is having and ensures that the client understands the operation to be performed

c. Explains all the risks of the surgical procedure

d. Ensures that the client signs the consent form before preoperative sedation is given

5. What is a *priority* nursing intervention that will assist a client about to undergo surgery to cope with fear of pain?

a. Describe the degree of pain expected.

b. Explain the availability of pain medication.

c. Divert the client when talking about pain.

d. Inform the client of the frequency of pain medication.

6. What is important for the nurse to ensure the client does right before being transported to the operating room?

a. The client must void before surgery.

b. The client must sign the consent form.

c. The client must take any oral preanaesthetic medications.

d. The client must remove all jewellery, which is secured by the nurse.

7. What should the nurse administering preoperative medications recognize before administering the medication?

a. Preoperative medications are used only to decrease client anxiety.

b. Intravenous medications can be administered only by an anaesthesiologist on the day of surgery.

c. A preoperative diazepam (Valium) tablet should be administered within 15 minutes of scheduled surgery.

d. Preoperative opioids given to decrease pain may help reduce intraoperative anaesthetic requirements.

8. Preoperative considerations for older adults include which of the following? (*Select all that apply*)

a. Using only large-print educational materials

b. Speaking louder for clients with hearing aids
c. Recognizing that sensory deficits may be present
d. Providing warm blankets to prevent hypothermia
e. Teaching important information early in the morning

1. d; 2. c; 3. c; 4. b; 5. a; 6. a; 7. d; 8. c, d.

CHAPTER 21

Nursing Management

Intraoperative Care

Written by, Anita Jo Shoup, David M. Horner *

Adapted by, Debra Clendinneng

LEARNING OBJECTIVES

1. Describe the roles and responsibilities of the perioperative nurse in the management of patients undergoing surgery.
2. Differentiate the purposes of the three different areas of the surgical suite and the proper attire for each area.
3. Identify characteristics of the OR environment that contribute to patient safety and infection prevention.
4. Describe the activities and responsibilities of the members of the surgical team.
5. Prioritize the needs of patients undergoing surgery.
6. Describe basic principles of aseptic technique used in the operating room.
7. Discuss the importance of safety in the positioning of patients related to surgical procedure, equipment, and anaesthesia.
8. Differentiate between general and regional or local anaesthesia, including advantages, disadvantages, and rationale for choice of the anaesthetic technique.
9. Identify the basic techniques used to induce and maintain general anaesthesia.

10. Discuss techniques for administering local and regional anaesthesia.

KEY TERMS

anaesthesia care team, p. 405
anaesthesiologist, p. 404
circulating nurse, p. 403

spinal anaesthesia, p. 413
surgeon, p. 404
surgical suite, p. 401

Traditionally, surgery has been performed in hospital operating rooms (ORs). However, the advent of advanced surgical technologies, improvements in the administration of anaesthesia, and changes in the Canadian health care system have altered where and how surgery is delivered. Depending on the acuity of the surgical procedure, it can be performed on an outpatient basis in diverse environments like surgi-centres, ambulatory care settings, and clinics. Today, the majority of surgeries are minimally invasive (MIS) and offer the benefits of shorter hospital stays, decreased postoperative pain and incidence of surgical site infection, and, consequently, a faster return to a normal lifestyle

(Rothrock, 2015). The impact of MIS for the surgical team is shorter procedures requiring quicker turnovers and less time available for perioperative teaching of patient and caregivers. Conversely, complex procedures and use of advanced technologies such as robotics may require longer setups and surgical time.

Despite the variety of settings and range of surgical complexity, the principles of intraoperative patient care remain the same and are discussed in detail in this chapter.

Physical Environment

Department Layout

The **surgical suite** is a controlled environment designed to maximize infection control and provide a seamless flow of patients, personnel, and operative instruments, equipment, and supplies. The suite is divided into three distinct areas: unrestricted, semirestricted, and restricted. The *unrestricted* area provides access to all people in street clothes, who can interact with those in scrub uniforms. These areas typically include the patient admissions area, a staff locker room, the communication or control centre, and offices. The *semirestricted* area includes the peripheral support areas, such as work and storage areas for clean and sterile supplies. Authorized personnel can access semirestricted areas but must wear surgical attire and cover all head and facial hair. *Restricted* areas include the ORs and all areas where sterile supplies are opened. Personnel wear surgical attire and masks (Operating Room Nurses Association of Canada [ORNAC], 2017). Since the restricted area is designed to reduce cross-contamination, personnel may not bring in personal belongings, food, or beverages (ORNAC, 2017), and clean and sterile items must be separated from contaminated supplies and waste by space, time, and traffic patterns. For example, sterile surgical supplies move from the medical device reprocessing department (MDRD) through the clean core and into the restricted OR. Supplies contaminated after surgery are covered or otherwise contained and transported through the peripheral or semirestricted areas to the MDRD decontamination area (ORNAC, 2017).

Preoperative Holding Area

The preoperative **holding area** is an admission and waiting area inside or adjacent to the surgical suite. This preoperative unit may be a centralized area that accommodates numerous patients or a single-patient area immediately outside the OR designated for the surgical procedure. In the holding area, the perioperative nurse identifies and assesses the patient, gives preoperative medications, and, in some

institutions, initiates intravenous (IV) infusions before the patient is transferred into the OR or to an anaesthesia block room. Hospitals that have instituted anaesthesia block rooms have the ability to do neuraxial (spinal and epidural) and peripheral nerve blocks. The presence of these holding rooms reduces anaesthesia prep time in the OR, thus increasing anaesthesia and surgical efficiency (Chazapis, Kaur, & Kamming, 2014). Family or caregivers are often permitted to wait in the holding area with the patient until it is time to be transferred to the OR. This helps relieve patient anxiety.

Operating Room

The **operating room (OR)** is a unique acute care setting specially designed for surgery (Figure 21-1) that, in a hospital, is usually adjacent to the *postanaesthesia care unit* (PACU) and the surgical intensive care unit (ICU). This positioning allows for quick patient transport and proximity to anaesthesia and surgical personnel if complications arise.

FIGURE 21-1 A hybrid operating room. Hybrid ORs are advanced, flexible operating rooms that combine traditional surgical capabilities with the latest imaging modalities such as radiography, computed tomographic (CT) scan, and magnetic resonance imaging (MRI) to improve operating efficiencies.
Source: Courtesy of Healthcare Purchasing News. imageBROKER/Alamy Stock Photo.

ORs are designed using infection-control and safety principles. Airborne transmission of microorganisms and dust is controlled by high-efficiency particulate air (HEPA) filters in the ventilating systems, and controlled positive pressure airflow helps remove anaesthetic gas and toxic fumes. Proper air exchange, temperature, and humidity control provide physical comfort and inhibit bacterial proliferation (ORNAC, 2017). OR furniture and equipment are manufactured from materials that resist the corroding effects of disinfectants, are adjustable, and can be moved. Equipment is checked frequently to ensure proper functioning and electrical safety. Lighting provides a low- to high-intensity range for a precise view of the surgical site (Figure 21-2). Effective integrated voice-over Wi-Fi aids communication workflows in the OR: hands-free communication allows sterile team members to converse without touching anything and provides seamless connectivity between the OR and other support areas. Further, medical devices such as IV infusion pumps, monitors, and radiology machines can connect wirelessly to a network, providing a cord-free environment (Extreme Marketing Team, 2014).

Surgical Team

Registered Nurse

The registered nurse (RN) provides individualized nursing to patients throughout the surgical continuum. In order to address the patient's complex physiological, psychological, sociocultural, and spiritual responses to the surgical event, perioperative nurses require basic and expanded knowledge, skills, and abilities. The Operating Room Nurses Association of Canada (ORNAC) Standards for Perioperative Registered Nursing Practice present the evidence-informed rationale for the structure and resources required in the perioperative environment to promote safe, effective patient care through collaboration with the multidisciplinary team (ORNAC, 2017). Since 1995, perioperative nurses have been able to attain national certification through the Canadian Nurses Association (n.d.) and the designation Certified Perioperative Nurse (Canada). This certification reinforces ORNAC's mission to promote and advance excellence in perioperative patient care (ORNAC, 2017). Expanded roles of the perioperative nurse include registered nurse first assistant (RNFA) and nurse anaesthesiologist.

In the perioperative role, nurses perform either sterile activities (scrub nurse) or unsterile activities (circulating nurse). Canadian ORs have a mixture of registered and practical nurses. The scope of practice for practical nurses allows them to assume the scrub role; however, RNs may perform all aspects of perioperative practice.

Circulating Role.

The scope of perioperative registered nursing practice is a continuum of nursing activities that identify and meet the patient's unique needs throughout the perioperative experience (ORNAC, 2017). Competencies include practising professionally, providing physical and supportive care, promoting a safe environment, responding to urgent situations, and managing resources (ORNAC, 2017). The perioperative nurse orchestrates the preparation of the OR with other members of the surgical team. The nurse is usually the first member of

the surgical team to greet the patient on arrival to the surgical suite and advocates for the patient throughout the intraoperative experience by:

- Maintaining privacy, confidentiality, and dignity
- Providing physical care and comfort
- Ensuring safety
- Promoting communication—for example, explaining steps prior to induction and ensuring they can hear (e.g., hearing aids left in) (ORNAC, 2017)

Some specific intraoperative activities of the circulating nurse are outlined in Table 21-1.

TABLE 21-1
ACTIVITIES OF THE CIRCULATING NURSE

Circulating Role
The perioperative Registered Nurse shall practice in a manner that:
2.1.1 Assesses the health status of the patient
2.1.2 Develops, modifies, and documents the individualized plan of care, or a clinical pathway to meet the specific needs of the patient
2.1.3 Provides resources for the health care team to function efficiently
2.1.4 Provides physical comfort measures specific to each surgical patient
2.1.5 Provides appropriate care during the admission to the operating room, pre-induction, induction, intraoperative, and emergence phases
2.1.6 Performs the surgical count procedure concurrently with the scrub nurse and documents accurately
2.1.7 Uses a surgical conscience to maintain and monitor the integrity of the sterile field
2.1.8 Reduces risk by providing continuous, astute, and vigilant observation of the surgical team throughout the surgical phase, meeting the health care team and patient's needs
2.1.9 Acts as the patient's advocate throughout the perioperative period
2.1.10 Responds to complications and unexpected events during the perioperative period
2.1.11 Demonstrates leadership capabilities and skills to provide a safe and therapeutic environment for the patient
2.1.12 Organizes and coordinates appropriate resources in a timely manner in preparation for the subsequent patient
2.1.13 Provides and assists with procedures/devices required to complete patient care following the surgical procedure
2.1.14 Assists in the patient transfer and postoperative positioning
2.1.15 Accurately and appropriately documents nursing, surgical, and other health care team activities during the perioperative period
2.1.16 Promotes appropriate communication techniques to keep noise levels at a minimum
2.1.17 Assists with patient transport to a receiving unit and communicates pertinent patient information
2.1.18 Organizes and coordinates appropriate resources to ensure an efficient operating room turnover
2.1.19 Has knowledge and awareness of their organization's policies and procedures and implements appropriately

Source: Operating Room Nurses Association of Canada (ORNAC). (2017). *The ORNAC standards, guidelines, and position statements for perioperative registered nurses* (13th ed.). Kingston, ON: Author.

The perioperative nurse knows that all surgical procedures have a potential for adverse outcomes, so they implement evidence-informed guidelines for surgical care by establishing and maintaining infection-control measures, keeping current on new technologies, and carrying out the Surgical Safety Checklist—an interprofessional time out before the surgical incision to verify patient information (Canadian Patient Safety Institute [CPSI], 2015).

Since the implementation of this checklist in 2009, there have been mixed reports on its efficacy. In a Canadian research study, Urbach, Govindarajan, Saskin, and colleagues (2014) reported no significant reductions in operative mortality or complications after the implementation of surgical checklists in Ontario. Conversely, Haugen,

Søfteland, Almeland, and colleagues (2015) promote the use of the checklist, as their research demonstrated a robust reduction in postoperative morbidity and hospital length of stay. Institutions that perform surgery should consider the implementation of safe-surgery checklists and ensure they are applied judiciously (Stock & Sundt, 2015). (See the Resources at the end of this chapter for the Canadian adaptation of the Surgical Safety Checklist.)

Perioperative nurses use critical thinking in assessing patients on an ongoing basis and in responding to changing patient conditions. Examples of nursing activities that characterize each phase of the surgical experience are presented in Table 21-2.

TABLE 21-2

EXAMPLES OF NURSING ACTIVITIES SURROUNDING THE SURGICAL EXPERIENCE

Before Assessment
Home, Clinic, Preoperative Holding Area
• Performs preoperative assessment • Provides appropriate education to meet patient's needs • Involves family and other caregivers in interview and education
Surgical Unit
• Coordinates patient teaching with other nursing staff • Develops a nursing care plan
Surgical Suite
• Identifies patient • Verifies surgical site • Assesses patient's level of consciousness, skin integrity, mobility, emotional status, and functional limitations • Reviews chart
Planning
• Determines a plan of care that incorporates and respects patient's value system, lifestyle, ethnicity, and culture • Ensures all supplies and equipment needed for surgery are available, functioning properly, and sterile if appropriate
During Implementation
Maintenance of Safety
• Ensures integrity of sterile field • Ensures that sponge, needle, and instrument counts are correct • Positions patient to ensure correct alignment, exposure of surgical site, and prevention of injury • Prevents chemical injury from preparation solutions, pharmaceuticals • Ensures safe use of electrical equipment, lasers, and radiation (energy forms) • Safely labels and administers appropriate medications • Handles, labels, documents, and establishes chain of custody for specimens
Monitoring of Physical Status
• Monitors and reports changes in patient's vital signs • Monitors blood loss • Monitors urine output as applicable
Monitoring of Psychological Status
• Provides emotional support by using a patient-centric approach • Stands near or touches patient during procedures and induction • Ensures patient's right to privacy is maintained • Communicates patient's emotional status to other appropriate members of health care team
After Evaluation
Postanaesthesia, Discharge Area
• Determines patient's immediate response to surgical intervention • Monitors vital signs • Safely administers appropriate medications • Discharges according to protocols
Surgical Unit
• Evaluates effectiveness of nursing care in OR using patient outcome criteria • Determines patient's level of satisfaction with care given during perioperative period • Evaluates products used in care of patient in OR • Determines patient's psychological status • Assists with discharge planning
Home, Community Clinic

• Seeks patient's understanding of effects of anaesthetic drugs, surgery's impact on body image, effects of immobilization, and efficacy of pain control—including chronic pain postoperatively • Determines family's perceptions of surgery and ability to cope and function during surgical recuperation

OR, operating room.

The **circulating nurse** is not scrubbed, gloved, or gowned and remains in the unsterile field. This nurse documents nursing and medical activities throughout the perioperative period. Intraoperative documentation includes but is not limited to (ORNAC, 2017):

- Naming all personnel involved in patient care in the OR
- Recording event times, additional interventions such as fluoroscopy, and the surgical procedure performed
- Documenting the patient's positioning, surgical skin preparation, and placement of dispersive pad
- Documenting patient monitoring devices and type of anaesthesia
- Recording all equipment used on the patient including settings and serial numbers
- Noting information for prosthetic implants and other devices left in the patient such as catheters and drains
- Logging of specimens and documenting blood loss and the surgical count
- Making note of any untoward events

Practical Nurse

The scrub role is often performed by a practical nurse who has a perioperative certificate. Practical nurses may assume broader responsibilities depending on patient acuity and hospital policy.

Scrub Role.

The **scrub nurse** is often a practical nurse who performs surgical hand asepsis, is gowned and gloved in sterile attire, and remains in the sterile field assisting the surgical team by preparing and handling instruments. The scrub nurse's duties include setting priorities and ensuring an efficient aseptic setup for the surgical procedure. The nurse monitors aseptic technique throughout the procedure, performs the surgical count concurrently with the circulating nurse, and acts as the patient's advocate during the surgical procedure (ORNAC, 2017). Additionally, the scrub nurse implements patient safety protocols through accurate administration of medication, proper handling and counting of surgical instruments and supplies, management and labelling of specimens, and completion of postoperative documentation.

Surgeon and Assistant

The **surgeon** performs the surgical procedure and is primarily responsible for the following:

- Preoperative medical history and physical assessment, including need for surgical intervention, choice of surgical procedure, and management of preoperative workup
- Informed consent—explaining surgical risks, complications, and alternative treatment options and obtaining written consent
- Patient safety and surgical management in the OR
- Postoperative patient management

The surgeon's assistant holds retractors to expose surgical areas and assists with hemostasis and suturing. The surgeon's assistant is usually a physician but, in educational settings, may be a surgical resident who can perform some portions of the operation under the surgeon's direct

supervision. Some institutions employ RNFAs to assist in surgery under the direct supervision of the surgeon.

Registered Nurse First Assistant

The RNFA is a registered perioperative nurse with formal surgical education, skills, and knowledge who facilitates and supports the health care needs of the patient through the perioperative continuum. The scope of practice allows the RNFA to collaborate with the surgeon in planning preoperative, intraoperative, and postoperative patient care. Intraoperatively, RNFAs handle instruments, provide exposure, manipulate tissue, assist with hemostasis, and suture under direct supervision of the surgeon (ORNAC, 2017).

Anaesthesiologist

According to the Canadian Anesthesiologists' Society (2015), an **anaesthesiologist** is a physician responsible for a patient's comfort and safety during and after surgery. As vital members of the surgical team, anaesthesiologists are experts in administering potent drugs used to deliver general and regional anaesthesia and in ensuring absence of pain during surgery. Anaesthesiologists medically manage the unconscious or insensible patient during interventions requiring anaesthesia. This duty includes protecting vital functions, managing pulmonary and cardiac complications including cardiopulmonary resuscitation (CPR), and caring for critically ill patients.

In larger ORs and teaching hospitals, respiratory therapists or RNs can take advanced education and training in order to work with the anaesthesia care team as anaesthesia assistants. An **anaesthesia care team** is an anaesthesiologist-led care model in which anaesthesiologists practise among a team of other professionals such as nurse practitioners in anaesthesia care, anaesthesia assistants, RNs, and respiratory therapists.

Advanced Nursing Practice Roles

Registered Nurse Anaesthesia Assistant.

A registered nurse anaesthesia assistant (RNAA) is an RN with advanced education, knowledge, and skills in anaesthesia who works in collaboration with and under the supervision of an anaesthesiologist throughout the perioperative period (ORNAC, 2017).

An additional Canadian category of anaesthesia provider is the nurse practitioner in anaesthesia care (NP-A), which requires master's level preparation. These nurse practitioners with specialist education in anaesthesia care work as part of the anaesthesia care team, providing a range of services in preoperative, intraoperative, postoperative, and ambulatory care settings (Bloomberg Faculty of Nursing, 2015).

As the scope of anaesthesia increases, more practitioners are pursuing subspecialties in anaesthesia such as those in critical care, pain medicine and pediatric care, and cardiothoracic care. Nurses in advanced practice anaesthesia roles will have more opportunity to become involved in these areas (Butterworth, Mackey, & Wasnick, 2013).

Nursing Management Patient Before Surgery

Preoperative assessment data and health information provided by the patient and family ensure their active involvement in the care plan and establish baseline data for the perioperative team (Rothrock, 2015).

Psychosocial Assessment

The perioperative nurse must be knowledgeable about the patient's surgery and about its psychological ramifications in order to support the patient. For instance, many patients fear death as a complication of surgery. However, perioperative mortality rates in developed countries are very low, 1 176 per 1 million operations (Bainbridge, Martin, Arango, et al., 2012). Perioperative nurses use this type of current evidence to inform and reassure anxious patients. General questions regarding surgery or anaesthesia can be answered by the perioperative nurse: for example, “When will I go to sleep?” “Who will be in the room?” “How much of my body will be exposed and to whom?” “When will I wake up?” Specific questions relating to the surgical procedure are referred to the surgeon, who is legally responsible for informing the patient about all aspects of the operation (Rothrock, 2015).

Physical Assessment

The surgical patient receives a thorough physical preoperative assessment (see Chapter 20). *Vital signs* provide baseline data used to evaluate the effects of intraoperative medications and body positioning. *Height* and *weight* help the perioperative nurse choose the size of equipment and attachments required for the operating bed. An accurate weight helps calculate fluid requirements and medication dosage, which are determined per kilogram. *Thermoregulation* and the use of warming strategies are indicated by the patient's age, metabolic needs, and type and length of the planned surgical procedure. *Allergic reactions* may be avoided with effective preoperative screening. *Skin*

condition alerts the team to the presence of open or closed lesions that may predispose infections, and noting *skeletal and muscle impairments* helps prevent injury during positioning. Knowledge of perceptual difficulty, such as a *vision or hearing impairment*, allows the nurse to adapt communication techniques to the individual. An *altered level of consciousness* indicates the need for increasing safety measures and vigilance. Identifying sources of patient *pain* and communicating this to perioperative team members ensures patient comfort throughout this period.

Chart Review

Charting requirements vary with hospital policy, patient condition, and specific surgical procedures; for instance, ambulatory surgery facilities have healthier patients, so fewer preoperative tests may be required. Nursing review of the health record includes validating important findings and verifying that appropriate documentation is present, including (Steelman, 2015):

- Consents for:
    - Surgery and anaesthesia
    - Blood transfusion with notation of predeposit autologous donation or contraindications for transfusion (e.g., Jehovah's Witness)
    - Bone harvesting or allograft (receiving bone from another person)
- Preoperative checklist
- History and physical examination

Admitting the Patient

The nurse follows hospital protocol for patient admission to the preoperative holding area and OR. The perioperative nurse greets the patient using a respectful, caring communication style and institutes comfort measures to keep the patient warm and relaxed. The

identification process includes asking the patient to state his or her name, the surgeon's name, the operative procedure, and the site of surgery. This active communication process reduces the risk for error. The nurse compares the patient's unique identification number with the patient's identification band and chart (ORNAC, 2017). The admission procedure verifies items on the preoperative checklist such as NPO status, allergies, presence of dentures or prostheses, and so on. The nurse confirms informed consent, secures personal belongings, and confirms whether preoperative medication was administered (ORNAC, 2017). The patient must have time to get responses to last-minute questions. The nurse completes the chart review, documenting any abnormalities or changes. The patient is seen and assessed by the surgeon and anaesthesiologist before anaesthesia induction.

Once the admission process is complete, the patient may be offered complementary or alternative therapies to decrease anxiety and promote relaxation. Therapeutic touch, guided imagery, aromatherapy, music, and movies are modalities used for surgical patients (Jiménez-Jiménez, García-Escalona, Martín-López, et al., 2013).

Nursing Management Intraoperative Care

Room Preparation

Before the patient enters the OR, nurses start implementing the intraoperative care plan by ensuring all case-specific surgical instrumentation and supplies are available, have been properly sterilized, and are aseptically opened onto the sterile field. The scrub nurse sets up the instrument table, placing instruments and supplies in a predesignated spot so they can be handled systematically and accurately during the surgical procedure. The perioperative nurse determines the type of surgical count: full or partial, depending on the probability of leaving an instrument, sponge, or other item in the incision. Counts are conducted and documented in accordance with ORNAC guidelines and hospital policy (ORNAC, 2017).

Nurses verify the proper functioning and safe operation of electrical and mechanical equipment, ensure patient privacy by limiting personnel in the OR, and are infection-control stewards. The circulating nurse ensures that all people entering the OR are wearing surgical attire. Dress protocols include scrub pants and shirt, mask, protective eyewear, a cap or hood that covers all hair, and absence of jewellery or false nails (Figure 21-3).

FIGURE 21-3 Surgical attire is worn by all persons entering the operating room suite.

Once gowned and gloved, nurses create a sterile environment by disinfecting the incision site and placing sterile sheets (drapes) over the patient to expose only the incision area. Sterile team members can touch only items in the sterile field and must keep their hands at the level of the patient.

The circulating nurse remains outside the sterile field (at least 30 cm [1 foot] away from sterile items) and supports the patient by assisting the anaesthesiologist and surgical team, monitoring aseptic practice, providing ongoing supplies and communication, and documenting care.

Transferring the Patient.

Once the change-over in the OR is done, the patient is identified for the final time and transported into the room for surgery. There, a sufficient number of health care providers must be available to monitor and lift the patient from the stretcher to the OR table, and the wheels of both must be locked to prevent accidents. Once the patient is on the operating table, a safety strap is placed across the patient's thighs; the electrocardiogram monitor leads, oxygen saturation monitor, and blood pressure cuff are applied; and an IV catheter is inserted if it was not started before surgery.

Scrubbing, Gowning, and Gloving.

Although all personnel entering the OR must perform hand hygiene, the surgeon, scrub nurse, and surgical assistant must disinfect their hands and arms using a surgical hand antiseptic or scrub agent. The surgical hand antiseptic or scrub is a broad-spectrum agent that kills microorganisms on contact and supplies persistent protection because it inhibits microbial reproduction. There are different procedures for water-based and waterless hand preparation, and personnel must follow the manufacturer's written instructions and hospital policy (ORNAC, 2017).

After completing the scrub procedure, the team members enter the room and don sterile surgical gowns and gloves, which allow them then to manipulate and organize all sterile items for use during the procedure (Figure 21-4).

FIGURE 21-4 A sterile field is created before surgery. Source: Courtesy the Methodist Hospital, Houston, TX. Photograph by Donna Dahms, RN, CNOR.

Basic Aseptic Technique

The surgical team adheres to surgical aseptic principles with the intention of eliminating patient exposure to exogenous pathogenic microorganisms and thus preventing surgical site infection (Rothrock, 2015). Members of the surgical team share responsibility for monitoring aseptic practice and initiating corrective action when the sterile field is compromised (Rothrock, 2015).

In addition to protecting the surgical patient, the safety of perioperative health care providers must also be considered. Bloodborne pathogens spread via airborne, droplet, or contact transmission, so appropriate infection-control precautions addressing specific methods of transmission are implemented to protect the surgical team (ORNAC, 2017). These guidelines emphasize routine and transmission-based precautions (see Table 17-8), engineering and work practice controls, and the use of personal protective equipment such as gloves, gowns, caps, face shields, masks, and protective eyewear (see Table 17-9 and Table 21-3).

TABLE 21-3
MAINTAINING A STERILE FIELD IN THE OPERATING ROOM

Practice
2.16.1 Opened sterile supplies/setup shall not be left unattended. They shall be continuously monitored for possible contamination.
2.16.2 Unsterile persons shall not reach over the sterile field. Movement is from unsterile to unsterile areas. They should not pass between sterile fields.
2.16.3 Unsterile health care team members shall remain at a safe distance, at least 30 cm (1 ft.), from the sterile field. When approaching the sterile field, unsterile personnel should face the sterile field. Personnel should not pass between sterile fields.
2.16.4 Sterile persons shall not reach over unsterile areas.
2.16.5 Sterile personnel shall stay within the sterile field. Sterile persons shall not walk around or go outside the operating room.
2.16.6 The scrub team should remain close to and face the sterile field. Movement shall be between sterile areas only. If position changes are necessary, scrubbed personnel shall pass face to face or back to back. When changing positions, the scrub personnel should avoid changing levels; personnel either sit or stand. Hands shall be kept above waist level.
2.16.7 Talking should be kept to a minimum.
2.16.8 The sterile setup shall not be covered.
2.16.9 Cover unsterile equipment with sterile barriers before placing them over or in the sterile field. For example, C-arms, laparoscopic cameras, certain positioning devices should be draped for use.
2.16.10 Breaks in aseptic technique shall be recognized, monitored, documented (as per health care facility policy/procedure/protocol) and corrective action taken as soon as safely possible.

Source: Operating Room Nurses Association of Canada (ORNAC). (2017). *The ORNAC standards, guidelines, and position statements for perioperative registered nurses* (13th ed.). Kingston, ON: Author.

Assisting the Anaesthesiologist

In many ORs, it is the perioperative circulating nurse who assists the anaesthesiologist. The nurse is familiar with anaesthetic modalities and effects of anaesthetic drugs and can respond to complications and emergency situations with appropriate medication and equipment (ORNAC, 2017).

Before anaesthetic induction, the circulating nurse may help establish the following monitoring:

- Temperature, pulse, and respiration
- Blood pressure
- Electrocardiogram
- Oxygen saturation
- Arterial, central venous pressure, and pulmonary artery lines
- Input and output (urine, blood loss)

During induction of general anaesthesia through an IV, the nurse remains at the patient's side to ensure safety and to assist the anaesthesiologist by ensuring all necessary equipment is available and functional (e.g., suction is on, laryngoscope is fully lighted, monitoring is initiated) (Figure 21-5). After the patient loses consciousness, the anaesthesiologist can insert a **laryngeal mask airway (LMA)**—a supraglottic airway device that is easily placed and used as a method of elective ventilation—or administer a neuro-muscular blocking drug intravenously, causing skeletal muscle relaxation and enabling the anaesthesiologist to perform a direct laryngoscopy and tracheal intubation. Under direct supervision of the anaesthesiologist, the circulating nurse may assist intubation by applying cricoid pressure, supporting head positioning, administering oxygen, and inflating the endotracheal (ET) tube (ORNAC, 2017).

FIGURE 21-5 Commonly used anaesthesia equipment. *A,* Scissors. *B,* Supplemental oxygen mask. *C,* Nasal trumpet airway. *D,* Guedel oral airway. *E,* Supraglottic airway i-gel; laryngeal mask airway (LMA) "Unique." *F,* Cook intubating LMA. *G,* Endotracheal tube. *H,* Long- and short-handled laryngoscopes with curved Macintosh and straight Miller blades. *I,* Nasogastric/orogastric tube. *J,* Peripheral nerve stimulator. *K,* Elastic bougie endotracheal tube (ETT) introducer. *L,* ETT malleable stylet. *M,* Skin temperature probe. Source: Rothrock, J. C. (2015). *Alexander's care of the patient in surgery* (15th ed., p. 141). St. Louis: Elsevier.

When the patient is receiving regional anaesthesia (spinal, epidural, nerve block, etc.), the circulating nurse assists the anaesthesiologist by placing appropriate monitors on the patient and assisting and supporting patient positioning for the insertion (ORNAC, 2017).

Positioning the Patient

Proper patient positioning is a critical part of every procedure. The perioperative team must have in-depth knowledge about the surgical procedure in order to determine the patient's position and optimize surgical exposure. The time the patient will spend on the OR bed and any patient limitations such as arthritis or joint replacements require

special consideration (Hiezenroth, 2015). Anaesthesia blocks sensory nerve impulses, so the patient will not feel pain, discomfort, or stress being placed on nerves, muscles, bones, or skin. Improper positioning, however, may result in muscle strain, joint damage, pressure injuries, and untoward effects like hypotension and oxygen desaturation.

Proper positioning is a team effort that follows administration of the anaesthetic. The anaesthesiologist indicates when to position the patient and assists the surgeon, nurses, and auxiliary staff to comply with recommended safe positioning practices (Hiezenroth, 2015).

The patient's position ensures proper anatomical alignment and functioning while allowing access to the operative site, access for anaesthesia medication administration, patient monitoring, and patent airway maintenance. Principles for positioning include (1) ensuring correct skeletal alignment; (2) preventing pressure on nerves, skin over bony prominences, and eyes; (3) providing for adequate thoracic excursion; (4) preventing occlusion of arteries and veins; (5) providing modesty in exposure; and (6) recognizing and respecting individual needs such as previously assessed aches, pains, or deformities. The perioperative nurse collaborates with the surgical team to plan, implement, and monitor the patient's position throughout the surgical procedure.

As part of the intraoperative nursing care plan, extremities are secured and appropriate padding and support for at-risk areas (e.g., eyes during prone positioning) are provided. Obtaining sufficient physical or mechanical help in positioning avoids unnecessary strain on either the patient or perioperative team (ORNAC, 2017).

Patient positions include supine, prone, Trendelenburg, lateral decubitus, and lithotomy (Figure 21-6). Supine is the most common position and is suited for abdominal, cardiac, and breast surgeries. A variation of the supine is the Trendelenburg position, used in lower abdominal or pelvic surgery, for which it is necessary to see the pelvic organs. The prone position allows easy access for back surgeries (e.g., laminectomies). The lithotomy position is used for genito-urinary procedures such as vaginal hysterectomy and transurethral resection of the prostate.

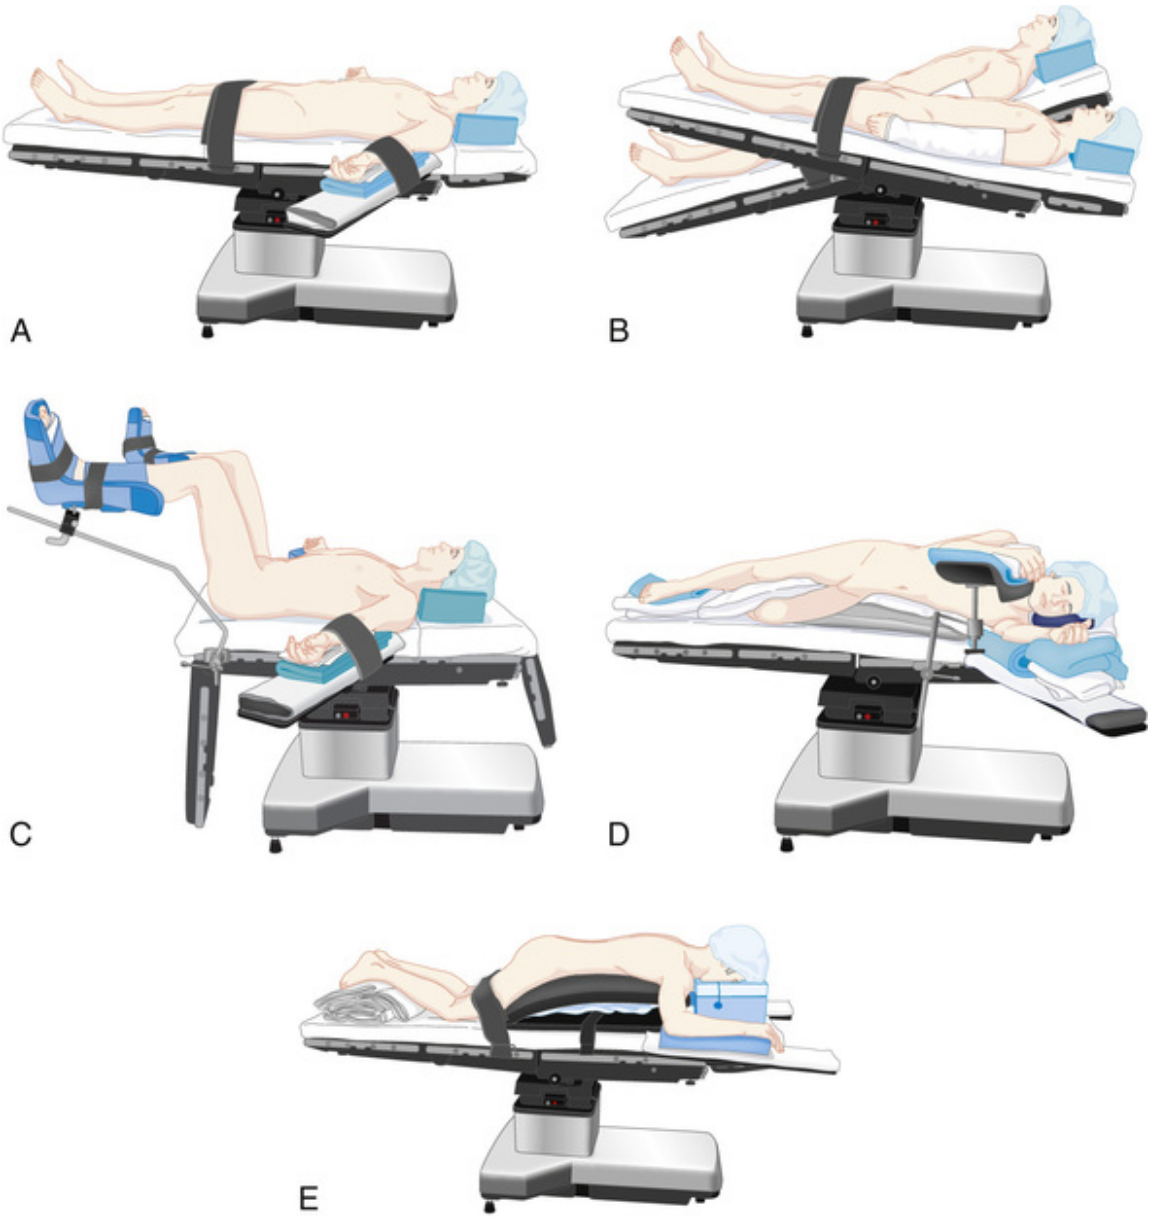

FIGURE 21-6 Common intraoperative patient positioning. **A,** Supine position: abdominal surgery. **B,** Trendelenburg position: pelvic surgery. **C,** Lithotomy position: abdominal perineal resection. **D,** Lateral decubitus position: thoracic surgery. **E,** Prone position with a Wilson frame: spinal surgery. Source: Miller, R. D. (Ed.). (2010). *Miller's anesthesia* (7th ed., pp. 1153, 1155, 1157, 1158, & 1160). Philadelphia: Churchill-Livingstone.

Once the patient is positioned, the circulating nurse applies an adhesive, flexible gel pad called a *dispersive electrode* on a well-muscled, dry, clean area as close to the operative site as possible, avoiding any bony areas, implanted prostheses, or scar tissue (Figure 21-7). The

dispersive pad is connected to the electrosurgical unit (ESU) or electrocautery, which is used by the surgeon to cauterize blood vessels and cut tissue. The dispersive electrode is a safety device that acts as a ground. If for any reason the current from the ESU is interrupted in its return through the dispersive electrode, thermal injury can occur (ORNAC, 2017). An alternative method for grounding the patient is to use a specifically designed gel mattress on the OR bed that connects to the ESU. Patient contact with the mattress provides adequate protection against tissue injury (ORNAC, 2017).

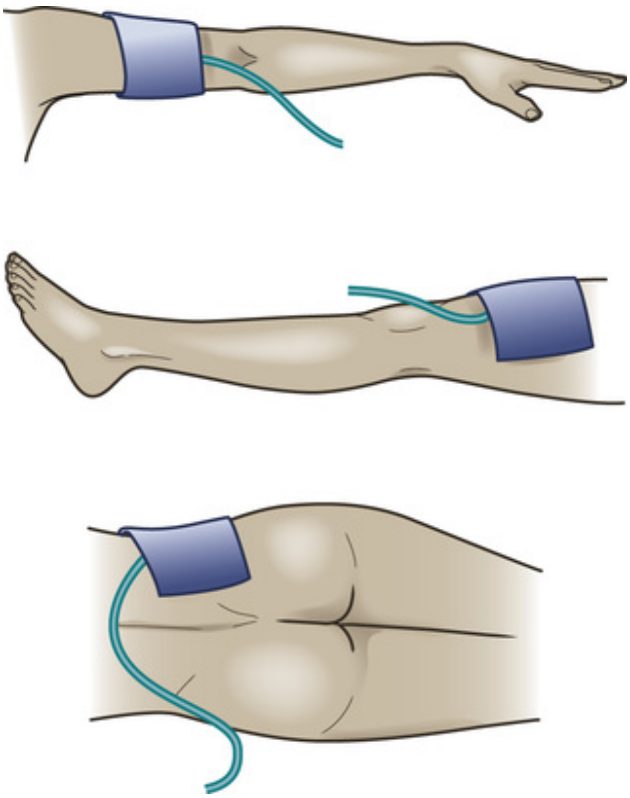

FIGURE 21-7 When an electrosurgical unit is used, well-vascularized muscle mass is an optimal site. Safety can be compromised by excessive hair, adipose tissue, bony prominences, fluid (edema), adhesive failure, and scar tissue.

Source: Courtesy Covidien, Mansfield, MA.

Preparing the Surgical Site

The purpose of skin preparation, or "prepping," is to reduce the number of transient and resident skin microorganisms at and surrounding the surgical incision site. Skin prep is usually the responsibility of the circulating nurse.

Before surgical skin preparation, body-piercing jewellery is removed. Hair is not removed unless it interferes with access to the surgical incision site. The rationale is that hair removal can traumatize skin by causing minor abrasions and increase the incidence of surgical site infections (ORNAC, 2017). In light of this evidence-informed information, surgical units must form their own policies and procedures for determining when hair removal is necessary, while considering the following:

- Hair removal is done after assessment of the patient's skin.
- Hair is clipped, not shaved.
- Clipping is performed close to the time of surgery and in an area outside the OR.
- A depilatory agent may be used for hair removal.
- Hair removal should be done with single-use clippers. Clippers with reusable heads must be disinfected between uses (ORNAC, 2017).

Before prepping the skin, the nurse verifies that the surgeon has marked the incision site with an indelible ink marker. Any lesions, irritation, or abrasions on or near the incision site are documented. The incision site is cleansed using a nontoxic agent that has a fast-acting, broad-spectrum, persistent antimicrobial action and that the patient has no allergies to (Spry, 2015). The area is scrubbed in a circular motion from the clean area (site of the incision) to the dirty area (periphery), with the exception of the umbilicus. If the incision is proximal to the umbilicus, the umbilical area is prepped first to prevent contaminants splashing onto a previously prepped area (ORNAC, 2017). Prep solution must not be allowed to pool, as it may cause chemical skin burns, and it must be allowed to dry thoroughly

before draping and using electrocautery or laser due to the risk for fire (alcohol and heat source) (ORNAC, 2017). After preparation of the skin, the sterile members of the surgical team drape the area leaving the incision exposed.

Safety Considerations

All surgical procedures can put the patient at risk for injury. Injuries include infections and physical injury related to positioning, anaesthesia, or equipment such as lasers and ESUs. The perioperative nurse follows safety protocols to prevent fires and burns. Airborne contaminants and surgical smoke from some equipment produce toxins and carcinogens that irritate the respiratory system and can aerosolize viruses, so smoke evacuators are used during these cases.

Safety Alert

Surgery is the service with the highest percentage of adverse events in Canadian hospitals (CPSI, 2015). Due to the serious repercussions of errors made during surgery, the Canadian Patient Safety Institute recommends using the safe-surgery checklist for all cases. Before administration of anaesthesia, the surgeon, anaesthesiologist, and nursing personnel do a briefing to ensure each item on the checklist has been addressed:

- Patient identity
- Site, side, and level of surgery
- Procedure being performed
- Antibiotic prophylaxis: was initial dose given, and is repeat dose necessary?
- Final surgical positioning of patient
- Any questions or concerns from surgical team members before proceeding

Once the patient is anaesthetized, positioned, prepped, and draped, the team members take a "time out" to reconfirm patient, procedure,

site or side, antibiotic dose, and positioning. The operation can then be conducted.

Before the surgeon leaves the OR, the team has a postoperative debriefing that reviews intraoperative patient care and identifies any concerns for patient recovery. These data become part of the hand-off information to the PACU or ICU nursing staff in the transfer of accountability (ORNAC, 2017).

Classification of Anaesthesia

Anaesthesia is classified according to the effect that it has on the patient's central nervous system and pain perception. **General anaesthesia** is an altered physiological state characterized by reversible loss of consciousness, skeletal muscle relaxation, amnesia, and analgesia. **Local anaesthesia** is the loss of sensation without loss of consciousness and can be induced topically or via intracutaneous or subcutaneous infiltration. **Regional anaesthesia** causes a reversible loss of sensation to a region of the body by blocking nerve fibres with the administration of a local anaesthetic. Examples include spinal, epidural, or peripheral nerve blocks. An advantage of this technique is that the patient remains conscious throughout the procedure.

Procedural (formerly *conscious*) **sedation** is a mild depression of consciousness that results from administration of IV sedatives, analgesics, or both so patients can tolerate minor procedures yet still maintain airway control and protective airway reflexes (Campbell, 2015).

The anaesthesiologist selects the anaesthetic technique and drugs in collaboration with the patient and surgeon. Considerations for choice of anaesthesia include the patient's physical and mental status, age, and allergy and pain history; the length of the surgery; the operative procedure; and discharge plans.

General Anaesthesia

General anaesthesia is the technique of choice for lengthy surgical procedures that require skeletal muscle relaxation and for surgery that requires the patient to be in uncomfortable positions for the duration. General anaesthesia is appropriate for anxious patients and for those who refuse or have contraindications for local or regional anaesthetics.

General anaesthesia can be produced by many different drugs but is primarily administered intravenously or by inhalation. Balanced anaesthetic technique refers to the use of nitrous oxide, neuro-muscular blocking drugs, and opioids during the maintenance phase of general anaesthesia. Table 21-4 presents common anaesthetic drugs

with advantages and disadvantages and the nursing interventions indicated for patients receiving them.

TABLE 21-4
DRUG THERAPY
General Anaesthesia

Drug	Advantage	Disadvantage	Nursing Implications
Preoperative Agents			
Lorazepam (Ativan)	Excellent for patients with anxiety	Must be administered cautiously to patients with hepatic or renal disease and to pediatric or geriatric patients	Ensure patients have signed consent before administering any premedication Ensure side rails on stretcher or bed are up
Midazolam	Short acting; excellent for inducing retrograde amnesia	Has a slower induction than thiopental	Used for premedication and as anaesthetic induction and maintenance agent; no pain on injection; often used in conjunction with regional anaesthetic
Induction Agents			
Propofol (Diprivan)	Ideal for short outpatient procedures because of rapid onset of action and elimination; may be used for induction and maintenance of anaesthesia	May cause bradycardia and other dysrhythmias, hypotension, apnea, phlebitis, nausea and vomiting, hiccups	Short action leads to minimal postoperative effects; monitor injection site for phlebitis; ensure cardiac monitoring if patient condition is unstable
Ketamine (Ketalar)	Can be administered by IV or IM route; potent analgesic and amnestic	May cause hallucinations and nightmares, increased intracranial and intraocular pressure, increased heart rate, hypertension	—
Inhalation Gases			
Volatile Liquids			
Isoflurane (Forane) Desflurane (Suprane) Sevoflurane	All volatile liquids: muscle relaxation, low incidence of nausea and vomiting *Isoflurane:* less cardiac depression, devoid of toxicity to body organs *Desflurane:* rapid induction and emergence, most widely used volatile agent *Sevoflurane:* predictable effects on cardiovascular and respiratory systems, smooth, rapid induction, nonirritating to respiratory system	All volatile liquids: myocardial depression, early onset of postoperative pain because of rapid elimination	Assess and treat pain during early anaesthesia recovery; assess for adverse effects such as cardiopulmonary depression with hypotension and prolonged respiratory depression, confusion, and nausea and vomiting

Drug	Advantage	Disadvantage	Nursing Implications
Gaseous Agents			
Nitrous oxide (N_2O)	Potentiates volatile agents, allowing a reduction in both their dosage and their adverse effects, and accelerates induction	Weak anaesthetic, rarely used alone; must be administered with oxygen to prevent hypoxemia	Produces little or no toxicity; monitor for effects of volatile liquids when N_2O used as an adjunct
Induction: Depolarizing Muscle Relaxants			
Succinylcholine (Quelicin)	Used with intubation or short cases; rapid onset	Can trigger MH crisis	Requires refrigeration; may cause fasciculation
Induction: Nondepolarizing Muscle Relaxants			
Intermediate Onset and Duration			
Atracurium	Used with intubation; maintains relaxation	May have slight histamine release	Requires refrigeration
Rocuronium (Zemuron)	Rapid onset; maintains relaxation	Can increase heart rate (vagolytic)	Eliminated via the kidneys and the liver
Longer Onset and Duration			
Pancuronium	Onset 1–3 min; maintains relaxation	May increase heart rate and blood pressure	Eliminated via the kidneys
Reversal: Cholinergic Agent			
Neostigmine bromide (Prostigmin)	Reverses nondepolarizing neuro-muscular blocker in 3–15 min	Cardiac arrhythmias	Given with atropine sulphate or glycopyrrolate; prevents breakdown of acetylcholine
Anticholinergics			
Atropine sulphate (Atropine)	Blocks effect of acetylcholine; can decrease vagal tone; increases heart rate, suppresses salivary, gastric, and bronchial secretions	May cause dry mouth, CNS symptoms (dizziness)	Used to treat bradycardia
Glycopyrrolate	Blocks effect of acetylcholine; can decrease vagal tone; increases heart rate; suppresses salivary, gastric, and bronchial secretions	Can have prolonged duration of effects	Does not cross blood–brain barrier; has lower incidence of dysrhythmias than atropine sulphate

CNS, central nervous system; *IM,* intramuscular; *IV,* intravenous; *MH,* malignant hyperthermia.

Intravenous Induction Agents.

Routine induction of general anaesthesia in adults usually includes intravenous drug administration, such as midazolam or propofol (Diprivan). These drugs induce a pleasant sleep, with a rapid onset of action that patients find desirable. A single dose lasts only a few minutes, which is long enough for an ET to be placed and an inhalation drug to be started.

In today's clinical anaesthesia, one or two inhalation drugs, in conjunction with a variety of IV medications, are given to produce an anaesthetic state. Inhalation drugs come as a liquid, are vaporized in an anaesthetic machine, and are then delivered to the brain and body tissues via the lungs (Nagelhout, 2014). These drugs are noted for ease of administration and the ability to monitor their alveolar concentration and thus the level of anaesthesia. When the inhalation gas is discontinued at the end of surgery, the drug leaves the tissues via the bloodstream and is excreted through the lungs with ventilation, allowing for rapid reversal of anaesthesia. It is routine practice to administer 100% oxygen (O_2) during emergence to assist with recovery (Nagelhout, 2014). Inhalation drugs are most commonly administered through a mask, an LMA, or an ET tube once the patient has been induced with an IV agent. The ET tube permits control of ventilation and airway protection, both to ensure patency and to prevent aspiration. Complications of ET intubation are associated with insertion and removal and include damage to teeth and lips, laryngospasm, laryngeal edema, postoperative sore throat, and hoarseness caused by injury to or irritation of the vocal cords or surrounding tissues.

IV Drugs and General Anaesthesia.

The administration of general anaesthesia is rarely limited to one agent. For instance, IV opioids, benzodiazepines, and neuro-muscular blocking drugs (muscle relaxants) result in analgesia, amnesia, and muscle relaxation. Maintenance of general anaesthesia can be achieved with total intravenous anaesthesia (TIVA) (Butterworth, Mackey, & Wasnick, 2013). On occasion, reversal agents may be required to speed up the reversal of muscle relaxants and opioids at the end of surgery. See Table 21-4 for nondepolarizing muscle relaxants.

Antiemetic drugs may be given preoperatively, intraoperatively, and postoperatively to prevent the nausea and vomiting that result from anaesthesia. (See Table 21-5 for IV drugs used in general anaesthesia.)

TABLE 21-5
DRUG THERAPY
IV Drugs Used in General Anaesthesia

Drugs	Uses During Anaesthesia	Adverse Effects	Nursing Interventions
Opioids			
Fentanyl Morphine sulphate Sufentanil Alfentanil	Induce and maintain anaesthesia, reduce stimuli from sensory nerve endings, provide analgesia during surgery	Respiratory depression, stimulation of vomiting centre, possible bradycardia and peripheral vasodilation (when combined with anaesthetics), high incidence of pruritus with both regional and IV administration	Assess respiratory status, monitor pulse oximetry findings, protect airway in anticipation of vomiting, use standing orders for antipruritics such as diphenhydramine (Benadryl) and low-dose naloxone
Benzodiazepines			
Midazolam Diazepam (Valium) Lorazepam (Ativan)	Induce and maintain anaesthesia	Potentiation of the effects of opioids, increasing the potential for respiratory depression; hypotension and tachycardia	Monitor cardiopulmonary status, level of consciousness
Antiemetics			
Ondansetron (Zofran) Metoclopramide Dimenhydrinate (Gravol) Promethazine (Histantil) Droperidol	Prevention of vomiting with aspiration during surgery, counteract the emetic effects of inhalation agents and opioids; droperidol often used during surgery; others more often used after surgery	*Droperidol:* dysrhythmias, laryngospasm, bronchospasm, tachycardia, hypotension, CNS alterations, extrapyramidal reactions; contraindicated for use in patients with Parkinson's disease or hypomagnesemia *Other antiemetics:* headache, dizziness, sedation, malaise, fatigue, musculo-skeletal pain, shivers, diarrhea, acute dystonic reactions, cardiovascular alterations; contraindicated for use with patients with hypomagnesemia	Monitor cardiopulmonary status, level of consciousness, and ability to move limbs *Droperidol:* administer with caution in patients with heart disease

CNS, central nervous system; *IV,* intravenous.

Opioids.

Opioids are used before surgery for sedation and analgesia, intraoperatively for induction and maintenance of anaesthesia, and after surgery for pain management. Opioids alter the perception and response to painful stimuli. When administered before the end of

surgery, the residual analgesia often carries over into the PACU, allowing the patient to awaken relatively pain free.

All opioids produce dose-related respiratory depression. Respiratory depression may be difficult to detect in the OR and, therefore, necessitates close observation and pulse oximetry monitoring. Respiratory depression can be reversed with naloxone.

Benzodiazepines.

Benzodiazepines are commonly used before surgery for their sedative and amnestic effects, and less commonly used as induction and maintenance agents. They are used for procedural sedation, as supplemental IV sedation during local and regional anaesthesia, and for postoperative anxiety and agitation. Midazolam is an excellent amnestic drug, has a short duration of action, and causes no pain on injection, so it is frequently used intramuscularly (IM) or intravenously for ambulatory surgery and procedural sedation. Flumazenil is a benzodiazepine antagonist that may be used to reverse marked benzodiazepine-induced respiratory depression.

Neuro-Muscular Blocking Drugs.

Neuro-muscular blocking drugs (muscle relaxants) are used during general anaesthesia to facilitate airway control and to optimize surgical working conditions by providing relaxation (paralysis) of skeletal muscles. These drugs interrupt the transmission of nerve impulses at the neuro-muscular junction. Based on their mechanisms of action, neuro-muscular blocking drugs are classified as either depolarizing or nondepolarizing muscle relaxants. The effects of nondepolarizing muscle relaxants are frequently reversed toward the end of the surgery by the administration of anticholinesterase drugs (e.g., neostigmine [Prostigmin], pyridostigmine [Mestinon]).

A disadvantage of muscle relaxants of special concern to the anaesthesiologist and postanaesthesia nurse is that their duration of action may outlast the surgical procedure, and reversal agents may not be effective in completely eliminating the residual effects. Patients receiving these drugs must be carefully observed for airway patency and adequacy of respiratory muscle movement. Lack of movement or poor return of reflexes and strength may indicate the need for an artificial airway and ventilator. If the patient is intubated, the ET

should not be removed without careful assessment of return of muscular strength, level of consciousness, and the minute volume (respiratory rate times tidal volume [amount of air inhaled and exhaled during a normal ventilation]).

Antiemetics.

Antiemetics, as previously described, are used before, during, and after surgery to prevent and treat nausea and vomiting associated with the administration of anaesthesia. The antiemetics listed in Table 21-5 are most frequently used before and after surgery.

Local Anaesthesia

Local anaesthetics block the initiation and transmission of electrical impulses along nerve fibres. With progressive increases in local anaesthetic concentration, the transmission of autonomic, then somatic sensory, and finally somatic motor impulses is blocked. This produces autonomic nervous system blockade, anaesthesia, and skeletal muscle paralysis in the area of the affected nerve.

Local anaesthesia allows an operative procedure to be performed on a particular part of the body without loss of consciousness or sedation. Because there is little systemic absorption of the drug, recovery is rapid, and the duration of action of the local anaesthetic frequently carries over into the postoperative period, providing continued analgesia. In addition, the use of a local anaesthetic in a regional technique provides an alternative to a general anaesthetic in a physiologically compromised patient.

The disadvantages of local anaesthetics include the technical challenges of performing the block, discomfort that may be associated with injections, inadvertent IV administration producing hypotension and potential seizures, and the inability to precisely match the duration of action of the drugs administered to the duration of the surgical procedure.

Methods of Administration.

There are a variety of methods for administering local anaesthetics (Table 21-6). *Topical application* is application of the agent directly to the skin, mucous membranes, or open surface. A mixture of local

anaesthetics (lidocaine and prilocaine) in a skin cream form can be applied to the skin to produce localized dermal anaesthesia (see Chapter 10). Anaesthetic cream should be applied to the site 30 to 60 minutes before painful procedures. *Local infiltration* is the injection of the agent into the tissues through which the surgical incision will pass.

TABLE 21-6
METHODS FOR ADMINISTERING LOCAL ANAESTHESIA

- Topical application
- Local infiltration
- Regional injection
- Peripheral nerve block
- Intravenous regional block (Bier block)
- Spinal anaesthesia (block)
- Epidural anaesthesia (block)

Regional (peripheral) nerve block is achieved by the injection of a local anaesthetic into or around a specific nerve or group of nerves. Nerve blocks may be used to provide intraoperative anaesthesia and postoperative analgesia and for the diagnosis and treatment of chronic pain. Examples of common regional nerve blocks include brachial plexus, intercostal, and retrobulbar blocks. IV regional nerve block (e.g., Bier block) is the IV injection of a local anaesthetic into an extremity following mechanical exsanguination using a compression bandage and a tourniquet. This type of block provides not only analgesia but also the ability to work in a bloodless field.

Spinal and Epidural Anaesthesia (Neuraxial Blocks).

Spinal and epidural anaesthesia are types of regional anaesthesia referred to as **neuraxial blocks.** Neuraxial anaesthesia blocks pain transmission during surgery and may be used in combination with other techniques (e.g., inhalation or IV anaesthesia) to balance anaesthetic options, thus maximizing benefits and reducing adverse effects of any particular anaesthetic modality (Olson, Pellegrini, & Movinsky, 2014).

Spinal anaesthesia involves the injection of a local anaesthetic into the cerebro-spinal fluid found in the subarachnoid space, usually below the level of L2. The local anaesthetic mixes with cerebro-spinal fluid, and depending on the extent of its spread, various levels of

anaesthesia are achieved. Because the local anaesthetic is administered directly into the cerebro-spinal fluid, a spinal anaesthetic produces an autonomic, sensory, and motor blockade. Patients experience vasodilation and may become hypotensive as a result of the autonomic block, will feel no pain as a result of the sensory block, and will be unable to move as a result of the motor block. The duration of action of the spinal anaesthetic depends on the agent selected and the dose administered. A spinal anaesthetic may be used for intra-abdominal surgery; procedures involving the lower extremities, pelvis, or groin (hernia); and back and spinal surgery.

An **epidural block** involves injection of a local anaesthetic into the epidural (extradural) space via either a thoracic or a lumbar approach. The anaesthetic agent does not enter the cerebro-spinal fluid but works by binding to nerve roots as they enter and exit the spinal cord. This allows the anaesthesiologist to titrate the dosage of medication and better control the extent of sensory or motor block (Olson, Pellegrini, & Movinsky, 2014). A low concentration of local anaesthetic ensures sensory pathways are blocked but allows motor fibres to remain intact. In higher doses, both sensory and motor fibres are blocked (Figure 21-8). Epidural anaesthesia may be the sole anaesthetic for a surgical procedure, or a catheter may be placed to allow for intraoperative use and postoperative analgesia, using lower doses of epidural local anaesthetic, usually combined with an opioid. Epidural anaesthesia is commonly used during labour, as it has minimal impact on maternal and fetal physiology yet offers a comfortable delivery while allowing for immediate maternal–infant bonding. Furthermore, it provides flexibility for surgical options if the patient must convert to Caesarean section (Olson, Pellegrini, & Movinsky, 2014). Epidurals are also used for lower extremity vascular procedures and hip and knee replacements. (Table 21-7 lists some differences between epidural and spinal anaesthetics.)

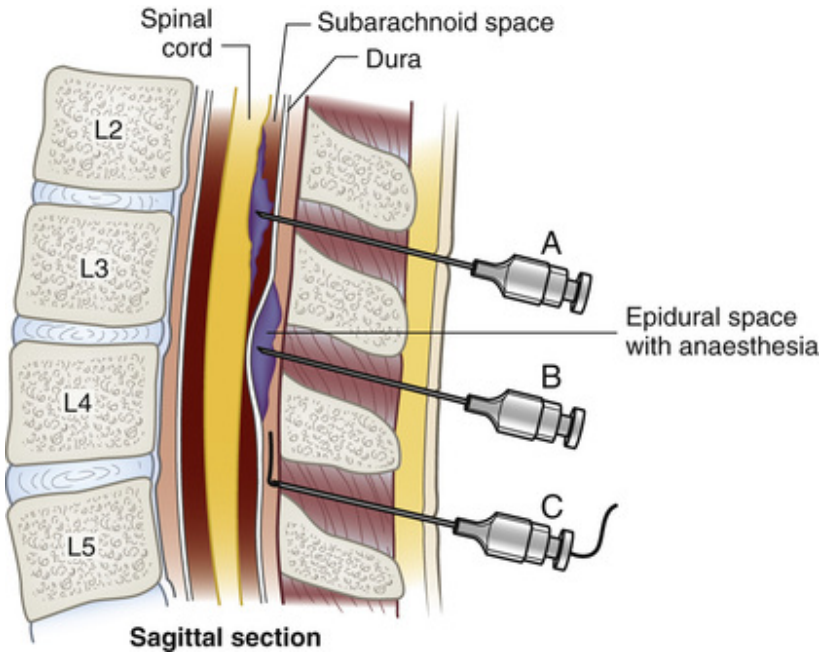

FIGURE 21-8 Location of needle point and injected anaesthetic relative to dura. *A,* Epidural catheter. *B,* Single-injection epidural. *C,* Spinal anaesthesia. (Interspaces most commonly used are L4–L5, L3–L4, and L2–L3.)

TABLE 21-7
DIFFERENCES BETWEEN EPIDURAL AND SPINAL ANAESTHETICS

Drugs	Injection Space	Potential Complications	Postoperative Monitoring
Spinal Anaesthetic (Local)			
Bupivacaine (Marcaine) Lidocaine Tetracaine (Ametop)	Most commonly used interspaces: L4–L5, L3–L4, and L2–L3	Hypotension, total spinal anaesthesia, post–dural puncture headache	Vital signs Motor and sensory block Urinary output and bladder distension Headache assessment
Spinal Anaesthetic (Analgesia)			
Fentanyl Morphine sulphate (preservative-free)	Most commonly used interspaces: L4–L5, L3–L4, and L2–L3	Hypotension; pruritus; urinary retention; nausea, vomiting; infection; epidural hematoma; oversedation *Contraindications:* Septicemia, ↑ ICP, hypovolemia, neurological disease, anticoagulation therapy, spinal fracture	Vital signs Motor and sensory block Urinary output and bladder distension Headache assessment
Epidural Anaesthetic (Local)			
Ropivacaine (Naropin) Lidocaine Bupivacaine	Between the ligamentum flavum and the dura	Bupivacaine can be associated with cardiac toxicity if injected intravascularly	Respiratory assessment Vital signs Sedation score
Epidural Anaesthetic (Analgesia)			
Morphine sulphate (preservative-free) Fentanyl Sufentanil	The dura	Hypotension; pruritus; urinary retention; nausea, vomiting; infection; epidural hematoma; oversedation *Contraindications:* Septicemia, ↑ ICP, hypovolemia, neurological disease, anticoagulation therapy, spinal fracture	Urinary output and bladder distension Assessment for pruritus, nausea, or vomiting Pain assessment Assessment for catheter migration (numbness or tingling) Assessment of dressing and insertion site Headache assessment

ICP, intracranial pressure.

During the surgical procedure that uses either spinal or epidural anaesthesia, the patient can remain fully conscious, or sedation can be achieved intravenously. The onset of spinal anaesthesia is faster than that of an epidural, but the results are similar. The patient must be closely observed for signs of autonomic nervous system blockade, including hypotension, bradycardia, nausea, and vomiting. As well,

inadvertent high blocks or excessive drug dosages can lead to cardiac and respiratory depression (ORNAC, 2017).

One advantage of epidural (extradural) over spinal (subarachnoid) anaesthesia is a decreased incidence of post–spinal anaesthesia headache due to leakage of spinal fluid at the site of injection. The incidence of headache decreases with the use of smaller-gauge (25- to 27-gauge) and noncutting spinal needles.

Because there are varying perceptions of relative and absolute contraindications for administering neuraxial anaesthesia, it is preferable to formulate an anaesthetic plan specific to the patient's unique health status. The following situations and conditions must be considered when determining whether or not to use spinal or epidural anaesthesia or both (Olson, Pellegrini, & Movinsky, 2014):

- Patient refusal or inability to cooperate
- Increased intracranial pressure
- Coagulopathies
- Skin infection at injection site
- Musculo-skeletal deformities
- Hypovolemia and shock
- Diabetic neuropathies
- Cardiac fixed-volume states
- Extreme inebriation or opioid sedation

Procedural (Conscious) Sedation

Procedural sedation is achieved through administration of sedatives, with or without analgesics. It reduces the patient's anxiety and discomfort when undergoing a noninvasive or minimally invasive procedure (Orlewicz, Coleman, Dudley, et al., 2016). Examples of interventions done under procedural sedation include (a) interventional radiology, (b) endoscopy, (c) wound debridement, (d) central line and chest tube placement, (e) dental surgery, and (f) more extensive surgery such as breast biopsy and some cosmetic and reconstructive procedures. Traditionally, this monitored anaesthetic care (MAC) has been provided by and supervised by

anaesthesiologists. Practice is changing, however, with many of these surgical and diagnostic procedures being done outside the OR. Patients may be monitored by other health care team members, such as nurses or anaesthesia assistants, with an anaesthesiologist close by in case of a need to convert to a general anaesthetic or in case of complications.

The Canadian Anesthesiologists' Society (2015) advises using the modified Ramsay sedation scale to determine the patient's level of consciousness. There are six levels in total, with the extremes of (1) the patient is awake, anxious, and agitated and (6) the patient is asleep and does not respond to pain.

Nurses receive education and training in procedural sedation, which is an advanced skill (ORNAC, 2017), before taking on the monitoring role. They should not perform circulating duties at the same time because complications can occur quickly.

Patient After Surgery

The anaesthesiologist anticipates the end of the surgical procedure and titrates doses of anaesthetic drugs so there will be minimal effects at the end of the surgical procedure, allowing the patient greater physiological control during the transfer to the PACU or designated recovery area.

The anaesthesiologist and the perioperative nurse or another member of the surgical team accompany the patient to the PACU. A report of the patient's status and of the procedure is communicated to staff there. The OR nurse evaluates the patient's response to nursing care based on outcome criteria established when the plan of care was developed and transfers nursing care accountability to the health care providers in the PACU using a written and verbal report. The verbal report of nursing care provides continuity of care from one health care provider to another, decreases the risk for error, and provides an opportunity for family-centred care. For instance, the perioperative nurse may have information on where the family is waiting for news of the surgical outcome. Although, traditionally, the surgeon, keeping confidentiality issues in mind, is responsible for providing postoperative information to family or significant others, some hospital policies allow a family member or significant other to visit in

the PACU once the patient is stable. Hand-off communication should include the patient's situation, background, assessment, and recommendations (SBAR). Examples of information included are (Murray, 2015):

- Name and age of patient
- Preoperative diagnosis and comorbid medical problems
- Allergies
- Time of next antibiotic dose, surgical medication administration (e.g., local anaesthesia)
- Operative procedure performed
- Intake/output, vital signs
- Drains, dressing/packing
- Foley catheter, nasogastric tube, and intraoperative drainage
- Intraoperative positioning and postoperative skin assessment
- Physical issues such as loose teeth, deafness, blindness, arthritis
- Psychological disorders and language barriers
- Existence of advance directives
- Intraoperative complications if any

Age-Related Considerations

Patient During Surgery

Anaesthetic drugs are safe and predictable but must be administered to older adults judiciously. Currently, the majority of patients over 65 have one or more chronic problems that may be a risk factor during surgery. In conjunction with physiological deficits due to aging, these may cause varying and unique responses to anaesthetics, blood and fluid management, hypothermia, pain, and the tolerance for the surgical procedure and positioning (Papanier Wells & Flanagan, 2015).

OR nurses must understand the geriatric assessment data required to formulate an intraoperative plan of care—for example, risk for impaired skin integrity (Papanier Wells & Flanagan, 2015):

Risk is related to the patient's current skin condition, such as less elasticity due to decreased collagen, decreased turgor due to dehydration, and decreased peripheral circulation and sensation.

Outcome is that skin integrity remains intact throughout surgery.

Interventions to accomplish this outcome may include assessing the likelihood for pressure injuries, avoiding friction and shearing when moving the patient, ensuring the patient's pressure points are adequately padded when positioned, minimizing tape used to secure devices, and preventing moisture on the linens.

Evaluation takes place immediately postoperatively, when the nurse assesses and documents the patient's skin condition.

Exceptional Clinical Events in the Operating Room

Unanticipated intraoperative events demand immediate interventions by all perioperative team members. Such events include anaphylactic reactions, malignant hyperthermia, hemorrhage due to trauma or disseminated intravascular coagulation (DIC), cardiac arrest, and intraoperative death (ORNAC, 2017).

Anaphylactic Reactions

Anaphylaxis is a severe form of allergic reaction, manifesting with life-threatening pulmonary and circulatory complications. Initial clinical manifestations of anaphylaxis may be masked by anaesthesia. Anaesthesiologists administer an array of drugs to patients, such as anaesthetics, antibiotics, blood products, and plasma expanders, and because they are parenterally administered, they can stimulate an allergic response, so vigilance and rapid intervention are essential. An anaphylactic reaction causes hypotension, tachycardia, bronchospasm, and, possibly, pulmonary edema. Anaesthetics, antibiotics, and latex are responsible for many perioperative allergic reactions. (Anaphylaxis is discussed in Chapter 16.)

Latex allergy remains a concern in the perioperative setting, despite fewer surgical products being manufactured from natural rubber latex. Reactions to natural rubber latex range from urticaria to anaphylaxis, with symptoms appearing immediately or at some time during the surgical procedure.

Policies and procedures must ensure that the health care team can provide a latex-safe environment for patients and staff with potential or actual latex allergy (ORNAC, 2017). (Latex allergies are discussed in Chapter 16.)

Malignant Hyperthermia

Malignant hyperthermia (MH) is a rare, potentially fatal metabolic disease characterized by hyperthermia with rigidity of skeletal

muscles that can affect genetically susceptible patients. It is triggered by commonly administered anaesthetic drugs, particularly succinylcholine (Anectine), which is given during general anaesthesia. MH susceptibility has an inherited autosomal dominant pattern, and thus children of a susceptible parent have a 50% chance of having the genetic defect (Malignant Hyperthermia Association of the United States [MHAUS], 2015). (Autosomal dominant disorders are discussed in Chapter 15.) The MH defect is hypermetabolism of skeletal muscle resulting from altered control of intracellular calcium, leading to muscle contracture, hyperthermia, hypoxemia, lactic acidosis, and hemodynamic and cardiac alterations that can result in cardiac arrest and death. The first sign of MH is often severe masseter muscle rigidity (MMR) that occurs after the administration of succinylcholine and is noted by the anaesthesiologist when trying to establish an airway. MMR should be considered an indication of MH, and treatment should be initiated right away. Other physiological changes, such as a rise in end-tidal carbon dioxide (CO_2) and body temperature, are delayed signs of MH (MHAUS, 2015).

The definitive treatment of MH is prompt administration of dantrolene (Dantrium), which slows metabolism and provides symptomatic support to correct hemodynamic instability, acidosis, hypoxemia, and elevated temperature. A treatment protocol in the form of an interactive MH-emergency smartphone application or a hardcopy poster is available from the Malignant Hyperthermia Association of the United States (MHAUS; see the Resources section at the end of this chapter).

To prevent an MH episode, the nurse must obtain a careful family history and be alert to MH susceptibility preoperatively. The patient known or suspected to be at risk for MH can be anaesthetized with minimal risk if appropriate precautions are taken. Patients with MH susceptibility should inform family members so they are aware of the health care risks and can wear a health alert bracelet or choose to be genetically tested by having a muscle biopsy (ORNAC, 2017).

Major Blood Loss

Surgery can pose a risk for blood loss. If major blood loss occurs during surgery, the circulating nurse assists the anaesthesiologist with

fluid replacement. Initially, crystalloids and colloid solutions are given to maintain fluid volume, but when hemorrhage is significant, blood or blood components may be administered (Lynn & Winner, 2014). Estimating intraoperative blood loss is difficult and requires the circulating nurse to monitor and record all blood accumulation in the suction container (fluid total minus irrigation solution) and to weigh surgical sponges to account for blood from the operative site. Anaesthesiologists may perform serial hemoglobin, hematocrit, and blood gas monitoring using point-of-use monitors in the OR; however, these do not measure blood loss, so, ultimately, it is the anaesthesiologist's calculations and knowledge of the patient's condition that determine the need for blood transfusion therapy (Lynn & Winner, 2014).

New and Future Considerations

Dramatic and rapid changes in perioperative health care are occurring through disruptive technology—ideas and devices that revolutionize how surgery is conceptualized and performed.

Holomers are holographic medical electronic representations of people based on CT scans with physiological processes and vital signs. The computer-generated virtual reality image of organs allows for surgical training and practice on the "virtual patient" before surgery. Add the use of robotics, combined with computer-assisted surgery, and surgeons can achieve surgical precision and enhanced patient outcomes (Rothrock, 2015).

Research is being conducted on high-intensity focused ultrasound (HIFU), which generates heat that can either coagulate tissue and blood or vaporize tissue. By combining HIFU with diagnostic ultrasonography, it will be possible to diagnose a source of internal bleeding, focus the HIFU, and stop the bleeding externally without surgical intervention.

Miniaturization in conjunction with tissue engineering of synthetic organs (Souriau, Herrera Morales, Castagné, et al., 2015) and intelligent prostheses will soon allow replacement of most body parts.

There is also ongoing research data leading to better treatment for patients undergoing surgery—for example, revised fasting guidelines for healthy patients undergoing elective surgery (Rothrock, 2015). (Chapter 20 discusses preoperative fasting guidelines used by the Canadian Anesthesiologists' Society.)

Another example of the surgery of the future is "bloodless surgery," which uses advanced techniques to minimize patient blood loss (Ashley, 2015).

Exciting innovations like these hold much promise for the future of surgery and of health care in general.

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. What is the perioperative nurse's primary responsibility for the care of the client undergoing surgery?
   a. Developing an individualized plan of nursing care for the client
   b. Carrying out specific tasks related to surgical policies and procedures
   c. Ensuring that the client has been assessed for safe administration of anaesthesia
   d. Performing a preoperative history and physical assessment to identify client needs
2. What is the proper attire for the semirestricted area of the surgery department?
   a. Street clothing
   b. Surgical attire and head cover
   c. Surgical attire, head cover, and mask
   d. Street clothing with the addition of shoe covers
3. What is one characteristic of the OR environment that facilitates the prevention of infection in the surgical client?
   a. Adjustable lighting
   b. Conductive furniture
   c. Filters in the ventilating system
   d. Explosion-proof electrical plugs
4. Which of the following activities might a nurse perform in the role of a scrub nurse during surgery? (*Select all that apply*)
   a. Checking electrical equipment
   b. Preparing the instrument table
   c. Passing instruments to the surgeon and assistants
   d. Coordinating activities occurring in the operating room
   e. Maintaining accurate counts of sponges, needles, and instruments

5. What is the most important intervention to perform when a client arrives to the OR with musculo-skeletal impairments?
   a. Ensure proper preparation of the skin.
   b. Ensure the anaesthesiologist uses muscle relaxants.
   c. Ensure positioning on the OR bed to prevent injury.
   d. Provide detailed explanations about the surgical activities.
6. The practical nurse in the OR knows that which of the following is not acceptable for ensuring a sterile field?
   a. Unsterile personnel remaining at least 30 cm from the sterile field
   b. Reaching over the sterile field to place sterile items on the sterile back table
   c. Covering unsterile items such as laparoscopic cameras with sterile barriers before placing them on the sterile field
   d. Flipping a sterile item from a paper peel pack onto the sterile field
7. Which of the following is not a consideration when positioning the surgical client?
   a. Providing modesty for the client
   b. Avoiding compression of nerve tissue
   c. Providing correct skeletal alignment
   d. Ensuring that students in the room can see the operative site
8. A client is scheduled for an abdominal hysterectomy. She is extremely anxious and has a tendency to hyperventilate when upset. What is the most appropriate type of anaesthetic for this client?
   a. A spinal block
   b. An epidural block
   c. A general anaesthetic
   d. A local anaesthetic
9. Why is IV induction for general anaesthesia the method of choice for most clients?
   a. The client is not intubated.
   b. The drugs are nonexplosive.
   c. Induction is rapid and pleasant.

d. The odour of the drug is not offensive.

10. What is the name for the injection of the local anaesthetic into the tissues through the surgical incision?

a. Nerve block

b. Local infiltration

c. Topical application

d. Regional application

CHAPTER 22

Nursing Management

Postoperative Care

Written by, Christine R. Hoch

Adapted by, Debra Clendinneng

LEARNING OBJECTIVES

1. Identify the components of an initial postanaesthesia assessment.
2. Identify the nursing responsibilities in admitting patients to the postanaesthesia care unit (PACU).
3. Explain the etiology and nursing assessment and management of potential problems of patients in the PACU.
4. Describe the initial nursing assessment and management after transfer from the PACU to the general care unit.
5. Explain the etiology and nursing assessment and management of potential problems during the postoperative period.
6. Differentiate discharge criteria from phase I and phase II postanaesthesia care.

syncope, p. 424

The postoperative period begins immediately after surgery and continues until the patient is discharged from medical care. This chapter focuses on the postoperative nursing care required for patients undergoing surgery. After surgery, the primary focus is on protecting the patient, who has been put in physiological risk during surgery, and preventing complications while the body heals. The problems and nursing care related to specific surgical procedures are discussed in the appropriate chapters of this text.

Postoperative Care in the Postanaesthesia Care Unit

The patient's immediate recovery period occurs in a *postanaesthesia care unit* (PACU). It is located adjacent to the operating room (OR) to minimize the transport distance of the patient after surgery and to provide ready access to surgical and anaesthesia personnel. There are three levels of postanaesthesia care, depending on the patient's surgical procedure, anaesthesia, and individualized needs (Table 22-1).

TABLE 22-1
PHASES OF POSTANAESTHESIA CARE

Phase I
• Care during the immediate postanaesthesia period • Focused on the patient's basic life-sustaining needs • Constant, vigilant monitoring *Goal:* Prepare patient for safe transfer to phase II or inpatient unit
Phase II
• Surgery patient is ambulatory *Goal:* Prepare patient for transfer to extended-care environment or home with discharge teaching
Extended Observation
• Ongoing care for patients who will be admitted to the unit and those who require observation or interventions *Goal:* Prepare patient for self-care

Source: American Society of PeriAnesthesia Nurses. (2016). *Perianesthesia nursing core curriculum* (3rd ed.). St. Louis: Elsevier.

Postanaesthesia Care Unit Admission

Admission of the patient to the PACU is a transfer of care from the anaesthesiologist and perioperative nurse to the PACU or perianesthesia nurse. These team members determine what phase of care the patient is assigned.

Postanaesthesia Care Unit Progression

The rate at which patients move through the phases of care in the PACU depends on their condition. An inpatient or outpatient who is stable and recovering well is admitted to phase I care but may rapidly be discharged to either phase II care or an inpatient unit. An accelerated system of care, *fast-tracking,* involves admitting ambulatory surgery patients who have received general, regional, or local anaesthesia directly to phase II care. Patients' safety is the primary consideration when determining what level of postoperative care is provided.

Initial Assessment

On patient admission to the PACU, the anaesthesiologist and perioperative nurse give a verbal report to the admitting perianesthesia nurse. Table 22-2 summarizes the components of a complete anaesthesia report. While the patient is in the PACU, priority care includes the monitoring and management of respiratory and circulatory functions, pain, temperature, and surgical site and the assessment of the patient's response to the reversal of anaesthetic, such as sedation score and level of spinal block.

TABLE 22-2
POSTANAESTHESIA ADMISSION REPORT

General Information
• Patient name
• Age
• Anaesthesiologist name
• Surgeon name
• Surgical procedure
Patient History
• Indication for surgery
• Medical history, medications, allergies
Intraoperative Management
• Anaesthetic medications received
• Other medications received before surgery or intraoperatively
• Blood loss
• Fluid replacement totals, including blood transfusions
• Urine output
Intraoperative Course
• Unexpected anaesthetic events or reactions
• Unexpected surgical events
• Vital signs and monitoring trends
• Results of intraoperative laboratory tests

Assessment should begin with an evaluation of the patient's airway, breathing, and circulation (ABCs) (Table 22-3). The first priority is to establish a patent airway. In order to breathe adequately, the patient may need stimulation, repositioning to the right side, or a chin tilt. If these measures do not work, an oral or nasal airway may be used.

TABLE 22-3
INITIAL POSTANAESTHESIA CARE UNIT ASSESSMENT

Airway • Patency • Oral or nasal airway • Endotracheal tube **Breathing** • Respiratory rate and quality • Auscultated breath sounds • Pulse oximetry • Supplemental oxygen **Circulation** • ECG monitoring—rate and rhythm • Blood pressure • Temperature and colour of skin • Peripheral pulses	**Neurological** • Level of consciousness • Orientation • Sensory and motor status **Gastro-Intestinal–Genito-Urinary** • Intake (fluids, irrigations) • Output (emesis, urine, drains) **Surgical Site** • Dressings and drainage **Pain** • Incision • Other

ECG, electrocardiogram.

Pulse oximetry monitoring is initiated on admission because it provides a noninvasive means of assessing the adequacy of oxygenation and alerts nurses to any respiratory compromise.

Oxygen therapy is used if the patient had general anaesthesia or if ordered by the anaesthesiologist. Oxygen therapy, given via nasal cannula or face mask, aids in eliminating anaesthetic gases and meets the increased oxygen demand due to decreased blood volume or increased cellular metabolism. If the patient requires postoperative ventilation, a ventilator is provided. During the initial assessment, signs of inadequate oxygenation and ventilation should be identified (Table 22-4).

TABLE 22-4
CLINICAL MANIFESTATIONS OF INADEQUATE OXYGENATION

Central Nervous System	**Integumentary System**
• Restlessness	• Cyanosis
• Agitation	• Prolonged capillary refill
• Muscle twitching	• Flushed and moist skin
• Seizures	**Respiratory System**
• Coma	• Alterations ranging from increased to absent respiratory effort
Cardiovascular System	• Use of accessory muscles
• Hypertension	• Abnormal breath sounds
• Hypotension	• Abnormal arterial blood gases
• Tachycardia	**Renal System**
• Bradycardia	• Urine output 30 mL/hour
• Dysrhythmias	

Electrocardiographic (ECG) monitoring may be initiated to determine cardiac rate and rhythm. Deviations from preoperative findings must be noted and evaluated. Blood pressure (BP) should be measured and compared with baseline readings. Invasive monitoring (e.g., arterial BP monitoring) initiated in the OR will be monitored in the PACU. Body temperature, skin colour and condition, and capillary refill should also be assessed. Any evidence of inadequate circulatory status requires prompt intervention.

The *initial neurological assessment* focuses on level of consciousness; orientation; sensory and motor status; and size, equality, and reactivity of the pupils. Hearing is the first sense to return in the unconscious patient, so the nurse should explain all activities to the patient from the moment of PACU admission, including that the surgery is completed, that the patient is in the recovery room, and that the family or significant other has been notified.

A patient who has had a regional anaesthetic (e.g., spinal or epidural) should be assessed for residual sensory and motor blockade by testing for sensation and movement.

Urinary system assessment focuses on intake, output, and fluid balance. Intraoperative fluid totals are communicated during the anaesthesia report. The PACU nurse should note the presence of all intravenous (IV) lines, irrigation solutions and infusions, and output devices such as catheters. IV infusions are regulated according to postoperative orders. If the patient is nauseated or vomiting, the

nurse should administer antiemetic medications as ordered. The colour and amount of emesis should be charted.

The surgical site is assessed by noting the condition of dressings, and the colour and amount of drainage from the incision site or wound drains should be documented. All data obtained in the admission assessment are documented on a specific PACU record.

The goal of PACU care is to identify actual and potential patient problems that may occur as a result of anaesthetic administration and surgical intervention, so the perianesthesia nurse is continually assessing, adjusting diagnoses, and intervening appropriately. Common postoperative problems that require nursing interventions are airway compromise (obstruction), respiratory insufficiency (hypoxemia and hypercarbia), cardiac compromise (hypotension, hypertension, and dysrhythmias), neurological compromise (emergence delirium and delayed awakening), hypothermia, pain, and nausea and vomiting (Figure 22-1). Each of these problems and appropriate nursing interventions are discussed in this chapter.

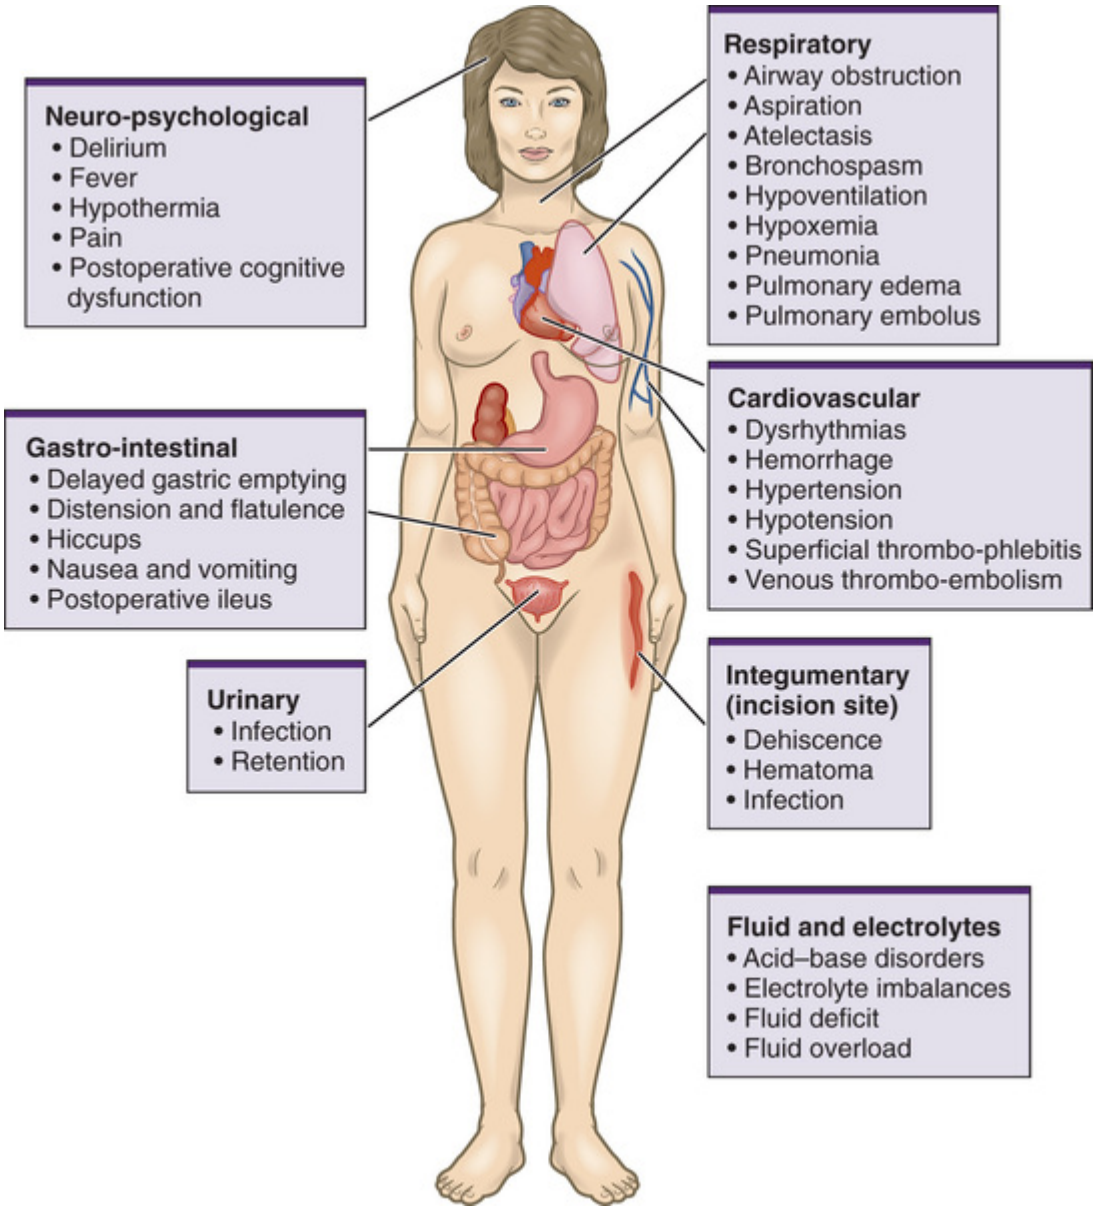

FIGURE 22-1 Potential problems in the postoperative period.

Potential Alterations in Respiratory Function

Etiology

Postanaesthesia Care Unit.

In the immediate postanaesthetic period, the most common causes of airway compromise include obstruction, hypoxemia, and hypoventilation (Table 22-5). Patients at particular risk include those who had general anaesthesia; are older; have a smoking history or lung disease; are obese; or have undergone airway, thoracic, or abdominal surgery. However, respiratory complications may occur in any patient who was anaesthetized.

TABLE 22-5

COMMON IMMEDIATE POSTOPERATIVE RESPIRATORY COMPLICATIONS

Complications and Causes	Mechanisms	Manifestations	Interventions
Airway Obstruction			
Tongue falling back	Muscular flaccidity associated with decreased consciousness and muscle relaxants Most pronounced in supine position Occurrence immediately after surgery but also postoperatively if patient is heavily sedated	Use of accessory muscles Snoring respirations Decreased air movement	Patient stimulation Jaw thrust Chin lift Artificial airway Side positioning
Retained thick secretions	Secretion stimulation by anaesthetic agents Dehydration of secretions	Noisy respirations Wheezing	Suctioning Deep breathing and coughing IV hydration IPPB with mucolytic agent Chest physical therapy
Laryngospasm *Cause:* Most likely to occur after removal of endotracheal tube	Irritation from endotracheal tube or anaesthetic gases	Inspiratory stridor (crowing respiration) Sternal retraction Acute respiratory distress	O_2 therapy Positive pressure ventilation IV muscle relaxant Lidocaine Corticosteroids
Laryngeal edema	Allergic reaction to medication Mechanical irritation from intubation Fluid overload	Similar to laryngospasm	O_2 therapy Antihistamines Corticosteroids Sedatives Possible intubation
Atelectasis *Cause:* Secretions or decreased lung volumes	Mucus blockage of bronchioles Reduced alveolar surfactant (the substance that holds alveoli open)	↓ Breath sounds ↓ O_2 saturation (Figure 22-3) May affect a portion or entire lobe of lungs May occur immediately or in early postoperative period	O_2 therapy Deep breathing Incentive spirometry Early mobilization

Complications and Causes	Mechanisms	Manifestations	Interventions
Pulmonary edema *Cause:* Accumulation of fluid in alveoli from fluid overload, left ventricular failure, prolonged airway obstruction, sepsis, or aspiration	↑ Hydrostatic pressure ↓ Interstitial pressure ↑ Capillary permeability	Crackles on auscultation Infiltrates seen on chest radiograph Fluid overload ↓ O_2 saturation Productive cough with clear to pink sputum	O_2 therapy Diuretics Fluid restriction
Pulmonary embolism *Cause:* Peripheral venous thrombus	Thrombus dislodged from peripheral venous system and lodged in pulmonary arterial system	Acute tachypnea Dyspnea Tachycardia Hypotension ↓ O_2 saturation	O_2 therapy Cardiopulmonary support Anticoagulant therapy
Aspiration *Cause:* Gastric contents (acidic) in respiratory system *Risk factors:* Obesity, pregnancy, history of hiatal hernia, GERD, peptic ulcer, or trauma	Inhalation of regurgitated gastric contents	Potentially serious airway emergency Symptoms: broncho-/laryngospasm, hypoxemia, atelectasis, interstitial edema, alveolar hemorrhage, and respiratory failure. Crackles ↓ O_2 saturation	Prevention is optimal: Premedicate with histamine H_2-receptor antagonist (e.g., famotidine [Pepcid]) before anaesthesia induction Protect airway during induction and emergence from anaesthesia when aspiration occurs O_2 therapy Cardiac support Antibiotics
Bronchospasm *Causes:* History of asthma or COPD; irritation during intubation or extubation; aspiration; suctioning; or chemical mediator release as a result of an allergic response	Increased bronchial smooth muscle tone with resultant closure of small airways Airway edema develops; secretions build up in airway	Wheezing Dyspnea Tachypnea ↓ O_2 saturation Use of accessory muscles	O_2 therapy Bronchodilators
Hypoventilation	Depression of central respiratory drive secondary to anaesthesia or pain medication Neuro-muscular blockade, neuro-muscular disease, or combination of both	↓ Respiratory rate or effort **Hypoxemia** (low oxygen tension in the blood, characterized by a variety of nonspecific clinical signs and symptoms) ↑ Arterial partial pressure of carbon dioxide—hypercapnia ($PaCO_2$)	O_2 therapy Ventilator assistance, manual or mechanical Reversal agent

Complications and Causes	Mechanisms	Manifestations	Interventions
Depression of central respiratory drive	Medullary depression from anaesthetics, opioids, or sedatives	Shallow respirations ↓ Respiratory rate, apnea ↓ PaO_2 ↑ $PaCO_2$	Stimulation Reversal of opioids or benzodiazepines Mechanical ventilation Deep breathing
Poor respiratory muscle tone	Neuro-muscular blockade Neuro-muscular disease	As above	Reversal of paralysis Mechanical ventilation
Mechanical restriction	Tight casts, dressings, positioning, and obesity prevent lung expansion	As above	Elevated head of bed Repositioning Loosening of dressings
Pain	Shallow breathing to prevent incisional pain	As above Complaints of pain Guarding behaviour	Opioid analgesic therapy in reduced dosage
Hypoxemia *Causes:* Atelectasis, aspiration, broncho-/laryngospasm, pulmonary edema, pulmonary embolism	PaO_2 <60 mm Hg O_2Sat <90–92% (common cause is atelectasis)	Nonspecific clinical signs and symptoms: agitation to somnolence, hypertension to hypotension, tachycardia to bradycardia	Deep breathing Coughing Increasing oxygen delivery

COPD, chronic obstructive pulmonary disease; *GERD,* gastro-esophageal reflux disease; *IPPB,* intermittent positive pressure breathing; *IV,* intravenous; O_2, oxygen; $PaCO_2$, arterial partial pressure of carbon dioxide; PaO_2, arterial partial pressure of oxygen.

Airway obstruction is a blockage of the airway, most commonly caused by the patient's tongue (Figure 22-2).

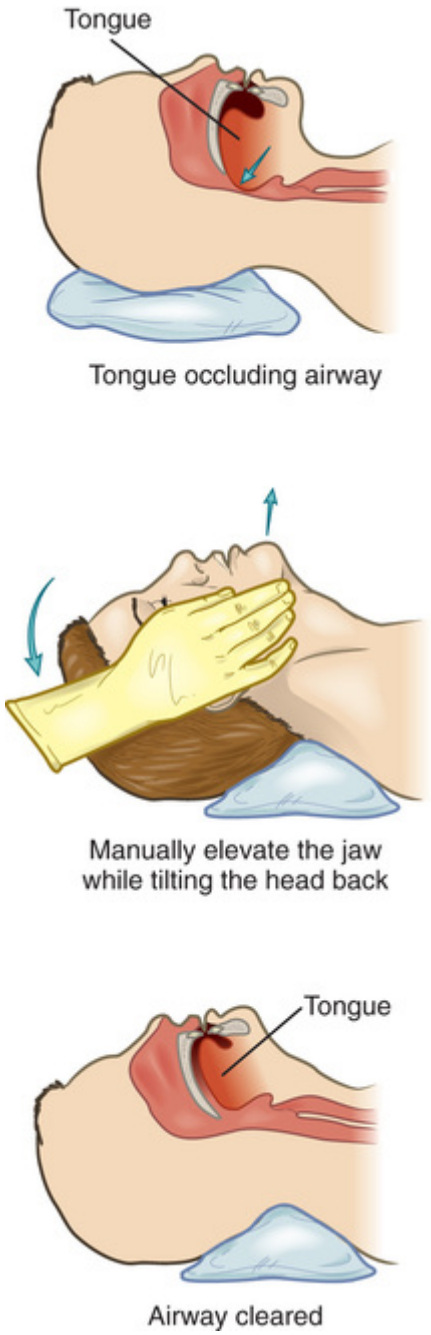

FIGURE 22-2 Causes and relief of airway obstruction caused by the patient's tongue.

Atelectasis is a complete or partial collapse of a lung or segment of a lung that occurs when the alveoli become deflated (Figure 22-3).

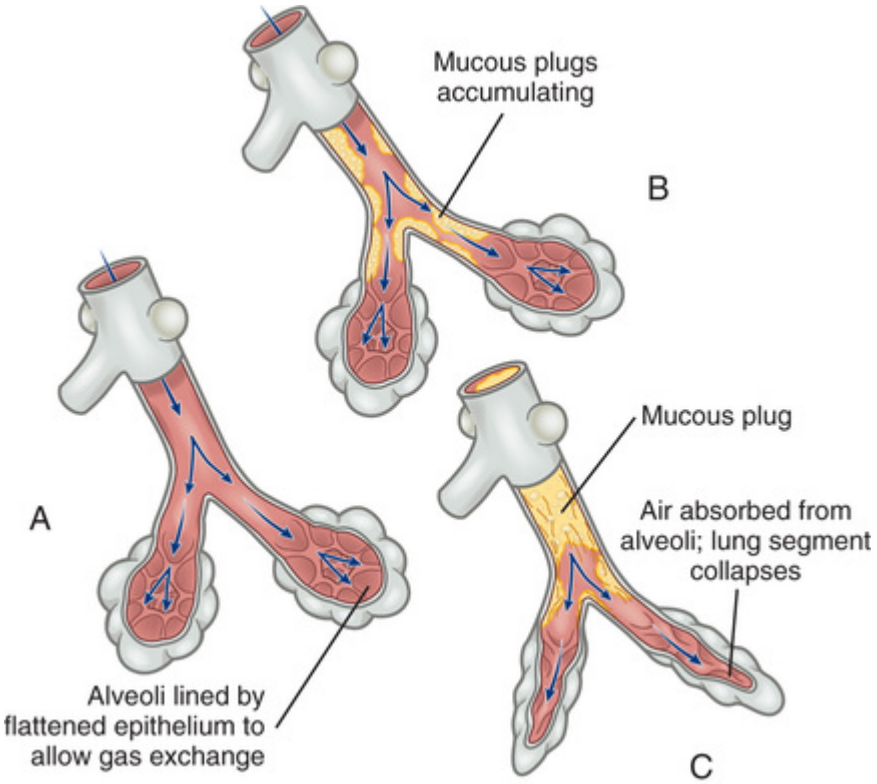

FIGURE 22-3 Postoperative atelectasis. **A,** Normal bronchiole and alveoli. **B,** Mucous plugs in bronchioles. **C,** Collapse of alveoli caused by atelectasis following absorption of air.

Clinical Unit.

Common causes of respiratory problems for postoperative patients in the clinical unit are atelectasis and pneumonia, especially after abdominal or thoracic surgery. Postoperatively, bronchial secretions increase when the respiratory passages have been irritated by heavy smoking, acute or chronic pulmonary infection or disease, and the drying of mucous membranes that occurs with intubation, inhalation anaesthesia, and dehydration. Subsequent postoperative development of mucous plugs that block small bronchi and decreased surfactant production are directly related to hypoventilation, constant recumbent position, ineffective coughing, and history of smoking. Without intervention, the affected lung segment can collapse, become infected, and progress to pneumonia within 2 to 3 days postoperatively.

Nursing Management Respiratory Complications

Nursing Assessment

For an adequate respiratory assessment, nurses in the PACU and clinical unit settings must evaluate airway patency; chest symmetry; and the depth, rate, and character of respirations. The chest wall should be observed for symmetry of movement with a hand placed lightly over the xiphoid process. Slow breathing or diminished chest and abdominal movement during the respiratory cycle may indicate impaired ventilation. The nurse should determine whether abdominal or accessory muscles are being used for breathing, as their use may indicate respiratory distress. Breath sounds should be auscultated anteriorly, laterally, and posteriorly. Decreased or absent breath sounds are detected when airflow is diminished or obstructed. The presence of crackles or wheezes necessitates notifying the physician.

Regular monitoring of vital signs and use of pulse oximetry in conjunction with thorough respiratory assessment permit the nurse to recognize early signs of respiratory complications. Hypoxemia from any cause may be reflected by rapid breathing, gasping, apprehension, restlessness, and a rapid or thready pulse.

The characteristics of sputum or mucus should be noted and recorded. Mucus from the trachea and throat is colourless and thin in consistency. Sputum from the lungs and bronchi can be thick with a slight yellow or pink tinge.

Nursing Diagnoses

Nursing diagnoses and collaborative problems related to potential postoperative respiratory complications for the patient in the PACU or clinical unit include but are not limited to the following:

- *Ineffective airway clearance* related to *excessive mucus, retained secretions*

- *Ineffective breathing pattern* related to *pain, respiratory muscle fatigue*
- *Impaired gas exchange* (related to *hypoventilation*)
- *Risk for aspiration* as evidenced by *decrease in level of consciousness, depressed gag reflex*
- Potential complications: pneumonia, atelectasis

Nursing Implementation

Postanaesthesia Care Unit.

Nursing interventions in the PACU are designed to prevent and treat respiratory problems. Proper patient positioning facilitates respirations and protects the airway. Unless contraindicated by the surgical procedure, the unconscious patient is positioned in a lateral "recovery" position that keeps the airway open and reduces risk for aspiration if vomiting occurs (Figure 22-4). Once conscious, the patient is usually returned to a supine position with the head of the bed elevated. This position maximizes thoracic expansion by decreasing the pressure of the abdominal contents on the diaphragm.

FIGURE 22-4 Position of patient during recovery from general anaesthesia.

Safety Alert

Position the unconscious patient in a lateral “recovery” position (see Figure 22-4) to keep the airway open and reduce the risk for aspiration if vomiting occurs.

Clinical Unit.

Deep breathing is encouraged to facilitate gas exchange and promote the return to consciousness. The patient should be taught to take in slow, deep breaths, ideally through the nose; to hold the breath; and then to exhale slowly. This type of breathing is also useful as a relaxation strategy when the patient is anxious or in pain. Other nursing interventions appropriate for specific respiratory complications are detailed in Table 22-5.

Deep breathing and coughing techniques in the postoperative phase help the patient prevent alveolar collapse and move respiratory secretions to larger airway passages for expectoration. The patient should be stimulated to take three to four deep breaths every 5 to 10 minutes. As well, the sustained maximal inspiratory (SMI) manoeuvre can be used to increase lung volumes postoperatively. The patient inhales to the limit of his or her lung capacity and holds air in the lungs for 3 to 5 seconds before exhaling. Using an incentive spirometer is helpful in providing visual feedback of respiratory effort. The patient is taught to use an incentive spirometer preoperatively by inhaling into the mechanism, holding the ball for about 3 seconds, and then exhaling. This is done 10 to 15 times, and then the patient is encouraged to cough. This technique is used to improve oxygenation and prevent or reverse atelectasis (Odom-Forren, 2013). Diaphragmatic or abdominal breathing is accomplished by inhaling slowly and deeply through the nose, holding the breath for a few seconds, and then exhaling slowly and completely through the mouth. Placing the patient's hands lightly over the lower ribs and upper abdomen allows the patient to feel the abdomen rise during inspiration and fall during expiration.

Effective coughing is essential in mobilizing secretions (see Chapter 30). If secretions are present in the respiratory passages, deep breathing often will move them up to stimulate the cough

reflex, and then they can be expectorated. Splinting an abdominal incision with a pillow or a rolled blanket provides support to the incision and aids in coughing and expectoration of secretions (Figure 22-5).

FIGURE 22-5 Techniques for splinting wound when coughing.

The patient's position should be changed every 1 to 2 hours to allow full chest expansion and increase perfusion of both lungs. Ambulation, not just sitting in a chair, should be aggressively carried out unless contraindicated by the surgical procedure performed or other concurrent diagnoses. Adequate and regular analgesic medication should be provided because incisional pain often deters patient participation in effective ventilation and ambulation. The patient should be reassured that these activities will not cause the incision to separate. Adequate parenteral or oral hydration is essential to maintain the integrity of mucous membranes and keep secretions thin and loose for easy expectoration.

Potential Alterations in Cardiovascular Function

Etiology

Postanaesthesia Care Unit.

In the immediate postanaesthetic period, common cardiovascular complications include hypotension, hypertension, and dysrhythmias. Patients at greatest risk for alterations in cardiovascular function include those with altered respiratory function or a cardiac history, older adults, and debilitated or critically ill patients.

Hypotension is evidenced by signs of hypoperfusion to the vital organs, especially the brain, heart, and kidneys. Clinical signs of disorientation, loss of consciousness, chest pain, oliguria, and anuria reflect hypoxemia and the loss of physiological compensation. Timely intervention may prevent the devastating complications of cardiac ischemia or infarction, cerebral ischemia, renal ischemia, and bowel infarction.

A common cause of hypotension in the PACU is unreplaced intraoperative fluid and blood loss, or postsurgical internal hemorrhage. If changes in level of consciousness and vital signs are detected, treatment is directed toward restoring circulating volume. If there is no response to fluid administration, cardiac dysfunction should be presumed to be the cause of hypotension.

Primary cardiac dysfunction, as in myocardial infarction, cardiac tamponade, or pulmonary embolism, results in an acute fall in cardiac output. Secondary myocardial dysfunction occurs as a result of the negative chronotropic (rate-derived) and negative inotropic (force-derived) effects of drugs, such as β-adrenergic blockers, digoxin, or opioids. Other causes of hypotension include decreased or low systemic vascular resistance and dysrhythmias.

Hypertension, a common finding in the PACU, is most frequently the result of sympathetic nervous stimulation resulting from pain, anxiety, bladder distension, or respiratory compromise.

Hypertension may result from hypothermia or pre-existing hypertension and be seen after revascularization in vascular and cardiac surgery.

Dysrhythmias are often the result of an identifiable cause other than myocardial injury. The leading causes include hypokalemia, hypoxemia, hypercarbia, alterations in acid–base status, circulatory instability, and pre-existing heart disease. Hypothermia, pain, surgical stress, and many anaesthetic agents are also capable of causing dysrhythmias.

Clinical Unit.

Postoperative fluid and electrolyte imbalances contribute to alterations in cardiovascular function. Imbalances develop as a result of a combination of the body's normal response to the stress of surgery, excessive fluid losses, and improper IV fluid replacement, which directly affects cardiac output. Fluid retention during the first 2 to 5 postoperative days can be the result of the stress response (see Chapter 8). This body response maintains both blood volume and BP (see Chapter 8, Figure 8-5). Fluid retention results from the secretion and release of two hormones by the pituitary gland—antidiuretic hormone (ADH) and adrenocorticotrophic hormone (ACTH)—and activation of the renin–angiotensin–aldosterone system. ADH release leads to increased H_2O reabsorption and decreased urinary output, increasing blood volume. ACTH stimulates the adrenal cortex to secrete aldosterone. Fluid losses resulting from surgery decrease kidney perfusion, stimulating the renin–angiotensin–aldosterone system and causing marked release of aldosterone (see Chapter 19). Both of the mechanisms that increase aldosterone lead to significant sodium and fluid retention, which also increases blood volume.

Fluid overload may occur during this period of fluid retention when IV fluids are administered too rapidly, when chronic disease (e.g., cardiac or renal) exists, or with older-adult patients. Conversely, fluid deficit may be related to slow or inadequate fluid replacement, which leads to decreases in cardiac output and tissue perfusion. Untreated preoperative dehydration or intraoperative or

postoperative losses from vomiting, bleeding, wound drainage, or suctioning may contribute to fluid deficits.

Hypokalemia results when potassium is lost through the urinary and gastro-intestinal (GI) tracts and not replaced by IV fluids. Low serum potassium levels directly affect the contractility of the heart, thus contributing to decreased cardiac output and overall body tissue perfusion. Adequate replacement of potassium usually entails administration of 40 mmol/day. However, it should not be given until adequate renal function has been established. A urine output of at least 30 mL/hr is generally considered indicative of adequate renal function.

Cardiovascular status is affected by the state of tissue perfusion or blood flow. The stress response contributes to an increase in clotting tendencies in the postoperative patient by increasing platelet production. Deep-vein thrombosis (DVT) may form in leg veins as a result of inactivity, body position, and pressure, all of which lead to venous stasis and decreased perfusion. DVT, common in older adults and obese or immobilized individuals, is a potentially life-threatening complication because it may lead to pulmonary embolism. Patients with a history of DVT have a greater risk for pulmonary embolism. Pulmonary embolism should be suspected in any patient complaining of tachypnea, dyspnea, and tachycardia, particularly when the patient is already receiving oxygen therapy. Manifestations may include chest pain, hypotension, hemoptysis, dysrhythmias, or heart failure. Definitive diagnosis requires pulmonary angiography. Superficial thrombo-phlebitis is an uncomfortable but less ominous complication that may develop in a leg vein as a result of venous stasis or in the arm veins as a result of irritation from IV catheters or solutions. If a piece of a clot becomes dislodged and travels to the lung, it can cause a pulmonary infarction of a size proportionate to the vessel in which it lodges.

Syncope (fainting) is another factor that reflects the cardiovascular status. It may indicate decreased cardiac output, fluid deficits, defects in cerebral perfusion, or orthostatic hypotension, a fall in BP when the patient sits or stands. This results from peripheral dilation when blood leaves the central body organs, most notably the brain, and moves to the periphery, causing the person to feel faint.

Nursing Management Cardiovascular Problems

Nursing Assessment

Cardiovascular assessment involves frequent monitoring of vital signs, usually every 15 minutes or more often until they stabilize, and then less frequently. Postoperative vital signs are compared with preoperative and intraoperative readings to determine when the signs are stabilized at the patient's normal level. The anaesthesiologist or surgeon should be notified if any of the following occur:

1. Systolic BP is less than 90 mm Hg or greater than 160 mm Hg.
2. Pulse rate is less than 60 beats per minute (bpm) or greater than 120 bpm.
3. Pulse pressure (difference between systolic and diastolic pressures) narrows.
4. BP gradually decreases during several consecutive readings.
5. An irregular cardiac rhythm develops.
6. There is a significant variation from preoperative readings.

Cardiac monitoring is recommended for patients who have a history of cardiac disease and for all older-adult patients who have undergone major surgery, regardless of whether they have cardiac problems. The apical–radial pulse should be assessed, and irregularities should be reported.

Assessment of skin colour, temperature, and moisture provides valuable information for detecting cardiovascular problems. Hypotension accompanied by a normal pulse and warm, dry, pink skin usually represents the residual vasodilating effects of anaesthesia and suggests a need for continued observation. Hypotension accompanied by a rapid pulse and cold, clammy, pale skin may be caused by impending hypovolemic shock and necessitates immediate treatment.

Assessment of cardiovascular function includes regular monitoring of the patient's BP, heart rate, pulse, and skin temperature and colour. Peripheral circulation, dressing, and drains should also be assessed. Results should be compared with the preoperative status and the immediate postoperative and intra-operative findings.

Nursing Diagnoses

Nursing diagnoses and collaborative problems related to potential cardiovascular complications in the PACU and the clinical unit include but are not limited to:

- *Decreased cardiac output* (related to hypovolemia, dysrhythmias)
- *Ineffective peripheral tissue perfusion* related to *sedentary lifestyle* (prolonged immobility)
- *Risk for imbalanced fluid volume*
- Potential complications: hypovolemic shock, venous thrombo-embolism

Nursing Implementation

Postanaesthesia Care Unit.

Nursing interventions in the PACU are designed to prevent and treat cardiovascular complications. Treatment of hypotension should begin with oxygen therapy to promote oxygenation of hypo-perfused organs. Volume status should be assessed, and errors of BP measurement should be ruled out. Because the most common cause of hypotension is fluid loss, IV fluid boluses should be given to normalize BP. Primary cardiac dysfunction may necessitate drug intervention. Peripheral vasodilation and hypotension may necessitate administration of vasoconstrictive agents to normalize systemic vascular resistance.

Hypertension treatment addresses the cause of sympathetic nervous system stimulation. Treatment may include use of analgesics and assistance in voiding. Rewarming corrects hypothermia-induced hypertension. If the patient has pre-existing hypertension or has undergone cardiac or vascular surgery, drug therapy designed to reduce BP may be required.

Most dysrhythmias seen in the PACU have identifiable causes, so treatment is directed toward eliminating the cause. Correcting physiological alterations often corrects the dysrhythmias. In the event of life-threatening dysrhythmias, protocols of advanced cardiac life support are applied (see Chapter 38).

Clinical Unit.

An accurate intake and output record should be kept during the postoperative period, and laboratory findings (e.g., electrolytes, hematocrit) should be monitored. Nursing responsibilities relating to IV management are critical during this period. In particular, the nurse should be alert for symptoms of too slow or too rapid a rate of fluid replacement. The infusion site should also be assessed for discomfort and the hazards associated with the IV administration of potassium, such as cardiac arrhythmias. Thirst is one of the most annoying discomforts of postoperative patients. This may be related to the drying effects of anticholinergic drugs, anaesthetic gases, and fluid deficits. Adequate and regular mouth care is helpful while the patient cannot ingest food or drink by mouth.

When confined to bed, patients should alternately flex and extend all joints 10 to 12 times every 1 to 2 hours while awake. The muscular contraction produced by these exercises and by ambulation facilitates venous return from the lower extremities. The ambulating patient should pick up the feet rather than shuffling them so as to maximize muscular contraction. When the patient is sitting in a chair or lying in bed, there should be no pressure to impede venous flow through the popliteal space. Crossed legs, pillows behind the knees, and extreme elevation of the knee gatch must be avoided.

The use of unfractionated heparin or low-molecular-weight heparin is a prophylactic measure for venous thrombosis and

pulmonary embolism (Rieker, 2014); however, a systematic review by Beitland, Sanden, Kjærvik, and colleagues (2015) revealed a beneficial effect of low-molecular-weight heparin over unfractionated heparin. Some surgeons routinely prescribe use of elastic stockings or mechanical aids such as sequential compressive devices to stimulate the massaging and milking actions that are transmitted to the veins when leg muscles contract. These devices may actually impair circulation if the legs remain inactive or if the devices are sized or applied improperly. Elastic stockings must be removed and reapplied at least twice daily for skin care and inspection.

Before the patient may ambulate, the nurse should first raise the head of the patient's bed for 1 to 2 minutes and then assist the patient to sit on the side of the bed while monitoring the radial pulse for rate and quality. If no changes or complaints are noted, ambulation can be started. Nurses should use transfer belts or have adequate personnel to assist ambulation if the patient is unsteady or unable to transfer herself or himself. If the patient complains of feeling faint during ambulation, the nurse should provide assistance to ease the patient to a supine position until recovery is evidenced by BP stability. While faintness is often frightening for the patient, it poses no real physiological danger, although injury can result from a fall.

Potential Alterations in Neurological Function

Etiology

Postanaesthesia Care Unit.

Occasionally, patients may wake up from anaesthesia in an agitated state referred to as *emergence delirium* (Figure 22-6). This is a reversible neurological alteration in which patients may be disoriented and exhibit bizarre behaviour (Rothrock, 2015). **Emergence delirium** can include restlessness; agitation; disorientation to place, time, and person; thrashing; and shouting. Primarily pediatric and older-adult patients are affected, and it is usually noted about half an hour after surgery but may manifest in up to 24 hours in older adults. Contributing factors include:

FIGURE 22-6 Emergence delirium in the postanaesthesia care unit: contributing factors and treatment. Source: Redrawn from Rothrock, J. C. (2015). *Alexander's care of the patient in surgery* (15th ed., p. 277). St. Louis: Mosby.

- Hypoxia
- Anaesthetic agents
- Bladder distension
- Immobility
- Sensory and cognitive impairments
- Inadequate pain control
- Electrolyte abnormalities
- Presence of an endotracheal tube
- Polypharmacy
- Dehydration and malnutrition

- State of anxiety before surgery

If delirium occurs, the nurse should first rule out hypoxia. Once the cause is determined, the patient can receive appropriate treatment. Nurses may also be able to positively affect the patient's recovery by using interventions that decrease anxiety (Rothrock, 2015).

Delayed awakening is another possible problem after surgery. Fortunately, the most common cause of delayed awakening is prolonged drug action, particularly of opioids, sedatives, and inhalational anaesthetics, as opposed to neurological injury. Normally, the anaesthesiologist can predict awakening based on the drugs used in surgery.

Nursing Management Neurological Complications

Nursing Assessment

After surgery, the nursing assessment should include the patient's level of consciousness, orientation, and ability to follow commands; the size, reactivity, and equality of the pupils; and the patient's sensory and motor status. If the patient had a regional anaesthetic, the level of anaesthetic effect should also be determined by assessing the level of numbness and number of dermatomes blocked. If the neurological status is altered, possible causes should be determined.

Nursing Diagnoses

Nursing diagnoses related to potential neurological complications for the patient in the PACU and the clinical unit include but are not limited to the following:

- *Risk for acute confusion* as evidenced by *sensory deprivation, pharmaceutical agent*
- *Risk for injury* as evidenced by *alteration in cognitive functioning, alteration in sensation*
- *Impaired verbal communication* related to *central nervous system impairment, emotional disturbance*

Nursing Implementation

Postanaesthesia Care Unit.

The most common cause of postoperative agitation is hypoxemia, so the nurse needs to evaluate respiratory function. Once hypoxemia has been ruled out and all potentially known causes have been addressed, sedation may prove beneficial in controlling the agitation

and provide patient and staff safety. Emergence delirium and delays in awakening are time limited and will resolve before the patient is discharged from the PACU. If necessary, benzodiazepines and opioids may be pharmacologically reversed with antagonists.

Until the patient is awake and able to communicate effectively, it is the responsibility of the PACU nurse to act as a patient advocate and to maintain patient safety at all times. Measures to accomplish this include having the side rails up, securing IV lines and artificial airways, verifying the presence of identification and allergy bands, and monitoring physiological status.

Clinical Unit.

On the postoperative unit, the nurse prevents or manages postoperative delirium by maintaining fluid and electrolyte balance, ensuring adequate nutrition and sleep, providing pain management, ensuring proper bowel and bladder function, and aiding early mobilization. Specific aids, such as clocks, calendars, and photographs, help orient the patient.

Psychological problems in the postoperative period can be limited by providing adequate support for the patient, for example, by listening to and talking with the patient, explaining, reassuring, and encouraging caregiver presence.

Some common alterations in neurological function seen on the clinical unit may be related to medications for pain management, sleep deprivation, or sensory overload. It is important that the nurse complete a central nervous system assessment for all patients who have undergone surgery. In the case of patients who are receiving pain medication, the nurse must ensure that they are responsive and oriented to person, place, and time. For patients who have received a spinal or epidural anaesthetic, the nurse must assess sensation and motor function. An ice pack may be used to check a patient's motor block as the effects of the spinal anaesthetic are resolving.

Pain and Discomfort

Etiology

Postanaesthesia Care Unit.

Despite the availability of analgesic drugs and pain-relieving techniques, pain remains a common problem and a significant fear for the patient in the PACU and during the postoperative period. Pain may be the result of surgical manipulation, positioning, or the presence of internal devices such as an endotracheal tube or a catheter, or it may occur as the patient begins to mobilize after surgery.

Clinical Unit.

On the surgical unit, postoperative pain is caused by the interaction of a number of physiological and psychological factors. Skin and underlying tissues have been traumatized during surgery, and there may be reflex muscle spasms around the incision. Anxiety and fear, sometimes related to the anticipation of pain, create tension and further increase muscle tone and spasm. The effort and movement associated with deep breathing, coughing, and changing position may aggravate pain by creating tension or pull on the incisional area.

When the internal viscera are cut, no pain is felt. However, pressure in the internal viscera elicits pain. Therefore, deep visceral pain may signal the presence of a complication such as intestinal distension or bleeding that can occur in the immediate postoperative phase or abscess formation, which can be apparent within 3 to 5 days postoperatively.

Nursing Management Pain

Nursing Assessment

Postanaesthesia Care Unit.

Pain assessment may be difficult in the PACU and in the early postoperative period on the clinical unit. The patient's self-report is the most important means of measuring pain intensity. Physiological indicators such as vital signs are not good indicators of pain, as research has demonstrated no significant correlation between the patient's self-reported intensity of pain and elevated heart rate and BP (Odom-Forren, 2015). When caring for patients who cannot self-report, the nurse should observe for behavioural clues of pain such as crying, restlessness, a wrinkling face or brow, or moaning.

Clinical Unit.

Postoperative pain is usually most severe within the first 48 hours and subsides thereafter. Variation is considerable, however, and is affected by the procedure performed and the patient's individual pain tolerance or perception. A comprehensive pain assessment includes the following:

- Location
- Intensity, assessed using a reliable, valid pain assessment tool (e.g., verbal descriptor, numeric rating, or visual analogue)
- Quality (e.g., neuropathic pain may be described as “burning” or “shooting”)
- Factors that relieve and aggravate
- Effect of pain on function
- Comfort–function goal (e.g., for the postoperative patient, link pain control to the

ability to deep-breathe, turn, or ambulate)

The nurse assesses the effectiveness of all pain control measures (e.g., epidural catheters, patient-controlled analgesia [PCA]) (Odom-Forren, 2014). (See Chapter 10 for a more detailed discussion of pain assessment.)

Nursing Diagnoses

Nursing diagnoses for the patient experiencing pain and discomfort in the PACU and clinical unit include but are not limited to the following:

- *Acute pain* related to *physical injury agent* (surgical procedure)
- *Chronic pain* related to *injury agent, emotional distress*

Nursing Implementation

Postanaesthesia Care Unit.

IV opioids provide the most rapid relief. Medications are administered slowly and titrated to allow for optimal pain management with minimal to no adverse drug effects. More sustained relief may be obtained through the use of epidural catheters, PCA, or regional anaesthetic blockade. Nonpharmacological interventions are used to supplement pain medications and include such measures as touch, application of heat or cold, massage, imagery, music, biofeedback, and reuniting the patient and family (Odom-Forren, 2015).

Pain management is most successful when the treatment plan is developed by the patient, anaesthesiologists, and PACU nurse. The goals should be to determine the most effective therapy, drug, and dose and the best response to therapy. Once the patient is discharged from the PACU to an inpatient unit, the nurse replaces

the PACU nurse as a member of the pain management team. (For more information on nursing assessment and management of patients in pain, see Chapter 10.)

Clinical Unit.

On the surgical unit, postoperative pain relief is a nursing responsibility because the surgeon's orders for analgesic medication and other comfort measures are usually written on an as-needed basis. Pain should be reassessed, as per the assessment protocol previously mentioned, when the patient complains of pain and before and after analgesic administration. When pain is stabilized, pain should be assessed at least every 4 to 8 hours during the first 1 to 2 days postoperatively (Odom-Forren, 2013). Patient complaints of either chest or leg pain should be reported, as it may indicate a complication. If it is gas pain, opioid medication may aggravate it. The nurse should notify the physician and request a change in the order if the analgesic either fails to relieve pain or makes the patient excessively lethargic or somnolent.

During the first 48 hours or longer, opioid analgesics (e.g., morphine) are required to relieve moderate to severe pain. After that, nonopioid analgesics, such as nonsteroidal anti-inflammatory drugs (NSAIDs), may be sufficient as pain intensity decreases.

Effective pain management will reduce harmful complications, promote optimal healing, and allow patients to participate in necessary activities such as ambulating (Rothrock, 2015). Although opioid analgesics are often essential for the postoperative patient's comfort, adverse effects such as constipation, nausea and vomiting, respiratory depression, and hypotension are common. Patient-controlled analgesia (PCA) is one of the most common ways to deliver opioid analgesia. PCA provides immediate analgesia and maintains a constant, steady blood level of the analgesic agent. PCA allows for self-administration of a preset bolus dose of analgesia by the patient (Odom-Forren, 2013). (PCA is discussed in Chapter 10.)

Epidural analgesia is the infusion of pain-relieving medications through a catheter placed into the epidural space surrounding the spinal cord. The goal of epidural analgesia is delivery of medication

directly to opiate receptors in the spinal cord. The administration is through a bolus, continuous infusion, or patient-controlled epidural analgesia and is monitored by the nurse (Odom-Forren, 2013).

Potential Alterations in Temperature

Etiology

Postanaesthesia Care Unit.

Hypothermia sets in when a person's core temperature is less than 35°C. The perianesthesia nurse should monitor the patient's temperature with an electronic oral temperature device (Odom-Forren, 2015). Postoperative hypothermia may be the result of heat loss during long, open surgical procedures due to the low ambient temperature in the OR, the use of cold irrigation fluids, or both.

Patients predisposed to hypothermia include older adults, children under 2 years—especially neonates—burn patients, females, and patients under general or neuraxial anaesthesia (Odom-Forren, 2015). Complications from hypothermia may include prolonged emergence from anaesthesia, increased likelihood of impaired wound healing and surgical site infection, bleeding, and cardiac incidences (Odom-Forren, 2015).

Active rewarming of hypothermic patients is achieved by applying external warming devices to the body and head. Although the application of warm blankets is traditionally done in the PACU, the use of forced-air warmers is an evidence-informed initiative that also effectively rewarms patients (Odom-Forren, 2015). When using any external warming device, the nurse should monitor the patient's body temperature at 15-minute intervals and use care to prevent thermal skin injuries. Oxygen therapy via nasal prongs or mask is used to treat the increased demand for oxygen that accompanies the increase in body temperature. Shivering is usually quickly suppressed by opioids.

Clinical Unit.

Temperature variation in the postoperative period provides valuable information about the patient's status. Fever may occur at any time during the postoperative period (Table 22-6). A mild elevation (≤38°C) during the first 48 hours usually reflects the surgical stress

response. A moderate elevation (>38°C) is caused more frequently by respiratory congestion or atelectasis and less frequently by dehydration. After the first 48 hours, a moderate to marked elevation (>37.7°C) is usually caused by infection.

TABLE 22-6

SIGNIFICANCE OF POSTOPERATIVE TEMPERATURE CHANGES

Time After Surgery	Temperature	Possible Causes
≤12 hours	Hypothermia to 35°C	Effects of anaesthesia Body heat loss in surgical exposure
First 24–48 hours	Elevation to 38°C	Inflammatory response to surgical stress
	>38°C	Lung congestion, atelectasis
Third day and later	Elevation above 37.7°C	Wound infection Urinary infection Respiratory infection Phlebitis

Nursing Management Potential Temperature Complications

Nursing Assessment

Frequent assessment of the patient's temperature in the days after surgery helps detect patterns of hypothermia or fever that may be present postoperatively. The nurse should observe the patient for early signs of inflammation and infection so that any complications that arise may be treated in a timely manner. Infections may include:

- Wound infection
- Respiratory tract infection
- Urinary tract infection (secondary to catheterization)
- IV site superficial thrombo-phlebitis (temperature elevation 7 to 10 days after surgery)
- Hospital-associated diarrhea caused by *Clostridium difficile*
- Septicemia (microorganisms enter bloodstream during surgery, especially in GI or genito-urinary procedures)

Nursing Diagnoses

Nursing diagnoses related to potential postoperative temperature complications may include but are not limited to the following:

- *Hypothermia* related to *decrease in metabolic rate, inactivity*

- *Hyperthermia* related to *increase in metabolic activity, dehydration*
- *Risk for hypothermia* as evidenced by *inefficient nonshivering thermogenesis* (general anaesthesia, surgical procedure)

Nursing Implementation

Postanaesthesia Care Unit.

Passive rewarming (i.e., shivering) raises basal heat metabolism, so active rewarming using forced-air warmers or other devices, such as radiant warmers or heated water mattresses, is preferable. During rewarming, the nurse should also monitor a patient who has an increase in temperature, specifically for symptoms of malignant hyperthermia, because symptoms may not be evident until the postoperative phase. (See the discussion of malignant hyperthermia in Chapter 21). Oxygen therapy via nasal prongs or mask is used to address the increased demand for oxygen that accompanies the increased body temperature. (See Chapter 71 for more on the management of hypothermia.)

Clinical Unit.

The nurse's role with respect to postoperative fever may be preventive, diagnostic, therapeutic, or a combination of these. The patient's temperature is usually measured every 4 hours for the first 48 hours after surgery and then less frequently if no problems develop. As well, the nurse maintains meticulous care of the wound and the IV site and encourages airway clearance. If fever develops, chest radiographs may be done, and, depending on the suspected cause, cultures of the wound, urine, or blood may be obtained. If infection is determined to be the source of the fever, antibiotics are started right away. If the fever rises above 39.4°C, antipyretic drugs and body-cooling measures may be employed.

Potential Gastro-Intestinal Problems

Etiology

Postanaesthesia Care Unit.

Nausea and vomiting are significant problems in the immediate postoperative period and are often the reason for unanticipated hospital admission of day-surgery patients, increased patient discomfort, delays in discharge, and patient dissatisfaction with the surgical experience.

Clinical Unit.

Slowed GI motility and altered patterns of food intake may lead to the development of several distressing postoperative symptoms that are most pronounced after abdominal surgery. Nausea and vomiting may be caused by the action of anaesthetics or opioids, delayed gastric emptying, slowed peristalsis resulting from the handling of the bowel during surgery, or resumption of oral intake too soon after surgery (Table 22-7).

TABLE 22-7

POSTOPERATIVE DIETS

Clear Fluids
Broth, gelatin, water, tea, black coffee
Fluids
Milk, coffee with cream, cream soups
Soft Diet
Fish, cottage cheese, pasta, eggs, mousse, pudding
Full Diet
Regular diet *Patients can also be placed on special diets, such as diabetic or low sodium.*

Nursing Management Gastro-Intestinal Problems

Nursing Assessment

Nausea and Vomiting.

Postoperative nausea and vomiting (PONV) is a complex physiological interaction between the following: the vomiting centre in the brain stem, the chemoreceptor trigger zone, the internal ear, the vagus nerve, the limbic system, and the cerebral cortex. PONV occurs in approximately 30% of all surgical patients and 80% of high-risk patients. PONV leads to delayed PACU or hospital discharge and, sometimes, subsequent readmission. As well as being a major cause of distress for patients, it can lead to more severe postoperative complications such as (Peterson, 2013):

- Aspiration
- Wound dehiscence
- Increased intracranial pressure
- Increased cardiovascular demand, predisposing compromised patients to myocardial infarctions

Primary risk factors for PONV include the following (Odom-Forren, 2014):

Patient-specific

- Age <50 years old
- Female gender
- History of motion sickness or PONV
- Nonsmoker

Anaesthesia-related

- Use of volatile anaesthetics
- Use of nitrous oxide
- High doses of opioids intra- and postoperatively

Surgery-related

- Duration of surgery >1 hour
- Type of surgery, specifically laparoscopy

These risk factors can be determined in the preoperative assessment so that prophylaxis can be planned using either one medication such as ondansetron (Zofran) or a combination of medications that minimize PONV.

Nonpharmacological interventions that may be used in combination for PONV or for postdischarge nausea and vomiting (PDNV) include transcutaneous electrical nerve stimulation, acupuncture, acupressure, acupoint stimulation, and aromatherapy (isopropyl alcohol and peppermint) (Odom-Forren, 2014). Nurses should document the quantity and characteristics (including colour) of the emesis.

Ileus

Postoperative Ileus.

Postoperative ileus (POI) is a delay in the return of the GI system's normal peristalsis, specifically after GI surgery. It is characterized by abdominal distension and tenderness or pain. Stomach motility returns in 1 to 2 days, and bowel motility in 3 to 5 days. Laparoscopic colon surgery is associated with a shorter period of ileus than open surgery. Abdominal distension during this time may require insertion of a nasogastric tube for symptomatic relief and the lowering of opioid doses or provision of pain relief with NSAIDs to reduce inflammation (Cagir, 2016).

Paralytic Ileus.

Paralytic ileus is impairment of intestinal motility (ileus that persists for more than 2 to 3 days) postoperatively. It can be associated with the large and small intestine and resolves with treatment; it is not a mechanical obstruction. Peristalsis stops, and the patient complains of abdominal pain, distension, nausea, vomiting, and poor appetite. Nursing care on the postoperative unit consists of measuring the patient's abdominal girth for distension and auscultating the abdomen in all four quadrants to determine presence, frequency, and characteristics of bowel sounds. Bowel sounds are frequently absent or diminished, and the abdomen will sound tympanic to percussion. Early bowel sounds may signal return of small intestine motility; however, full return of bowel function is indicated by the passage of flatus or stool (Jackson, 2015). When paralytic ileus does not resolve spontaneously, the patient may require diagnostic tests to rule out mechanical blockage that would require surgical intervention.

Nursing Diagnoses

Nursing diagnoses and collaborative problems related to potential GI complications in the PACU and clinical unit may include but are not limited to the following:

- *Nausea* related to *noxious environmental stimuli*
- *Risk for aspiration* as evidenced by *delayed gastric emptying, depressed gag reflex, increase in intragastric pressure*
- *Risk for deficient fluid volume* as evidenced by *active fluid volume loss*
- *Imbalanced nutrition: less than body requirements* related to *inability to ingest food, inability to absorb nutrients*

- Potential complications: fluid and electrolyte imbalance

Nursing Implementation

Postanaesthesia Care Unit.

Intervention for *nausea and vomiting* is primarily the use of antiemetic or prokinetic drugs (see Chapter 44). In the PACU, oral fluids should be given only as indicated and tolerated. IV fluids will provide hydration until the patient is able to tolerate oral fluids. Care should also be taken to prevent aspiration in case the patient vomits while still sleepy from anaesthesia. Having suction equipment readily available at the bedside and positioning the patient in the lateral recovery position will help protect the patient from aspiration (see Figure 22-4). Other interventions that may be effective include placing the patient in the upright position; encouraging slow, deep breathing; doing mouth care; using distraction; and providing emotional support.

Clinical Unit.

Depending on the nature of the surgery, the patient may resume oral intake as soon as the gag reflex returns. While the patient is on nothing-by-mouth status, IV infusions are given to maintain fluid and electrolyte balance. Once oral intake is allowed, clear liquids are started and the IV infusion is continued, usually at a reduced rate. If oral intake is well tolerated by the patient, the IV is discontinued and the diet is advanced progressively until a regular diet is tolerated.

The nurse should assess the patient regularly to detect the resumption of normal intestinal peristalsis, as evidenced by the return of bowel sounds and the passage of flatus. The patient may need to be encouraged to expel flatus and be reassured that expulsion is necessary and desirable. Gas pains, which tend to become pronounced on the second or third postoperative day, may be relieved by ambulation and frequent repositioning. Positioning the patient on the right side permits gas to rise along the transverse

colon and facilitates its release. Resumption of a normal diet after bowel sounds have returned will also enhance the return of normal peristalsis. A patient who does not improve with conservative measures will need to be reassessed and may require additional surgery.

Potential Alterations in Urinary Function

Etiology

Low Urine Output.

In patients with normal renal function, a urinary output of ≈30 mL/hr is expected in the PACU. This lower output is caused by increased aldosterone and antidiuretic hormone secretion resulting from the stress of surgery, fluid restriction before surgery, loss of fluids during surgery, drainage, and diaphoresis. By the second or third day, the patient's urinary output should return to the normal level of 0.5 to 1 mL/kg/hr (≈60 mL/hr). Persistent low urinary output, or oliguria, can indicate inadequate renal perfusion and pending renal failure. Restoring renal blood flow and urine production can prevent renal failure.

Acute urinary retention can occur in the postoperative period for a variety of reasons. Surgical genito-urinary trauma can cause swelling and bleeding. Anaesthesia depresses the nervous system, allowing the bladder to fill more completely than normal before the urge to void is felt. Neuraxial anaesthesia can cause autonomic blockade of sacral nerves, resulting in a hypotonic bladder. After lower abdominal or pelvic surgery, spasms or guarding of the abdominal and pelvic muscles interferes with their normal function, resulting in urinary retention. Pain may alter perception, interfering with the patient's awareness of the sensation arising as the bladder fills. Voiding may be impaired by lack of skeletal muscle activity (decreased smooth bladder muscle tone). As well, the supine position reduces the ability to relax the perineal muscles and the external sphincter.

Anticholinergic, antispasmodic, and opioid drugs are some medications that prevent the complete emptying of the bladder.

Nursing Management Potential Urinary Problems

Nursing Assessment

The urine of the patient after surgery should be examined for both quantity and quality. The colour, amount, consistency, and odour of the urine should be noted. In-dwelling catheters should be assessed for patency, and urine output should be approximately 60 mL/hr. Most people urinate approximately 200 mL of urine within 6 to 8 hours after surgery. If no voiding occurs, the abdominal contour should be inspected and the bladder palpated and percussed for distension or a bladder scanner used to detect bladder volumes.

Nursing Diagnoses

Nursing diagnoses and collaborative problems related to potential urinary complications for the patient after surgery include but are not limited to the following:

- *Urinary retention* related to *anaesthetic drugs, pain*
- Potential complication: acute kidney injury, catheter-associated urinary tract infections (CAUTIs)

Nursing Implementation

There may be a postoperative order to catheterize the patient in 8 to 12 hours if voiding has not occurred; however, there are ways for the nurse to facilitate voiding. Some measures known to help include positioning the patient—sitting for women and standing for men—ambulating, putting a commode in place, providing reassurance,

running water, providing water to drink, or pouring warm water over the perineum.

In assessing the need for catheterization, the nurse considers fluid intake during and after surgery and determines bladder fullness (e.g., palpable fullness above the symphysis pubis, discomfort when pressure is applied over the bladder, the presence of the urge to void). Urinary tract infections are the most common complication associated with urinary catheterization and commonly occur in the first postoperative week. Patients should be catheterized only when absolutely necessary, using aseptic protocol, and the catheter should be removed as soon as it is no longer required.

Potential Alterations in the Integument

Etiology

Despite advances in surgical technologies and techniques, environmental conditions, antibiotic regimens, and sterilization methods, surgery remains an invasive procedure that can predispose patients to surgical site infections (SSIs). An SSI is an infection that occurs within 30 days of surgery or up to 1 year after implant surgery. It has at least one of the following signs or symptoms (Keast & Swanson, 2014):

- Purulent discharge
- Isolation of organisms from wound fluid or tissue
- Pain, tenderness, local edema, warmth
- Physician or health care team member diagnosis

According to the Centers for Disease Control and Prevention (CDC; 2017) in the United States, SSIs account for 31% of all health care–associated infections (HAIs) and have a mortality rate of 3%. In Canada, Keast and Swanson (2014) report that because 75% of all surgery is done on an outpatient basis, detecting and caring for SSIs in the community are the most common reasons for community nursing visits. Having community nurses provide leading-edge wound care practice is decreasing the need for patient readmission to hospital and thus saving health care costs (Canadian Nurses Association [CNA], 2013).

Wounds are a significant, costly, and preventable barrier to successful recovery from routine surgical interventions, so reducing the incidence of SSIs is essential, and much evidence is now available

to support prevention practices, for example, the Wound Care Instrument developed collaboratively by the Canadian Association of Wound Care and the Canadian Association for Enterostomal Therapy (Canadian Association of Wound Care and Canadian Association for Enterostomal Therapy, 2011). (Wound healing and complications are discussed in Chapter 14.)

SSIs are caused by (Keast & Swanson, 2014):

- Introduction of endogenous bacteria (from the patient) into the wound
- Introduction of exogenous contamination (from the surgical environment) into the wound
- Inability of the individual to resist infection due to reduced immune capacity (disease, malnutrition, medication) or other factors

Table 22-8 provides guidelines for the prevention of SSIs.

TABLE 22-8

RECOMMENDATIONS FOR PREVENTION OF SURGICAL SITE INFECTIONS

Intervention	Guidelines for SSI Prevention
Perform holistic preoperative assessment and manage preoperative risk	Document patient's age, weight, general health, medications, coexisting health conditions, glycemic control, recent weight loss or gain, state of being overweight or obese, physical activity levels, present and past smoking history, and previous experiences with anaesthetic. *Example:* Advanced age relates to decreased healing potential and diminished immune factors. Complete a nutritional assessment or lab analysis for serum albumin and total protein or both. Improve diet preoperatively.
Manage intraoperative risk	Maintain patient homeostasis (e.g., temperature, glucose levels, O_2 saturation >95%). Ensure strict adherence to aseptic practice by surgical personnel. Minimize tissue trauma through gentle handling and limited use of electrocautery, and when closing incision, eliminate dead space below the skin. Use antibiotics prophylactically.
Manage postoperative risk	Maintain body temperature. Ensure adequate oxygenation. Use clean, intact wound dressing (e.g., waterproof dressing for 48 hours or aseptic technique for dressing change). Control pain.
Educate patients and families on signs and symptoms of SSIs	Provide information in easy-to-understand verbal and written form, including: • How to recognize an SSI (i.e., a little redness around wound edge is normal and can be expected for the first few days after surgery; redness spreading out more than 2 cm from incision, pain, swelling, or pus are SSI danger signs that must be reported to doctor) • Who to contact if infection is suspected • How to care for wound at home • Antibiotic regimen
Identify and treat SSIs	Ensure early diagnosis. Open incision to remove sutures and infected tissue and to drain. Use dressings to promote secondary healing. Follow evidence-informed recommendations for antibiotics.
Debride necrotic tissue	*(Necrotic tissue prolongs inflammation and may harbour aerobic and anaerobic bacteria and toxins.)* Choose debridement technique based on wound condition, resources, and patient condition.
Choose dressing or device to manage exudate and bacterial burden	Choose a dressing based on: • Depth of wound • Exudate and odour control • Conformability • Antimicrobial efficacy • Ease of removal • Patient safety and comfort
Consider adjunctive therapies	Use topical NPWT (e.g., for sternal and abdominal dehiscence, use growth factors, antibacterial honey, larva therapy [maggots], anti-scarring agents, and antiseptic-impregnated sutures).

Intervention	Guidelines for SSI Prevention
Implement a surgical site surveillance program	*(Collating infection rates for individual surgeons and surgical procedures reduces infection rates and identifies trends and causative agents. Surveillance programs must be in the community and extend a minimum of 30 days postoperatively and up to 1 year for implants.)* Help evaluate effectiveness of preventive strategies. Determine compliance to guidelines (e.g., teamwork, collaboration, and effective communication).

NPWT, negative-pressure wound therapy; *SSI,* surgical site infection.

Adapted from Keast, D., & Swanson, T. (2014). Ten top tips: Managing surgical site infections. *Wounds International, 5*(3), 15–16. Retrieved from *http://www.woundinfection-institute.com/wp-content/uploads/2014/11/SSI_11422.pdf*.

Nursing Management Surgical Wounds

Nursing Assessment

Wound assessment requires gathering information through questioning, observation, physical examination, and clinical investigation and using this information to formulate a wound care plan. It is recommended that the physical assessment be done in three zones: wound bed, wound edge, and periwound skin (Dowsett, Protz, Drouard, et al., 2015). Assessment includes:

- *Appearance:* Note the colour of wound, bruising, redness, and approximation of the incision.
- *Size:* Note the length, width, depth and shape of the wound and any signs of the wound opening (i.e., dehiscence or evisceration).
- *Exudate:* Check the wound for exudate type (e.g., watery, purulent), odour, and amount. A small amount of serous drainage is common, and it changes from sanguineous (red) to serosanguineous (pink) to serous (clear yellow). Draining will decrease over time.
- *Edema:* Excessive swelling may indicate wound complications.
- *Pain:* Sudden onset or persistent severe incisional pain may indicate infection, hemorrhage, or hematoma.
- *Drains:* Note the placement and security of drain or tube. Check the collection device; empty

as required and document.

Wound dehiscence (separation and disruption of previously joined wound edges) may be preceded by a sudden discharge of brown, pink, or clear drainage. Wound evisceration (protrusion of the visceral organs though a wound opening) can occur after surgery and is considered a medical emergency. If evisceration occurs, place sterile, saline-soaked towels over any extruding tissue, keep the patient on nothing-by-mouth status, observe the patient for signs and symptoms of shock, and call the surgeon immediately.

Nursing Diagnoses

Nursing diagnoses related to surgical wounds of the patient after surgery include but are not limited to the following:

- *Impaired skin integrity* related to *chemical injury agent*
- *Risk for surgical site infection* as evidenced by *invasive procedure, type of surgical procedure, comorbidity*

Nursing Implementation

When drainage occurs on the dressing, the type, amount, colour, consistency, and odour of drainage should be noted and recorded. Expected drainage from tubes is outlined in Table 22-9. The effect of position changes on drainage should also be assessed. The surgeon should be notified of any excessive or abnormal drainage and significant changes in vital signs.

TABLE 22-9
EXPECTED DRAINAGE FROM TUBES AND CATHETERS

Substance	Daily Amount	Colour	Odour	Consistency
In-Dwelling Catheter				
Urine*	500–700 mL, 1–2 days postoperative; 1 500–2 500 mL thereafter (output = 0.5–1 mL/kg/hr)	Clear, yellow	Ammonia	Watery
Nasogastric Tube, Gastrostomy Tube				
Gastric contents	≤1 500 mL/day	Pale, yellow–green, brown Bloody following gastro-intestinal surgery	Sour	Watery
Hemovac, Jackson-Pratt				
Wound drainage	Variable with procedure	Variable with procedure Usually serosanguineous	Same as wound dressing	Variable
T Tube				
Bile	500 mL	Bright yellow to dark green	Acid	Thick

*See Chapter 47.

Immediately after surgery, the incision is usually covered with a dressing. Surgical wound dressings are left dry and untouched for a minimum of 48 hours after surgery. This permits re-establishment of the protective, natural bacteria-proof barrier. The nurse changes the dressing according to employer policy. Wound healing and care are discussed in Chapter 14.

Potential Alterations in Psychological Function

Etiology

Anxiety and depression may occur in the postoperative patient. These states may be more pronounced in the patient who has had radical surgery (e.g., colostomy, amputation), or who has received a poor prognosis (e.g., inoperable tumour). A history of a neurotic or psychotic disorder should alert the nurse to the possibility of postoperative anxiety and depression. However, these responses may develop in any patient as part of the grief response to loss of a body organ or disturbance in body image (e.g., mastectomy or hysterectomy) and may be exacerbated by a lowered response to stress.

The patient who lives alone or requires rehabilitation after surgery may also develop anxiety and depression when faced with the need for assistance after surgery until strength and independence can be regained. The discharge nurse may refer a patient to community service and arrange home care nursing visits before discharge if the patient needs assistance, wound therapy, or monitoring after returning home (CNA, 2013).

In caring for the older adult, nurses in Canada must be cognizant of the increasing incidence of delirium, dementia, and depression in that segment of the population. Nurses must possess the knowledge and skills to screen for and differentiate between these conditions, which can have overlapping clinical features (Registered Nurses' Association of Ontario, 2016).

After surgery, confusion or delirium may arise from physiological sources, including fluid and electrolyte imbalances; hypoxemia; medication effects; sleep deprivation; and sensory alteration, deprivation, or overload.

Delirium tremens may also occur in some patients after surgery as a result of alcohol withdrawal. Delirium tremens is a reaction characterized by restlessness, insomnia, nightmares, tachycardia,

apprehension, confusion and disorientation, irritability, and auditory or visual hallucinations. (Management of delirium tremens is discussed in Chapter 11.)

Nursing Management Psychological Function

Nursing Diagnoses

Nursing diagnoses related to potential postoperative alterations in psychological function include but are not limited to the following:

- *Anxiety* related to *threat to current status*
- *Disturbed body image* related to *alteration in self-perception*
- *Disturbed sleep pattern* related to *environmental barrier* (unfamiliar setting, insufficient privacy)

Nursing Implementation

Nurses must observe and evaluate the patient's behaviour and plan appropriate interventions to ensure proper treatment of symptoms, prevent adverse outcomes, and improve the patient's quality of life on discharge. Supportive measures include taking time to listen to and talk with the patient, offering explanations and reassurance, and working collaboratively with family or significant others for discharge planning.

The nurse should discuss the patient's expectations for activity and the assistance that will be needed following discharge. The older patient may be particularly distressed if an immediate return to home is not feasible. The patient must be included in discharge planning and provided with the information and support to make informed decisions about continuing care.

Recognition of alcohol withdrawal syndrome in a patient not previously known to abuse alcohol presents a particular challenge. Any unusual or disturbed behaviour should be reported immediately so that diagnosis can be made and treatment instituted.

Discharge From the Postanaesthesia Care Unit

The patient leaving the PACU may be discharged to an intensive care unit, an inpatient unit, an ambulatory care unit, or home. The choice of discharge site is based on patient acuity, access to follow-up care, and the potential for postoperative complications. The decision to discharge the patient from the PACU is based on written discharge criteria, which can take the form of a standardized scoring system used to determine the patient's general condition and readiness for discharge. Examples of discharge criteria are provided in Table 22-10.

TABLE 22-10

POSTANAESTHESIA AND AMBULATORY SURGERY DISCHARGE CRITERIA

Postanaesthesia Discharge Criteria
• Patient awake (or baseline) • Vital signs stable • No excess bleeding or drainage • No respiratory depression • Oxygen saturation >90% • Report given
Ambulatory Surgery Discharge Criteria
• All PACU discharge criteria met • No IV opioids for last 30 minutes • Minimal nausea and vomiting • Voided (if appropriate to surgical procedure or orders) • Able to ambulate if age appropriate and not contraindicated • Responsible adult present to accompany patient • Written discharge instructions given and understood

PACU, postanaesthesia care unit; *IV,* intravenous.

Care of the Postoperative Patient on the Clinical Unit

Before discharging the patient from the PACU to the clinical unit, the PACU nurse should provide a verbal report about the patient to the receiving nurse. The report summarizes the operative and postanaesthetic period.

The nurse receiving the patient on the clinical unit assists PACU transport personnel in transferring the patient from the PACU stretcher onto the bed. Care must be taken to protect IV lines, wound drains, dressings, and traction devices. The use of a draw sheet or transfer board and sufficient personnel facilitates transfer of the patient.

On the clinical unit, vital signs should be obtained, and patient status should be compared with the report provided by the PACU. Documentation of the transfer is then completed, followed by a more in-depth assessment (Table 22-11). Postoperative orders and appropriate nursing care are then initiated.

TABLE 22-11

NURSING ASSESSMENT AND CARE OF PATIENT ON ADMISSION TO CLINICAL UNIT
General Anaesthetic Versus Spinal or Epidural Anaesthetic

General Anaesthetic
1. Verify patient identification using name band and medical record number. 2. Note any allergies and ensure presence of an allergy bracelet if applicable. 3. Record time of patient's return to unit. 4. Take baseline vital signs. 5. Assess airway and breath sounds. 6. Assess neurological status, including level of consciousness and movement of extremities. 7. Assess wound, wound closure and dressing, and drainage and nasogastric tubes. • Note length of tubing where applicable. • Ensure all drains and tubings are secured in place (minimizes risk of accidental discontinuation and resulting tissue trauma). • Note type and amount of drainage. • Note any packing to an open wound. • Connect tubing to gravity or suction drainage. 8. Assess colour and appearance of skin. 9. Assess urinary status. • Note time of voiding. • Note presence of catheter, if any, and total output. • Check for bladder distension or urge to void. • Note catheter patency; check integrity of insertion site and size of Foley catheter. 10. Assess pain and discomfort. • Note last dose and type of pain control. • Note current pain intensity. 11. Position for comfort and safety (bed in low position, side rails up). 12. Check IV infusion. • Note type of solution. • Note amount of fluid remaining. • Note flow rate. 13. Attach call light within patient's reach, and orient patient to its use. 14. Ensure that emesis basin and tissues are available. 15. Determine emotional condition and support needed. 16. Check for presence of family member or significant other. 17. Orient patient and family to immediate environment. 18. Check and carry out postoperative orders.
Spinal or Epidural Anaesthetic
1. Record time of patient's return to unit. 2. Take baseline vital signs. 3. Assess airway and breath sounds. 4. Assess neurological status, including level of consciousness and movement of extremities. • Assess spinal insertion or epidural insertion site; ensure that there is a continuous epidural infusion in place and that the dressing and catheter are secure. • Assess motor and sensory blockade from spinal anaesthetic. 5. Assess wound, wound closure, dressing, and drainage tubes. • Note type and amount of drainage. • Note any packing to an open wound. • Connect tubing to gravity or suction drainage. 6. Assess colour and appearance of skin. 7. Assess urinary status.

- Note time of voiding.
- Note presence of catheter, if any, and total output.
- Check for bladder distension or urge to void.
- Note catheter patency; check integrity of insertion site and size of Foley catheter.

8. Assess pain and discomfort.
    - Note last dose and type of pain control.
    - Note current pain intensity.
9. Position for comfort and safety (bed in low position, side rails up).
10. Check IV infusion.
    - Note type of solution.
    - Note amount of fluid remaining.
    - Note flow rate.
11. Attach call light within patient's reach, and orient patient to its use.
12. Ensure that emesis basin and tissues are available.
13. Determine emotional condition and support.
14. Check for presence of family member or significant other.
15. Orient patient and family to immediate environment.
16. Check and carry out postoperative orders.

IV, intravenous.

Although many of the problems that may occur in the PACU are time limited to the immediate postoperative period, complications may occur during the extended postoperative recovery period on the clinical unit. Nursing assessment and management are based on awareness of the potential complications of surgery in general as well as complications specific to the surgical procedure. (A comprehensive nursing care plan for the postoperative patient is available on the Evolve website.)

Planning for Discharge and Follow-Up Care

Ambulatory and Inpatient Surgery Discharge

Ambulatory Surgery Discharge.

Ambulatory surgery accounts for 75% to 80% of all surgical procedures in Canada (Keast & Swanson, 2014). Despite the obvious advantages of ambulatory surgery (e.g., patient convenience, lower health care costs), because these patients are in the health care setting for such a short time, it is difficult to complete all the required teaching. Optimally, the patient and any caregivers should be contacted 1 or more days before surgery to collect assessment data and to provide teaching that will be needed after surgery. The patient's lower anxiety level at this time may enhance learning.

The patient leaving an ambulatory surgery setting must be mobile and alert so as to be able to provide self-care when discharged to home. Postoperative pain must be controlled. Overall, the patient must be stable and near the level of preoperative functioning for discharge from the unit. On discharge, instructions specific to the type of anaesthesia received and the surgery are given to the patient and caregiver verbally and reinforced with written directions. The patient may not drive and must be accompanied by a responsible adult at the time of discharge. A follow-up evaluation of the patient's status is made by telephone, and any specific questions and concerns are addressed.

As more complex surgical procedures are being done on an ambulatory basis, the nurse should carefully determine not only readiness for discharge but also the home care needs of the individual, including availability of assistive personnel (e.g., family, friends), access to a pharmacy for prescriptions, access to a phone in the event of an emergency, and access to follow-up care.

Discharge From the Clinical Unit.

Preparation for the patient's discharge should be an ongoing process throughout the surgical experience, beginning during the preoperative period. During the preoperative assessment, the nurse must determine if the patient will need additional health care support upon returning home. Arrangements for home care nurses and community resources are initiated so that they are in place when the patient is discharged. The patient is educated about what he or she will have to do postoperatively and, as events unfold, gradually assumes greater responsibility for self-care. As discharge approaches, the nurse should be certain that the patient and any caregivers have the following information:

- Care requirements for wound site and any dressings, including bathing recommendations
- Action and possible adverse effects of any medications and when and how to take them
- Activities allowed and prohibited; when various physical activities can be resumed safely (e.g., driving a car, returning to work, sexual intercourse, leisure activities)
- Dietary restrictions or modifications
- Symptoms to be reported (e.g., development of incisional tenderness or increased drainage, discomfort in other parts of the body)
- Where and when to return for follow-up care
- Answers to any individual questions or concerns

The nurse should specifically document in the record the discharge instructions provided to the patient and family. For the patient, the postoperative phase of care continues and extends into the recuperative period. Assessment and evaluation of the patient

after discharge may be accomplished by a follow-up call or by a visit from a nurse (e.g., home health nurse).

Increasingly, patients with many medical or surgical needs are being discharged from hospital. They may be transferred to transitional care facilities, to long-term care facilities, or directly to their homes (see Chapter 6). When discharged directly to home, it is expected that the patient, with assistance from family, friends, or home health care services, will continue self-care in the home. This may include dressing changes, wound care, catheter or drain care, home antibiotics, or continued physical therapy. Working through the discharge planner for the hospital unit or through the case manager, the nurse can facilitate the transition of care from hospital-based to community-based without jeopardizing the quality of care.

Informatics in Practice

Discharge Teaching

If the nurse is discharging a patient who requires a complex dressing change and thinks that written instructions are not adequate, the nurse should consider using a video either on the hospital's television system or from the Internet (e.g., YouTube). If using a video from the Internet, the nurse should check it first to ensure that the procedure is properly done. The nurse could also take a series of pictures that demonstrate how to perform the procedure. The patient and caregiver can view the video or pictures at home as a reference when performing the procedure.

Age-Related Considerations

Patient After Surgery

Aging is a chronological, functional, and physiological process, and all these factors must be considered when determining the postoperative needs of the older patient. The nurse should understand that normal aging and chronic disease can impact surgical outcomes (Papanier Wells & Flanagan, 2015). The older adult has decreased respiratory function and ability to cough, due to reduced thoracic compliance. These alterations in pulmonary status increase the work of ventilation and decrease the ability to eliminate some pharmacological agents. Reactions to anaesthetic agents must be carefully monitored and their postoperative elimination assessed before the patient is left without close supervision. Pneumonia is a common postoperative complication in older adults.

Vascular function in the older adult is altered because of atherosclerosis and decreased elasticity in the blood vessels. Cardiac function is often compromised, and compensatory responses to changes in BP and fluid volume are limited. Circulating blood volume is decreased, and hypertension is common. Cardiovascular parameters must be closely monitored throughout surgery and the postoperative period.

Drug toxicity is a potential problem in the older adult as renal perfusion decreases, thus reducing elimination of drugs excreted by the kidney. Decreased liver function also leads to decreased drug metabolism and thus increased drug activity. Renal and liver function must be carefully assessed in the postoperative phase of the patient's care to prevent drug overdose and toxicity.

Observing for changes in mental status is an important part of postoperative care in older adults. Predisposing factors for postoperative delirium in this population include such things as >80 years old, alcohol abuse, lower education level, polypharmacy, sensory impairments, low mobility, and major surgery. Anaesthetics, notably anticholinergic drugs and benzodiazepines, increase the risk for delirium. One way for the nurse to lessen delirium is to ensure

adequate postoperative pain control (Papanier Wells & Flanagan, 2015). An acute change in mental status can have a potentially reversible cause, such as an infection or an adverse effect of analgesic medication. (Dementia and delirium are discussed in Chapter 62.)

Pain is a multidimensional experience, and assessment should include how pain affects function, mood, activities, and quality of life. Older patients are at great risk for undertreated pain. They may be hesitant to request pain medication, believing that pain is an inevitable consequence of surgery and that acknowledging it is a sign of weakness. Nurses must be alert to nonverbal indications of pain and should also assess pain using a standardized scale that is explained to the patient each time it is used. The presence of postoperative pain should always be assumed in the cognitively impaired patient who cannot reliably respond (Papanier Wells & Flanagan, 2015). Surgery will usually result in pain, and, if untreated, pain could have a negative effect on recovery. (Pain is discussed in Chapter 10.)

A comprehensive, multidisciplinary approach is recommended when caring for older adults, and all health care personnel delivering geriatric care must be educated in it and competent. When older adults undergo surgery, nurses have the opportunity to enhance outcomes and improve the patient's quality of life (Papanier Wells & Flanagan, 2015)

Case Study

Patient After Surgery

Source: Blend Images/Shutterstock.com.

Patient Profile

Edward Lee, a 74-year-old retired university professor, has just undergone surgery for a fractured hip. He fell off a ladder while painting his house. Mr. Lee's medical history includes type 2 diabetes and COPD. The surgery, performed while the patient was under general anaesthesia, lasted 3 hours.

Subjective Data

- Walks 30 to 50 km/wk
- Smokes one pack of cigarettes per day × 58 years
- Has always had problems sleeping
- Has difficulty hearing; wears hearing aid
- Is upset with injury and its impact on his life
- Is a widower and has no relatives or friends nearby who are able to assist with care
- Reports pain is 8 on a 0-to-10 scale on arrival to PACU

Objective Data

- Admitted to PACU with abduction pillow between his legs, one peripheral IV catheter, a self-suction drain from the hip dressing, an in-dwelling urinary catheter
- Oxygen (O_2) saturation 91% on 40% O_2 face mask

Interprofessional Care

Postoperative Orders

- Vital signs per PACU routine
- Capillary blood glucose level on arrival and every 4 hours: Call for blood glucose level <3.9 mmol/L to >13.9 mmol/L; follow employer guidelines for management of hypoglycemia
- 0.45% normal saline at 100 mL/hr
- Morphine via patient-controlled analgesia 1 mg q10min (20 mg max in 4 hr) for pain
- Advance diet as tolerated
- Incentive spirometry q1hr × 10 while awake
- O_2 therapy to keep O_2 saturation >90%
- Respiratory: Ventolin 2.5 mg via nebulizer every 4 hours PRN for wheezing
- Neuro-vascular checks q1hr × 4 hours
- Empty and measure self-suction drain every shift
- Strict intake and output

Discussion Questions

1. What are the potential postanaesthesia problems with Mr. Lee?
2. ***Priority decision:*** What priority nursing interventions would be appropriate to prevent these problems from occurring?
3. What factors may predispose Mr. Lee to the following problems: atelectasis, infection, pulmonary embolism, and nausea and vomiting?
4. What criteria would determine when Mr. Lee is sufficiently recovered from general anaesthesia to be discharged to the clinical unit?
5. What potential postoperative problems on the clinical unit might be expected?
6. ***Priority decision:*** Based on the assessment data presented, what are two priority nursing diagnoses? Are there any collaborative problems?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. When a client is admitted to the PACU, what are the *priority* interventions the nurse performs?
   a. Assess the surgical site, noting presence and character of drainage.
   b. Assess the amount of urine output and the presence of bladder distension.
   c. Assess for airway patency and quality of respirations and obtain vital signs.
   d. Review results of intraoperative laboratory values and medications received.
2. A client is admitted to the PACU after major abdominal surgery. During the initial assessment, the client tells the nurse he thinks he is "going to throw up." What would be the *priority* nursing intervention?
   a. Increase the rate of the IV fluids.
   b. Obtain vital signs, including O_2 saturation.
   c. Position client in lateral recovery position.
   d. Administer antiemetic medication as ordered.
3. After admission of the postoperative client to the clinical unit, which assessment data require the *most* immediate attention?
   a. O_2 saturation of 85%
   b. Respiratory rate of 13/min
   c. Temperature of 38°C
   d. Blood pressure of 90/60 mm Hg
4. A 70-kg postoperative client has an average urine output of 25 mL/hr during the first 8 hours. Given this assessment, what would the *priority* nursing intervention(s) be?

a. Perform a straight catheterization to measure the amount of urine in the bladder.

b. Notify the physician and anticipate obtaining blood work to evaluate renal function.

c. Continue to monitor the client because this is a normal finding during this time period.

d. Evaluate the client's fluid volume status since surgery and obtain a bladder ultrasound.

5. The nurse on the postoperative unit is caring for a client who had a laparoscopic partial colectomy. On postoperative day 2, the client is complaining of abdominal distension and discomfort. Which of the following interventions may be appropriate for this client? (*Select all that apply*)

a. Increase the dose of opioids for pain relief.

b. Insert a nasogastric tube.

c. Reassure the client that this complication should subside in a day or two.

d. Monitor the client's abdominal girth by measuring for distension and auscultate the abdomen in all four quadrants.

6. Discharge criteria for the Phase II client include which of the following? (*Select all that apply*)

a. No nausea or vomiting

b. Ability to drive himself or herself home

c. No respiratory depression

d. Written discharge instructions understood

e. Opioid pain medication given 45 minutes ago

1. c; 2. c; 3. a; 4. d; 5. b, c, d; 6. c, d, e.

CHAPTER 23

Nursing Assessment

Visual and Auditory Systems

Written by, Sharon L. Lewis

Adapted by, Marian Luctkar-Flude

LEARNING OBJECTIVES

1. Describe the structures and functions of the visual and auditory systems.
2. Describe the physiological processes involved in normal vision and hearing.
3. Identify the significant subjective and objective assessment data related to the visual and auditory systems that should be obtained from the patient.
4. Describe the appropriate techniques used in the physical assessment of the visual and auditory systems.
5. Differentiate normal from common abnormal findings of a physical assessment of the visual and auditory systems.
6. Explain how age-related changes in the visual and auditory systems correspond to differences in assessment findings.
7. Describe the purpose, the significance of results, and the nursing responsibilities related to diagnostic studies of the visual and auditory systems.

KEY TERMS

The Visual System

Structures and Functions

The visual system consists of the external tissues and structures surrounding the eye, the external and internal structures of the eye, the refractive media, and the visual pathway. The external structures are the eyebrows, eyelids, eyelashes, lacrimal system, conjunctiva, cornea, sclera, and extraocular muscles. The internal structures are the iris, lens, ciliary body, choroid, and retina. The entire visual system is important for visual function. Light reflected from an object in the field of vision passes through the transparent structures of the eye and, in doing so, is *refracted* (bent) so that a clear image can fall on the retina. From the retina, the visual stimuli travel through the visual pathway to the occipital cortex, where they are perceived as an image.

Structures and Functions of Vision

Eyeball.

The eyeball, or globe, is composed of three layers (Figure 23-1). The tough outer layer is composed of the sclera and the transparent cornea. The middle layer consists of the uveal tract (iris, choroid, and ciliary body), and the innermost layer is the retina. The anterior chamber lies between the iris and the posterior surface of the cornea, whereas the posterior chamber lies between the anterior surface of the lens and the posterior surface of the iris. These chambers are filled with aqueous humor secreted by the ciliary body. The anatomic space *(vitreous cavity)* between the posterior lens and the retina is filled with a gel substance *(vitreous humor,* or *vitreous).*

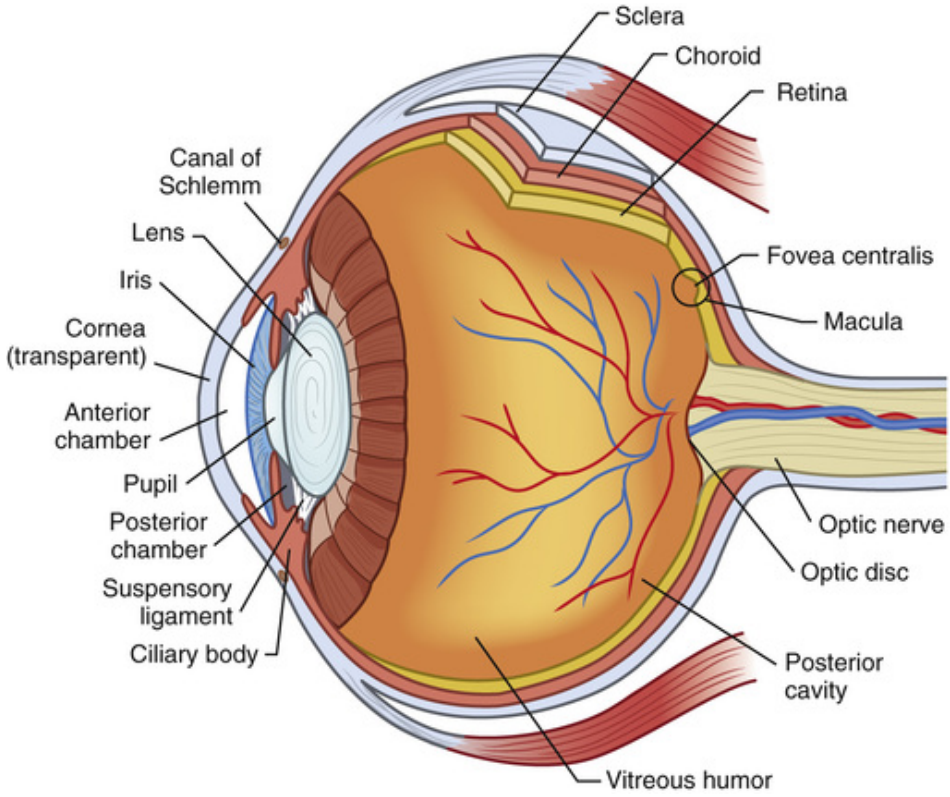

FIGURE 23-1 The human eye. Source: Adapted from Patton, K. T., & Thibodeau, G. A. (2013). *Anatomy and physiology* (8th ed., p. 527). St. Louis: Mosby.

Refractive Media.

For light to reach the retina, it must pass through a number of structures: the cornea, the aqueous humor, the lens, and the vitreous humor. All of these structures must remain clear for light to reach the retina and stimulate the photoreceptor cells. The cornea, which is normally transparent, is the first structure through which light passes. It is responsible for the majority of light refraction necessary for clear vision.

Aqueous humor, produced by the ciliary process, is a clear, watery fluid that fills the anterior and posterior chambers of the anterior cavity of the eye. It bathes and nourishes the lens and the endothelium of the cornea. It drains through the trabecular meshwork located in the angle. This circular canal conveys fluid into scleral veins, which enter the circulation of the body. Normal intraocular pressure is between 10 and 21 mm Hg; excess production or decreased outflow of the aqueous humor can cause an elevation in this pressure, a condition termed *glaucoma.*

The **lens** is a biconvex structure located behind the iris and supported in place by small fibres collectively called the *suspensory ligament* (also called the *zonule*) that connect the lens to the ciliary body. The primary function

of the lens is to bend light rays, which enables them to fall onto the retina. Anything altering the clarity of the lens affects light transmission.

Vitreous humor is located in the vitreous cavity, the large area behind the lens and in front of the retina (see Figure 23-1). Light passing through the vitreous humor may be blocked by any nontransparent substance within, such as the cellular debris (often called *floaters*). The effect on vision varies, depending on the amount, type, and location of the substance blocking the light.

Refractive Errors.

Refraction is the ability of the eye to bend light rays so that they fall on the retina. In the normal eye, parallel light rays are focused through the lens into a sharp image on the retina. The state that enables this process is termed *emmetropia,* which means that light is focused exactly on the retina, not in front of it or behind it. The condition in which the light does not focus properly is called a *refractive error.*

The individual with **myopia** can see near objects clearly (nearsightedness), but objects in the distance appear blurred. The individual with **hyperopia** can see distant objects clearly (farsightedness), but near objects appear blurred. **Astigmatism** is an imperfection in the curvature of the cornea or in the shape of the eye's lens that causes blurred or distorted vision for both near and far objects. **Presbyopia** is a normal aging change in which the lens of the eye loses its elasticity and flexibility, which results in an inability to focus on close objects, usually beginning at approximately age 40.

Visual Pathways.

Once the image travels through the refractive media, it is focused on the retina, inverted, and reversed left to right. For example, if the visualized object is in the upper part of the left temporal visual field, it is focused in the lower part of the nasal retina, upside down, and as a mirror image. From the retina, the impulses travel through the optic nerve to the optic chiasm, where the nasal fibres of each eye cross over to the other side. The optic chiasm is the X-shaped space just in front of the pituitary gland where the optic nerve fibres partially cross. Fibres from the left field of both eyes form the left optic tract and travel to the left occipital cortex. The fibres from the right field of both eyes form the right optic tract and travel to the right occipital cortex. Because of this arrangement of the nerve fibres in the visual pathways, it is possible to determine the anatomical location

of abnormalities in those nerve fibres from the specific visual field defect (Figure 23-2).

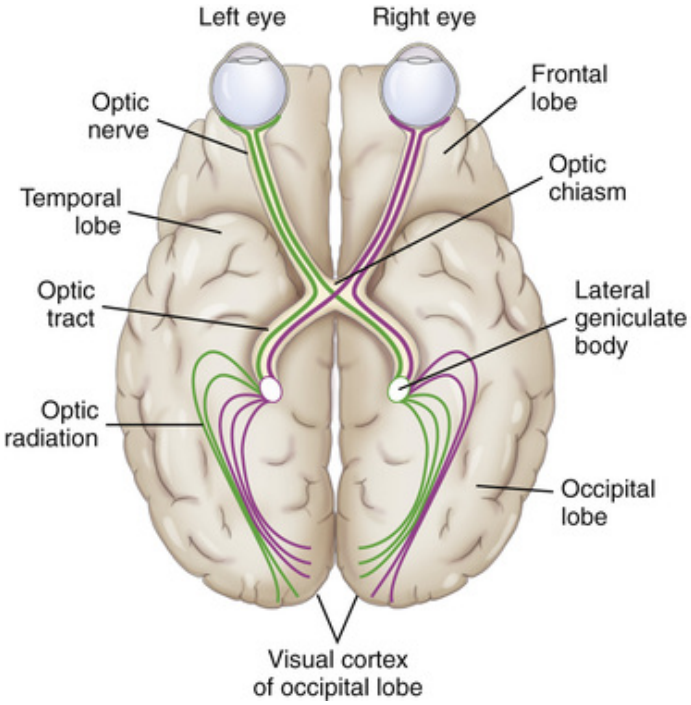

FIGURE 23-2 The visual pathway. Fibres from the nasal portion of each retina cross over to the opposite side of the optic chiasm, terminating in the lateral geniculate body of the opposite side. The location of a lesion in the visual pathway determines the resulting visual defect.

External Structures and Functions

Eyebrows, Eyelids, and Eyelashes.

Eyebrows, eyelids, and eyelashes serve an important role in protecting the eye. They provide a physical barrier to dust and foreign particles. The eye is further protected by the surrounding bony orbit and by fat pads located below and behind the *globe,* or eyeball.

The upper and lower eyelids join at the medial and lateral canthi. The upper eyelid blinks spontaneously approximately 15 times a minute. Blinking distributes tears over the anterior surface of the eyeball and helps control the amount of light entering the visual pathway (Figure 23-3).

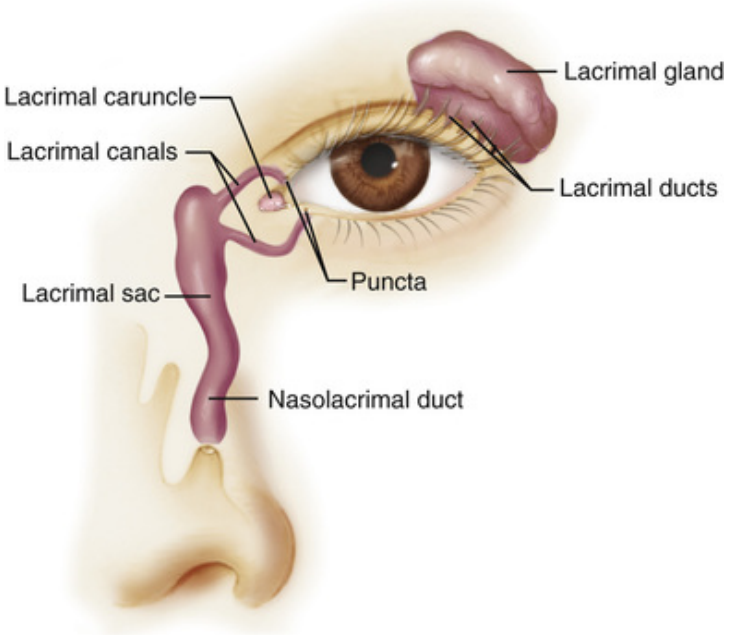

FIGURE 23-3 External eye and lacrimal apparatus. Tears produced in the lacrimal gland pass over the surface of the eye and enter the lacrimal canal. From there, the tears are carried through the nasolacrimal duct to the nasal cavity.

The eyelids open and close through the action of muscles innervated by cranial nerve (CN) VII, which is the facial nerve. Muscular action also helps hold the eyelids against the eyeball.

The **conjunctiva** is a transparent mucous membrane that covers the inner surfaces of the eyelids (the palpebral conjunctiva) and extends over the **sclera** (the bulbar conjunctiva), forming a "pocket" under each eyelid. Glands in the conjunctiva secrete mucus and tears. The sclera, an opaque structure commonly referred to as the "white" of the eye, is formed by collagen fibres meshed together. The sclera forms a tough shell that helps protect the intraocular structures.

The transparent and avascular cornea allows light to enter the eye (see Figure 23-1). The curved cornea refracts (bends) incoming light rays to help focus them on the retina. The cornea consists of six layers: the epithelium, Bowman's layer, the stroma, Dua's layer, Descemet's membrane, and the endothelium (Dua, Faraj, Said, et al., 2013). The epithelium consists of a layer of cells that helps protect the eye. Epithelial cells regenerate when damaged. The stroma consists of collagen fibrils. The cornea is maintained by the lacrimal system, which consists of the lacrimal gland and ducts, the lacrimal canals and puncta, the lacrimal sac, and the nasolacrimal duct (Figure 23-3). In addition to the lacrimal gland,

other glands provide secretions to make up the mucous, aqueous, and lipid layers of the tear film. The tear film moistens the eye and provides oxygen to the cornea.

Each eye is moved by three pairs of extraocular muscles and controlled by three cranial nerves: (a) superior and inferior rectus muscles (CN III), (b) medial (CN III) and lateral rectus muscles (CN VI), and (c) superior (CN IV) and inferior oblique muscles (CN III). Neuro-muscular coordination enables simultaneous movement of the eyes in the same direction (conjugate movement).

Internal Structures and Functions

The iris (plural: irides) is the colourful part of the eye. This structure has a small, round opening in its centre, the pupil, which allows light to enter the eye. The pupil constricts through action of the iris sphincter muscle (innervated by CN III [oculomotor nerve]) and dilates through action of the iris dilator muscle (innervated by CN V [trigeminal nerve]) to control the amount of light that enters the eye.

The lens, as described previously, is a structure behind the iris whose function is to bend light rays so that they fall onto the retina. The shape of the lens is modified by action of the ciliary body as part of **accommodation,** the convergence of the eyes and the constriction of the pupils that occurs when the eyes refocus from a far object to a near object. This enables a person to focus on near objects, as in reading a book. The choroid is a highly vascular structure that nourishes the ciliary body, the iris, and the outer portion of the retina. It lies inside and parallel to the sclera and extends from the area where the optic nerve enters the eye to the ciliary body (see Figure 23-1). The ciliary body consists of the ciliary muscles, which surround the lens and lie parallel to the sclera; the ciliary zonules, which attach to the lens capsule; and the ciliary processes, which constitute the terminal portion of the ciliary body. The ciliary processes lie behind the peripheral part of the iris and secrete aqueous humor.

The **retina** is the innermost layer of the eye that extends and gives rise to the optic nerve. Neurons make up the major portion of the retina. Therefore, retinal cells cannot regenerate if destroyed. The retina lines the inside the eyeball, extending from the area of the optic nerve to the ciliary body (see Figure 23-1). It is responsible for converting images into a form that the brain can understand and process as vision. The retina is composed of two types of photoreceptor cells: rods and cones. Rods are stimulated in dim or darkened environments, and cones are receptive to

colours in bright environments. The centre of the retina is the *fovea centralis,* a pinpoint depression composed only of densely packed cones (Thibodeau & Patton, 2012). This area of the retina provides the sharpest visual acuity. Surrounding the fovea is the *macula,* an area smaller than 1 square millimetre, which has a high concentration of cones and is relatively free of blood vessels. With the exception of the macula, the retina is nourished by retinal arterioles and veins. This blood supply enters the eye through the optic disc, located nasally from the macula. The optic disc is the area where the optic nerve (CN II) exits the eyeball. Within the disc is the physiological cup, a depression that can be visualized through the pupil with the ophthalmoscope. The retinal veins and arteries can also be visualized in this way and can provide information about the condition of the vascular system in general.

Age-Related Considerations

The Visual System

Every structure of the visual system is subject to changes as the individual ages. Whereas many of these changes are relatively benign, others may compromise visual acuity severely in the older adult. The psychosocial effect of poor vision or blindness can be highly significant. Visual impairment increases with age; the number of people with vision loss doubles every decade after age 40 and triples after age 75 (National Coalition for Vision Health, 2011). Age-related changes in the visual system and differences in assessment findings are presented in Table 23-1.

TABLE 23-1

AGE-RELATED DIFFERENCES IN ASSESSMENT
Visual System

Changes	Differences in Assessment Findings
Eyebrows and Eyelashes	
Loss of pigment in the hair	Greying of eyebrows, eyelashes
Eyelids	
Loss of orbital fat, decreased muscle tone	Entropion, ectropion, mild ptosis
Tissue atrophy, prolapse of fat into eyelid tissue	Blepharodermachalasis (excessive upper eyelid skin)
Plaques	Xanthelasma
Conjunctiva	
Tissue damage related to chronic exposure to ultraviolet light or to other chronic environmental exposure	Pinguecula (small, yellowish spot seen usually on the medial aspect of the conjunctiva)
Sclera	
Lipid deposition	Yellowish (as opposed to bluish) scleral colour
Cornea	
Cholesterol deposits in peripheral cornea	Arcus senilis (milky or yellow ring encircling periphery of cornea; see Figure 23-1)
Tissue damage related to chronic exposure	Pterygium (thickened, triangular bit of pale tissue that extends from the inner canthus of the eye to the nasal border of the cornea)
Decrease in water content, atrophy of nerve fibres	Decreased corneal sensitivity and corneal reflex
Epithelial changes	Loss of corneal lustre
Accumulation of lipid deposits	Blurring of vision
Lacrimal Apparatus	
Decreased tear secretion	Dryness
Malposition of the eyelid that results in tears overflowing the eyelid margins instead of draining through the puncta	Tearing, irritated eyes
Iris	
Increased rigidity of iris	Decreased pupil size
Dilator muscle atrophy or weakness	Slower recovery of pupil size after light stimulation
Loss of pigment	Change of iris colour
Shrinking and stiffening of ciliary muscle	Decrease in near vision and accommodation
Lens	
Biochemical changes in lens proteins, oxidative damage, chronic exposure to ultraviolet light	Cataracts
Increased rigidity of lens	Presbyopia
Opacities in the lens (may also be related to opacities in the cornea and the vitreous humor)	Complaints of glare, impairment of night vision
Accumulation of yellow substances	Yellow colouring of lens
Retina	
Retinal vascular changes related to atherosclerosis and hypertension	Narrowed, pale, straighter arterioles; acute branching
Decrease in cones	Changes in colour perception, especially blue and violet
Loss of photoreceptor cells, retinal pigment, epithelial cells, and melanin	Decreased visual acuity
Age-related macular degeneration as a result of vascular changes	Loss of central vision
Vitreous Humor	
Liquefaction and detachment of the vitreous humor	Increased complaints of “floaters” or light flashes

Assessment

Assessment of the visual system may be as simple as determining a patient's visual acuity or as complex as collecting complete subjective and objective data pertinent to the visual system. To perform an appropriate ophthalmic evaluation, the nurse must determine which parts of the data collection are important for each patient. Table 23-2 lists suggested questions to ask while the health history is documented, to obtain subjective data related to the visual system.

TABLE 23-2

HEALTH HISTORY
Visual System: Questions for Obtaining Subjective Data

Vision Difficulty
• Do you have any visual difficulties or change in your visual acuity?* Describe the change in your vision. Describe how this affects your daily life. • Did it come on slowly or progress slowly? Does it affect one or both eyes? Is it constant or intermittent? Do you see spots or floaters move in front of your eyes?* Do you see light flashes?* • Do you have a blind spot?* Do you have any night blindness?* • For older adults: Are you experiencing any visual difficulties when you climb stairs or drive at night? • Do you use any visual aids such as glasses or contact lenses?
Eye Pain
• Do you have any eye pain?*
Strabismus or Diplopia
• Have you ever had a history of crossed eyes, or do you have double vision?*
Redness or Swelling
• Do you have redness or swelling in your eyes?* • Do you have any discharge or watering from your eyes?*
Family History
• Do you have a family or personal history of diseases such as atherosclerosis, diabetes, thyroid disease, hypertension, arthritis, or cancer that might affect your eyes?* • Do you have a family or personal history of ocular problems such as cataracts, tumours, glaucoma, refractive errors (especially myopia and hyperopia), or retinal degenerative conditions (e.g., macular degeneration, retinal detachment, retinitis pigmentosa)?*
Nutrition and Elimination
• Do you take any nutritional supplements?* • Does your visual problem affect your ability to obtain and prepare food?* • Do you have to strain to void or defecate?*
Sleep
• Is your vision affected by the amount of sleep you get?* • Is your sleep affected by your eye problem?*
Reproduction–Sexuality
• Has your eye problem caused a change in your sex life?* • For women: Are you pregnant? Do you use birth control pills?
Self-Care History
• Do you have regular eye examinations? When was your last test? • Do you wear glasses or contact lenses? When was the last time your eye prescription was checked? Was it changed? • Have you ever been tested for colour vision?* • Do you wear protective eyewear (sunglasses, safety goggles, or hats)?* • Do you wear contact lenses? If so, how do you take care of them? • If you use eye drops, how do you instill them? • Do you spend long periods of time in the sun?* Do you wear sunglasses? • Do you smoke, or are you regularly exposed to second-hand smoke? • Have you ever been tested for glaucoma?* Results?
Social and Occupational History
• Do you have any problems at work or home because of your eyes?* • Does your eye problem affect your ability to read?* • Have you made any changes in your social activities because of your eyes?* • Are your activities limited in any way by your eye problem?* • Are there any environmental conditions at home or work that may have an effect on your eyes (e.g., smoke, dust, chemicals, flying sparks)?* If so, do you use goggles for eye protection? • Do you participate in any leisure activities that have the potential for eye injury?* • Do you work for long hours at the computer?*
Coping Abilities
• How does your eye problem make you feel about yourself? Has it created stress for you?*

- If you have a vision loss, how do you cope?* Are you able to maintain your same living environment?* Do you use large-print books or Braille?*

*If yes, describe.

Source: Adapted from Jarvis, C., Browne, A. J., MacDonald-Jenkins, J., & Luctkar-Flude, M. (2014). *Physical examination & health assessment* (2nd Canadian ed., pp. 303–305). Toronto: Elsevier Canada.

Subjective Data

Past Health History.

Information about the patient's health history should include both ocular and nonocular history. The nurse should ask specifically about systemic diseases—such as diabetes, hypertension, cancer, rheumatoid arthritis, sexually transmitted infections, acquired immune deficiency syndrome, muscular dystrophy, myasthenia gravis, multiple sclerosis, inflammatory bowel disease, and hypothyroidism or hyperthyroidism—because many of these diseases have ocular manifestations. It is particularly important to determine whether the patient has any history of cardiac or pulmonary disease because the eye drops often used to treat glaucoma (β-adrenergic blockers) may have serious adverse effects, including bradycardia, orthostatic hypotension, bronchospasm, and heart failure (Skidmore-Roth, 2012).

Medications.

If the patient takes any medications, the nurse should obtain a complete list, including over-the-counter medicines, eye drops, herbal therapies, or dietary supplements. Many patients do not think that over-the-counter drugs, eye drops, or herbal therapies are “real” medications and may not mention their use unless specifically questioned. However, many of these drugs have ocular effects. For example, many preparations for colds contain a form of epinephrine (e.g., pseudoephedrine) that can dilate the pupil. The nurse should also note the use of any antihistamines or decongestants because these drugs can cause ocular dryness. The nurse should specifically ask whether the patient uses any prescription drugs such as corticosteroids, thyroid medications, oral hypoglycemic agents, or insulin. Long-term use of corticosteroids can contribute to development of glaucoma or cataracts. It is especially important to note whether the patient is taking any β-adrenergic blocker eye drops because they may potentiate the effects of corticosteroids. The nurse should also ask female patients whether they are taking birth control pills or are pregnant because

hormonal changes can affect the wearing of contact lenses. Finally, the nurse should determine whether the patient has allergies to medications or other substances such as dust, pollens, pets, cosmetics, or scents.

Surgery or Other Treatments.

Surgical procedures related to the head, eye, or brain should be noted. Brain surgery and subsequent swelling can cause pressure on the optic nerve or tract, which results in alterations in vision. Any laser procedures involving the eye should also be documented, as should the effect of any eye surgery or laser treatment on visual acuity. The nurse should ask the patient about previous trauma to the head. Also, inquiring about headaches is important because migraines may create visual disturbances.

A history of tests for visual acuity should be obtained, including the date of the most recent examination and change in glasses or contact lens prescriptions, as well as testing for glaucoma and what the results were. The nurse should specifically ask about a history of strabismus, amblyopia, cataracts, retinal detachment, refractive surgery, glaucoma, and any trauma to the eye, its treatment, and sequelae.

The patient's intake of vitamins and trace minerals can be important to ocular health. Supplementation with vitamins C and E, minerals copper and zinc, and the phytochemicals lutein and zeaxanthin may help delay the progression of eye diseases such as age-related macular degeneration (Age-Related Eye Disease Study 2 [AREDS2] Research Group, 2013). (See the "Determinants of Health" box later in this section.) However, vitamin and antioxidant supplements have not been shown to prevent or delay onset of age-related macular degeneration and may have harmful effects (Evans & Lawrenson, 2012).

For a patient who has undergone or will undergo ophthalmological surgical procedures, the nurse should assess the patient's elimination pattern and determine the potential for constipation, inasmuch as straining to defecate (the Valsalva manoeuvre) can raise intraocular pressure. Although there is some evidence that elevation of the intraocular pressure during normal activities is not detrimental in relation to the surgical incision made during eye surgery, many surgeons do not want such patients to strain.

Case Study

Patient Introduction

Source: Zurijeta/Shutterstock.com.

Fatimah Abdullah is an 81-year-old woman who comes to the emergency department with the complaint that her vision "looks like everything is covered with spider webs."

Critical Thinking

Throughout this assessment chapter, think about Ms. Abdullah with the following questions in mind:

1. What are possible causes of Ms. Abdullah's visual disturbances?
2. What type of assessment should be most appropriate: comprehensive, focused, or emergency?
3. What questions should the nurse ask Ms. Abdullah?
4. What should be included in the physical assessment? What would the nurse be looking for?
5. What diagnostic studies might be ordered?

See pp. 445 and 448 for more information on Ms. Abdullah.

Self-Care History.

The nurse should assess the patient's ocular health care activities, including regular eye examinations and awareness of the importance of eye safety practices, such as wearing protective eyewear during potentially hazardous activities or while playing sports and avoiding noxious fumes and other eye irritants. Information about the use of sunglasses in bright light should be obtained as prolonged exposure to ultraviolet light can affect the retina and may contribute to cataract formation. Nighttime driving habits and any problems encountered in nighttime driving should be noted. For a patient who wears contact lenses, the nurse should assess the patient's use and care habits, which may indicate a need for teaching, inasmuch as many contact lens wearers do not care for them properly

(Wu, Willcox, & Stapleton, 2015). The nurse should ask about time spent working on computers or handheld devices because eye strain is a common problem. The 20/20 rule can be promoted: Every 20 minutes, patients should look away from their computer screen for 20 seconds (American Optometric Association, 2015).

Environmental exposures at home or work can cause trauma or irritation to the eyes; eye protection should be discussed. Patients should be asked whether they smoke or are regularly exposed to second-hand smoke. Smokers are at greater risk for developing age-related macular degeneration (see the "Determinants of Health" box). If patients use eye drops, the nurse should ascertain whether they are aware of correct methods for instilling drops to avoid contamination of the container.

Determinants of Health

Macular Degeneration

Gender

- The incidence of macular degeneration is higher among women than among men. Early-onset menopause can also increase the risk for developing macular degeneration.*

Biology and Genetic Endowment

- The risk of developing macular degeneration increases with a family history (first generation).†
- White individuals are more likely to develop macular degeneration than any other ethnic group.†
- Vision problems are more common among new immigrants and refugees than in the general Canadian population.‡

Personal Health Practices and Coping Skills

- Smoking increases the risk of developing macular degeneration four-fold. Smokers also develop the disease approximately 10 years earlier

than nonsmokers. Twenty percent of vision loss may be avoided by staying smoke-free.†

- Adequate exercise and a healthy diet (leafy vegetables, omega-3 fatty acids) reduces the risk of macular degeneration. Antioxidants and zinc can slow the progression of intermediate and advanced macular degeneration and thereby minimize vision loss.†
- Ultraviolet radiation damages the retina, which leads to macular degeneration.†

References

Pottie K, Greenaway C, Feightner J, et al. Evidence-based clinical guidelines for immigrants and refugees: Vision health. *Canadian Medical Association Journal*. 2011;183(12):E898–E900; 10.1503/cmaj.090313.

Social and Occupational Health History.

The patient's ability to maintain necessary or desired roles and responsibilities in home, work, and social environments can be negatively affected by ocular problems. For example, macular degeneration may decrease the patient's visual acuity to a level inadequate for functioning at work. In many occupations, employees work in conditions in which eye injury may occur. For example, factory workers may be at risk from flying debris. Information should be obtained about eye safety practices, such as use of goggles or safety glasses. Workers can also be exposed to eyestrain in the office from video display terminals, poor lighting, and glare. An ergonomic consultation may be beneficial.

A patient with diabetes may not be able to see well enough to self-administer insulin. This patient may resent dependence on a family member who takes over this function. The patient with *exophthalmos* (marked protrusion of eyeballs) may be embarrassed by his or her appearance and avoid usual social activities. The nurse should sensitively inquire whether the patient's preferred roles and responsibilities have been affected by the ocular problem.

The nurse should also inquire about leisure activities during which the patient may incur an ocular injury. For example, during gardening, woodworking, and other craft activities, foreign bodies can scratch or enter the cornea or conjunctiva or even penetrate the globe. Injuries to the globe or the bony orbit can also occur after blows to the head or eye during sports activities such as racquetball, baseball, and tennis. Other leisure activities such as needlepoint, fly tying, or birdwatching may have high-level visual demands and produce eye strain.

Coping Abilities.

Patients with temporary or permanent visual problems may experience emotional stress. The nurse should assess the patient's coping strategies and availability of support systems, and perform a more comprehensive psychosocial assessment if it is indicated.

Case Study

Subjective Data

Source: Zurijeta/Shutterstock.com.

A focused subjective assessment of Fatimah Abdullah revealed the following information.

Vision Difficulty: Had no vision problems until today. Wears eyeglasses for seeing distances and reading. Now having difficulty reading. Reports seeing periodic light flashes and small white spots "floating" in the air. Denies eye pain, itching, or tearing.

Past Health History: Extraocular extraction of cataract on right eye with implantation of intraocular lens 2 mo ago. Type 2 diabetes mellitus and hypertension.

Medications: Glyburide (DiaBeta), 5 mg/day; metoprolol (Lopressor), 50 mg PO daily.

Self-Care History: States she was compliant with postoperative regimen of antibiotic and corticosteroid eyedrops and with office follow-up with eye surgeon. Recovery from surgery was uneventful, and eyedrops were discontinued 2 wk ago. Does not have allergies. Walks in the mall at least 1 km three times a week. No resistance or isotonic exercises. Has had difficulty moving bowels with increased straining. Trying prune juice to help.

Coping Abilities: Afraid she is having a stroke.

See pp. 442 and 448 for more information on Ms. Abdullah.

Objective Data

Physical Examination.

Physical examination of the visual system includes inspecting ocular structures and determining their functional status. Assessment of ocular structures should include examining the ocular adnexa, the external eye, and internal structures. Some structures, such as the retina and blood vessels, must be visualized with the aid of equipment, such as the ophthalmoscope. Physiological functional assessment includes determining the patient's visual acuity and ability to judge closeness and distance; assessing extraocular muscle function; evaluating visual fields; observing pupil function; and measuring intraocular pressure.

Assessment of the visual system may include all of the components described in the following material, or it may be as brief as measuring the patient's visual acuity. The nurse assesses what is appropriate and necessary for the specific patient. All of the following assessments are in the nurse's scope of practice, but some necessitate special training. Normal findings of a physical assessment of the visual system are outlined in Table 23-3. Age-related visual changes and differences in assessment findings are listed in Table 23-1. Assessment techniques related to vision are summarized in Table 23-4. Common abnormalities found during assessment are listed in Table 23-5.

TABLE 23-3
NORMAL FINDINGS IN PHYSICAL ASSESSMENT OF THE VISUAL SYSTEM

• Visual acuity: 20/20 in both eyes; no diplopia • External eye structures: symmetrical and without lesions or deformities • Lacrimal apparatus: nontender and without drainage • Conjunctiva: clear; sclera: white • Pupils: equal, round, and reactive to light and accommodation (PERRLA) • Lens: clear • Extraocular movements: intact • Optic disc margins: sharp • Retinal vessels: normal, with no hemorrhages or spots

TABLE 23-4

NURSING ASSESSMENT
Visual System

Technique	Description	Purpose
Basic Techniques		
Visual acuity testing	Patient reads from Snellen chart at a distance of 6 m (distance vision test) and from Jaeger test type at a distance of 35 cm (near vision test); examiner notes smallest print that patient can read on each chart.	To determine patient's distance and near visual acuity
Confrontation visual field test	Patient faces examiner, covers one eye, fixates on examiner's face, and counts number of fingers that the examiner brings into patient's field of vision.	To determine whether patient has a full field of vision, without obvious scotomas
Pupil function testing	Examiner shines light into patient's pupil and observes pupillary response; each pupil is examined independently; examiner also checks for consensual and accommodative response.	To determine whether patient has normal pupillary response
Extraocular muscle functioning	Patient faces examiner, holds head still, and follows (with eyes only) object that examiner moves through six cardinal positions of gaze. Examiner also tests corneal light reflex.	To determine whether muscles and cranial nerves III, IV, and VI are functioning normally
Colour vision testing	Patient identifies numbers or paths formed by pattern of dots in a series of colour plates.	To determine patient's ability to distinguish colours
Advanced Techniques*		
Tono-Pen tonometry	Covered end of probe gently touches the anaesthetized corneal surface several times; examiner records several readings to obtain a mean intraocular pressure (see Figure 23-6).	To measure intraocular pressure (normal pressure is 10–22 mm Hg)
Ophthalmoscopy	Examiner holds ophthalmoscope close to patient's eye, shining light into back of eye and looking through aperture on ophthalmoscope; examiner adjusts dial to select one of the lenses in ophthalmoscope that produces the desired amount of magnification to inspect ocular fundus.	To observe retina and optic nerve head
Keratometry	Examiner aligns the projection and notes the readings of corneal curvature.	To measure the corneal curvature; often performed before fitting of contact lenses, before refractive surgery, or after corneal transplantation

*Performed by qualified health care provider.

TABLE 23-5

ASSESSMENT ABNORMALITIES
Visual System

Finding	Description	Possible Etiology and Significance
Subjective Data		
Pain	Foreign body sensation	Superficial corneal erosion or abrasion; can result from contact lens wear or trauma or from foreign body in the conjunctiva or cornea
	Severe, deep, throbbing	Anterior uveitis, acute glaucoma, infection; acute glaucoma also associated with nausea, vomiting
Photophobia	Persistent abnormal intolerance to light	Inflammation or infection of cornea or anterior uveal tract (iris and ciliary body), conjunctivitis
Blurred vision	Gradual or sudden inability to see clearly	Refractive errors, corneal opacities, cataracts, migraine aura, retinal changes (detachment, macular degeneration)
Appearance of spots, floaters, or light flashes (photopsias)	Seeing spots, "spider webs," "a curtain," or floaters within the field of vision, or flashes or flickers of light	Most common: liquefaction of the vitreous humor (benign phenomenon); other possible causes include hemorrhage into the vitreous humor, retinal holes, or retinal tears Light flashes may occur as the retina is being tugged, torn, or detached
Dryness	Discomfort, sandy or gritty sensation, irritation, or burning	Decreased tear formation or changes in tear composition because of aging or various systemic diseases
Diplopia	Double vision	Abnormalities of extraocular muscle action related to muscle or cranial nerve abnormality
Glare	Headache, ocular discomfort, reduced visual acuity	Related to corneal inflammation or to opacities in cornea, lens, or vitreous humor that scatter the incoming light; can also result from light scatter around edges of an intraocular lens; worse at night, when pupil is dilated
Objective Data		
Eyelids		
Allergic reactions	Redness, excessive tearing, and itching of eyelid margins	Many possible allergens; associated eye trauma can occur from rubbing itchy eyelids
Hordeolum (stye)	Small, superficial white nodule along eyelid margin	Infection of a sebaceous gland of eyelid; causative organism is usually bacterial (most commonly *Staphylococcus aureus*)
Blepharitis	Redness, swelling, and crusting along eyelid margins	Bacterial invasion of eyelid margins; often chronic
Ptosis	Drooping of upper eyelid margin; unilateral or bilateral	Mechanical causes as a result of eyelid tumours or excess skin; myogenic causes such as myasthenia gravis or neurogenic causes
Entropion	Inward turning of upper or lower eyelid margin, unilateral or bilateral	Congenital causes resulting in development abnormalities
Ectropion	Outward turning of lower eyelid margin	Mechanical causes as a result of eyelid tumours, herniated orbital fat, or extravasation of fluid
Conjunctiva		
Conjunctivitis	Redness, swelling of conjunctiva; possibly itching	Bacterial or viral infection; may be allergic response or inflammatory response to chemical exposure
Subconjunctival hemorrhage	Appearance of blood spot on sclera; may be small or can affect entire sclera	Conjunctival blood vessels rupture, leaking blood into the subconjunctival space
Cornea and Sclera		
Corneal abrasion	Localized painful disruption of the epithelial layer of cornea; can be visualized with fluorescein dye	Trauma; overwear or improper fit of contact lenses
Jaundice	Yellow discoloration* of the entire sclera	Related to liver dysfunction or hemolytic disease

Finding	Description	Possible Etiology and Significance
Globe		
Exophthalmos	Protrusion of globe beyond its normal position within bony orbit; sclera often visible above iris when eyelids are open	Intraocular or periorbital tumours; hyperthyroidism; Crouzon's syndrome
Pupil		
Anisocoria	Pupils are unequal (constricted)	Central nervous system disorders; in a small percentage of the population, slight difference in pupil size is normal
Abnormal response to light or accommodation	Pupils respond asymmetrically or abnormally to light stimulus or accommodation	Central nervous system disorders, general anaesthesia
Iris		
Heterochromia	Irides are different colours†	Congenital causes (Horner's syndrome); acquired causes (chronic iritis, metastatic carcinoma, diffuse iris nevus or melanoma)
Extraocular Muscles		
Strabismus	Deviation of eye position in one or more directions	Overaction or underaction of one or more extraocular muscles
Lens		
Cataract	Opacification of lens; pupil can appear cloudy or white when opacity is visible behind pupil opening	Aging, trauma, diabetes, long-term systemic corticosteroid therapy
Visual Field Defect		
Peripheral	Partial or complete loss of peripheral vision	Glaucoma; interruption of visual pathway (e.g., tumour); migraine headache
Central	Loss of central vision	Macular disease

*Yellow colour is normal after a diagnostic study necessitating intravenous fluorescein injection.

†Most cases of heterochromia occur by chance and are not associated with any other symptoms or problems.

The initial observation of the patient can provide information that will help the nurse focus the assessment. A patient with impaired colour vision may dress in clothing with unusual colour combinations. A patient with diplopia may hold the head in a skewed position in an attempt to see a single image. A patient with a corneal abrasion or photophobia may cover the eyes with the hands or wear dark glasses to try to block out room light. The nurse can make a crude estimate of depth perception by extending a hand for the patient to shake.

During the initial observation, the nurse should also observe the overall facial and ophthalmic appearance of the patient. The eyes should be symmetrical and normally positioned on the face. The globes should not have a bulging or sunken appearance.

Assessing Functional Status

Visual Acuity.

Before the patient receives any care, the nurse should record the patient's visual acuity for medical and legal reasons. To assess distance visual acuity, the patient sits or stands 6 metres (20 feet) from the Snellen chart with the usual correction (glasses or contact lenses) left in place unless they are used solely for reading. The nurse asks the patient to cover the left eye with an eye spoon and to read through the chart to the smallest line of letters that the patient can possibly discern. The nurse notes the smallest line the patient can read with 50% or fewer errors. The nurse then asks the patient to cover the right eye, and the process is repeated. At the left of most rows of the Snellen chart is a fraction (e.g., "20/30") in which the numerator represents the distance the patient is from the chart and the denominator represents the distance at which a normal eye could see the letters in the row. For example, a patient with a visual acuity of 20/30 sees at 20 feet what the patient with no vision problems would see at 30 feet. The larger the denominator, the worse the visual acuity. If vision is poorer than 20/30, the patient should be referred to an ophthalmologist or optometrist (Jarvis, Browne, MacDonald-Jenkins, et al., 2014). *Legal blindness* is defined as the best corrected vision in the better eye of 20/200 or worse. If a patient cannot read letters, the nurse can use an eye chart with pictures, numbers, or symbols, such as the STYCAR graded-balls test, the Sheridan-Gardiner letter-matching test, or the Snellen E chart.

To evaluate visual acuity when the patient is unable to see even the largest letters, the nurse holds up a number of fingers in front of the patient at successively closer distances and asks the patient to count them. If the patient cannot count the fingers, the nurse asks the patient to indicate whether he or she can see hand motion or light from a penlight in front of the face.

If the patient has a complaint of near vision problems, and for all patients 40 years of age or older, the nurse tests near visual acuity. The patient is instructed to hold a Jaeger chart 35 cm (14 inches) from the eyes. The nurse covers the patient's left eye with an eye spoon, asks the patient to read successively smaller lines of print from the chart, and records the visual acuity corresponding to the smallest line of print that the patient can read comfortably. The procedure is repeated with the right eye covered. A normal result is 14/14. A result of 14/20 means the person can read at 14 inches what someone with normal vision reads at 20 inches. If a screening card is not available, the nurse can assess near vision acuity by asking the patient to read from a newspaper.

Extraocular Muscle Functions.

The nurse observes the corneal light reflex to evaluate for weakness or imbalance of the extraocular muscles. In a darkened room, the nurse asks the patient to look straight ahead while a penlight is shone directly on the cornea. The light reflection should be located in the centre of both corneas as the patient faces the light source.

To assess eye movement, the nurse should hold a finger or object 25 to 30 cm from the patient's nose. The patient is asked to follow the movement of the object or finger with only his or her eyes through the six cardinal positions of gaze (Figure 23-4). This test can indicate weakness or paralysis in the extraocular muscles or dysfunction in a cranial nerve (oculomotor nerve [CN III], trochlear nerve [CN IV], and abducens nerve [CN VI]).

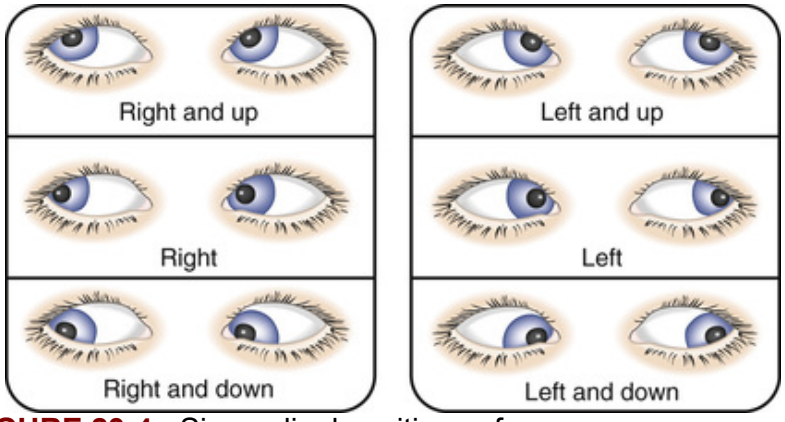

FIGURE 23-4 Six cardinal positions of gaze. Source: Adapted from Bowling, Brad. (2015). *Kanski's clinical ophthalmology: A systematic approach* (8th ed, p. 731). New York: Saunders.

Pupil Function.

To determine pupil function, the nurse inspects the pupils and their reactions to light. Pupil size is noted before reaction to light is checked. Pupils should be equal in size and round and should react briskly to light. With age, pupil size decreases (Jarvis, Browne, MacDonald-Jenkins, et al., 2014). In a small percentage of the population, pupils are unequal in size (anisocoria). Pupils should react to light directly (pupil constricts when a light shines into the eye) and consensually (pupil of one eye constricts when a light shines into opposite eye). Accommodation should also be present: when the patient looks at a distant object 0.6 to 0.9 metres away and then is asked to focus on an object 7 to 8 cm from the nose, the nurse should observe convergence of the patient's eyes and constriction of the

pupils. Normal pupil function may be documented as **PERRLA** (**p**upils **e**qual, **r**ound, **r**eactive to **l**ight and **a**ccommodation).

Case Study

Objective Data: Physical Examination

Source: Zurijeta/Shutterstock.com.

Physical examination findings of Fatimah Abdullah are as follows: PERRLA. No abnormalities noted on visual examination of external eye structures. EOM [extraocular movement] intact and symmetrical.

Diagnostic Studies

Ophthalmoscopic examination on Ms. Abdullah identifies a partial retinal detachment, which is confirmed via ultrasonography.

See pp. 442 and 445 for more information on Ms. Abdullah.

Assessing Structures.

The visual system is unique because the nurse can directly inspect not only the external structures but also many of the internal structures by using special equipment such as the ophthalmoscope and the slit-lamp microscope, which enables examination of conjunctiva, sclera, cornea, anterior chamber, iris, lens, vitreous humor, and retina under magnification. The *ophthalmoscope,* a hand-held instrument with a light source and magnifying lenses, is held close to the patient's eye to visualize the posterior part of the eye. Little pain or discomfort is associated with these examinations.

Eyebrows, Eyelashes, and Eyelids.

All structures should be present, symmetrical, and without deformities, redness, or swelling. Eyelashes extend outward from the eyelid margins. In normal closing, the upper and lower eyelid margins just touch. The lacrimal puncta should be open and positioned properly against the globe. If the sac is inflamed, pressure over the lacrimal sac may cause purulent material to ooze from the puncta.

Conjunctiva and Sclera.

The nurse can examine the conjunctiva and sclera at the same time, evaluating colour, smoothness, and presence of any lesions or foreign bodies. The conjunctiva covering the sclera is normally clear, with fine blood vessels visible, more commonly in the periphery.

The sclera is normally white, but its colour may become yellowish in older individuals because of lipid deposition in the sclera. A pale blue cast caused by scleral thinning can also be normal in older adults and infants (who have naturally thinner sclerae). A slightly yellow cast may also be normal finding in some dark-skinned people.

Cornea.

The cornea should be clear, transparent, and shiny. The iris should appear flat and not bulge toward the cornea. The area between the cornea and iris should be clear, with no blood or purulent material visible in the anterior chamber.

Iris.

Both irides should be of similar colour and shape. However, a colour difference between the irides is normal in a small proportion of individuals. Round or notched areas of missing iris tissue are often the result of cataract or glaucoma surgery. The nurse should determine the cause of these round, notched, or triangular areas and document the findings.

Retina and Optic Nerve.

To assess these structures, the nurse uses an ophthalmoscope to magnify the ocular structures and bring them into crisp focus (Figure 23-5). This enables the examiner to directly view arteries, veins, and the optic nerve. The nurse directs the beam of light from the ophthalmoscope obliquely into the patient's pupils and should note the appearance of a *red reflex*. This reflex is a result of light's reflecting off the retina. Any dense area in the lens or nontransparent material in the vitreous humor decreases the red

reflex. The optic nerve or disc is examined for size, colour, and abnormalities. The optic disc is creamy yellow with distinct margins. A slight blurring of the nasal margin is common.

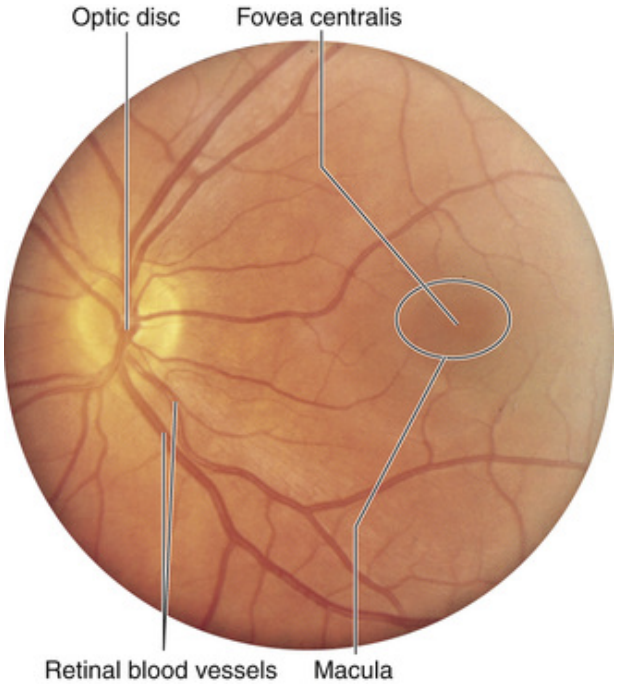

FIGURE 23-5 Illustration of magnified view of retina through the ophthalmoscope. Source: Adapted from Patton, K. T., & Thibodeau, G. (2013). *Anatomy and physiology* (8th ed., p. 528). St Louis: Mosby.

A central depression in the disc, called the *physiologic cup,* is the exit site for the optic nerve. The cup should be less than half the diameter of the disc. Normally, no hemorrhages or exudates are present in the fundus (retinal background). Careful inspection of the fundus can reveal the presence of retinal holes, tears, detachments, or lesions. Small hemorrhages can be associated with diabetes or hypertension and can appear in various shapes, such as dots or flames. Finally, the nurse examines the macula for shape and appearance. This area of high reflectivity is devoid of any blood vessels.

The nurse can obtain important information about the vascular system and the central nervous system through direct visualization with an ophthalmoscope. Skilled use of this instrument requires practice.

Focused Assessment.

A focused assessment (see the following "Focused Assessment" box) may be performed by a general nurse when a patient is admitted to a medical-surgical unit or an outpatient clinic. Inspection of the eyes may be performed routinely as part of the assessment of a hospitalized patient. In addition, the nurse should assess for and document use of glasses or contact lenses. Assessment for PERRLA may be performed routinely as part of neurological assessment of a hospitalized patient (see Chapter 58).

Focused Assessment

Visual System

Use this checklist to make sure the key assessment steps have been performed.

Subjective

Ask the patient about any of the following, and note responses.

Changes in vision (e.g., acuity, blurred)	Y	N
Eye redness, itching, discomfort	Y	N
Drainage from eyes	Y	N

Objective: Physical Examination

Inspect

Eyes for any discoloration or drainage	✓
Conjunctiva and sclera for colour and vascularity	✓
Lens for clarity	✓
Eyelid for ptosis	✓

Assess

Vision based on patient's looking at nurse or Snellen chart	✓
Extraocular movements	✓
Peripheral vision	✓
Pupil function: PERRLA	✓

PERRLA, Pupils equal, round, reactive to light and accommodation.

Special Assessment Techniques

Colour Vision.

Testing the patient's ability to distinguish colours can be an important part of the overall assessment because some occupations may require accurate colour discrimination. The Ishihara colour test determines the patient's ability to distinguish a pattern of colour in a series of colour plates. Older adults have a loss of colour discrimination at the blue end of the colour spectrum and loss of sensitivity throughout the entire spectrum, especially when cataracts are present.

Stereopsis.

Stereoscopic vision allows a patient to see objects in three dimensions. Any event causing a patient to have monocular vision (e.g., enucleation, patching) results in loss of stereoscopic vision, which impairs the individual's depth perception. This condition can have serious consequences: for example, if the patient trips over a step when walking or follows too closely behind another vehicle when driving.

Intraocular Pressure.

Testing intraocular pressure is important because high intraocular pressure is a major risk factor for glaucoma. Intraocular pressure can be measured by a variety of methods, including the Tono-Pen (Figure 23-6). Use of the Tono-Pen is common because it is simple and results are very accurate. The surface of the anaesthetized cornea is touched lightly several times with the covered end of the probe. The instrument records several readings and provides a mean measurement on a digital light-emitting diode (LED) screen located on the front surface. Normal intraocular pressure ranges from 10 to 22 mm Hg.

FIGURE 23-6 Tono-Pen tonometry. Source: Courtesy the Eye Institute, Department of Ophthalmology and Visual Services, University of Iowa Health Care, Iowa City, Iowa.

Diagnostic Studies

Diagnostic studies provide important objective data to the nurse monitoring the patient's condition and planning appropriate interventions. Table 23-6 presents the most common basic diagnostic studies of the visual system.

TABLE 23-6

DIAGNOSTIC STUDIES
Visual System

Study	Description and Purpose	Patient Education*
Refractometry	Subjective measure of refractive error; multiple lenses are mounted on rotating wheels. While patient sits looking through apertures at Snellen acuity chart, lenses are changed; patient chooses lenses that make acuity sharpest. Cycloplegic drugs are used to paralyze accommodation during refraction process.	Procedure is painless; patient may need help holding the head still. Pupil dilation makes it difficult for the patient to focus on near objects; dilation may last 3–4 hr.
Ultrasonography	A-scan probe is placed on patient's anaesthetized cornea; used primarily for axial length measurement for calculating power of intraocular lens implanted after cataract extraction. B-scan probe is applied to patient's closed eyelid; used more often than A-scan for diagnosis of ocular disorders such as intraocular foreign bodies or tumours, opacities in the vitreous humor, and retinal detachments.	Procedure is painless (cornea is anaesthetized).
Fluorescein angiography	Fluorescein (a nonradioactive, non-iodine dye) is intravenously injected into antecubital or other peripheral vein, followed by serial photographs (over 10-min period) of the retina through dilated pupils. Provides diagnostic information about flow of blood through pigment epithelial and retinal vessels; often used in patients with diabetes to accurately locate areas of diabetic retinopathy before laser destruction of neovascularized area.	Fluorescein is toxic to tissue if extravasation occurs; systemic allergic reactions are rare, but the nurse should be familiar with emergency equipment and procedures. The patient should be informed that dye can sometimes cause transient nausea or vomiting and transient yellow discoloration of urine and skin.
Amsler grid test	Test is self-administered with a hand-held card printed with a grid of lines (similar to graph paper); patient fixates on centre dot and records any perceived abnormalities of the grid lines, such as wavy, missing, or distorted areas. Test is used to monitor macular problems.	Regular testing is necessary to identify any changes in macular function.

*Patient education regarding the purpose and method of testing is a nursing responsibility for all diagnostic procedures.

Safety Alert

Nurses should avoid using the abbreviations *OS* for left eye, *OD* for right eye, and *OU* for both eyes when documenting in patients' charts or transcribing medication orders because they can be easily confused with each other and with the abbreviations *AD*, *AS*, and *AU* for the ear. Use of these abbreviations can contribute to communication errors and potentially serious medication errors (Institute for Safe Medication Practices Canada, 2016).

The Auditory System

Structures and Functions

The auditory system is composed of the peripheral and central auditory systems. The peripheral auditory system includes the structures of the ear itself: external, middle, and inner ear (Figure 23-7). This system is concerned with the reception and perception of sound. The external and middle portions of the ear function to conduct and amplify sound waves from the environment. The inner ear serves functions of hearing and balance. The central auditory system (the brain and its pathways) integrates and assigns meaning to what is heard.

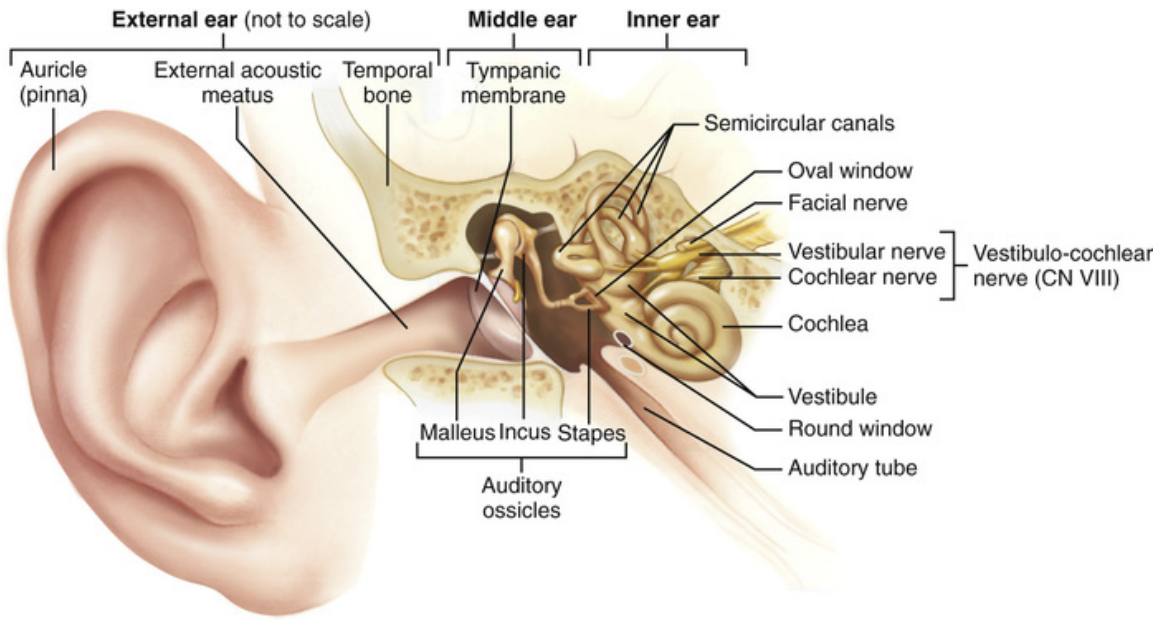

FIGURE 23-7 External, middle, and inner ear. *CN,* cranial nerve.

Source: Adapted from Patton, K. T., & Thibodeau, G. A. (2013). *Anatomy and physiology* (8th ed., p. 518). St. Louis: Mosby.

External Ear

The external ear consists of the auricle (pinna) and the external auditory canal. The *auricle* is composed of cartilage and connective tissue covered with epithelium, which also lines the external auditory canal (see Figure 23-7). The *external auditory canal* is a slightly S-shaped tube about 2.5 cm in

length in the adult. The skin that lines the canal contains fine hairs and sebaceous (oil) glands and ceruminous (wax) glands. The hairs and wax help prevent dust and other foreign objects from entering the ear canal (Herlihy, 2014).

Hair is present in the outer half of the canal. The inner half of the ear canal is highly sensitive. The function of the external ear and canal is to collect and transmit sound waves to the *tympanic membrane* (eardrum). This shiny, translucent, pearl-grey membrane is composed of epithelial cells, connective tissue, and mucous membrane. It serves as a partition and instrument of sound transmission between the external auditory canal and middle ear.

Middle Ear

The middle ear cavity is an air space located in the temporal bone. Mucosa lines the middle ear and is continuous from the nasal pharynx via the Eustachian (auditory) tube. The *Eustachian tube* functions to equalize atmospheric air pressure between the middle ear and throat and allows the tympanic membrane to move freely. It opens during yawning and swallowing. Blockage of this tube can occur with allergies, nasopharyngeal infections, or enlarged adenoids.

The middle ear contains three tiny bones or *(ossicles): malleus, incus,* and *stapes.* Vibrations of the tympanic membrane cause the ossicles to move and transmit sound waves to the oval window. The resulting vibration in the oval window causes fluid in the inner ear to move and stimulate hearing receptors. The round window sits below the oval window and is covered with a thin membrane called the *fenestra cochlea;* it also opens into the inner ear and acts as a pressure valve that moves outward as fluid pressure builds in the inner ear. The superior part of the middle ear is called the *epitympanum* (attic). It also communicates with air cells within the mastoid bone. The facial nerve (CN VII) passes above the oval window of the middle ear. The thin, bony covering of the facial nerve can become damaged by chronic ear infection, skull fracture, or trauma during ear surgery. Such damage can cause problems with voluntary facial movements, eyelid closure, and taste discrimination. Permanent damage to the facial nerve can also result.

Inner Ear

The inner ear is composed of a bony labyrinth (maze) surrounding a membrane. This complex contains the functional organs for hearing and

balance. The receptor organ for hearing is the *cochlea,* a coiled structure. It contains the *organ of Corti,* whose tiny hair cells respond to stimulation of selected portions of the basilar membrane according to pitch. This stimulus is converted into an electrochemical impulse and then transmitted by the cochlear branch of the vestibulo-cochlear nerve (CN VIII; formerly called the *acoustic nerve*) to the temporal lobe of the brain to process and interpret the sound.

Three semicircular canals and the vestibule make up the membranous labyrinth, which is housed in the bony labyrinth and enables the sense of balance. The membranous labyrinth is filled with endolymphatic fluid, and the bony labyrinth is filled with perilymphatic fluid. The fluid cushions these two sensitive organs and communicates with the brain and the subarachnoid spaces of the brain. The nervous stimuli are communicated by the vestibular portion of CN VIII. Debris or excessive pressure within the lymphatic fluid can cause disorders such as vertigo.

Transmission of Sound and Implications for Hearing Loss

Sound waves are conducted by air (air conduction) and picked up by the auricles and the auditory canal. The sound waves strike the tympanic membrane, causing it to vibrate. The central area of the tympanic membrane is connected to the malleus, which also starts to vibrate, transmitting the vibration to the incus and then the stapes. As the stapes moves back and forth, it pushes the membrane of the oval window in and out. Movement of the oval window produces waves in the perilymph. Pathological disturbances in the external ear canal or the middle ear may cause a conductive hearing loss, resulting in an alteration in the patient's perception of or sensitivity to sounds.

Once sound has been transmitted to the liquid medium of the inner ear, the vibration is picked up by the tiny sensory hair cells of the cochlea, which initiate nerve impulses. These impulses are carried by nerve fibres to the main branch of the acoustic portion of CN VIII and then to the brain. Disruptions of the inner ear or along the nerve pathway from the inner ear to the brain can result in sensorineural hearing loss. This may result in an alteration of the patient's perception of or sensitivity to specific tones. Impairment within the central auditory system causes *central hearing loss.* This type of hearing loss causes difficulty in understanding the meaning of words that are heard. (Types of hearing loss are discussed further in Chapter 24.)

The bones of the skull can also transmit sound directly to the inner ear (bone conduction). This can be demonstrated by placing the stem of a vibrating tuning fork on the patient's head, against the skull.

Age-Related Considerations

The Auditory System

Age-related changes of the auditory system can result in hearing impairment. **Presbycusis,** or hearing loss caused by aging, can also result from insults from a variety of sources. Noise exposure, vascular or systemic diseases, poor or inadequate nutrition, ototoxic drugs, and pollution during the lifespan can damage delicate hair cells of the organ of Corti or cause atrophy of lymph-producing cells. Sound transmission is diminished by calcification of the ossicles. Dry cerumen in the external canal can also interfere with transmission of sound. **Tinnitus,** or the perception of ringing in the ears, may accompany hearing loss that results from the aging process.

Hearing loss, especially in an older adult, can have serious implications for the quality of life, including progressive physical and psychosocial dysfunction (Seidel, Ball, Dains, et al., 2011). As the average lifespan increases, the number of people with hearing loss will also increase. Early identification of hearing problems will ensure that patients are more active and healthy as they age.

Age-related changes in the auditory system and differences in assessment findings are presented in Table 23-7.

TABLE 23-7

AGE-RELATED DIFFERENCES IN ASSESSMENT
Auditory System

Changes	Differences in Assessment Findings
External Ear	
Increased production of and drier cerumen	Impacted cerumen; potential hearing loss
Increased hair growth	Visible hair, especially in men
Loss of elasticity in cartilage	Collapsed ear canal
Middle Ear	
Atrophic changes of tympanic membrane	Conductive hearing loss
Inner Ear	
Hair cell degeneration, neuron degeneration in auditory nerve and central pathways, reduced blood supply to cochlea, calcification of ossicles	Presbycusis, diminished sensitivity to high-pitched sounds, impairment in speech reception, tinnitus
Less effective vestibular apparatus in semicircular canals	Alterations in balance and body orientation
Brain	
Decline in ability to filter out unwanted and unnecessary sound	Difficulty hearing in a noisy environment, heightened sensitivity to loud sounds

Assessment

Assessment of the auditory system includes assessment of the *vestibular* (balance) system because the auditory and vestibular systems are so closely related. Initially, the nurse should try to categorize symptoms related to balance and distinguish them from symptoms related to hearing loss or tinnitus. Problems with balance may manifest as nystagmus or vertigo. **Nystagmus** is abnormal eye movements that may be observed by other people as twitching of the patient's eyeball or may be described by the patient as a blurring of vision with head or eye movement. **Vertigo** is a sense that the person or objects around the person are moving or spinning and is usually stimulated by movement of the head. Dizziness is a sensation of being off-balance that occurs when the person is standing or walking. It does not occur when the person is lying down. Health history questions to ask a patient with an auditory problem are listed in Table 23-8.

TABLE 23-8

HEALTH HISTORY
Auditory System: Questions for Obtaining Subjective Data

Earache
• Do you have earache or another kind of pain in your ear?*
• Where is it located? Can you describe the pain?
• Do you have any symptoms of a cold or a sore throat?*
• What measures have you used to relieve the pain?* Were they effective?
Discharge
• Have you experienced discharge from your ears? How much and what colour?
• Have you had ear infections? How frequent? How were they treated?
Hearing Loss
• Was the hearing loss sudden or gradual?*
• Is it all your hearing or just hearing of certain sounds that has decreased?
• Where do you notice the hearing loss (e.g., conversations in a crowd, telephone conversations, watching television)?
• Have you travelled by airplane recently?
• Do you have any allergies that result in ear problems?*
• How does your hearing loss affect your daily life at home and at work?
Environmental Noise
• Do you have loud noise in your home or work environment?*
• Do you work near loud noises such as heavy machinery or drums in a band?
Tinnitus
• Have you ever experienced ringing, crackling, or buzzing in your ears?*
• Does the noise seem louder at certain times?*
• When does it bother you the most?
• What things have you tried that help?
Vertigo
• Have you felt vertigo—a spinning sensation?*
• Have you felt dizzy, as if you were falling or losing your balance?*
• Do you ever experience lightheadedness or giddiness?*
• Have you ever fallen because of the dizziness?*
• How does your dizziness affect your daily life?*
Nutrition and Elimination
• Do you have any food allergies that affect your ears?*
• Do you notice any differences in symptoms with changes in your diet?*
• Does your ear problem cause nausea that interferes with your food intake?*
• Does chewing or swallowing cause you any ear discomfort?
• Does straining during a bowel movement cause you ear pain?*
Activities of Daily Living and Exercise
• Does your ear problem cause you to change your usual activity or exercise?*
• Do you need help with certain activities (e.g., lifting, bending, climbing stairs, driving, speaking) because of symptoms?*
• Do you have any limitations in activities of daily living because of your symptoms?*
• Is your sleep disturbed by symptoms of pain, tinnitus, or dizziness?*
Self-Care History
• When did you last have your ears checked?
• How do you clean your ears?
• Do you use any devices to improve your hearing (e.g., hearing aid, special volume control, headphones for television or audio devices)?*
• How long have you used a hearing aid? Do you have any problems using or maintaining your hearing aid?*
• Do you use any means to protect your ears such as headphones or earplugs?* When?
• Do you use personal sound systems such as iPhones or MP3 players?*
Coping Abilities
• Is your ability to communicate and understand affected by your symptoms?*
• What effect has your ear problem had on your work, family, or social life?

- How does your ear problem make you feel about yourself?
- Do you consider your ear problem a stressor?*
- How do you cope with your ear problem?

*If yes, describe.

Source: Adapted from Jarvis, C., Browne, A. J., MacDonald-Jenkins, J., et al. (Eds.). (2014). *Physical examination and health assessment* (2nd Canadian ed., pp. 346–348). Toronto: Elsevier Canada.

Subjective Data

Important Health History

Current Health of Auditory System.

The nurse should inquire about earache or pain in the ear. Such pain may be caused by ear problems such as middle ear infection, or may be referred pain originating in the teeth or temporo-mandibular joint. If pain is present, the patient should be asked to describe the pain and the treatments used for relief. If the patient has experienced any ear infections or has a history of chronic ear infections, this may contribute to increased hearing loss. Pus or bloody discharge may indicate an ear infection, whereas clear discharge may consist of cerebro-spinal fluid, particularly if the patient has received any head trauma. The nurse should note the time of onset of the hearing loss, whether it was sudden or gradual, and the person who noted the onset. Gradual hearing losses are most often noted by people who communicate regularly with the patient. Sudden losses and those exacerbated by some other condition are most often reported by the patient. If a hearing loss is identified in an older adult patient, the nurse can use the questions from the Hearing Handicap Inventory for Older Persons (Table 23-9). Referral is recommended for individuals scoring 10 or higher on the inventory.

TABLE 23-9
THE HEARING HANDICAP INVENTORY FOR OLDER PERSONS*

Does a hearing problem cause you
1. (E) To feel embarrassed when meeting new people?
2. (E) To feel frustrated when talking to members of your family?
3. (S) To have difficulty understanding when someone speaks in a whisper?
4. (E) To feel handicapped?
5. (S) To have difficulty when visiting friends, relatives, or neighbours?
6. (S) To attend religious services less often than you would like?
7. (E) To have arguments with family members?
8. (S) To have difficulty when listening to television or radio?
9. (E) To feel that your hearing limits or hampers your personal or social life?
10. (S) To have difficulty when in a restaurant with relatives and friends?

*Overall scoring: *yes* = 4 points; *sometimes* = 2 points; *no* = 0 points.

(E), question referring to emotional handicap; *(S),* question referring to social handicap.

Source: Adapted from Bance, M. (2007). Hearing and aging. *Canadian Medical Association Journal,* 176(7), 925–927. By permission of the publisher. © 1982 Canadian Medical Association. Copied under licence from Access Copyright. Further reproduction, distribution or transmission is prohibited except as otherwise permitted by law.

If the patient has experienced any ringing, crackling, or buzzing sensation, the nurse should note time of onset and whether the patient is taking any medications that might cause tinnitus. Symptoms such as dizziness, tinnitus, and hearing loss are recorded in detail in the patient's own words. This careful description could help differentiate the cause.

Past Health History.

Many problems related to the ear are sequelae of childhood illnesses or result from problems of adjacent organs. Consequently, a careful assessment of past health problems is important.

The patient should be questioned about previous problems regarding the ears, especially problems experienced during childhood. The frequency of acute middle ear infections (otitis media), perforations of the eardrum, drainage, and history of mumps, measles, or scarlet fever should be recorded. Congenital hearing loss can result from infectious diseases (e.g., rubella, influenza, or syphilis), teratogenic medications, or hypoxia in the first trimester of pregnancy. Information regarding family members with hearing loss and type of hearing loss is important. Some congenital hearing loss is hereditary. The age at onset of presbycusis also follows a familial pattern. Head injury should be documented because it can result in hearing loss. Information about food and environmental allergies is important because they can cause the Eustachian tube to become edematous and prevent aeration of the middle ear.

Medications.

The nurse should obtain information about current or past medications that are ototoxic (cause damage to CN VIII) and can produce hearing loss, tinnitus, and vertigo. The amount and frequency of acetylsalicylic acid (ASA; Aspirin) use is important because tinnitus can result from high ASA (Aspirin) intake. Aminoglycosides, any other antibiotics, salicylates, antimalarial agents, chemotherapeutic drugs, diuretics, and nonsteroidal anti-inflammatory drugs are groups of drugs that are potentially ototoxic (Lehne, 2012). Careful monitoring for hearing and balance problems is essential. Many drugs produce hearing loss that may be reversible if treatment is stopped. The nurse should also inquire about the use of herbal or alternative therapies, including ear candling. Health Canada (2011) does not recommend ear candling because patients have experienced burns and hearing loss as a result.

Surgery or Other Treatments.

The nurse should obtain information about previous hospitalizations for ear surgery (e.g., myringotomy, tympanoplasty), tonsillectomy, and adenoidectomy. Use of and satisfaction with a hearing aid should be documented. Problems with impacted cerumen should also be noted.

Nutrition and Elimination.

Both alcohol and sodium affect the amount of endolymph in the inner ear system. Patients with Ménière's disease generally notice some improvement in their symptoms with alcohol restriction and a low-sodium diet. Improvements and exacerbations associated with food intake should be noted. The patient should also be questioned about any ear pain or discomfort that occurs with chewing or swallowing, which might decrease nutritional intake. This situation is often associated with a problem in the middle ear.

Assessment of clenching or grinding of the teeth helps differentiate problems of the ear from referred pain of the temporo-mandibular joint. The nurse should ask about dental problems and dentures.

Elimination patterns and their association with ear problems are of interest mainly in patients with perilymph fistula or in patients immediately after surgery. Frequent constipation or straining with bowel or bladder elimination may interfere with healing of a perilymph fistula or its repair. A patient who has just undergone stapedectomy especially needs to prevent the increase in intracranial (and consequent inner ear) pressure associated with straining during bowel movements. Stool

softeners may be ordered postoperatively for a patient who reports chronic problems with constipation.

Activities of Daily Living and Exercise.

Activity and exercise review is most important in assessing a patient with vestibular problems. If vertigo is a problem, the patient should be questioned about the onset, duration, and frequency of this symptom. Patients who have Ménière's disease demonstrate increasing inability to compensate for environmental input as the day progresses. Symptoms are experienced particularly in the evening. In contrast, patients with chronic vertigo syndrome (benign paroxysmal positional vertigo) note that the symptoms improve throughout the day as adjustment to the visual and positional input from the environment occurs. The nurse and the patient should identify a list of activities and exercises that aggravate and relieve dizziness and vertigo or cause nausea or vomiting. Frequent repetition of an activity that causes symptoms (habituation) may help the body adjust so that the activity is no longer a problem.

A patient with chronic tinnitus should be questioned about sleep problems. Tinnitus can disturb sleep and activities conducted in a quiet environment. Affected patients should be asked whether they have used or tried any masking devices or techniques to drown out the tinnitus. The nurse should also assess for snoring because it can be caused by swelling or hypertrophy of tissue in the nasopharynx. This excessive tissue can impair the functioning of the Eustachian tube and cause the sensation of ear fullness or pain.

Self-Care History.

Patients should be questioned about personal practices such as the most recent ear examination, use of cotton ear swabs, use of earphones for personal listening devices, and measures used to preserve hearing. Patients should be questioned about contact with environments that have excessive noise levels, such as work with jet engines and machinery, firing of firearms, and electronically amplified music. The use of protective ear covers or earplugs is good practice for people in high-noise environments and is important to document.

If the patient is a swimmer, the frequency and duration of swimming and use of ear protection should be documented. It is also important to note the type of water (pool, lake, or ocean) in which the swimming takes place to help identify contact with contaminated water. Placement of any

item in the ear, including hearing aids, that can cause trauma to the skin increases risk of infection.

Coping Abilities.

Patients should be questioned about the effect the ear problem has had on family life, work responsibilities, and social relationships. Hearing loss can strain family relations and create misunderstandings. Failure to acknowledge hearing loss and failure to seek treatment can further hinder family relationships. Many jobs rely on the ability to hear accurately and respond appropriately. If a hearing loss is present, the nurse should gather detailed information of its effect on the patient's job. The patient should be assisted to realistically evaluate the job situation.

The unpredictability of vertigo attacks can have devastating effects on all aspects of a patient's life. Ordinary activities such as driving, child care, housework, climbing stairs, and cooking all acquire an element of danger. The patient should be asked to describe the effect of the vertigo on the many roles and responsibilities of life. Compensatory practices to avoid the development of dangerous situations should also be noted.

Hearing loss often leaves the patient feeling isolated from valued social relationships. The nurse should historically document social activities such as playing cards, going to movies, and attending religious functions from before and since the hearing loss occurred. Comparison of the frequency and enjoyment of the events can indicate whether a problem is present. The nurse should determine whether hearing loss or deafness has interfered with the patient's establishment of a satisfactory sex life. Although intimacy does not depend on the ability to hear, it could interfere with establishing or maintaining a relationship.

Objective Data

Physical Examination.

During the health history interview, the nurse can collect valuable objective data regarding the patient's ability to hear. Clues such as posturing of the head and appropriateness of responses should be noted. Does the patient ask to have certain words repeated? Does the patient intently watch the examiner but miss comments when not looking at the examiner? Such observations are significant and should be recorded. This is also important because many patients are unaware of hearing loss or do not admit to changes in hearing until moderate losses have occurred. A normal assessment of the ear is described in Table 23-10.

TABLE 23-10

NORMAL FINDINGS IN PHYSICAL ASSESSMENT OF THE AUDITORY SYSTEM

- Ears: symmetrical in location and shape
- Auricles and tragus: nontender, without lesions
- Canal: clear; tympanic membrane: intact; landmarks and light reflex: intact
- Ability to hear low whisper at 30 cm; Rinne's test results: air conduction is better than bone conduction; Weber's test results: no lateralization

Age-related changes of the auditory system and differences in assessment findings are listed in Table 23-7.

External Ear.

The external ear is inspected and palpated before examination of the external canal and tympanum. The auricle, preauricular area, and mastoid area are observed for symmetry of the ears, colour of skin, temperature, nodules, swelling, redness, and lesions. The auricle and mastoid areas are then palpated for tenderness and nodules. Grasping the auricle may elicit a pain response, especially if inflammation of the external ear or canal is present.

External Auditory Canal and Tympanum.

Before inserting an otoscope, the nurse should inspect the canal opening for patency, palpate the tragus, and gently move the auricle to check for discomfort. A speculum only slightly smaller than the size of the ear canal is selected. The patient's head is tipped to the opposite shoulder. The top of the auricle is grasped and gently pulled up and backward in adults and slightly down and backward in children to straighten the canal. The otoscope, held in one of the examiner's hands and stabilized on the patient's head by the fingers of the other hand, is inserted slowly (Figure 23-8). A tight seal of the speculum is essential during this step of the examination. The canal is observed for size and shape and for the colour, amount, and type of cerumen. The tympanic membrane separates the external ear from the middle ear. If a large amount of cerumen is present, the tympanic membrane may not be visible. The tympanic membrane is observed for colour, landmarks, contour, and intactness (Figure 23-9). It is pearl-grey, white, or pink; shiny; and translucent.

FIGURE 23-8 Otoscopic examination of the adult ear. The auricle is pulled up and back. The examiner's hand holding the otoscope is braced against the patient's face for stabilization. Source: Courtesy Maureen Barry.

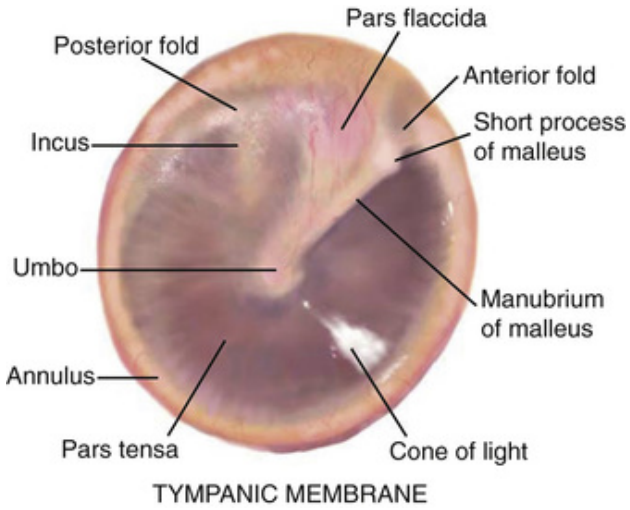

FIGURE 23-9 Illustration of normal landmarks of the right tympanic membrane, as seen through an otoscope. Source: Jarvis, C. (2015). *Physical examination and health assessment* (7th ed.). St. Louis: Elsevier.

The handle *(manubrium)* of the malleus and the end *(umbo)* are formed from the short process of the malleus and should be visible through the membrane. The somewhat anterior position and concave shape of the tympanic membrane causes the light from the otoscope to reflect back as a

cone of light with crisp edges. If the tympanic membrane is bulging or retracted, the edges of the light reflex do not have the cone shape; instead, the reflected light spreads out or moves and has irregular edges (diffuse). The circumference of the tympanum is thickened into a dense, whitish, fibrous ring, or *annulus,* except in the superior area. The tympanum within the annulus *(pars tensa)* is taut. Above the short process of the malleus is the *pars flaccida,* the flaccid part of the tympanum. The malleolar folds are anterior and posterior to the short process of the malleus. The middle and inner ear cannot be examined with the otoscope because of the tympanic membrane. Table 23-11 summarizes common abnormalities of the auditory system that are found in the assessment.

TABLE 23-11

ASSESSMENT ABNORMALITIES
Auditory System

Finding	Description	Possible Cause and Significance
External Ear and Canal		
Sebaceous cyst behind ear	Usually within skin, possible presence of black dot (opening to sebaceous gland)	Removal or incision and drainage if painful
Tophi	Hard nodules in the helix or antihelix, consisting of uric acid crystals	Associated with gout, metabolic disorder; further diagnosis needed
Impacted cerumen	Wax that has not been excreted from the ear normally; no visualization of eardrum	Decreased hearing possible, sensation of fullness in auditory canal; removal necessary before otoscopic examination can be conducted
Discharge in canal	Infection of external ear, usually painful	Swimmer's ear, infection of external ear; possibly caused by ruptured eardrum and otitis media
Swelling of auricle, pain	Infection of glands of skin, hematoma caused by trauma	Aspiration (for hematoma)
Scaling or lesions	Change in usual appearance of skin	Seborrheic dermatitis, squamous cell carcinoma, atrophic dermatitis
Exostosis	Bony growth extending into canal, causing narrowing of canal	Possible interference with visualization of tympanum; usually asymptomatic
Tympanum		
Retracted eardrum	Appearance of shorter, more horizontal malleus; cone of light is absent or bent	Vacuum in middle ear, blockage of Eustachian tube, negative pressure in middle ear
Hairline fluid level, yellow-amber bubbles above fluid level	Caused by transudate of blood and serum; meniscus of fluid produces hairline appearance	Serous otitis media
Bulging red or blue eardrum, lack of landmarks	Middle ear filled with fluid (pus, blood)	Acute otitis media; perforation possible
Perforation of eardrum (central or marginal)	Previous perforations of the eardrum that have failed to heal; thin, transparent layer of epithelium surrounding eardrum	Chronic otitis media, mastoiditis
Recruitment	Disproportionate loudness of sound; difficulty in using hearing aid	Malfunction of inner ear

Focused Assessment.

A focused assessment (see the following "Focused Assessment" box) may be performed by a general nurse when a patient is admitted to a medical-surgical unit or an outpatient clinic. The ears may be inspected routinely as part of the assessment of a hospitalized patient. In addition, the nurse should assess for the presence of a hearing aid and document whether the patient has been using it.

Focused Assessment

Auditory System

Use this checklist to make sure the key assessment steps have been performed.

Subjective

Ask the patient about any of the following, and note responses.

Changes in hearing	Y	N
Ear pain	Y	N
Ear drainage	Y	N

Objective: Physical Examination

Inspect

Alignment and position of ears on head	✓
Size, shape, symmetry, colour, and skin intactness	✓
External auditory meatus for discharge or lesions	✓

Assess

Hearing, according to ability to respond to conversation, respond to a whisper, or hear a ticking watch	✓

Diagnostic Studies

Table 23-12 describes diagnostic studies commonly used to assess the auditory system.

TABLE 23-12
DIAGNOSTIC STUDIES
Auditory System

Study	Description and Purpose	Nursing Responsibility
Auditory		
Pure tone audiometry	Sounds are presented through earphones in soundproof room. Patient responds nonverbally when sound is heard. Response is recorded on an audiogram. Purpose is to determine patient's hearing range in terms of decibels (dB) and hertz (Hz) for diagnosing conductive and sensorineural hearing loss. Tinnitus can cause inconsistent results.	Nurse does not usually participate in examination.
Bone conduction	Tuning fork is placed on mastoid process, and hearing by bone conduction is recorded. Helps diagnose conductive hearing loss.	Nurse may perform test.
One- and two-syllable word lists	Words are presented and recorded at comfortable level of hearing to determine percentage correct and word understanding.	Nurse may perform test.
Auditory evoked potential	Procedure is similar to electroencephalography (see Chapter 58, Table 58-8). Electrodes are attached to patient in darkened room. Electrodes are placed typically at vertex, mastoid process, or earlobes and forehead. A computer is used to record auditory activity in isolation from other electrical activity of the brain.	Nurse should explain procedure to patient. Nurse should not leave patient alone in the darkened room.
Electrocochleography	Test is useful for uncooperative patient or for patient who cannot volunteer useful information. Test records electrical activity in the cochlea and auditory nerve.	Nurse does not usually participate in examination.
Auditory brainstem response	Electrical peaks along auditory pathway of inner ear to brain are measured, and diagnostic information is related to acoustical neuromas, brainstem problems, and stroke.	Nurse does not usually participate in examination.
Tympanometry (impedance audiometry)	Useful in diagnosis of middle ear effusions. A probe is placed snugly in the external ear canal, and positive and negative pressures are then applied. Compliance of the middle ear is then noted in response to the pressures.	Nurse does not usually participate in examination.
Vestibular		
Caloric test stimulus	Endolymph of the semicircular canals is stimulated by irrigation of cold (20°C) or warm (36°C) solution into ear. Patient is seated or in supine position. Observation of type of nystagmus, nausea and vomiting, falling, or vertigo is helpful in diagnosing disease of labyrinth. Decreased response indicates decreased function and thus disease of vestibular system. Other ear is tested similarly, and results from both are compared.	Nurse instructs patient to eat no more than a light meal before test, to prevent nausea. Nurse observes patient for vomiting and assists patient if necessary. Nurse ensures patient safety.
Electronystagmography	Electrodes are placed near patient's eyes, and movement of eyes (nystagmus) is recorded on graph during specific eye movements and when ear is irrigated. Study aids in diagnosing diseases of vestibular system.	Nurse instructs patient to eat no more than a light meal before test, to prevent nausea. Nurse observes patient for vomiting and assists patient if necessary. Nurse ensures patient safety.

Study	Description and Purpose	Nursing Responsibility
Posturography	A balance test in which one semicircular canal can be isolated from others to determine site of lesion.	Nurse informs patient that test is time consuming and uncomfortable but that the test can be discontinued any time at patient's request.
Rotary chair testing	The patient is seated in a chair driven by a motor under computer control. Test is an evaluation of peripheral vestibular system.	Nurse instructs patient to eat no more than a light meal before test, to prevent nausea. Nurse observes patient for vomiting and assists patient if necessary. Nurse ensures patient safety.

Tests for Hearing Acuity

Tests involving the whispered and the spoken voice can provide gross screening information about the patient's ability to hear. Audiometric testing provides more detailed information that can be used for diagnosis and treatment. In the *whispered voice test,* the examiner stands 30 to 60 cm behind the patient and, after exhaling, speaks in a low whisper. A louder whisper is used if the patient does not respond correctly. Spoken voice, increasing in loudness, is similarly used. The patient is asked to repeat numbers or words or answer questions. One ear at a time is tested while hearing in the other ear is masked to prevent sound transmission around the head. During testing, the nontest ear is masked by the patient, who occludes the ear, or by the examiner, who gently occludes the auditory canal with a finger and rubs the tragus in a circular motion.

Tuning-Fork Tests.

Tuning-fork tests aid in differentiating between conductive and sensorineural hearing loss. For this examination, 512-Hz tuning forks are generally used. Both skill and experience are necessary to ensure accurate results. If a problem is suspected, further evaluation by pure-tone audiometry is essential. The most common tuning-fork tests are Rinne's test and Weber's test.

In Rinne's test, the base of an activated tuning fork is held first against the patient's mastoid bone to evaluate bone conduction and then 1 to 5 cm in front of the patient's ear canal to evaluate air conduction. The patient reports whether the sound is louder behind the ear (on the mastoid bone) or next to the ear canal. When the sound is no longer perceived behind the

ear, the fork is moved next to the ear canal until the patient indicates that the sound is no longer heard. The test result is positive when the patient reports that air conduction is heard longer than bone conduction. This can indicate normal hearing or a sensorineural loss. If the patient hears the tuning fork better by bone conduction, the test result is negative, indicating that conductive hearing loss is present.

In Weber's test, an activated tuning fork is placed on the midline of the patient's skull, on the forehead, or on the teeth. The patient is asked to indicate where the sound is heard best. In conditions of normal auditory function, the patient perceives a midline tone best. If a patient has a conductive hearing loss in one ear, sound is heard louder (lateralizes) in that ear. If a sensorineural loss is present, sound is louder (lateralizes) in the unaffected ear.

Results of tuning-fork tests are subjective. A patient with inconsistent test results or questionable results should be referred for more objective audiometric evaluation.

Audiometry.

Audiometry is beneficial as a screening test for hearing acuity and as a diagnostic test for determining the degree and type of hearing loss. The audiometer produces pure tones at varying intensities to which the patient can respond. Sound is characterized by the number of vibrations or cycles that occur each second. *Hertz* (Hz) is the unit of measurement used to classify the frequency of a tone; the higher the frequency, the higher the pitch. Hearing loss can affect certain sound frequencies. The specific pattern produced on the audiogram by these losses can assist in the diagnosis of the type of hearing loss. The intensity or strength of a sound wave is expressed in terms of decibels (dB), ranging from 0 to 110 dB. The intensity of a sound required to make any frequency barely audible to the average normal ear is 0 dB. *Threshold* refers to the signal level at which pure tones are detected (pure tone thresholds) or the signal level at which the patient correctly hears 50% of the signals (speech detection thresholds).

Normal speech is approximately 40 to 65 dB; a soft whisper is 20 dB. Normally, a child and a young adult can hear frequencies from about 16 to 20,000 Hz, but hearing is most sensitive between 500 and 4000 Hz. This range is similar to that of the frequencies contained in speech. A 40- to 45-dB loss in these frequencies causes moderate difficulty in hearing normal speech. A hearing aid may be helpful because it makes sound information louder, although not clearer. A hearing aid may not be helpful to a patient who has problems with discrimination of sounds or sound information

because the consonants are still not heard well enough to make speech understandable.

Screening Audiometry.

Screening audiometry is the testing of large numbers of people with a fast, simple test to detect possible hearing problems. A pass–fail criterion is used to identify people who will need additional diagnostic testing. People who fail the screening should be referred to an audiologist for pure-tone (threshold) audiometry.

Pure-Tone Audiometry.

A pure-tone audiometer produces tones at specific frequencies and intensities and is used by an audiologist to determine the hearing range of the patient in terms of decibels and hertz. Tinnitus can cause inconsistent results.

Specialized Tests

Specialized tests of the auditory system are most often performed in an outpatient setting by an audiologist. An audiologist can perform many additional tests with the use of audiometers and computers that record electrical activity from the middle ear, the inner ear, and the brain (see Table 23-12). The test most commonly performed by audiologists is pure-tone audiometry. More sophisticated tests are available to determine the origin of certain hearing losses. These include evoked potential studies (also called *auditory brainstem response*) and electrocochleography. Computed tomography and magnetic resonance imaging are used to diagnose the site of a lesion, such as a tumour of the auditory nerve.

Test for Vestibular Function

Table 23-12 describes diagnostic studies commonly used to assess vestibular function. Results of these tests can be altered by use of caffeine, other stimulants, sedatives, and antivertigo agents.

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. In a client who has a hemorrhage in the vitreous cavity of the eye, where is the blood accumulating?
   a. In the aqueous humor
   b. Between the lens and the retina
   c. Between the cornea and the lens
   d. In the space between the iris and the lens
2. Why might intraocular pressure increase?
   a. Edema of the corneal stroma
   b. Dilation of the retinal arterioles
   c. Blockage of the lacrimal canals and ducts
   d. Increased production of aqueous humor by the ciliary process
3. Which of the following should the nurse question clients about if they are using eye drops to treat glaucoma?
   a. Use of corrective lenses
   b. Their usual sleep pattern
   c. A history of heart or lung disease
   d. Sensitivity to opioids or depressants
4. For a client with an ophthalmic problem, the nurse should always assess for which of the following?
   a. Visual acuity
   b. Pupillary reactions
   c. Intraocular pressure
   d. Confrontation visual fields
5. Which of the following normal findings would the nurse expect during assessment of the auditory system?
   a. Absence of the cone of light
   b. Pearl-grey tympanic membrane
   c. Lateralization with Weber's test
   d. Bone conduction greater than air conduction

6. Which of the following are common age-related changes in the auditory system? *(Select all that apply)*
   a. Drier cerumen
   b. Tinnitus in both ears
   c. Auditory nerve degeneration
   d. Atrophy of the tympanic membrane
   e. Greater ability to hear high-pitched sounds
7. Before fluorescein is injected for angiography, what should the nurse do? *(Select all that apply)*
   a. Obtain an emesis basin.
   b. Ask whether the client is fatigued.
   c. Administer a topical anaesthetic.
   d. Inform client that skin may turn yellow.
   e. Assess for allergies to iodine-based contrast media.

1. b; 2. d; 3. c; 4. a; 5. b; 6. a, c, d; 7. a, d.

CHAPTER 24

Nursing Management

Visual and Auditory Problems

Written by, Sharon L. Lewis

Adapted by, Ruby Sangha

LEARNING OBJECTIVES

1. Compare and contrast the types of refractive errors and appropriate corrections.
2. Describe the etiology of and collaborative care for extraocular disorders.
3. Review the pathophysiological features and clinical manifestations of selected intraocular disorders and the nursing management and collaborative care of affected patients.
4. Discuss the nursing measures that promote the health of the eyes and ears.
5. Explain the general preoperative and postoperative care of the patient undergoing ophthalmological or otological surgery.
6. Summarize the action and uses of drug therapy for treating problems of the eyes and ears.
7. Explain the pathophysiological features and clinical manifestations of common ear problems and the nursing management and collaborative care of affected patients.
8. Compare the causes, management, and rehabilitative potential of conductive and sensorineural hearing loss.
9. Explain the use of, care of, and patient teaching related to assistive devices for eye and ear problems.

10. Describe the common causes and assistive measures for uncorrectable visual impairment and deafness.
11. Describe the measures used to assist the patient in adapting psychologically to decreased vision and hearing.

retinopathy, p. 472
strabismus, p.468

This chapter describes visual and auditory problems, with an emphasis on their pathophysiological features and clinical manifestations and on the collaborative care and nursing management of affected patients. Assistive devices for visual and hearing impairment are also discussed.

Visual Problems

The eye contains numerous structures, all of which are critical for proper functioning of the visual system. These components include, most anteriorly, the tear film and cornea; the anterior segment structures, including the iris and lens; and posterior structures, including the vitreous, retina, and optic nerve. The optic nerves of both eyes meet and cross at the optic chiasm. At this point, the information from both eyes is combined and then splits according to the visual field. Information from the visual fields travels via the right or left optic tract, which terminates in the posterior part of the brain in the occipital cortex.

Loss of some or all vision doubles the difficulties associated with activities of daily living, halves the ease of social functioning, doubles the incidence of falls and mortality rates, triples the risk of depression, and quadruples the risk of hip fractures (National Coalition for Vision Health, 2011).

Correctable Refractive Errors

The most common visual problem is **refractive error**. In this defect, light rays focus either in front of or behind the retina. The cornea is responsible for two-thirds of the refractive power of the eye, and the lens is responsible for one-third of refractive power. In addition to their combined refractive power, the length of the eye is an important determinant of potential refractive error. When light rays are out of focus, the patient may experience blurry vision, eye strain *(asthenopia),* headaches, or generalized eye discomfort. The principal refractive errors of the eye can be corrected by the use of lenses in the form of eyeglasses or contact lenses, by refractive surgery, or by surgical implantation of an artificial lens. Refractive errors in young children should be corrected because such children may develop **amblyopia** (reduced or no vision in affected eye) also known as "lazy eye," which may result in permanent vision loss if not treated in early childhood, ideally before the age of 5 (Canadian Ophthalmological Society, 2007). Undetected and untreated refractive errors and cataracts in persons older than 65 can lead to falls and unintentional injuries. Falls and fractures are of particular concern because of the effect on the individual's independence and long-term health (Bell, Hawranik, & McCormac, 2011).

Safety Alert

Upon admission to hospital, older adult patients should undergo vision screening and, when it is warranted, be referred to an appropriate eye care specialist.

Myopia (nearsightedness) is an inability to accommodate for objects at a distance. It causes light rays to be focused in front of the retina. Myopia may occur because of excessive light refraction by the cornea or lens or because of an abnormally long eye.

Hyperopia (farsightedness) is an inability to accommodate for near objects. The light rays focus behind the retina, and so the patient must use accommodation to focus the light rays on the retina for near objects. This type of refractive error occurs when the cornea or lens does not have adequate focusing power or when the eyeball is too short.

Presbyopia is the loss of accommodation associated with age. This condition generally appears at approximately age 40. As the eye ages, the lens becomes larger, firmer, and less elastic. These changes, which progress with aging, result in an inability to focus on near objects. The first sign of presbyopia is often the need to hold reading material farther away.

Astigmatism is caused by an irregular corneal curvature. This irregularity causes the incoming light rays to be bent unequally. Consequently, the light rays do not converge in a single point of focus on the retina. Astigmatism can occur in conjunction with any of the other refractive errors.

Aphakia is the absence of the lens, which results in significant refractive error. Without the focusing ability of the lens, images are projected behind the retina. In rare cases, the lens may be absent congenitally, or it may be removed during cataract surgery. A lens that is traumatically injured is removed and replaced with an intraocular lens (IOL) implant. The lens accounts for approximately 30% of ocular refractive power.

Nonsurgical Corrections

Corrective Glasses.

Myopia, hyperopia, presbyopia, and astigmatism can be modified by the appropriate corrective lenses. Myopia necessitates a "minus" *(concave)* corrective lens, whereas hyperopia and presbyopia necessitate a "plus" *(convex)* corrective lens. Glasses for presbyopia are often called *reading glasses* because they are usually worn only for close work. The presbyopic correction may also be combined with a correction for another refractive error, such as myopia or astigmatism. In these combined glasses, the presbyopic correction is in the lower portion of the spectacle lens. A traditional bifocal or trifocal has visible lines. A newer type of corrective glasses for presbyopia, the progressive lens, is actually a multifocal lens in which the transition from near to far correction is graduated seamlessly over a range in the middle area of the lens. This eliminates the visible lines between the different corrective lenses. The lower lens in multifocal glasses may predispose older people to falls because viewing the environment through their lower lenses impairs important visual capabilities (contrast sensitivity and depth perception) for detecting environmental hazards, particularly in unfamiliar environments (Tareef, 2011).

Contact Lenses.

Use of contact lenses is another way to correct refractive errors; they are available in rigid and soft types. The rigid types are available in standard and gas-permeable forms. Their care requires separate solutions for cleaning, storing, and wetting. The soft types are available in many forms. The most commonly used soft contact lenses are the standard and disposable forms, which are less durable and more expensive than rigid forms. Contact lenses generally provide better vision than do glasses because the patient has more normal peripheral vision without the distortion and obstruction of glasses and their frames. This is especially true with high refractive errors. Contact lenses are made from various plastic and silicone substances, which are very permeable by oxygen, have a high water content, and thus enable longer wearing time with greater comfort. If the oxygen supply to the cornea is decreased, the cornea becomes swollen, visual acuity decreases, and the patient experiences severe discomfort.

Altered or decreased tear formation can make wearing contact lenses difficult. Tear production can be decreased by medications such as antihistamines, decongestants, diuretics, hormone medications such as oral contraceptives, and the hormones produced during pregnancy.

Environmental factors such as wind, fans, and dust may also decrease the tear film. Allergic conjunctivitis with itching, tearing, and redness can also affect contact lens wear.

In general, the nurse must know whether the patient wears contact lenses, the pattern of wear (daily versus extended), and care practices. Shining a light obliquely on the eyeball can help the nurse visualize a contact lens. The patient should know the signs and symptoms of contact lens problems that must be managed by the eye care professional. These symptoms are remembered better with the mnemonic device *RSVP:* **r**edness, **s**ensitivity, **v**ision problems, and **p**ain.

Safety Alert

The nurse should stress the importance of removing contact lenses immediately when the patient experiences RSVP symptoms.

Surgical Therapy

Surgical procedures are designed to eliminate or reduce the need for eyeglasses or contact lenses and correct refractive errors by changing the focus of the eye. Surgical management for refractive errors includes laser surgery and IOL implantation.

Laser Surgery.

Laser-assisted in situ keratomileusis (LASIK) may be considered for patients with low to moderately high degrees of myopia, hyperopia, and astigmatism. It has revolutionized refractive surgery, and millions of LASIK procedures have been performed worldwide. The procedure first involves using a laser or surgical blade to create a thin flap in the cornea. Through new "wave-front" technology, the laser is then programmed to use a map of the patient's cornea to sculpt the cornea and correct the refractive error. The flap is then repositioned and adheres on its own without sutures in a few minutes (Sutton, Lawless, & Hodge, 2014). Perceptions of glare, halos, and starbursts and poor night vision are negative consequences for some patients despite uncomplicated and successful surgery (Government of Canada, 2012).

Photorefractive keratectomy is indicated for low to moderate degrees of myopia, hyperopia, and astigmatism and is a good option for a patient

with insufficient corneal thickness for a LASIK flap. In this procedure, only the epithelium is removed, and the laser is used to sculpt the cornea to correct the refractive error. *Laser-assisted epithelial keratomileusis* (LASEK) is similar to photorefractive keratectomy except that the epithelium is replaced after surgery.

Implantation.

Intracorneal ring segments are two semicircular pieces of plastic that are implanted between the layers of the cornea to treat mild forms of myopia. They are designed to change the shape of the cornea by adjusting the focusing power. Intracorneal ring segments can be removed, and the cornea usually returns to its original shape within a few weeks.

Refractive IOL implantation is an option for patients with severe myopia or hyperopia. Like cataract surgery, it involves the removal of the patient's natural lens and implantation of an IOL, which is a small plastic lens to correct a patient's refractive error. Because this requires entering the eye, the risk of complications is higher. New accommodating IOLs correct both myopia and presbyopia.

Phakic IOLs are sometimes referred to as *implantable contact lenses.* They are implanted into the eye without removal of the eye's natural lens. They are used for patients with severe myopia and hyperopia. Unlike the refractive IOL, the phakic IOL is placed in front of the eye's natural lens. Leaving the natural lens in the eye preserves the ability of the eye to focus for reading vision. The Artisan IOL is one type of phakic IOL used for moderate to severe myopia.

Uncorrectable Visual Impairment

In 2012, approximately 750 000 Canadians were identified as having a *seeing disability,* defined as either difficulty seeing ordinary newsprint with corrective lenses if those are usually worn or difficulty seeing the face of someone 4 m across a room with corrective lenses if those are usually worn (Statistics Canada, 2016). The partially sighted individual may actually have significant vision. It is important in working with a visually impaired patient to understand that a person classified as blind may have useful vision. Appropriate responses and interventions depend on the nurse's understanding of an individual patient's visual abilities.

Levels of Visual Impairment

Total blindness is defined as no light perception and no usable vision. *Functional blindness* is the condition in which the patient has some light perception but no usable vision. A patient with either total or functional blindness may use vision substitutes such as guide dogs and canes for ambulation. Vision enhancement techniques are not helpful.

There are approximately 108 000 legally blind Canadians (visual acuity less than 20/200) and another 278 000 with visual impairment (visual acuity between 20/50 and 20/200) (Health Professions Regulatory Advisory Council, 2010, p. 7). More than 5.5 million Canadians have a major eye disease that could cause vision loss (Canadian National Institute for the Blind [CNIB], 2015a). Most cases of vision impairment and blindness are caused by conditions such as age-related macular degeneration, glaucoma, diabetic retinopathy, and cataracts. These conditions are preventable, treatable, or both. The prevalence of vision loss in Canada is expected to increase nearly 30% by 2025 (CNIB, 2015a).

A *legally blind individual* meets the criteria developed by the federal government to determine eligibility for government programs and income tax benefits (Table 24-1). A legally blind individual may have some usable vision. The *partially sighted individual* who is not legally blind has a corrected visual acuity greater than 20/200 in the better eye and more than 20 degrees of visual field, but the visual acuity is 20/50 or worse in the better eye. The patient who is partially sighted but also legally blind can benefit greatly from vision enhancement techniques.

TABLE 24-1

DEFINITION OF BLINDNESS IN CANADA

Legal blindness is defined as follows:
• Central visual acuity for distance: 20/200 or worse in the better eye (with correction) • Visual field: no more than 20 degrees in its widest diameter or in the better eye.

Nursing Management Visual Impairment

Nursing Assessment

It is important to determine how long a patient has had a visual impairment because recent loss of vision has particular implications for nursing care. To determine how the patient's visual impairment affects normal functioning, the nurse should question the patient about the level of difficulty encountered when he or she performs certain tasks. For example, the nurse may ask how much difficulty the patient has when reading a newspaper, writing a cheque, moving from one room to the next, or viewing television. Other questions can help the nurse determine the personal meaning that the patient attaches to the visual impairment. The nurse can ask how the vision loss has affected specific aspects of the patient's life, whether the patient has lost a job, or in what activities the patient no longer engages because of the visual impairment. Techniques such as describing where personal items are located, warning the patient when the nurse will be providing direct care, and informing the patient where food items are located on the tray are helpful strategies (Jensen, 2012). In older adult patients in all health care settings, vision can be assessed with the evidence-informed Focus on Falls Prevention Program Vision Screening Tool (Figure 24-1). This tool was specifically adapted and designed to screen vision in older patients and has proved to be successful in effectively identifying such patients who require a referral to an eye specialist. Improving vision in older patients can prevent falls and associated fractures (Bell, Hawranik, & McCormac, 2011).

FIGURE 24-1 **A,** An older patient undergoing vision screening with the Focus on Falls Prevention Program Vision Screening Tool. **B,** Focus on Falls Prevention Program Vision Screening Tool. Source: Courtesy Focus on Falls Prevention Vision Screening Program, Winnipeg, Manitoba.

Patients may attach many negative meanings to the impairment because of societal opinions about blindness. For example, patients may view the impairment as punishment or view themselves as useless and burdensome. It is also important to determine a patient's primary coping strategies, the patient's emotional reactions, and the availability and strength of the patient's support systems.

Nursing Diagnoses

Nursing diagnoses depend on the degree of visual impairment and how long it has been present. Nursing diagnoses for a visually impaired patient include, but are not limited to, the following:

- *Risk for injury* as evidenced by *alteration in sensation* (visual impairment)
- *Self-care deficits* related to *perceptual disorders* (visual impairment)
- *Readiness for enhanced self-care*
- *Grieving* (related to loss of vision)

Planning

For a patient with recently impaired vision or a patient with impaired adjustment to longstanding visual impairment, the overall goals are that the patient will (a) make a successful adjustment to the impairment, (b) verbalize feelings related to the loss, (c) identify personal strengths and external support systems, and (d) use appropriate coping strategies. If the patient has been functioning at an appropriate or acceptable level, the goal is to maintain the current level of function.

Nursing Implementation

Health Promotion.

When a partially sighted patient is at risk for preventable further visual impairment, the nurse should encourage the patient to seek appropriate health care. For example, the patient with vision loss from glaucoma may prevent further visual impairment by complying with prescribed therapies and suggested ophthalmological evaluations.

Acute Intervention.

The nurse provides emotional support and direct care to patients with visual impairment of recent onset. Active listening and facilitating are important components of nursing care for such a patient. The nurse should allow the patient to express anger and grief and should help the patient identify fears and successful coping strategies. The patient's family is intimately involved in the experiences that follow vision loss. With the patient's knowledge and permission, the nurse should include family members in discussions and encourage members to express their concerns.

Many people are uncomfortable around a blind or partially sighted individual because they are not sure what behaviours are appropriate. Sensitivity to the person's feelings without being overly solicitous or stifling the person's independence is vital in creating a therapeutic nursing presence.

The nurse should always communicate in a normal conversational tone and manner with the patient and address the patient directly, not the caregiver or friend who may accompany the patient. Common courtesy dictates introducing oneself and any other persons who approach a blind or partially sighted patient and saying goodbye on leaving. Making eye contact with the partially sighted patient accomplishes several objectives. It ensures that the nurse speaks while facing the patient so that the patient has no difficulty hearing the nurse. The nurse's head position confirms that the nurse is attentive to the patient. Also, establishing eye contact ensures that the nurse can observe the patient's facial expressions and reactions.

Orientation to the environment lessens patients' anxiety or discomfort and facilitates independence. In orienting a partially sighted or blind patient to a new area, the nurse should identify one object as the focal point and describe the location of other objects in relation to it. For example, the nurse may say, “The bed is straight ahead, approximately 10 steps. The chair is to the left of the bed, and the nightstand is to the right, near the head of the bed. The bathroom is to the left of the foot of the bed.” The nurse should explain any activities or noises occurring in the patient's immediate surroundings.

The nurse should assist the patient in ambulating to each major object in the area, using the *sighted-guide technique.* When using this technique, the nurse stands slightly in front and to one side of the patient and offers an elbow for the patient to hold. The nurse serves as the sighted guide, walking slightly ahead of the patient with the patient holding the back of the nurse's arm. When using this technique in any situation, the nurse describes the environment to help orient the patient. For example, the nurse may say, “We're going through an open doorway and approaching two steps down. There is an obstacle on the left.” To assist the patient to sit, place one of his or her hands on the back of the chair.

The nurse should be familiar with common vision deficits such as cataracts, refractive errors, macular degeneration, glaucoma, and diabetic retinopathy and their associated nursing strategies for care. For example, age-related macular degeneration entails loss of central vision,

and the patient is best cared for by being approached from the side. This condition affects a person's ability to see detail required for reading, writing, preparing meals, and recognizing faces. Caring for the patient with glaucoma, which entails loss of peripheral vision, is better when the nurse directly faces the patient. Vision loss from glaucoma primarily affects a person's mobility, especially in a dynamic moving environment (Popescu, Boisjoly, Schmaltz, et al., 2011).

Ambulatory and Home Care.

Rehabilitation after partial or total loss of vision can foster independence, self-esteem, and productivity. The nurse should know what services and devices are available for a partially sighted or blind patient and should be prepared to make appropriate referrals for those services and devices. For patients who are legally blind and those with low-degree vision, the primary resource for services is the Canadian National Institute for the Blind (CNIB). A list of agencies that serve the partially sighted or blind patient is available from this institute (see the Canadian Resources at the end of this chapter).

Braille or audio books for reading and a cane or guide dog for ambulation are examples of vision substitution techniques. These are usually most appropriate for patients with no functional vision. For most patients who have some remaining vision, vision enhancement techniques can provide enough help for them to learn to ambulate, read printed material, and accomplish activities of daily living.

Optical Devices for Vision Enhancement.

A wide range of technological advances have become available to assist people with low-degree vision. These devices include desktop video magnification/closed-circuit units, electronic hand-held magnifiers, text-to-speech scanners, e-readers, and computer tablets (material read aloud, magnification, image zooming, brighter screen, voice recognition). Many of these devices require some training and practice for successful use. The nurse should encourage patients to practise with the device so that they can use it successfully.

Nonoptical Methods for Vision Enhancement.

Approach magnification is a simple but sometimes overlooked technique for enhancing the patient's residual vision. The nurse can

recommend that the patient sit closer to the television or hold books closer to the eyes, which the patient may be reluctant to do unless encouraged. Contrast enhancement techniques include watching television in black and white, placing dark objects against a light background (e.g., a white plate on a black placemat), using a black felt-tip marker to write, and using contrasting colours (e.g., a red stripe at the edge of steps or curbs). Increased lighting can be provided by halogen lamps, direct sunlight, or gooseneck lamps that can be aimed directly at the reading material or other near objects. Large type is often helpful, especially in conjunction with other optical or nonoptical vision enhancements.

Evaluation

The overall expected outcomes are that the patient with severe visual impairment will

- Have no further loss of vision
- Be able to use adaptive coping strategies
- Not experience a decrease in self-esteem or social interactions
- Function safely within her or his own environment

Age-Related Considerations

Visual Impairment

Older adults are at an increased risk for vision loss caused by eye disease (Akpek & Smith, 2013). Older adults may have other deficits, such as cognitive impairment or limited mobility, that further affect the ability to function in usual ways. Financial resources may meet normal needs but can be inadequate in meeting increased demands of vision services or devices.

Older adult patients may become confused or disoriented when visually compromised. The combination of decreased vision and confusion increases the risk of falls, which have potentially serious consequences for older adults. Decreased vision may compromise an older adult's ability to function, which raises concerns about maintaining independence and damaging the patient's self-image. Because of decreased manual dexterity, some older adults may have difficulty instilling prescribed eye drops. It is important to provide proper instruction and demonstration. Having the patient demonstrate the technique is an important aspect of nursing education and reassurance for patients. Eye drop assistive devices are available for purchase at pharmacies in Canada, and their use can be suggested.

Eye Trauma

Although the eyes are well protected by the bony orbit and by fat pads, everyday activities can result in ocular trauma. Ocular injuries can involve the ocular adnexa, the superficial structures, or the deeper ocular structures. Eye trauma is one of the leading causes of vision impairment in Canada; an estimated 720 000 Canadians sustain eye injuries that necessitate medical attention every year (CNIB, 2012). Of all Canadian workers, 40% do not get needed visual aids, and approximately 200 per day suffer eye injuries. Furthermore, many of these injuries are serious enough to cause workers to lose work time, and some can lead to permanent eye damage or blindness. A Canadian online eye injury registry has been developed to gather data about the pattern and types of eye injuries that occur. Table 24-2 outlines emergency management of an eye injury. Types of ocular trauma

include blunt injuries, penetrating injuries, and chemical exposure injuries. Causes of ocular injuries include automobile accidents, falls, injuries from sports and leisure activity, assaults, and work-related situations. Trauma is often a preventable cause of visual impairment. Almost 90% of all eye injuries could be prevented by the wearing of protective eyewear during potentially hazardous work, hobbies, or sports activities. The nurse's role in individual and community education is extremely important in reducing the incidence of ocular trauma.

TABLE 24-2

EMERGENCY MANAGEMENT
Eye Injury

Cause
Trauma
Blunt: Fist; other blunt objects *Penetrating:* Fragments such as glass, metal, wood; knife, stick, or other large object
Chemical Burn
• Alkaline • Acid
Thermal Burn
• Direct burn from curling iron or other hot surface • Indirect burn from ultraviolet light (e.g., welding torch, sun lamp)
Foreign Bodies
• Glass • Metal • Wood • Plastic • Ceramic
Possible Assessment Findings Depending on Cause
• Pain • Photophobia • Redness: diffuse or localized • Swelling • Ecchymosis • Tearing • Blood in the anterior chamber • Absence of eye movements • Fluid drainage from eye (e.g., blood, CSF, aqueous humor) • Abnormal or decreased vision • Visible foreign body • Prolapsed globe • Abnormal intraocular pressure • Visual field defect
Interventions
Initial
• Determine mechanism of injury. • Ensure airway, breathing, and circulation. • Assess for other injuries. • Assess for chemical exposure. • In case of chemical exposure, begin ocular irrigation *immediately;* do not stop until emergency personnel arrive to continue irrigation. Use sterile saline or water if saline is unavailable. • Do not attempt to treat the injury (except as noted above for chemical exposure). • Assess visual acuity. • Do not put pressure on the eye. • Instruct patient not to blow nose. • Stabilize foreign objects. • Cover injured eye or eyes with dry, sterile patches, and a protective shield. • Do not give the patient food or fluids. • Elevate head of bed to 45 degrees. • Do not put medication or solutions in the eye unless ordered by physician. • Administer analgesic drugs as appropriate.
Ongoing Monitoring
• Reassure the patient. • Monitor pain.

- Anticipate surgical repair for penetrating injury, globe rupture, or globe avulsion.

CSF, cerebro-spinal fluid.

Extraocular Disorders

Inflammation and Infection

One of the most common conditions encountered by ophthalmologists is inflammation or infection of the external eye. Many external irritants or microorganisms can affect the eyelids and conjunctiva and can involve the avascular cornea. The nurse is responsible for teaching the patient appropriate interventions related to the specific disorder.

Hordeolum.

An external **hordeolum** (commonly called a *stye*) is an infection of the sebaceous glands in the eyelid margin (Figure 24-2). The most common bacterial infective pathogen is *Staphylococcus aureus*. The affected area rapidly becomes red, swollen, circumscribed, and acutely tender. The nurse should instruct the patient to apply warm, moist compresses at least four times a day until it improves. This may be the only treatment necessary. If it tends to recur, the patient should be taught to perform eyelid scrubs daily. In addition, use of appropriate antibiotic ointments or drops may be indicated.

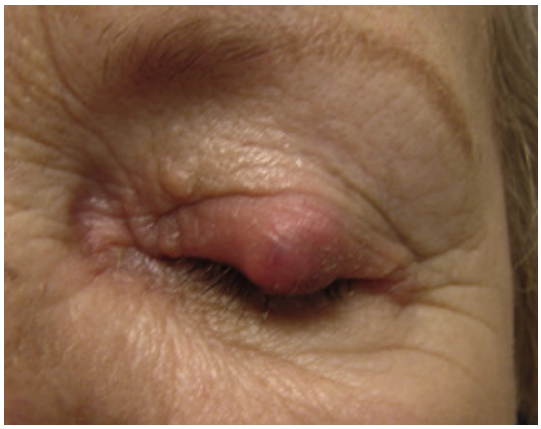

FIGURE 24-2 External hordeolum (stye) on the upper eyelid caused by staphylococcal infection. Source: Courtesy Cory J. Bosanko, OD, FAAO, Eye Centers of Tennessee, Crossville, Tennessee.

Chalazion.

A *chalazion* is a chronic inflammatory granuloma of the meibomian (sebaceous) glands in the eyelid. A hordeolum may evolve into a chalazion. A chalazion may also occur as a response to the material released into the eyelid when a blocked gland ruptures. The chalazion usually appears on the upper eyelid as a swollen, tender, reddened area that may be painful. Initial treatment is similar to that for a hordeolum. If warm, moist compresses are ineffective in causing spontaneous drainage, the ophthalmologist may surgically remove the lesion (this is normally an office procedure), or the ophthalmologist may inject the lesion with corticosteroids.

Blepharitis.

Blepharitis is a chronic inflammatory process of the eyelid margin. It is a common eye disorder throughout the world and can affect any age group. The cause is unknown and probably multifactorial. Bacteria have been implicated in playing a significant role. It may be associated with several systemic diseases such as rosacea or seborrheic dermatitis. It is related to other ocular conditions such as dry eye, chalazion, conjunctivitis, and keratitis. Symptoms include a burning sensation, irritation, tearing, photophobia, blurred vision, and redness of the conjunctiva. These symptoms are usually worse in the morning because the inflamed eyelids are in close contact with the ocular surface and tear production is decreased overnight as a result of less blinking. Basic treatment includes a long-term commitment to eyelid hygiene. Warm compresses and washing the eyelid margins with baby shampoo diluted in water and applied gently with a cotton-tipped swab are recommended. An antibiotic-corticosteroid ointment can be used for short periods only.

Conjunctivitis.

Conjunctivitis is an infection or inflammation of the conjunctiva, the mucous membrane that lines the eyelids and covers the conjunctiva. These infections may be caused by bacteria or viruses (Durning, 2013). Conjunctival inflammation may result from exposure to allergens or chemical irritants. Symptoms include ocular redness, discharge, burning, and sometimes itching and light sensitivity. It can occur in one or both eyes and is contagious. Careful hand hygiene and the use of

individual or disposable towels help prevent the spread of the condition (Callahan, 2012).

Bacterial Infections.

Acute bacterial conjunctivitis *(pinkeye)* is a common infection. Although it occurs in every age group, epidemics commonly occur among children because of their poor personal hygiene habits. In adults and children, the most common causative microorganism is *S. aureus. Streptococcus pneumoniae* and *Haemophilus influenzae* are other common causative pathogens, but they are seen more often in children than in adults. A patient with bacterial conjunctivitis may complain of discomfort, pruritus, tearing, redness, and a mucopurulent drainage. Although this initially occurs in one eye, it generally spreads within 48 hours to the unaffected eye. The infection is usually self-limiting, but treatment with antibiotic drops shortens the course of the disorder.

Viral Infections.

Conjunctival infections may be caused by many different viruses. A patient with viral conjunctivitis may complain of tearing, foreign body sensation, redness, and mild photophobia. This condition is usually mild and self-limiting. However, it can be severe, with considerable discomfort and subconjunctival hemorrhaging. Adenovirus conjunctivitis may be contracted in contaminated swimming pools and through direct contact with an infected patient. Treatment is usually palliative. If the patient's symptoms are severe, topical corticosteroids provide temporary relief but do not cure the infection. Antiviral drops are ineffective and therefore not indicated.

Chlamydial Infections.

Trachoma is a chronic conjunctivitis caused by *Chlamydia trachomatis* (serotypes A through C). It is a major cause of blindness worldwide. It is responsible for visual impairment in approximately 1.8 million people, and 0.5 million of those people are irreversibly blind (World Health Organization, 2016). This preventable eye disease is transmitted mainly via contact with the hands and by flies. Adult inclusion conjunctivitis (AIC) is caused by *C. trachomatis* (serotypes D through K). Manifestations of both trachoma and AIC are mucopurulent ocular discharge, irritation, redness, and eyelid swelling. For unknown reasons, AIC does not carry the long-term consequences of trachoma.

AIC also differs from trachoma in that it is common in economically developed countries, whereas trachoma is most common in underdeveloped countries. Antibiotic therapy is usually effective for trachoma and AIC.

Although antibiotic treatment may be successful in adults with AIC, these patients have a high risk of concurrent chlamydial genital infection, as well as other sexually transmitted infections. The nurse's teaching plan for this patient should include the implications of AIC for sexual activity and reproductive health.

Allergic Conjunctivitis.

Conjunctivitis caused by exposure to an allergen can be mild and transitory, or it can be severe enough to cause significant swelling, sometimes causing the conjunctiva to balloon beyond the eyelids. The defining symptom of allergic conjunctivitis is itching. The patient may also complain of burning, redness, and tearing. In the acute stage, the patient may also have white or clear exudate. If the condition is chronic, the exudate is thicker and becomes mucopurulent. The patient may develop allergic conjunctivitis in response to pollens, in addition to animal dander, ocular solutions and medications, or even contact lenses. The nurse should instruct the patient to avoid the allergen if it is known. Artificial tears can be effective in diluting the allergen and washing it from the eye. Effective topical medications include antihistamines and corticosteroids.

Keratitis.

Keratitis is an inflammation or infection of the cornea that can be caused by a variety of microorganisms or by other factors. The condition may involve the conjunctiva, the cornea, or both. When it involves both, the disorder is termed *keratoconjunctivitis.*

Bacterial Infections.

When the epithelial layer is disrupted, the cornea can become infected by a variety of bacteria. Topical antibiotics are generally effective, but eradicating the infection may require subconjunctival antibiotic injection or, in severe cases, intravenous antibiotics. Risk factors include mechanical or chemical corneal epithelial damage, contact lens wear, debilitation, nutritional deficiencies, immuno-suppressed states, and use

of contaminated products (e.g., lens care solutions and cases, topical medications, cosmetics).

Viral Infections.

Herpes simplex virus (HSV) keratitis is the most frequently occurring infectious cause of corneal blindness in the Western hemisphere. It is a growing problem, especially among immuno-suppressed patients. It may be caused by HSV-1 or HSV-2 (genital herpes), although HSV-2 ocular infection is much less common. The resulting corneal ulcer has a characteristic dendritic (tree-branching) appearance (Farooq & Shukla, 2012). Pain and photophobia are common. In up to 40% of patients, herpetic keratitis heals spontaneously. The spontaneous healing rate increases to 70% if the cornea is debrided to remove infected cells. Collaborative therapy includes corneal debridement, followed by topical therapy with trifluridine (Viroptic) for 2 to 3 weeks. Topical corticosteroids are usually contraindicated because they contribute to a longer course and possible deeper ulceration of the cornea. Drug therapy may also include oral acyclovir (Zovirax).

The varicella-zoster virus causes both chicken pox and herpes zoster ophthalmicus (HZO). HZO may occur by reactivation of an endogenous infection that has persisted in latent form after an earlier attack of varicella or by contact with a patient with chicken pox or herpes zoster. It occurs most frequently in older adults and in immuno-suppressed patients. Collaborative care of a patient with acute HZO may include analgesics for the pain, topical corticosteroids to reduce inflammation, antiviral drugs such as acyclovir (Zovirax) to reduce viral replication, mydriatic drugs to dilate the pupil and relieve pain, and topical antibiotics to combat secondary infection. The patient may apply warm compresses and povidone-iodine gel to the affected skin (gel should not be applied too near the eye).

Epidemic keratoconjunctivitis is the most serious ocular adenoviral disease. This condition is spread by direct contact, including sexual activity. In the medical setting, contaminated hands and instruments can be the source of spread. The patient may complain of tearing, redness, photophobia, and sensation of a foreign body in the eye. In most patients, the disease involves only one eye. Treatment is primarily palliative and includes ice packs and dark glasses. In severe cases, therapy can include mild topical corticosteroids to temporarily relieve symptoms and topical antibiotic ointment. The nurse's most important

role is to teach the patient and caregivers the importance of good hygienic practices to avoid spreading the disease.

Other Causes of Keratitis.

Keratitis may also be caused by fungi (most commonly *Aspergillus, Candida,* and *Fusarium* species), especially in the case of ocular trauma in an outdoor setting in which fungi are prevalent in the soil and moist organic matter. *Acanthamoeba* keratitis is caused by a parasite that is associated with contact lens wear, probably as a result of using contaminated lens care solutions or cases. Homemade saline solution is particularly susceptible to *Acanthamoeba* contamination. The nurse should instruct all patients who wear contact lenses about good lens care practices. Medical treatment of fungal and *Acanthamoeba* keratitis is difficult. The *Acanthamoeba* organism is resistant to most drugs. If antimicrobial therapy fails, the patient may require corneal transplantation.

Exposure keratitis occurs when the patient cannot adequately close the eyelids. The patient with exophthalmos (protruding eyeball) caused by thyroid eye disease or masses posterior to the globe is susceptible to exposure keratitis.

Corneal Ulcer.

Tissue loss caused by infection of the cornea produces a *corneal ulcer* (infectious keratitis) (Figure 24-3). The infection can be caused by bacteria, viruses, or fungi. Corneal ulcers are often very painful, and patients may feel as if a foreign body is in the eye. Other symptoms can include tearing, purulent or watery discharge, redness, and photophobia. Treatment is generally aggressive to prevent permanent loss of vision. Antibiotic, antiviral, or antifungal eye drops may be prescribed as frequently as every hour, night and day, for the first 24 hours. An untreated corneal ulcer can result in corneal scarring and perforation (hole in the cornea). Corneal transplantation may be indicated.

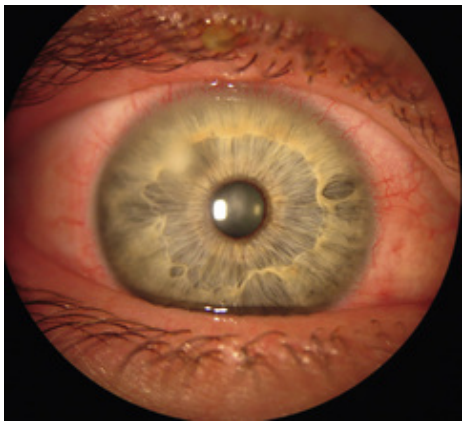

FIGURE 24-3 Corneal ulcer. Infection associated with poor contact lens care. Source: Courtesy Cory J. Bosanko, OD, FAAO, Eye Centers of Tennessee, Crossville, Tennessee.

Nursing Management Inflammation and Infection

Nursing Assessment

The nurse should assess ocular changes—such as edema, redness, decreasing visual acuity, the sensation that a foreign body is present, or discomfort—and document the findings in the patient's record. In the assessment, the nurse should also consider the psychosocial aspects of the patient's condition, especially when the patient's vision is also impaired.

Nursing Diagnoses

Nursing diagnoses for the patient with inflammation or infection of the external eye include, but are not limited to, the following:

- *Acute pain* related to *biological injury agent* (infection)
- *Anxiety* related to *threat to current status* (major change in health status)

Planning

The overall goals are that the patient with inflammation or infection of the external eye will (a) avoid spread of infection, (b) maintain an acceptable level of comfort and functioning during the course of the specific ocular problem, (c) maintain or improve visual acuity, (d) comply with the prescribed therapy, and (e) engage in appropriate health-seeking behaviours.

Nursing Implementation

Health Promotion.

Careful asepsis and frequent, thorough hand hygiene are essential to prevent spreading organisms from one eye to the other, to other

patients, to family members, and to the nurse. The patient and family require information about avoiding sources of ocular irritation or infection and responding appropriately if an ocular problem occurs. Patients with infective disorders that may be transmitted sexually or who have an associated sexually transmitted infection need specific information about those disorders. The nurse should inform the patient about the appropriate use and care of lenses and lens care products.

Acute Intervention.

Apply warm or cool compresses if indicated for the patient's condition. Darkening the room and providing an appropriate analgesic are other comfort measures. If the patient's visual acuity is decreased, the nurse may need to modify the patient's environment or activities for safety.

The patient may require eye drops as frequently as every hour. If the patient receives two or more different types of drops, the nurse should stagger the eye drop dosing to promote maximum absorption. For example, if two different eye drops are ordered hourly, the nurse should administer one kind of drop on the hour and the other kind of drop on the half-hour unless otherwise prescribed. This staggered schedule promotes maximum absorption. The patient who needs frequent eye drop administration may experience sleep deprivation.

Ambulatory and Home Care.

The patient's primary need in the home environment is for information about required care and how to accomplish that care. The patient and family also need information about proper techniques for medication administration. If the patient's vision is compromised, the nurse should provide suggestions for alternative ways to accomplish necessary daily activities and self-care. A patient who wears contact lenses and develops infections should discard all opened or used lens care products and cosmetics to decrease the risk of reinfection from contaminated products (a common problem and a probable source of infection for many patients).

Evaluation

The overall expected outcomes are that the patient with inflammation or infection of the external eye will

- Cooperate with the treatment plan
- Experience relief from ocular discomfort
- Effectively cope with functional changes if visual acuity is decreased
- Obtain specific information to prevent recurrent disease

Dry Eye Disorders

Keratoconjunctivitis sicca (dry eyes) is a common complaint, particularly of older adults and individuals with certain systemic diseases such as scleroderma and systemic lupus erythematosus. Patients with dry eyes complain of irritation or the sensation of sand in the eye and that the sensation typically worsens throughout the day. This condition is caused by a decrease in the quality or quantity of the tear film, and treatment is directed at the underlying cause. If it is caused by lacrimal duct dysfunction, the condition may respond to hot compresses and eyelid massage. With decreased tear secretion, the patient may use artificial tears or ointments. They should be used sparingly because preservatives in the drops or overuse can cause further ocular irritation. In severe cases, closure of the lacrimal puncta may be necessary. Patients with dry eyes in association with dry mouth may have Sjögren's syndrome (see Chapter 67).

Strabismus

Strabismus is a condition in which the patient cannot consistently focus both eyes simultaneously on the same object (Figure 24-4). One eye may deviate inward *(esotropia),* outward *(exotropia),* upward *(hypertropia),* or downward *(hypotropia).* Strabismus in adults may be caused by thyroid disease, neuro-muscular problems of the eye muscles, retinal detachment repair, or cerebral lesions. The primary complaint with strabismus is double vision.

FIGURE 24-4 Strabismus with right exotropia and fixation of the left eye. Source: Courtesy Cory J. Bosanko, OD, FAAO, Eye Centers of Tennessee, Crossville, Tennessee.

Corneal Disorders

Corneal Scars and Opacities

The cornea is a transparent tissue that allows light rays to enter the eye and focus on the retina, thus producing a visual image. Any wound causes the cornea to become abnormally hydrated and decreases the normal transparency. A rigid contact lens can be effective in correcting the irregular astigmatism that results from corneal scars. In other situations, the treatment for corneal scars or opacities is *penetrating keratoplasty* (corneal transplantation). In this surgical procedure, the ophthalmological surgeon removes the full thickness of the patient's cornea and replaces it with a donor cornea that is sutured into place (Figure 24-5). Vision may not be restored for up to 12 months. Corneal problems leading to blindness are uncommon, but if they occur, corneal transplantation can preserve vision that otherwise would be lost.

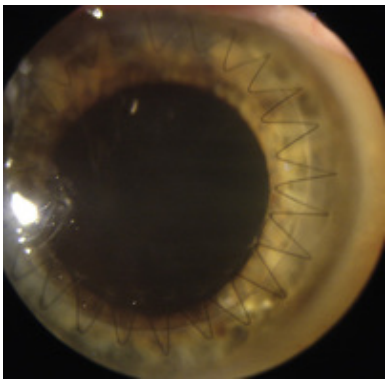

FIGURE 24-5 Sutures on a donated cornea after penetrating keratoplasty (corneal transplantation). Source: Courtesy Cory J. Bosanko, OD, FAAO, Eye Centers of Tennessee, Crossville, Tennessee.

Corneal transplantation surgery is one of the fastest and safest of all tissue or organ transplantation procedures (Güell, El Husseiny, Manero, et al., 2014). The time between the donor's death and the removal of the tissue should be as short as possible. Most surgeons prefer this interval to be 4 hours or less. The eye banks test donors for human immunodeficiency virus (HIV) and hepatitis B and C viruses. The tissue is preserved in a special nutritive solution, and it can be kept for up to 5 days in the storage medium, if used for transplantation. Improved methods of tissue procurement and preservation, refined surgical techniques, postoperative topical corticosteroids, and careful follow-up have decreased the incidence of graft rejection. Matching the blood type of the donor and the recipient may also improve the success rate (National Eye Institute, 2013).

Keratoconus

Keratoconus is a noninflammatory, usually bilateral disease that has a familial tendency. It can be associated with Down syndrome, atopic dermatitis, Marfan syndrome, aniridia (congenital absence of the iris), and retinitis pigmentosa (hereditary disease characterized by bilateral primary degeneration of the retina beginning in childhood and progression to blindness by middle age).

The anterior cornea thins and protrudes forward, taking on a cone shape. Keratoconus usually appears during adolescence and slowly progresses between the ages of 20 and 60 years. The only symptom is blurred vision. The astigmatism may be corrected with glasses or rigid contact lenses. Intacs inserts, for example, are two clear plastic lenses

surgically inserted on the cornea's perimeter to reduce astigmatism and myopia. Intacs inserts are generally used to delay the need for corneal transplantation when contact lenses or glasses no longer help a patient achieve adequate vision. The cornea can perforate as central corneal thinning progresses. In advanced cases, a penetrating keratoplasty is indicated before perforation.

Intraocular Disorders

Cataract

A **cataract** is an area of opacity within the lens. The patient may have a cataract in one or both eyes. If cataracts are present in both eyes, one cataract may affect the patient's vision more than the other. Cataracts are one of the leading causes of vision loss in Canada. Nearly 2.5 million Canadians have some form of cataract, and this number is expected to double by 2031 (CNIB, 2015c). Cataract removal is the most common surgical procedure for Canadians older than 65 years (Hatch, Campbell, Bell, et al., 2012).

Causes and Pathophysiological Processes.

Although most cataracts are age related *(senile cataracts),* they can be associated with other factors. These include blunt or penetrating trauma, congenital factors such as maternal rubella, exposure to radiation or ultraviolet light, certain drugs such as systemic corticosteroids or long-term topical corticosteroids, and ocular inflammation. Patients with diabetes mellitus tend to develop cataracts at a younger age than average.

Cataract development is mediated by a number of factors. In senile cataract formation, it appears that altered metabolic processes within the lens cause an accumulation of water and alterations in the lens fibre structure. These changes affect lens transparency, causing vision changes.

Clinical Manifestations.

Patients with cataracts may complain of a decrease in vision, abnormal colour perception, and glare. Glare results from light scatter caused by the lens opacities, and it may be significantly worse at night when the pupil dilates. The visual decline is gradual, but the rate of cataract

development varies from patient to patient. Secondary glaucoma can also occur if the enlarging lens causes an increase in intraocular pressure (IOP).

Diagnostic Studies.

Diagnosis is based on decreased visual acuity or other complaints of visual dysfunction. The opacity is directly observable by ophthalmoscopic or slit-lamp microscopic examination. A totally opaque lens creates the appearance of a white pupil. Table 24-3 outlines other diagnostic studies that may be helpful in evaluating the visual effect of a cataract.

TABLE 24-3
COLLABORATIVE CARE
Cataract

Diagnostic Studies
• History and physical examination • Visual acuity measurement • Ophthalmoscopy (direct and indirect) • Slit-lamp microscopy • Glare testing, potential acuity testing in selected patients • Keratometry and A-scan ultrasonography (if surgery is planned) • Other tests (e.g., visual field perimetry) may be indicated to determine cause of visual loss
Collaborative Therapy
Nonsurgical
• Prescription change for glasses • Strong reading glasses or magnifiers • Increased lighting • Lifestyle adjustment
Acute Care: Surgical Therapy
Preoperative
• Mydriatic, cycloplegic drugs (see Table 24-4) • Nonsteroidal anti-inflammatory drugs • Topical antibiotics • Antianxiety medications
During Surgery

• Removal of lens:
  • Phacoemulsification (see Figure 24-6)
  • Extracapsular extraction
• Correction of surgical aphakia
• Intraocular lens implantation (most frequent type of correction)
• Contact lens

Postoperative
• Topical antibiotic • Topical corticosteroid or other anti-inflammatory drug • Mild analgesic drug if necessary • Eye shield and activity as preferred by patient's surgeon

Collaborative Care.

The presence of a cataract does not necessarily indicate a need for surgery. For many patients, the diagnosis is made long before they actually decide to have surgery. Nonsurgical therapy may postpone the need for surgery. Collaborative care for cataracts is described in Table 24-3.

Nonsurgical Therapy.

Currently, the only way to "cure" cataracts is through surgical removal. If the cataract is not removed, the patient's vision will continue to deteriorate. However, specific strategies may help the patient. In many cases, changing the patient's eyewear prescription can improve the level of visual acuity, at least temporarily. Other visual aids, such as strong reading glasses or magnifiers of some type, may help the patient with close vision. Increasing the amount of light to read or accomplish other near-vision tasks is another useful measure. The patient may be willing to adjust his or her lifestyle to accommodate for visual decline. For example, if glare makes it difficult to drive at night, a patient may elect to drive only during daylight hours and to have a family member drive at night. Sometimes, informing and reassuring the patient about the disease process makes the patient comfortable about choosing nonsurgical measures, at least temporarily.

Surgical Therapy.

When palliative measures no longer provide an acceptable level of visual function, the patient is an appropriate candidate for surgery. The patient's occupational needs and lifestyle changes are also factors affecting the decision to undergo surgery. In some instances, factors other than the patient's visual needs may influence the need for surgery. Lens-induced problems such as increased IOP may necessitate lens removal. Opacities may prevent the ophthalmologist from obtaining a clear view of the retina in a patient with diabetic retinopathy or other sight-threatening pathological conditions. In those cases, the cataract may be removed to allow the surgeon to visualize the retina and adequately manage the problem.

Preoperative Phase.

The patient's preoperative preparation should include an appropriate documentation of the history and a physical examination. Because almost all patients undergo the procedure under local anaesthesia, many physicians and surgical facilities do not require an extensive preoperative physical assessment. However, most patients with cataracts are older adults and may have several medical problems that should be evaluated and controlled before surgery. The surgeon may order preoperative antibiotic eye drops. The patient should not have food or fluids for approximately 6 to 8 hours before surgery. Almost all patients with cataracts are admitted to a surgical facility on an outpatient basis (see the "Evidence-Informed Practice" box). The patient is normally admitted several hours before surgery to allow adequate time for necessary preoperative procedures.

Evidence-Informed Practice

Research Highlight

What Surgical Location Has Better Outcomes for Cataract Surgery?

Clinical Question

In adults with cataracts (P), does day surgery (I) or inpatient surgery (C) result in better visual acuity 4 months postoperatively, and which surgical location is safer and more cost effective (O)?

Best Available Evidence

Systematic review of randomized controlled trials

Critical Appraisal and Synthesis of Evidence

- Meta-analysis of two randomized controlled trials (n = 1 284). Only one study with 1 034 subjects was methodologically sound, and evidence is based primarily on this study.
- No significant differences in visual acuity were found between patients who underwent day surgery and those who underwent

inpatient surgery, as measured with the Snellen chart 4 months after surgery.
- Significantly more early complications (e.g., increased intraocular pressure) were reported in the patients who underwent day surgery, with no relevance to vision acuity at 4 months.
- Costs for inpatient surgery were 20% higher than those for day surgery.
- Quality-of-life scores, patient satisfaction, and cataract symptom scores were similar for both patient groups.

Conclusions

- Day surgery is safe and, subjectively, preferred by patients.
- Day surgery provides the same visual outcome as inpatient surgery.

Implications for Nursing Practice

- Provide information that day-surgery outcomes are comparable to those of inpatient surgery and less costly.
- Quality of life may be improved if day surgery allows the patient to begin home recuperation sooner.

P, patient population of interest; *I*, intervention or area of interest; *C*, comparison of interest or comparison group; *O*, outcome or outcomes of interest (see Chapter 1).

Fedorowicz Z, Lawrence D, Gutierrez P, et al. Day care versus in-patient surgery for age-related cataract. *Cochrane Database of Systematic Reviews*. 2011;(7); 10.1002/14651858.CD004242.pub4 [CD004242].

The instillation of dilating and nonsteroidal anti-inflammatory eye drops helps maintain pupil dilation and reduce inflammation, respectively. One type of drug used for dilation is a mydriatic, an α-adrenergic agonist that produces pupillary dilation by causing contraction of the iris dilator muscle. Another type of drug is a cycloplegic, an anticholinergic drug that produces paralysis of accommodation (cycloplegia) and thus pupillary dilation (mydriasis) by blocking the effect of acetylcholine on the ciliary body muscles. Examples of mydriatic and cycloplegic drugs are listed in Table 24-4, and nursing considerations are discussed in the "Nursing Management: Cataracts" section. Many patients receive preoperative antianxiety medication before the injection of local anaesthetic.

TABLE 24-4

DRUG THERAPY
Topical Medications for Pupil Dilation

Examples	Onset	Duration	Comments
Mydriatic Drugs			
Phenylephrine hydrochloric acid (Mydfrin)	45–60 min	4–6 hr	May cause tachycardia and elevation in blood pressure, especially in older adult patient; can cause a reflexive decrease in heart rate when blood pressure rises Punctal occlusion should be used to limit systemic absorption
Cycloplegic Drugs			
Tropicamide (Mydriacyl)	20–40 min	4–6 hr	1% Solution used in cycloplegic refraction; 0.5% solution used in fundus examination
Cyclopentolate HCl acid (Cyclogyl)	30–75 min	6–24 hr	Has been associated with psychotic reactions and behavioural disturbances Used in cycloplegic refraction, fundus examination, and uveitis
Homatropine hydrobromide (Isopto Homatropine)	30–60 min	1–3 days	Used in cycloplegic refraction, uveitis; may be used for pupil dilation to allow patient to see around a central lens opacity
Atropine sulphate (Isopto Atropine)	30–180 min	6–12 days	Used in cycloplegic refraction, uveitis

Drug Alert

Cycloplegics and Mydriatics

- Instruct patient to wear dark glasses to minimize photophobia.
- Monitor for signs of systemic toxicity (e.g., tachycardia, central nervous system effects).

Intraoperative Phase.

Cataract extraction is an intraocular procedure. The anterior capsule is opened and the lens nucleus and cortex are removed, leaving the remaining capsular bag intact. In extracapsular extraction, the surgeon can remove the lens nucleus by "scooping" it out with a lens loop or by *phacoemulsification,* in which the nucleus is fragmented by ultrasonic vibration and aspirated from inside the capsular bag (Mayo Clinic, 2013; Figure 24-6). In either case, the remaining cortex is aspirated with an irrigation and aspiration instrument. The choice of placement and type

of incision varies among surgeons. Corneoscleral incisions necessitate closure with sutures, whereas scleral tunnel incisions are self-sealing and necessitate no closing suture. The incision required for phacoemulsification is considerably smaller than that required with intracapsular or standard extracapsular surgery.

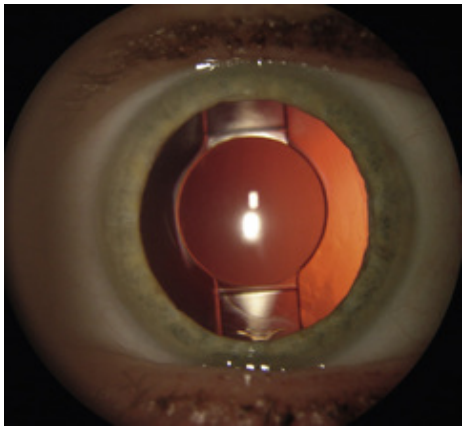

FIGURE 24-6 Intraocular lens implant after cataract surgery.
Source: Courtesy Cory J. Bosanko, OD, FAAO, Eye Centers of Tennessee, Crossville, Tennessee.

In almost all cases today, an IOL is implanted at the time of cataract extraction surgery. Because most patients undergo an extracapsular procedure, the lens of choice is a posterior chamber lens that is implanted in the capsular bag behind the iris. At the end of the procedure, additional medications such as antibiotics and corticosteroids may be administered. Depending on the type of anaesthetic, the patient's eye is covered with a patch or protective shield. If used, a patch or protective shield is usually worn overnight and removed during the first postoperative visit.

Postoperative Phase.

Unless complications occur, most patients are ready to go home as soon as the effects of sedative drugs have worn off. Postoperative medications usually include antibiotic drops to prevent infection and corticosteroid drops to decrease the postoperative inflammatory response. There is some evidence that postoperative activity restrictions and nighttime eye shielding are unnecessary. However, many ophthalmologists still prefer

that the patient avoid activities that increase the IOP, such as bending or stooping, coughing, or lifting.

During each postoperative examination, the ophthalmologist measures the patient's visual acuity, checks anterior chamber depth, assesses corneal clarity, and measures IOP. A flat anterior chamber may cause adhesions of the iris and cornea. The cornea may become hazy or cloudy from intraoperative trauma to the endothelium. Even on the day of surgery, the patient's uncorrected visual acuity in the operative eye may be good. However, it is not unusual or indicative of any problem if the patient's visual acuity is reduced immediately after surgery.

The postoperative eye drops are gradually reduced in frequency and finally discontinued when the eye has healed. When the eye is fully recovered, the patient receives a final prescription for glasses. The newest innovation is a multifocal IOL that corrects for both near and distance vision. Regardless of the type of IOL used, patients may still need glasses to achieve their best visual acuity.

Nursing Management Cataracts

Nursing Assessment

The nurse should assess the patient's distance and near visual acuity. If the patient is to undergo surgery, the nurse should especially note the visual acuity in the patient's nonoperative eye. With this information, the nurse can determine how visually compromised the patient may be while the operative eye is healing. In addition, the nurse should assess the psychosocial effect of the patient's visual disability and the patient's level of knowledge regarding the disease process and therapeutic options. Postoperatively, it is important to assess the patient's level of comfort and ability to follow the postoperative regimen.

Nursing Diagnoses

Nursing diagnoses for the patient with a cataract include, but are not limited to, the following:

- *Self-care deficits* related to *perceptual disorders* (visual impairment)
- *Anxiety* related to *unmet needs* (knowledge about surgical and postoperative experience)

Planning

Preoperatively, the overall goals are that the patient with a cataract will (a) make informed decisions regarding therapeutic options and (b) experience minimal anxiety. Postoperatively, the overall goals are that the patient with a cataract will (a) understand and comply with postoperative therapy, (b) maintain an acceptable level of physical and emotional comfort, and (c) remain free of infection and other complications.

Nursing Implementation

Health Promotion.

There are no proven measures to prevent cataract development. However, it is wise (and certainly does no harm) to suggest that the patient wear sunglasses, avoid extraneous or unnecessary radiation, and maintain good nutrition and appropriate intake of antioxidant vitamins (e.g., vitamins C and E). Also, information about vision enhancement techniques should be provided to the patient who chooses not to undergo surgery.

Acute Intervention.

Preoperatively, patients with cataracts need accurate information about the disease process and the treatment options, especially because cataract surgery is considered an elective procedure. Although cataracts are not a life-threatening condition, patients need to know that without surgery, some degree of visual disability will develop. The nurse should be available to give each patient and the family or caregivers information to help them make an informed decision about appropriate treatment.

For a patient who elects to have surgery, the nurse is able to provide information, support, and reassurance about the surgical and postoperative experience that can reduce or alleviate the patient's anxiety.

When administering topical medications for pupil dilation before surgery (see Table 24-4 for examples), the nurse should note that patients with dark irides may need a larger dose. Photophobia is common; therefore, decreasing the room lighting is helpful. These medications produce transient stinging and burning and are contraindicated for use in patients with narrow-angle glaucoma because angle-closure glaucoma may be produced. Mydriatic drugs can produce significant cardiovascular effects.

Table 24-5 outlines patient and caregiver teaching after eye surgery. Patients with a patch should be informed that they will not have depth perception until the patch is removed (usually within 24 hours). This necessitates special considerations to avoid possible falls or other injuries. The patient with significant visual impairment in the nonoperative eye requires more assistance while the operated eye is patched. Once the patch is removed (usually within 24 hours), most patients with visual impairment in the nonoperative eye have adequate vision for necessary activities because the implanted IOL provides

immediate visual rehabilitation in the operated eye. On occasion, a patient may require 1 or 2 weeks for the visual acuity in the operated eye to reach an adequate level for most visual needs. Such a patient also needs some special assistance until the vision improves.

TABLE 24-5
PATIENT & CAREGIVER TEACHING GUIDE
After Eye Surgery

Include the following information when teaching the patient and the caregiver after eye surgery.
1. Proper hygiene and eye care techniques to ensure that medications, dressings, and surgical wound are not contaminated during eye care
2. Signs and symptoms of infection and when and how to report those to allow early recognition and treatment of possible infection
3. Importance of complying with postoperative restrictions on head positioning, bending, coughing, and the Valsalva manoeuvre to optimize visual outcomes and prevent increased intraocular pressure
4. How to instill eye medications with the use of aseptic techniques and to comply with prescribed eye medication regimen to prevent infection
5. How to monitor pain, take pain medication, and report pain not relieved by medication
6. Importance of continued follow-up as recommended to maximize potential visual outcomes

Source: Adapted from Lamb, P., & Simms-Eaton, S. (2008), *Core curriculum for ophthalmic nursing* (3rd ed.). Dubuque, IA: Kendall-Hunt.

After cataract surgery, most patients experience little or no pain. There may be some scratchy sensation in the operative eye. Mild analgesics are usually sufficient to relieve any pain. If the pain is intense, the patient should notify the surgeon because this may indicate hemorrhage, infection, or increased IOP. The nurse should also instruct the patient to notify the surgeon of increased or purulent drainage, increased redness, or any decrease in visual acuity. (A nursing care plan for the patient after eye surgery is available on the Evolve website.)

Ambulatory and Home Care.

For a patient with cataracts who has not undergone surgery, the nurse can suggest ways in which the patient may modify activities or lifestyle to accommodate the visual deficit caused by the cataract. The nurse should also provide the patient with accurate information about appropriate long-term eye care.

Patients with cataracts who undergo surgery remain in the surgical facility for only a few hours. The patient and the family are responsible for almost all postoperative care. The nurse must give them written and verbal instructions before discharge. These instructions should include

information about postoperative eye care, activity restrictions, medications, follow-up visit scheduling, and signs and symptoms of possible complications. The patient's family should be included in the instruction because some patients may have difficulty with self-care activities, especially if the vision in the nonoperative eye is poor. The nurse should provide an opportunity for the patient and family to demonstrate any necessary self-care activities. Most patients experience little visual impairment after surgery.

IOL implants provide immediate visual rehabilitation, and many patients achieve a usable level of visual acuity within a few days after surgery. Also, the patient's eye may remain patched for only 24 hours, and many patients have good vision in the nonoperative eye. A few patients may experience significant visual impairment postoperatively: those who do not have an IOL implanted at the time of surgery, those who require several weeks to achieve a usable level of visual acuity after surgery, or those with poor vision in the nonoperative eye. For such patients, the time between surgery and receiving glasses or contacts can be a period of significant visual disability. The nurse can suggest ways in which the patient and the family can modify activities and the environment to maintain an adequate level of safe functioning. Suggestions may include getting assistance with going up stairs, removing area rugs and other potential obstacles, preparing meals for freezing before surgery, and obtaining audio books for diversion until visual acuity improves.

Evaluation

The overall expected outcomes are that after cataract surgery, the patient will

- Have improved vision
- Be better able to take care of self
- Have minimal to no pain
- Be optimistic about expected outcomes

Age-Related Considerations

Most patients with cataracts are older adults. When an older patient is visually impaired, even temporarily, she or he may experience a loss of independence, lack of control over her or his life, and a significant change in self-perception. Many older patients need emotional support and encouragement, as well as specific suggestions to allow a maximum level of independent function. The nurse should assure older patients that cataract surgery can be accomplished safely and comfortably with minimal sedation. A study in which nonagenarians (individuals aged 90 to 99) who underwent cataract surgery were compared with octogenarian patients (aged 80 to 89) revealed that nonagenarians are not at increased risk of ocular complications from cataract surgery (Tseng, Greenberg, Wu, et al., 2011).

Retinopathy

Retinopathy is a process of microvascular damage to the retina. It can develop slowly or rapidly and lead to blurred vision and progressive vision loss. In adults, retinopathy is most often associated with diabetes mellitus or hypertension.

Diabetic retinopathy is a common complication of diabetes mellitus, especially in patients with longstanding uncontrolled diabetes (Nentwich & Ulbig, 2015). It is the leading cause of visual disability and blindness in Canadians with longstanding uncontrolled diabetes (diabetes is discussed in Chapter 52). Because diabetes has been diagnosed in increasing numbers of Canadians, the incidence of diabetic retinopathy will continue to increase. In a Canadian study of diabetic retinopathy in Indigenous and non-Indigenous Canadians, the data indicated that ethnicity does play a significant role in the development and severity of diabetic retinopathy, but potential risk factors are not significantly different (Canadian Diabetes Association, 2013).
Nonproliferative retinopathy is the most common form of diabetic retinopathy and is characterized by capillary microaneurysms, retinal swelling, and hard exudates. Macular edema represents a worsening of the retinopathy, inasmuch as plasma leaks from macular blood vessels. As capillary walls weaken, they can rupture, which leads to intraretinal "dot or blot" hemorrhaging (Figure 24-7). This can lead to a severe loss

of central vision. As the disease advances, *proliferative retinopathy* may occur where new blood vessels grow. However, these blood vessels are abnormal, fragile, and predisposed to leak and thus predispose the patient to severe vision loss. Fluorescein angiography is used to detect diabetic macular edema, which may be treated with laser photocoagulation (Bressler, Beck, & Ferris, 2011).

FIGURE 24-7 Diabetic retinopathy. Intraretinal clot or blot hemorrhages. Source: Courtesy Cory J. Bosanko, OD, FAAO, Eye Centers of Tennessee, Crossville, Tennessee.

Hypertensive retinopathy is caused by blockages in retinal blood vessels that result from hypertension. (Hypertension is discussed in Chapter 35.) These changes may not initially affect a person's vision. On a routine eye examination, retinal hemorrhages and macular swelling can be noted. Sustained, severe hypertension can cause swelling of the optic disc and nerve *(papilledema)* and lead to sudden visual loss. Treatment, which may be required on an emergency basis, focuses on lowering the blood pressure. Normal vision is restored in patients with treatment of the underlying cause of the hypertension.

Retinal Detachment

A **retinal detachment** is a separation of the retina and the underlying pigment epithelium, with fluid accumulation between the two layers. The incidence of nontraumatic retinal detachment is approximately 1 per 15 000 individuals each year. This number is higher when aphakic individuals are included because retinal detachment is more likely to

occur in aphakic patients. In a patient with no other risk factors who has had a retinal detachment in one eye, the risk of detachment in the second eye is as high as 25% (Steel, 2014). Almost all patients with an untreated, symptomatic retinal detachment become blind in the involved eye.

Etiology and Pathophysiology

Retinal detachment has many causes, the most common of which is a retinal break. A *retinal break* is an interruption in the full thickness of the retinal tissue, and such breaks can be classified as tears or holes. *Retinal holes* are atrophic retinal breaks that occur spontaneously. *Retinal tears* can occur as the vitreous humor shrinks during aging and pulls on the retina. The retina tears when the traction force exceeds the strength of the retina. Once the retina has a break, liquid vitreous can enter the subretinal space between the sensory layer and the retinal pigment epithelium layer, causing a *rhegmatogenous* retinal detachment. Retinal detachment can also occur when abnormal membranes mechanically pull on the retina. Such detachments are called *tractional* detachments and are less common. A third type of retinal detachment is the *secondary* or *exudative* detachment, which occurs in conditions that allow fluid to accumulate in the subretinal space (e.g., choroidal tumours, intraocular inflammation). Risk factors for retinal detachment are listed in Table 24-6.

TABLE 24-6
RISK FACTORS FOR RETINAL DETACHMENT

- Increasing age
- Severe myopia
- Infection or eye trauma
- Retinopathy (diabetic)
- Eye diseases or tumours
- Cataract or glaucoma surgery
- Family or personal history of retinal detachment

Source: Adapted from Canadian National Institute for the Blind. (2015). *Retinal detachment.* Retrieved from *http://www.cnib.ca/en/your-eyes/eye-conditions/retinal-detachment/Pages/default.aspx.*

Clinical Manifestations

Patients with a detaching retina describe symptoms that include *photopsia* (light flashes), floaters, and a "cobweb," "hairnet," or ring in the field of vision. Once the retina has detached, the patient describes a painless loss of peripheral or central vision, "like a curtain" coming across the field of vision. The area of visual loss corresponds to the area of detachment. If the detachment is in the superior nasal retina, the visual field loss is in the inferior temporal area. If the detachment is small or develops slowly in the periphery, the patient may not be aware of a visual problem. The effects of a retinal detachment can be viewed online at VisionSimulations.com (see the Resources at the end of this chapter).

Diagnostic Studies

Visual acuity measurements should be the first diagnostic procedure with any complaint of vision loss (Table 24-7). The retinal detachment can be directly visualized through direct and indirect ophthalmoscopy or slit-lamp microscopy in conjunction with a special lens to view the far periphery of the retina. Ultrasonography may be useful for identifying a retinal detachment if the retina cannot be directly visualized (e.g., when the cornea, the lens, or the vitreous humor is hazy or opaque).

TABLE 24-7
COLLABORATIVE CARE
Retinal Detachment

Diagnostic Studies
• History and physical examination • Visual acuity measurement • Ophthalmoscopy (direct and indirect) • Slit-lamp microscopy • Ultrasonography if cornea, lens, or vitreous humor is hazy or opaque
Collaborative Therapy
Preoperative
• Mydriatic, cycloplegic eye drops (see Table 24-4) • Photocoagulation of retinal break that has not progressed to detachment
Surgery
• Laser photocoagulation • Cryotherapy (cryopexy) • Scleral buckling procedure • Draining of subretinal fluid • Vitrectomy • Intravitreal bubble
Postoperative
• Topical antibiotic • Topical corticosteroid • Analgesia • Mydriatics • Positioning and activity as preferred by patient's surgeon

Collaborative Care

Some retinal breaks are not likely to progress to detachment. The ophthalmologist simply monitors the patient, giving precise information about the warning signs and symptoms of impending detachment and instructing the patient to seek immediate evaluation if any of those signs or symptoms occurs. The ophthalmologist usually refers the patient with a detachment to a retinal specialist. Treatment objectives are to seal any retinal breaks and to relieve inward traction on the retina. Several techniques are used to accomplish these objectives (Schaal, Sherman, Barr, et al., 2011).

Surgical Therapy

Laser Photocoagulation and Cryopexy.

These techniques seal retinal breaks by creating an inflammatory reaction that causes a chorioretinal adhesion or scar. In *laser photocoagulation,* an intense, precisely focused light beam is used to

create an inflammatory reaction. The light is directed at the area of the retinal break. For retinal breaks accompanied by significant detachment, the retinal specialist may use photocoagulation intraoperatively in conjunction with scleral buckling. Tears or holes without accompanying retinal detachment may be treated prophylactically with laser photocoagulation if there is a high risk of progression to retinal detachment. When used alone, laser therapy is an outpatient procedure for which most patients require only topical anaesthesia. Patients may experience minimal adverse symptoms during or after the procedure.

Another method used to seal retinal breaks is *cryopexy.* This procedure involves the use of extreme cold to create the inflammatory reaction that produces the sealing scar. The ophthalmologist applies the cryoprobe instrument to the external globe in the area over the tear. This is usually done on an outpatient basis and with the use of a local anaesthetic. As with photocoagulation, cryotherapy may be used alone or during scleral buckling surgery. The patient may experience significant discomfort and eye pain after cryopexy. The nurse should encourage the patient to take the prescribed pain medication after the procedure.

Scleral Buckling.

Scleral buckling is an extraocular surgical procedure that involves compressing the globe so that the pigment epithelium, the choroid, and the sclera move toward the detached retina. The retinal surgeon sutures a silicone implant against the sclera, causing the sclera to buckle inward. The surgeon may place an encircling band over the implant if there are multiple retinal breaks, if suspected breaks cannot be located, or if there is widespread inward traction on the retina (Figure 24-8). To drain any subretinal fluid, a small-gauge needle is inserted to facilitate contact between the retina and the buckled sclera. Scleral buckling is usually done as an outpatient procedure with the patient under local anaesthesia.

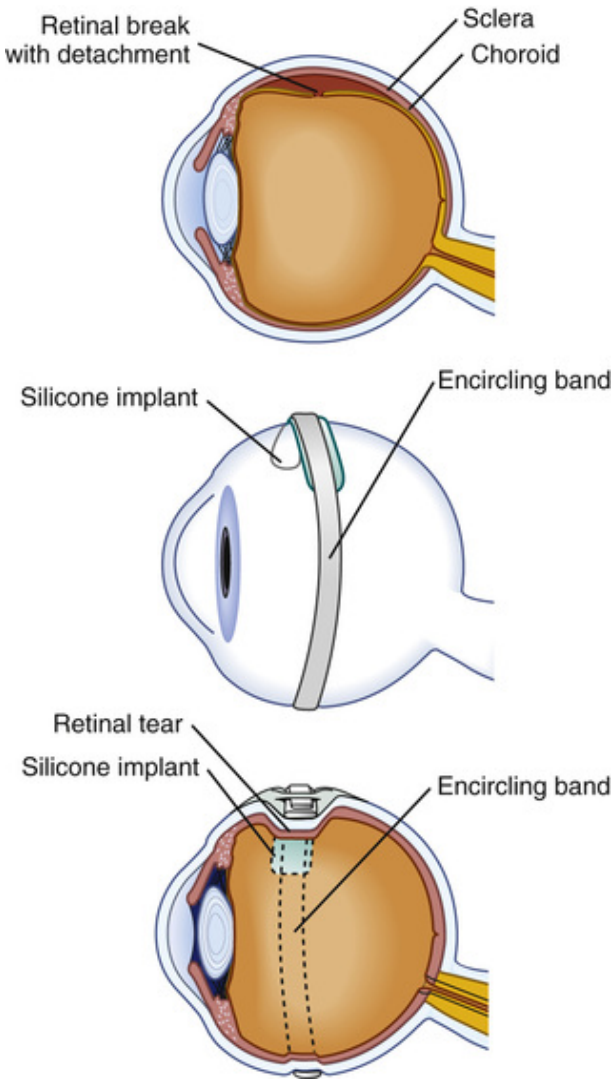

FIGURE 24-8 Retinal break with detachment *(top);* surgical repair by scleral buckling technique *(middle* and *bottom).*

Intraocular Procedures.

In addition to the extraocular procedures described, retinal surgeons may use one or more intraocular procedures in treating some retinal detachments. *Pneumatic retinopexy* is the intravitreal injection of a gas to form a temporary bubble in the vitreous that closes retinal breaks and provides apposition of the separated retinal layers. Because the intravitreal bubble is temporary, this technique is combined with laser photocoagulation or cryotherapy (cryopexy). A patient with an intravitreal bubble must position the head so that the bubble is in

contact with the retinal break. It may be necessary for the patient to maintain this position as much as possible for up to several weeks.

Vitrectomy (surgical removal of the vitreous) may be used to relieve traction on the retina, especially when the traction results from proliferative diabetic retinopathy. Vitrectomy may be combined with scleral buckling to provide a dual effect in relieving traction.

Postoperative Considerations in Scleral Buckling and Intraocular Procedures.

Reattachment procedures are successful in 90% of retinal detachments (Schaal, Sherman, Barr, et al., 2011). Visual prognosis varies, depending on the extent, length, and area of detachment. Postoperatively, the patient may be on bed rest and may require special positioning to maintain proper position of an intravitreal bubble. The patient may need multiple topical medications, including antibiotics, anti-inflammatory drugs, or dilating drugs. The level of activity restriction after retinal detachment surgery varies greatly. The nurse should verify the prescribed level of activity with the patient's surgeon and help the patient plan for any necessary assistance in relation to activity restrictions.

In most cases, retinal detachment is an urgent situation, and the patient is confronted suddenly with the need for surgery. The patient needs emotional support, especially during the immediate preoperative period when preparations for surgery can lead to additional anxiety. When the patient experiences postoperative pain, the nurse should administer prescribed pain medications and teach the patient to take the medication as necessary after discharge. The patient may go home within a few hours of surgery or may remain in the hospital for several days, depending on the surgeon and the type of repair.

Discharge planning and teaching are important, and the nurse should begin these processes as early as possible because the patient does not remain hospitalized long. Patient and caregiver teaching after eye surgery is discussed in Table 24-5. The patient is at risk for retinal detachment in the other eye. Therefore, the nurse should teach the patient the signs and symptoms of retinal detachment. The nurse can also promote use of proper protective eyewear to help avoid retinal detachments related to trauma.

Age-Related Macular Degeneration

Age-related macular degeneration (AMD) is an eye disease that begins after age 60 that progressively destroys the macula (the central portion of the retina), causing irreversible central vision loss. It is the leading cause of blindness and vision loss in Canada (CNIB, 2015b). AMD is a common eye condition, affecting 1.4 million people in Canada. Canadians who have AMD outnumber those who have breast cancer, prostate cancer, Parkinson's disease, or Alzheimer's disease combined (CNIB, 2015b).

AMD is divided into two forms: dry (nonexudative) and wet (exudative). People with *dry AMD*, which is the more common form (90% of all cases), often notice close vision tasks become more difficult. In this form, the macular cells start to atrophy, leading to a slowly progressive and painless vision loss.

Wet AMD is the more severe form. Wet AMD accounts for 90% of the cases of AMD-related blindness. Wet AMD has a more rapid onset and is characterized by the development of abnormal blood vessels in or near the macula.

Etiology and Pathophysiology

AMD is related to retinal aging. Genetic factors also appear to play a major role, and family history is a major risk factor for AMD (Mackey & Hewitt, 2014). A gene responsible for some cases of AMD has been identified. People who smoke cigarettes are twice as likely to develop late AMD as are nonsmokers (National Eye Institute, 2015). Other risk factors include long-term exposure to ultraviolet light, hyperopia, and light-coloured irides. Nutritional factors may play a role in the progression of AMD. A dietary supplement of vitamin C, vitamin E, beta-carotene, and zinc decreases the progression of advanced AMD but has no effect on people with minimal AMD or those with no evidence of AMD (Chew, Clemons, Agron, et al., 2013). Mechanisms of protection are also being discovered among non-antioxidant nutrients such as omega-3 fatty acids and the B vitamins. A proper nutritious diet is thought to be more protective than nutritional supplements. The nutrients with the strongest evidence of a protective effect include zinc, lutein, zeaxanthin, docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA). Older patients are at higher risk for zinc deficiency, which

may increase their risk of vision loss from AMD (Olson, Erie, & Bakri, 2011).

The dry form of AMD starts with the abnormal accumulation of yellowish extracellular deposits called *drusen* in the retinal pigment epithelium. The macular cells then undergo atrophy and degeneration. Wet AMD is characterized by the growth of new, fragile blood vessels from their normal location in the choroid to an abnormal location in the retinal epithelium. As the new blood vessels leak, scar tissue gradually forms. Acute vision loss may occur in some cases, with bleeding from subretinal neovascular membranes.

Clinical Manifestations

The patient may complain of blurred and darkened vision, the presence of *scotomas* (blind spots in the visual field), and *metamorphopsia* (distortion of vision). Many people may not notice unilateral early changes in their vision if the other eye is not affected.

Diagnostic Studies

In addition to visual acuity measurement, the primary diagnostic procedure is ophthalmoscopy. The examiner looks for drusen and other fundus changes associated with AMD. The Amsler grid test may help define the involved area, and the result provides a baseline for future comparison. Fundus photography and intravenous angiography with fluorescein or indocyanine green dyes, or both, may help to further define the extent and type of AMD.

Collaborative Care

Vision often does not improve for most people with AMD. Limited treatment options for patients with wet AMD include several medications that are injected directly into the vitreous cavity. Ranibizumab (Lucentis), and bevacizumab (Avastin) are selective inhibitors of endothelial growth factor that helps to slow vision loss in wet AMD. Adverse effects can include blurred vision, eye irritation, eye pain, and photosensitivity. The injections are given at 4- to 6-week intervals, depending on which drug is used. Retinal stability is determined by ocular coherence tomography, which allows the

physician to identify fluid in the central retina to determine the need for continued intravitreal injections.

Photodynamic therapy entails the use of verteporfin (Visudyne) intravenously and a "cold" laser to excite the dye. This procedure is used for cases of wet AMD and destroys the abnormal blood vessels without permanent damage to the retinal pigment epithelium and photoreceptor cells. Verteporfin is a photosensitizing drug that becomes active when exposed to the low-level laser light wave. Until the drug is completely excreted by the body, it can be activated by exposure to sunlight or other high-intensity light such as halogen; therefore, patients are cautioned to avoid direct exposure to sunlight and other intense forms of light for 5 days after treatment. After receiving therapy, patients must be completely covered because any exposure to skin by sunlight could activate the drug in that area, which would result in a thermal burn.

People at risk for developing advanced AMD should consider supplements of vitamins and minerals (in consultation with their health care provider). The cessation of smoking may also help in halting the progression of dry AMD to a more advanced stage.

Many patients with assistive devices for low-degree vision can continue reading and retain a licence to drive during the daytime and at lowered speeds. The permanent loss of central vision has significant psychosocial implications for nursing care. Nursing management of patients with uncorrectable visual impairment is discussed earlier in the chapter and is appropriate for patients with AMD. The nurse should avoid giving the impression that "nothing can be done" about the problem when caring for a patient with AMD. Although therapy will not recover lost vision, much can be done to augment the remaining vision.

Glaucoma

Glaucoma is a group of disorders characterized by elevated IOP and its consequences: optic nerve atrophy and peripheral visual field loss. Glaucoma is the second most common reason for vision loss in Canadians. It affects more than 400 000 Canadians and 67 million people worldwide (Glaucoma Research Society of Canada, 2016). Risk factors for glaucoma include family history, age, nearsightedness, diabetes, and ethnicity (e.g., individuals of African descent are more likely to develop

the disease). The incidence of glaucoma increases with age. Blindness from glaucoma is largely preventable with early detection and appropriate treatment.

Etiology and Pathophysiology

A proper balance between the rate of aqueous production (referred to as *inflow*) and the rate of aqueous reabsorption (referred to as *outflow*) is essential to maintain the IOP within normal limits. The place where the outflow occurs is the *angle* where the iris meets the cornea. When the rate of inflow is greater than the rate of outflow, IOP can rise above the normal limits. If IOP remains elevated, vision loss may be permanent.

Primary open-angle glaucoma (POAG) is the most common type of glaucoma. In POAG, the outflow of aqueous humor is decreased in the trabecular meshwork. The drainage channels become clogged, and damage to the optic nerve can then result.

Primary angle-closure glaucoma is due to a reduction in the outflow of aqueous humor that results from angle closure. Usually this is caused by the lens's bulging forward as a result of the aging process. Angle closure may also occur as a result of pupil dilation in the patient with anatomically narrow angles. An acute attack may be precipitated by situations in which the pupil remains in a partially dilated state long enough to cause an acute and significant rise in the IOP. This may occur because of drug-induced mydriasis, emotional excitement, or darkness. Drug-induced mydriasis may occur not only from topical ophthalmic preparations but also from many systemic medications (both prescription and over-the-counter drugs). The nurse should check drug records and documentation before administering medications to the patient with angle-closure glaucoma and instruct the patient not to take any mydriatic medications.

Clinical Manifestations

POAG develops slowly and without symptoms of pain or pressure. The patient usually does not notice the gradual visual field loss until peripheral vision has been severely compromised. Eventually, patients with untreated glaucoma have “tunnel vision,” in which only a small centre field can be seen and all peripheral vision is absent.

Acute angle-closure glaucoma causes definite symptoms, including sudden, excruciating pain in or around the eye. This is often accompanied by nausea and vomiting. Visual symptoms include blurred vision, ocular redness, and seeing coloured halos around lights. The acute rise in IOP may also cause corneal edema, which gives the cornea a frosted appearance.

Manifestations of subacute or chronic angle-closure glaucoma appear more gradually. The patient who has had a previous, unrecognized episode of subacute angle-closure glaucoma may report a history of blurred vision, ocular redness, eye or brow pain, or seeing coloured halos around lights. The effects of glaucoma can be viewed online at VisionSimulations.com (see the Resources at the end of this chapter).

Diagnostic Studies

IOP is usually elevated in glaucoma (normal IOP is 10–21 mm Hg). In cases of elevated pressures, the ophthalmologist usually repeats the measurements over time to verify the elevation. In open-angle glaucoma, IOP is usually between 22 and 32 mm Hg. In acute angle-closure glaucoma, IOP may exceed 50 mm Hg.

In open-angle glaucoma, slit-lamp microscopy reveals a normal angle. In angle-closure glaucoma, the examiner may note a markedly narrow or flat anterior chamber angle, an edematous cornea, a fixed and moderately dilated pupil, and ciliary injection (hyperemia of the ciliary blood vessels produces redness).

Measures of peripheral and central vision provide other diagnostic information. Whereas central acuity may remain 20/20 even in the presence of severe peripheral visual field loss, visual field perimetry may reveal subtle changes in the peripheral area of the retina early in the disease process, long before actual scotomas develop. In acute angle-closure glaucoma, central visual acuity is reduced if corneal edema is present, and the visual fields may be markedly decreased.

As glaucoma progresses, *optic disc cupping* may be one of the first signs of chronic open-angle glaucoma. The optic disc becomes wider, deeper, and paler (light grey or white); these characteristics are visible with direct or indirect ophthalmoscopy (Figure 24-9).

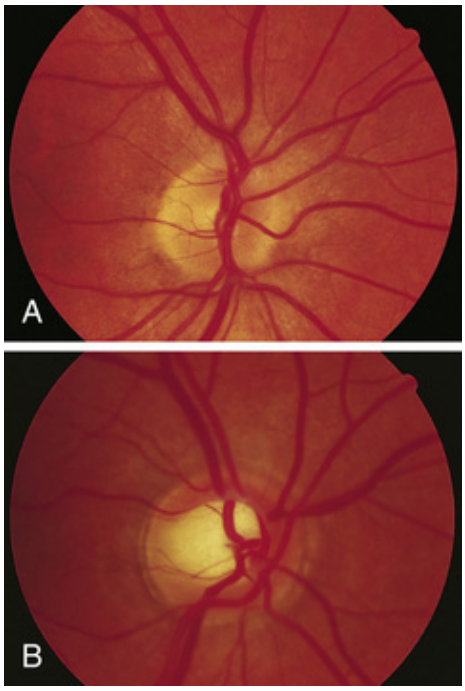

FIGURE 24-9 The optic disc. **A,** In the normal eye, the optic disc is pink with little cupping. **B,** In glaucoma, the optic disc is pale, and optic cupping is present. (Note the appearance of the retinal vessels, which travel over the edge of the optic cup and appear to dip into it.)

Collaborative Care

The primary focus of glaucoma therapy is to keep the IOP low enough to prevent optic nerve damage. Therapy varies with the type of glaucoma. The diagnostic studies and collaborative care of glaucoma are summarized in Table 24-8.

TABLE 24-8
COLLABORATIVE CARE
Glaucoma

Diagnostic Studies
• History and physical examination • Visual acuity measurement • Tonometry • Ophthalmoscopy (direct and indirect) • Slit-lamp microscopy • Gonioscopy • Visual field perimetry
Collaborative Therapy
Chronic Open-Angle Glaucoma
*Drug Therapy**
• β-Adrenergic blockers • α-Adrenergic agonists • Cholinergic drugs (miotics) • Carbonic anhydrase inhibitors
Surgical Therapy
• Argon laser trabeculoplasty (ALT) • Trabeculectomy with or without filtering implant
Acute Angle-Closure Glaucoma
• Topical cholinergic drug • Hyperosmotic drug • Laser peripheral iridotomy • Surgical iridectomy

*See Table 24-9.

Chronic Open-Angle Glaucoma.

Initial treatment in chronic open-angle glaucoma is with drugs (Table 24-9). The patient must understand that continued treatment and supervision are necessary because the drugs control, but do not cure, glaucoma.

TABLE 24-9
DRUG THERAPY
Acute and Chronic Glaucoma

Drug	Action	Adverse Effects	Nursing Considerations
β-Adrenergic Blockers			
Betaxolol (Betoptic)	Cardioselective β_1-adrenergic blocker; probably decreases aqueous humor production	Transient discomfort; systemic reactions (rarely reported) include bradycardia, heart block, pulmonary distress, headache, depression	Topical drugs; minimal effect on pulmonary and cardiovascular parameters Contraindicated for use in patients with bradycardia, cardiogenic shock, or overt cardiac failure. Systemic absorption can have additive effect with systemic β_1-adrenergic blocking drugs.
Levobunolol (Betagan) Timolol maleate (Timoptic)	Noncardioselective β_1- and β_2-blockers; probably decrease aqueous humor production	Transient ocular discomfort, blurred vision, photophobia, blepharoconjunctivitis, bradycardia, decreased blood pressure, bronchospasm, headache, depression	Topical drops; same effects and contraindications as for betaxolol; also contraindicated for use in patients with asthma or severe COPD
α-Adrenergic Agonists			
Apraclonidine (Iopidine) Brimonidine tartrate (Alphagan)	α-Adrenergic agonists; probably decrease aqueous humor production	Ocular redness; irregular heart rate	Topical drops; used to control or prevent acute rise in IOP after laser procedure (used before and immediately after ALT and iridotomy, Nd:YAG laser capsulotomy) For patient at risk for systemic reactions, teaching includes instructions to occlude puncta
Latanoprost (Xalatan)	Prostaglandin-F analogue	Increased brown iris pigmentation, ocular discomfort and redness, dryness, itching, and sensation of foreign body	Topical drops Teach patient not to take more than 1 drop per evening and to remove contact lens 15 min before instilling
Cholinergic Drugs (Miotics)			

Drug	Action	Adverse Effects	Nursing Considerations
Carbachol (Isopto Carbachol)	Parasympathomimetic; stimulates iris sphincter contraction, causing miosis and opening of trabecular meshwork, facilitating outflow of aqueous humor; also partially inhibits activity of cholinesterase	Transient ocular discomfort, headache, ache in brow area, blurred vision, decreased adaptation to darkness, syncope, excessive salivation, dysrhythmias, vomiting, diarrhea, hypotension, retinal detachment in susceptible individual (rare)	Topical drops Caution patient about decreased visual acuity caused by miosis, particularly in dim light
Pilocarpine (Isopto Carpine)	Parasympathomimetic; stimulates iris sphincter contraction, causing miosis and opening of trabecular meshwork, facilitating outflow of aqueous humor	Same as those of carbachol	Topical drops Same cautions as for carbachol
Carbonic Anhydrase Inhibitors			
Systemic			
Acetazolamide Methazolamide	Decreases production of aqueous humor	Paresthesias, especially "tingling" sensation in extremities; hearing dysfunction or tinnitus; loss of appetite; taste alteration; GI disturbances; drowsiness; confusion	Oral nonbacteriostatic sulphonamides Anaphylaxis and other sulpha type of allergic reactions may occur in patient allergic to sulpha drugs Diuretic effect can lower electrolyte levels Ask patient about acetylsalicylic acid (ASA; Aspirin) use; drug should not be given to patient receiving high-dose ASA (Aspirin) therapy
Topical			
Brinzolamide (Azopt) Dorzolamide (Trusopt)	Decreases production of aqueous humor	Transient stinging, blurred vision, redness	Same as for systemic drugs
Combination Therapy			
Timolol maleate and dorzolamide (Cosopt)	Combination of two drugs (β-adrenergic blocker and topical carbonic anhydrase inhibitors)	Same as those for timolol maleate and dorzolamide (described previously)	—
Hyperosmolar Drugs			

Drug	Action	Adverse Effects	Nursing Considerations
Mannitol solution (Osmitrol)	Increases extracellular osmolarity so that intracellular water moves to the extracellular and vascular spaces, reducing IOP	Nausea, vomiting, diarrhea, thrombophlebitis, hypertension, hypotension, tachycardia	Intravenous solution; used in acute glaucoma attacks or preoperatively when decreased IOP is desired Nurse must assess patient for susceptibility to pulmonary edema and HF before administering hyperosmolar drugs

ALT, argon laser trabeculoplasty; *COPD,* chronic obstructive pulmonary disease; *GI,* gastro-intestinal; *HF,* heart failure; *IOP,* intraocular pressure; *Nd:YAG*, neodymium:yttrium–aluminum–garnet (laser).

Argon laser trabeculoplasty (ALT) is a noninvasive option to lower IOP when medications are not successful or when the patient either cannot or will not use the drug therapy as recommended. ALT is an outpatient procedure that necessitates only topical anaesthesia. The laser stimulates scarring and contraction of the trabecular meshwork, which opens the outflow channels. ALT reduces IOP approximately 75% of the time. The patient uses topical corticosteroids for approximately 3 to 5 days after the procedure. The most common postoperative complication is an acute rise in IOP. The ophthalmologist examines the patient 1 week and again 4 to 6 weeks after surgery.

Filtration surgery, also called a *trabeculectomy,* may be indicated if medical management and laser therapy are not successful. The success rate of this surgery is 75% to 85%.

Acute Angle-Closure Glaucoma.

Acute angle-closure glaucoma is an ocular emergency that necessitates immediate intervention. Miotics and oral or intravenous hyperosmotic drugs are usually successful in immediately lowering the IOP (see Table 24-8). A laser peripheral iridotomy or surgical iridectomy is necessary for long-term treatment and prevention of subsequent episodes. These procedures allow the aqueous humor to flow through a newly created opening in the iris and into normal outflow channels. One of these procedures may also be performed on the other eye as a precaution because many patients often experience an acute attack in the other eye.

Safety Alert

Patients who take miotic drugs must be warned that they may experience decreased visual acuity, especially in dim light.

Nursing Management Glaucoma

Nursing Assessment

Because glaucoma is a chronic condition that necessitates long-term management, the nurse must assess the patient's ability to understand and adhere to the rationale and regimen of the prescribed therapy. In addition, the nurse should assess the patient's psychological reaction to the diagnosis of a potentially sight-threatening chronic disorder. The nurse must include the patient's caregiver in the assessment process because the chronic nature of this disorder affects the family in many ways. Some families may become the primary providers of necessary care, such as eye drop administration, if the patient is unwilling or unable to accomplish these self-care activities. The nurse also assesses visual acuity, visual fields, IOP, and fundus changes when appropriate.

Nursing Diagnoses

Nursing diagnoses for the patient with glaucoma include, but are not limited to, the following:

- *Risk for injury* as evidenced by *sensory integration dysfunction* (visual acuity deficits)
- *Self-care deficits* related to *perceptual disorders* (visual impairment)
- *Readiness for enhanced self-care*
- *Acute pain* related to *physical injury agent* (surgical process)

Planning

The overall goals are that the patient with glaucoma will (a) have no progression of visual impairment, (b) understand the disease process and the rationale for therapy, (c) comply with all aspects of therapy (including medication administration and follow-up care), and (d) have no postoperative complications.

Nursing Implementation

Health Promotion.

Loss of vision from glaucoma is a preventable problem. It is important to teach the patient and caregiver about the risk of vision loss from glaucoma and that this risk increases with age. The nurse should stress the importance of early detection and treatment in preventing visual impairment. A comprehensive ophthalmic examination is invaluable in identifying persons with glaucoma or those at risk of developing glaucoma. The Canadian Ophthalmological Society (2007) recommended an eye examination every 3 to 5 years until the age of 40 and then every 2 to 4 years until the age of 65. Patients with risk factors such as family history of glaucoma and those of African descent should have annual eye examinations. Because so many eye diseases tend to occur in older adults, those older than 65 should have an examination every 2 years (annually if they have any risk factors; Canadian Ophthalmological Society, 2007).

Acute Intervention.

Acute nursing interventions are directed primarily toward patients with acute angle-closure glaucoma and patients undergoing surgery for glaucoma. A patient with acute angle-closure glaucoma requires immediate IOP-lowering medication, which the nurse must administer in a timely and appropriate manner according to the ophthalmologist's prescription. Most surgical procedures for glaucoma are outpatient procedures. In the acute situation, the patient needs postoperative instructions and may require nursing comfort measures to relieve discomfort related to the procedure. Patient and caregiver teaching after eye surgery is discussed in Table 24-5.

Ambulatory and Home Care.

Because of the chronic nature of glaucoma, the patient needs encouragement to follow the therapeutic regimen and follow-up recommendations prescribed by the ophthalmologist. The patient needs accurate information about the disease process and treatment options, including the rationale underlying each option. In addition, the patient needs information about the purpose, the frequency, and the technique

of administering prescribed antiglaucoma drugs. In addition to verbal instructions, all patients should receive written instructions that contain the same information. The nurse may encourage adherence by helping the patient identify the most convenient and appropriate times for medication administration or by advocating a change in therapy if the patient reports unacceptable adverse effects.

Evaluation

The overall expected outcomes are that the patient with glaucoma will

- Have no further loss of vision
- Adhere to the recommended therapy
- Safely function within own environment
- Obtain relief from pain associated with the disease and surgery

Age-Related Considerations

Many older patients with glaucoma have systemic illnesses or take systemic medications that may affect their glaucoma therapy. In particular, patients who take a β-adrenergic blocking drug for glaucoma may experience an additive effect if they are also taking a systemic β-adrenergic blocking drug. All β-adrenergic blocking glaucoma drugs are contraindicated for use in patients that have bradycardia, a greater than first-degree heart block, cardiogenic shock, and overt cardiac failure. The non−cardioselective β-adrenergic blocking glaucoma drugs are also contraindicated in patients with severe chronic obstructive pulmonary disease (COPD) or asthma. The hyperosmolar drugs may precipitate heart failure or pulmonary edema in susceptible patients. Older patients receiving high-dose acetylsalicylic acid (ASA; Aspirin) therapy for rheumatoid arthritis should not take carbonic anhydrase inhibitors. The α-adrenergic agonists can cause tachycardia or hypertension, which may have serious consequences in older patients. The nurse must teach older patients to occlude the puncta to limit the systemic absorption of glaucoma medications.

Intraocular Inflammation and Infection

The term *uveitis* is used to describe inflammation of the uveal tract, the retina, the vitreous cavity, or the optic nerve. This inflammation may be caused by bacteria, viruses, fungi, or parasites. *Cytomegalovirus retinitis* is an opportunistic infection that occurs in patients with acquired immune deficiency syndrome (AIDS) and in other immuno-suppressed patients. The causes of sterile intraocular inflammation include autoimmune disorders, AIDS, malignancies, or disorders associated with systemic diseases such as inflammatory bowel disease. Pain and photophobia are common symptoms.

Endophthalmitis is an extensive intraocular inflammation of the vitreous cavity. Bacteria, viruses, fungi, or parasites can all induce this serious inflammatory response. The mechanism of infection may be endogenous, in which the infecting pathogen arrives at the eye through the bloodstream, or exogenous, in which the infecting pathogen is introduced through a surgical wound or a penetrating injury. Although rare, endophthalmitis is a devastating complication of intraocular

surgery or penetrating ocular injury and can lead to irreversible blindness within hours or days. Manifestations include ocular pain, photophobia, decreased visual acuity, headaches, reddened and swollen conjunctiva, and corneal edema.

When all the layers of the eye (vitreous humor, retina, choroid, and sclera) are involved in the inflammatory response, the patient has *panophthalmitis.* In the final stages of extensive cases, the scleral coat may undergo bacterial or inflammatory dissolution. Subsequent rupture of the globe spreads the infection into the orbit or eyelids.

Treatment of intraocular inflammation depends on the underlying cause. Intraocular infections must be treated with antimicrobial drugs, which may be delivered topically, subconjunctivally, intravitreally, systemically, or in some combination. Sterile inflammatory responses necessitate anti-inflammatory drugs such as corticosteroids. The patient with intraocular inflammation is usually uncomfortable and may be noticeably anxious and frightened. The nurse must provide accurate information and emotional support to the patient and the family. In severe cases, enucleation may be necessary. When patients lose visual function or even the entire eye, they grieve over the loss. The nurse's role includes helping patients through the grieving process.

Enucleation

Enucleation is the removal of the eye. The primary indication for enucleation is the combination of blindness and pain in the eye. These may result from glaucoma, infection, or trauma. Enucleation may also be indicated in ocular malignancies, although many malignancies can be managed with cryotherapy, radiation, and chemotherapy. The surgical procedure includes severing the extraocular muscles close to their insertion on the globe, inserting an implant to maintain the intraorbital anatomy, and suturing the ends of the extraocular muscles over the implant. The conjunctiva covers the joined muscles, and a clear conformer is placed over the conjunctiva until the permanent prosthesis is fitted. A pressure dressing helps prevent postoperative bleeding.

Postoperatively, the nurse observes the patient for signs of complications, including excessive bleeding or swelling, increased pain, displacement of the implant, or temperature elevation. Patient teaching should include instructions about the instillation of topical ointments or drops and wound cleansing. The nurse should also instruct the patient

how to insert the conformer into the socket in case it falls out. The patient is often devastated by the loss of an eye, even when enucleation occurs after a lengthy period of painful blindness. The nurse should recognize and validate the patient's emotional response and provide support to the patient and the family.

Approximately 6 weeks after surgery, the wound is sufficiently healed for the permanent prosthesis. The prosthesis is fitted by an ocular specialist and designed to match the remaining eye. The nurse should teach the patient how to remove, cleanse, and insert the prosthesis. Special polishing is required periodically to remove dried protein secretions.

Ocular Tumours

Benign and malignant tumours can occur in many areas of the eye, including the conjunctiva, retina, and orbit. Malignancies of the eyelid include basal cell and squamous cell carcinomas (see Chapter 26).

Uveal melanoma is a cancerous neoplasm of the iris, choroid, or ciliary body. It is the most common primary intraocular malignancy in adults, but it is much rarer than skin melanoma. Approximately 200 cases are diagnosed in Canada each year (Melanoma Network of Canada, 2015). It is more frequently found in light-skinned people older than 60 with chronic exposure to ultraviolet light. Genetic factors such as a mutated gene may also increase a person's risk (Nielsen, Dogrusöz, Bleeker, et al., 2015). Uveal melanoma can arise from pre-existing nevi in the eye. Tumours may be asymptomatic or associated with vision loss depending on their size and location and presence of hemorrhage and retinal detachment. As with other cancers, cancer stage and cell type are important variables in the patient's prognosis. Diagnostic testing may include ultrasonography, magnetic resonance imaging (MRI), and fine-needle aspiration biopsy. Uveal melanoma commonly appears as a dome-shaped, well-circumscribed, solid brown to golden pigment in the iris, choroid, or ciliary body (Figure 24-10). Many patients do not lose the affected eye, and some may experience good vision after treatment in that eye.

FIGURE 24-10 Uveal melanoma. A large tumour in the choroid, the most common location in the eye for melanoma. Source: Courtesy Cory J. Bosanko, OD, FAAO, Eye Centers of Tennessee, Crossville, Tennessee.

Depending on the status of the involved eye, treatment options can include enucleation, plaque radiation therapy (brachytherapy), external beam radiation, transpupillary photocoagulation, eye wall resection, and exenteration. Within 15 years, approximately 50% of all patients with uveal melanoma will develop metastases, most commonly in the liver.

Ocular Manifestations of Systemic Diseases

Many systemic diseases are accompanied by significant ocular manifestations. Ocular signs and symptoms may be the first finding or complaint in a patient with a systemic disease. One example is the patient with undiagnosed diabetes who seeks ophthalmic care for blurred vision. A thorough history and careful examination of the patient can reveal that the underlying cause of the blurred vision is lens swelling resulting from hyperglycemia. Another example is the patient who seeks care for a conjunctival lesion. The ophthalmologist may be the first health care provider to make the diagnosis of AIDS on the basis of the presence of a conjunctival Kaposi's sarcoma.

Auditory Problems

External Ear and Canal

Trauma

Trauma to the external ear can cause injury to the subcutaneous tissue that may result in a hematoma. If the hematoma is not aspirated, inflammation of the membranes of the ear cartilage (perichondritis) can result. Blows to the ear can also cause a conductive hearing loss if the ossicles in the middle ear are damaged or the tympanic membrane (TM) is perforated. Head trauma that injures the temporal lobe of the cerebral cortex can impair the ability to understand the meaning of sounds.

External Otitis

The skin of the external ear and the ear canal is subject to the same problems as skin anywhere on the body. **External otitis** involves inflammation or infection of the epithelium of the auricle and ear canal. Swimming may alter the flora of the external canal as a result of chemicals and contaminated water. This can result in an infection often referred to as "swimmer's ear." Trauma from picking the ear or using sharp objects (e.g., hairpins) to clean the ear frequently causes the initial break in the skin. Piercing of auricular cartilage carries a greater risk of infection than does soft-tissue piercing (Lee & Gold, 2011).

Causes.

Infections and skin conditions may cause external otitis. Bacteria or fungi may be the cause. *Pseudomonas aeruginosa* is the most common bacterial cause. Fungi, including *Candida albicans* and *Aspergillus* species, especially thrive in warm, moist climates. The warm, dark environment of the ear canal provides a good medium for the growth of microorganisms.

Malignant external otitis is a serious infection caused by *P. aeruginosa.* It occurs mainly in older patients with diabetes. The infection, which can spread from the external ear to the parotid gland and temporal bone (osteomyelitis), is usually treated with antibiotics.

Clinical Manifestations and Complications.

Ear pain *(otalgia)* is one of the first signs of external otitis. Even in mild cases, a patient may experience significant discomfort with chewing, moving the auricle, or pressing on the tragus. Swelling of the ear canal can muffle hearing. Drainage from the ear may be serosanguineous (blood-tinged fluid) or purulent (white to green thick fluid). Fever occurs when the infection spreads to surrounding tissue. Facial nerve paralysis may occur with malignant external otitis.

Nursing and Collaborative Management External Otitis

Diagnosis of external otitis is made by otoscopic examination of the ear canal. The nurse must be careful to avoid pain when pulling on the patient's auricle to straighten out the canal or when inserting the otoscope speculum. The eardrum may be difficult to see because of swelling in the canal. Culture and sensitivity studies of the drainage may be done. Moist heat, mild analgesics, and topical anaesthetic drops usually control the pain. Topical antibiotics include polymyxin B (Polysporin), neomycin (Neosporin), and chloramphenicol (Pentamycetin). Nystatin (Nyaderm) is used for fungal infections. Corticosteroids may also be used to decrease inflammation unless the infection is fungal, in which case their use is contraindicated. If the surrounding tissue is involved, systemic antibiotics are prescribed. Improvement should occur in 48 hours, but the patient must adhere to the prescribed therapy for 7 to 14 days for complete resolution.

Hands should be washed before and after otic drops (eardrops) are administered. The drops should be administered at room temperature; cold drops can cause vertigo by stimulating the semicircular canals, and heated drops can burn the tympanum. The tip of the dropper should not touch the ear during administration, so as to prevent contamination of the entire bottle. The ear is positioned so that the drops can run down into the canal. The patient should maintain this position for 2 minutes to allow the drops to spread. Sometimes drops are placed onto a wick of cotton that is placed in the canal. The nurse should instruct the patient not to push the cotton farther into the ear. Careful handling and disposal of material saturated with drainage is important. The nurse should also instruct the patient on methods to reduce the risk of external otitis (Table 24-10).

TABLE 24-10

PATIENT & CAREGIVER TEACHING GUIDE
Prevention of External Otitis

Include the following instructions when teaching the patient and caregiver how to prevent external otitis.
1. Do not put anything in your ear canal unless requested by your health care provider. 2. Report itching if it becomes a problem. 3. Cerumen (earwax) is normal. • It lubricates and protects the canal. • Report chronic excessive cerumen if it impairs your hearing. 4. Keep your ears as dry as possible. • Use earplugs if you are prone to swimmer's ear. • Turn your head to each side for 30 sec at a time to help water run out of the ears. • Do not dry with cotton-tipped applicators. • A hair dryer set to low and held at least 6 in from the ear can speed water evaporation.

Cerumen and Foreign Bodies in the External Ear Canal

Impacted cerumen can cause discomfort and decreased hearing. In older adults, the earwax becomes dense and drier. Hair becomes thicker and coarser, entrapping the hard, dry cerumen in the canal. Symptoms of cerumen impaction are outlined in Table 24-11. Management involves irrigation of the canal with body-temperature solutions to soften the cerumen. Special syringes, varying from a simple bulb syringe to special irrigating equipment, can be used. The patient is placed in a sitting position with an emesis basin under the ear. The auricle is pulled up and back, and the flow of solution is directed above or below the impaction. It is important that the ear canal not be completely occluded with the syringe tip. If irrigation does not remove the cerumen, mild lubricant drops may be used to soften it. Severe impaction may need to be removed by the health care provider.

TABLE 24-11

MANIFESTATIONS OF CERUMEN IMPACTION

• Hearing loss • Otalgia • Tinnitus • Vertigo • Cough • Cardiac depression (vagal stimulation)

Attempts to remove a foreign object from the ear canal may result in pushing it farther into the canal. Vegetable matter in the ear tends to swell and may create a secondary inflammation, which makes removal more difficult. Mineral oil or lidocaine drops can be used to kill an insect before removal under microscope guidance. Removal of impacted objects should be performed by the health care provider.

Ears should be cleaned with a washcloth and finger. Cotton-tipped applicators should be avoided: Penetration of the middle ear by a cotton-tipped applicator can cause serious injury to the TM and ossicles. The use of cotton-tipped applicators can also cause cerumen to become impacted against the TM and impair hearing.

Malignancy of the External Ear

Skin cancers are the only common malignancies of the ear. Rough sandpaper-like changes to the upper border of the auricle are premalignant lesions (actinic keratoses) associated with chronic sun exposure. They are often removed with liquid nitrogen. Malignancies in the external ear canal include basal cell carcinoma in the auricle and squamous cell carcinoma in the ear canal. If left untreated, they can invade underlying tissue. The nurse should teach the patient about the dangers of sun exposure and the importance of using hats and sunscreen when outdoors.

Middle Ear and Mastoid

Acute Otitis Media

Acute otitis media (AOM) is an infection of the tympanum, ossicles, and space of the middle ear. Swelling of the auditory tube as a result of colds or allergies can trap bacteria, causing a middle ear infection. Pressure from the inflammation pushes on the TM, causing it to become red, bulging, and painful. AOM is usually a childhood disease because in children the auditory tube that drains fluids and mucus from the middle ear is shorter and narrower, and its position is flatter, than that in adults (Le Saux & Robinson, 2016). Pain, fever, malaise, and reduced hearing are signs and symptoms of infections. Referred pain from the temporomandibular joint, teeth, gums, sinuses, or throat may also cause ear pain. Clinical practice guidelines include strategies such as

observation, antibiotics, and pain control (Thornton, Parrish, & Swords, 2011).

Collaborative care involves the use of antibiotics to eradicate the causative organism. Amoxicillin (Amoxil) is the current therapy of choice in North America. Surgical intervention is generally reserved for patients who do not respond to medical treatment. A *myringotomy* involves an incision in the tympanum to release the increased pressure and exudate from the middle ear. A tympanostomy tube may be placed for short- or long-term drainage. Prompt treatment of an episode of AOM generally prevents spontaneous perforation of the TM. In the adult patient for whom allergy may be a causative factor, antihistamines may also be prescribed.

Otitis Media With Effusion

Otitis media with effusion is an inflammation of the middle ear with a collection of fluid in the middle ear space. The fluid may be thin, mucoid, or purulent. If the Eustachian tube does not open and allow equalization of atmospheric pressure, negative pressure within the middle ear pulls fluid from surrounding tissues. This problem commonly follows upper respiratory tract or chronic sinus infections, barotrauma (caused by pressure change), or otitis media.

Complaints include a feeling of fullness of the ear, a "plugged" feeling or popping sensation, and decreased hearing. The patient does not experience pain, fever, or discharge from the ear. It is normal to have otitis media with effusion for weeks to months after an episode of AOM. It usually resolves in 75% to 90% of cases without treatment but may recur.

Chronic Otitis Media and Mastoiditis

Etiology and Pathophysiology.

Repeated attacks of AOM may lead to chronic otitis media, especially in adults who have a history of recurrent otitis in childhood. Organisms involved in chronic otitis media include *S. aureus, Proteus mirabilis,* and *P. aeruginosa.* Because the mucous membrane is continuous, both the middle ear and the air cells of the mastoid bone can be involved in the chronic infectious process.

Clinical Manifestations.

Chronic otitis media is characterized by a purulent exudate and inflammation that can involve the ossicles, Eustachian tube, and mastoid bone. It is often painless and may be accompanied by hearing loss, nausea, and episodes of dizziness. Hearing loss is a complication from inflammatory destruction of the ossicles, a TM perforation, or accumulation of fluid in the middle ear space.

Complications.

Untreated conditions can result in TM perforation and the formation of a *cholesteatoma* (a mass of epithelial cells and cholesterol in the middle ear). The cholesteatoma enlarges and can destroy the adjacent bones. Unless removed surgically, it can cause extensive damage to the ossicles and impair hearing.

Diagnostic Studies.

Otoscopic examination of the TM may reveal colour changes and mobility or a perforation (Figure 24-11). Culture and sensitivity tests of the drainage are necessary to identify the organisms involved so that the appropriate antibiotic therapy can be prescribed. Audiography may demonstrate a hearing loss as great as 50 to 60 dB if the ossicles have been damaged or separated. Sinus radiographic studies, MRI, or computed tomography of the temporal bone may demonstrate bone destruction, absence of ossicles, or the presence of a mass.

Source: Flint, P., Haughey, Lund, V., et al. (Eds.). (2010). *Cummings otolaryngology: Head and neck surgery* (5th ed.). St Louis: Mosby.

Collaborative Care.

The aims of treatment are to clear the middle ear of infection, repair the perforation, and preserve hearing (Table 24-12). Systemic antibiotic therapy is initiated on the basis of results of the culture and sensitivity tests. In addition, the patient may need to undergo frequent evacuation of drainage and debris in an outpatient setting. Otic and oral antibiotics are used to reduce infection. In many cases of chronic otitis media, the causative pathogen is resistant to antibiotics.

TABLE 24-12

COLLABORATIVE CARE
Chronic Otitis Media

Diagnostic Studies
• History and physical examination • Otoscopic examination • Culture and sensitivity tests of middle ear drainage • Mastoid radiography
Collaborative Therapy

• Ear irrigations
• Otic, oral, or parenteral antibiotics
• Analgesics
• Antiemetics
• Surgery
  • Tympanoplasty*
  • Mastoidectomy

*See Table 24-13.

Surgical Therapy.

Chronic TM perforations often do not heal with conservative treatment, and surgery is necessary. *Tympanoplasty (myringoplasty)* involves reconstruction of the TM, the ossicles, or both. A *mastoidectomy* is often performed with a tympanoplasty to remove infected portions of the mastoid bone. Removal of tissue stops at the middle ear structures that appear capable of conducting sound. Sudden pressure changes in the ear and postoperative infections can disrupt the surgical repair during the healing phase or cause facial nerve paralysis.

Nursing Management Chronic Otitis Media

After Tympanoplasty

Routine preoperative care is provided before tympanoplasty and includes teaching postoperative expectations (Table 24-13).

TABLE 24-13
PATIENT & CAREGIVER TEACHING GUIDE
After Ear Surgery

Include the following instructions when teaching the patient and caregiver after ear surgery.
1. Avoid sudden head movements. 2. Do not try to get out of bed without assistance. 3. Take drugs to reduce dizziness if prescribed. 4. Change positions slowly. 5. Avoid getting the head wet (including showering) until directed by surgeon. 6. Report fever, pain, an increase in hearing loss, or drainage from the ear. 7. Do not cough or blow the nose because this causes increased pressure in the Eustachian tube and middle ear cavity and disrupts healing. 8. If you need to cough or sneeze, leave the mouth open to help reduce the pressure. 9. Avoid crowds because respiratory infections may be contracted. 10. Avoid situations in which pressure or popping in the ears is normally experienced, such as high elevations or airplane travel.

After surgery, the patient is positioned flat and side-lying with the operated side up. It is normal for hearing to be impaired during the postoperative period if there is packing in the ear. A cotton-ball dressing is used for the incision made through the external auditory canal (endaural incision). The patient should be instructed to change the cotton packing and dressing daily. If a postauricular incision is used and a drain is in place, a mastoid dressing is used. A small gauze pad is cut to fit behind the ear, and fluffs are applied over the ear to prevent the outer circular head dressing from placing pressure on the auricle. The nurse should monitor the amount and type of drainage postoperatively, as well as the tightness of the dressing, to prevent tissue necrosis.

Otosclerosis

Otosclerosis is a hereditary autosomal dominant disease and the most common cause of hearing loss in young adults (Ferri, 2012). Spongy

bone develops from the bony labyrinth, causing immobilization of the footplate of the stapes in the oval window. This reduces the transmission of vibrations to the inner ear fluids and results in conductive hearing loss. Although otosclerosis is typically bilateral, hearing loss may progress more rapidly in one ear. The patient is often unaware of the problem until the loss becomes so severe that communication is difficult.

Otoscopic examination may reveal a reddish blush of the tympanum (Schwartz's sign) caused by the vascular and bony changes within the middle ear. Tuning fork tests help identify the conductive component of the hearing loss. On Rinne's test, sound is heard longer when the stem of the tuning fork is touching the mastoid bone (bone conduction) than when placed next to the ear (air conduction). In Weber's test, the sound is heard better through the skull bone in the ear than through air when conductive hearing loss is greater. Audiography demonstrates good hearing by bone conduction but poorer hearing by air conduction (air–bone gap). The difference between air and bone conduction levels of hearing is usually at least 20 to 25 dB in otosclerosis.

Collaborative Care.

The hearing loss associated with otosclerosis may be stabilized by the use of sodium fluoride with vitamin D and calcium carbonate to retard bone resorption and encourage calcification of bony lesions. Amplification of sound by a hearing aid can be effective because the inner ear function is normal. Surgical treatment involves partial removal of the stapes *(stapedectomy)* or complete removal with prosthesis insertion *(fenestration)*. Collaborative care of otosclerosis is described in Table 24-14.

TABLE 24-14
COLLABORATIVE CARE
Otosclerosis

Diagnostic Studies
• History and physical examination • Otoscopic examination • Rinne's test • Weber's test • Audiometry • Tympanometry
Collaborative Therapy

• Hearing aid
• Surgery (stapedectomy or fenestration)
• Drug therapy
  • Sodium fluoride with vitamin D
  • Calcium carbonate

These procedures are usually performed with the patient under conscious sedation. The ear with poorer hearing is repaired first, and the other ear may be operated on within a year. An endaural incision is made under visualization through the operating microscope. Gelfoam is used on the incision flap to limit bleeding. A cotton ball is placed in the ear canal, and a small dressing is used to cover the ear.

During surgery, patients often report an immediate improvement in hearing in the operated ear. Because of the accumulation of blood and fluid in the middle ear, the hearing level decreases postoperatively but improves with healing. After stapedectomy, 90% of patients experience an improvement in hearing, in many instances to near normal.

Nursing Management Otosclerosis

Nursing management of patients undergoing stapedectomy or fenestration is similar to that for patients who have undergone tympanoplasty. Postoperatively, patients may experience dizziness, nausea, and vomiting as a result of intraoperative stimulation of the labyrinth. Some patients demonstrate nystagmus because of disturbance of the perilymph fluid. The patient should take care to avoid sudden movements that may induce or exacerbate dizziness. The patient should avoid actions that increase inner ear pressure, such as coughing, sneezing, lifting, bending, and straining during bowel movements.

Inner Ear Problems

Three symptoms that indicate disease of the inner ear are vertigo, sensorineural hearing loss, and tinnitus. Symptoms of vertigo arise from the vestibular labyrinth, whereas hearing loss and tinnitus arise from the auditory labyrinth. Manifestations of inner ear problems overlap with some manifestations of central nervous system disorders.

Ménière's Disease

Ménière's disease (endolymphatic hydrops) is characterized by symptoms caused by inner ear disease, including episodic vertigo, tinnitus, fluctuating sensorineural hearing loss, and a sense of aural fullness. The patient experiences significant disability because of sudden, severe attacks of vertigo with nausea, vomiting, sweating, and pallor. Symptoms usually begin between the ages of 30 and 60 years (Tassinari, Mandrioli, Gaggioli, et al., 2015).

The cause of the disease is unknown, but it results in an excessive accumulation of endolymph in the membranous labyrinth. The volume of endolymph increases until the membranous labyrinth ruptures. Attacks may be preceded by a sense of fullness in the ear, increasing tinnitus, and muffled hearing. Patients with Ménière's disease may experience the feeling of being pulled to the ground (“drop attacks”). Some patients report that they feel as if they are whirling in space. Attacks may last hours or days and may occur several times a year. The clinical course of the disease is highly variable.

Nursing and Collaborative Management Ménière's Disease

Collaborative care of Ménière's disease (Table 24-15) includes diagnostic tests to rule out other causes of symptoms, including central nervous system disease. Audiography demonstrates a mild, low-frequency sensorineural hearing loss. Vestibular tests indicate decreased function.

TABLE 24-15

COLLABORATIVE CARE
Ménière's Disease

Diagnostic Studies
• History and physical examination • Audiometric studies (including speech discrimination, tone decay) • Vestibular tests (including caloric test, positional test) • Electronystagmography • Neurological examination • Glycerol test
Collaborative Therapy
Acute Care
Drug Therapy (One or More)
• Sedatives • Benzodiazepines • Anticholinergics • Antiemetics • Antihistamines
Surgical Therapy
Conservative Surgical Intervention
• Endolymphatic shunt • Vestibular nerve section
Destructive Surgical Intervention
• Labyrinthotomy • Labyrinthectomy
Ambulatory or Home Care
• Diuretics • Antihistamines • Calcium channel blockers • Sedatives • Hydrops diet: restriction of sodium, caffeine, nicotine, alcohol, and foods with monosodium glutamate (MSG)

A glycerol test may aid in the diagnosis. An oral dose of glycerol is given, followed by serial audiography over 3 hours. Improvement in hearing or speech discrimination supports a diagnosis of Ménière's disease. The improvement is attributed to the osmotic effect of glycerol

that pulls fluid from the inner ear. Although a positive test result is diagnostic of Ménière's disease, a negative test result does not rule out the condition.

During the acute attack, antihistamines, anticholinergic drugs, and benzodiazepines can be used to decrease the abnormal sensation and lessen symptoms such as nausea and vomiting. Acute vertigo is treated symptomatically with bed rest, sedation, and antiemetics or antivertigo drugs for motion sickness. The patient requires reassurance and counselling that the condition is not life-threatening. Management between attacks may include diuretics, antihistamines, calcium channel blockers, and a low-sodium diet. Diazepam (Valium) may be used to reduce the vertigo. Over time, most patients respond to the prescribed medications, but the attacks and hearing loss remain unpredictable.

Frequent and incapacitating attacks are indications for surgical intervention. Decompression of the endolymphatic sac and shunting are performed to reduce the pressure on the cochlear hair cells and to prevent further damage and hearing loss. If relief is not achieved, the vestibular nerve may be resected. When involvement is unilateral, surgical ablation of the labyrinth, resulting in loss of the vestibular and hearing cochlear function, is performed. Careful management can decrease the possibility of progressive sensorineural loss in many patients.

Nursing interventions are planned to minimize vertigo and provide for patient safety. During an acute attack, the patient is kept in a quiet, darkened room in a comfortable position. The patient needs to be taught to avoid sudden head movements or position changes. Fluorescent or flickering lights or television may exacerbate symptoms and should be avoided. An emesis basin should be available because vomiting is common. To minimize the patient's risk of falling, the nurse should keep the side rails up and the bed low in position when the patient is in bed. The patient should be instructed to call for assistance when getting out of bed. Medications and fluids are administered parenterally, and intake and output are monitored. When the attack subsides, the patient should be assisted with ambulation because unsteadiness may remain.

Benign Paroxysmal Positional Vertigo

Benign paroxysmal positional vertigo (BPPV) is a common cause of vertigo. Approximately 50% of cases of vertigo may be due to BPPV. In

BPPV, free-floating debris in the semicircular canal causes vertigo with specific head movements, such as those involved with getting out of bed, rolling over in bed, and sitting up from lying down (HealthLinkBC, 2014). The debris ("ear rocks") is composed of small crystals of calcium carbonate derived from the utricle in the inner ear. The utricle may be injured by head trauma, infection, or degeneration as a result of the aging process. However, for many patients, a cause cannot be found.

Symptoms include dizziness, vertigo, light-headedness, loss of balance, and nausea. Hearing loss is not characteristic, and symptoms tend to be intermittent. The symptoms of BPPV may be confused with those of Ménière's disease. Diagnosis is based on the results of auditory and vestibular tests.

Although BPPV is bothersome, it is rarely a serious problem unless an affected person falls. The Epley manoeuvre (canalith repositioning procedure) is effective in providing symptom relief for many patients (Balatsouras & Korres, 2012). In this manoeuvre, the ear debris is moved from areas in the inner ear that cause symptoms and repositioned into areas where they do not cause these problems. The Epley manoeuvre does not address the actual presence of debris; rather, it changes their location. A trained health care provider can instruct the patient in how to perform the Epley manoeuvre.

Acoustic Neuroma

An **acoustic neuroma** is a unilateral benign tumour that occurs where the vestibulo-cochlear nerve (cranial nerve VIII) enters the internal auditory canal. Early diagnosis is important because the tumour can compress the trigeminal and facial nerves and arteries within the internal auditory canal. Symptoms usually begin at 40 to 60 years of age.

Early symptoms are associated with compression and destruction of cranial nerve VIII. They include unilateral, progressive, sensorineural hearing loss; reduced touch sensation in the posterior ear canal; unilateral tinnitus; and mild, intermittent vertigo. Diagnostic tests include neurological, audiometric, and vestibular tests; computed tomographic scans; and MRI.

Surgery to remove small tumours generally preserves hearing and vestibular function. Large tumours (>3 cm) and the surgery required to remove them can leave the patient with permanent hearing loss and facial paralysis. The nurse should instruct the patient to report any clear,

colourless discharge from the nose. This may be cerebro-spinal fluid, and such leaks increase the risk of infection.

Hearing Loss and Deafness

Hearing loss is the fastest growing and one of the most prevalent, chronic conditions facing Canadians today (Hearing Foundation of Canada, 2014). Hearing loss has many causes; age-related presbycusis and noise-induced hearing loss are two of the most common. Nearly half the persons who need assistance with hearing disorders are 65 years of age or older. With the aging of the population, the prevalence of hearing loss is increasing. At age 50, one of every eight persons is hearing impaired. A disturbing trend is the number of young adults showing signs of hearing loss. The tiny hair cells located inside the ear pick up sound waves and convert them into electrical signals that the brain can interpret. When loud sounds are listened to constantly, the vibrations destroy the tiny hair cells, which contributes to hearing loss. Unlike other cells in the body, hair cells never grow back once they are damaged (Health Canada, 2012). Earbuds are of particular concern because volumes must be high in order to block out environmental distractions (Portnuff, Fligor, & Arehart, 2011). Causes of hearing loss are listed in Figure 24-12.

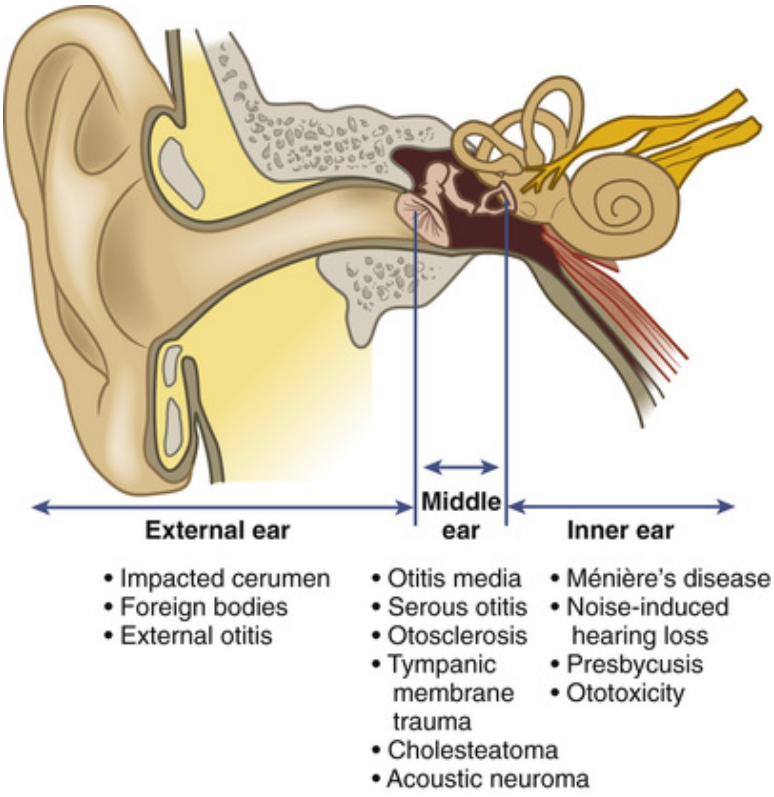

FIGURE 24-12 Causes of hearing loss, by location.

Types of Hearing Loss

Conductive Hearing Loss.

Conductive hearing loss occurs when conditions in the outer or middle ear impair the transmission of sound through air to the inner ear. A common cause is otitis media with effusion. Other causes are impacted cerumen, TM perforation, otosclerosis, and narrowing of the external auditory canal (Harkin & Kelleher, 2011).

Audiography demonstrates an air–bone gap of at least 15 decibel (dB). The term *air–bone gap* represents the situation in which hearing sensitivity is better by bone conduction than by air conduction. Patients may speak softly because they hear their own voices, which are conducted by bone, as being loud. Such patients hear better in a noisy environment. If correction of the cause is not possible, a hearing aid may help if the loss is greater than 40 to 50 dB.

Sensorineural Hearing Loss.

Sensorineural hearing loss is caused by impairment of function of the inner ear or the vestibulo-cochlear nerve (cranial nerve VIII). Congenital and hereditary factors, noise trauma over time, aging (presbycusis), Ménière's disease, and ototoxicity can cause sensorineural hearing loss.

Ototoxic drugs include ASA (Aspirin), nonsteroidal anti-inflammatory drugs (NSAIDs), antibiotics (aminoglycosides, erythromycin, vancomycin), loop diuretics, and chemotherapy drugs.

Systemic infections, such as Paget's disease of the bone, immune diseases, diabetes mellitus, bacterial meningitis, and trauma, are associated with this type of hearing loss. The two main problems associated with sensorineural loss are (a) the inability to understand speech despite the ability to hear sound and (b) the lack of understanding of the problem by other people. The ability to hear high-pitched sounds, including consonants, diminishes. Sounds become muffled and difficult to understand. An audiogram demonstrates a loss in decibel levels at the 4 000-Hz range and eventually the 2 000-Hz range. A hearing aid may help some patients, but it only makes sounds and speech louder, not clearer.

Mixed Hearing Loss.

Mixed hearing loss results from a combination of conductive and sensorineural causes. Careful evaluation is needed if corrective surgery for conductive loss is planned because the sensorineural component of the hearing loss will still remain.

Central and Functional Hearing Loss.

Central hearing loss involves the inability to interpret sound, including speech, because of a problem in the brain (central nervous system). Careful documentation of the history is helpful because there is usually a reference to deafness within the family. The patient should be referred to a qualified hearing and speech service if it is indicated.

Functional hearing loss may be caused by an emotional or a psychological factor. The patient does not seem to hear or respond to pure-tone subjective hearing tests, but no physical cause can be identified. Psychological counselling may help.

Classification of Hearing Loss.

Hearing loss can also be classified by the decibel (dB) level or loss as recorded on the audiogram. Normal hearing is in the 0- to 15-dB range.

Table 24-16 describes the levels hearing loss.

TABLE 24-16

CLASSIFICATION OF HEARING LOSS

Decibel (dB) Loss	Meaning
0–15	Normal hearing
16–25	Slight hearing loss
26–40	Mild impairment
41–55	Moderate impairment
56–70	Moderately severe impairment
71–90	Severe impairment
>90	Profound deafness*

*Most people in this category have been deaf since birth (congenitally deaf).

Clinical Manifestations.

Common early signs of hearing loss are answering questions inappropriately, not responding when not looking at the speaker, asking others to speak up, and showing irritability with others who do not speak up. Other behaviours that suggest hearing loss include straining to hear, cupping the hand around the ear, reading lips, and an increased sensitivity to slight increases in noise level. Often, the patient is unaware of minimal hearing loss or may compensate by using these mannerisms. Family and friends who get tired of repeating or talking loudly are often first to notice hearing loss.

Deafness is often called the “unseen handicap” because it is not until conversation is initiated with a deaf adult that the difficulty in communication is realized. It is important that the health care provider be aware of the need for thorough validation of the deaf person's understanding of health teaching. Descriptive visual aids can be helpful.

Interference in communication and interaction with others can be the source of many problems for the patient and caregiver. Often the patient refuses to admit or may be unaware of impaired hearing. Irritability is common because the patient must concentrate very hard to understand speech. The loss of clarity of speech is most frustrating to a patient with sensorineural hearing loss. The patient may hear what is said but not understand it. Withdrawal, suspicion, loss of self-esteem, and insecurity are commonly associated with advancing hearing loss.

Nursing and Collaborative Management Hearing Loss and Deafness

Health Promotion

Environmental Noise Control.

Noise is the most preventable cause of hearing loss. Figure 24-13 lists the levels of environmental noise generated by common indoor and outdoor sounds. Sudden severe loud noise (acoustic trauma) and chronic exposure to loud noise (noise-induced hearing loss) can damage hearing. Acoustic trauma causes hearing loss by destroying the hair cells of the organ of Corti. Sensorineural hearing loss as a result of increased and prolonged environmental noise, such as amplified sound, is occurring in young adults at an increasing rate. Amplified music (e.g., on iPods or MP3 players) should not exceed 50% of maximum volume. Health teaching must emphasize avoidance of continued exposure to noise levels greater than 70 dB.

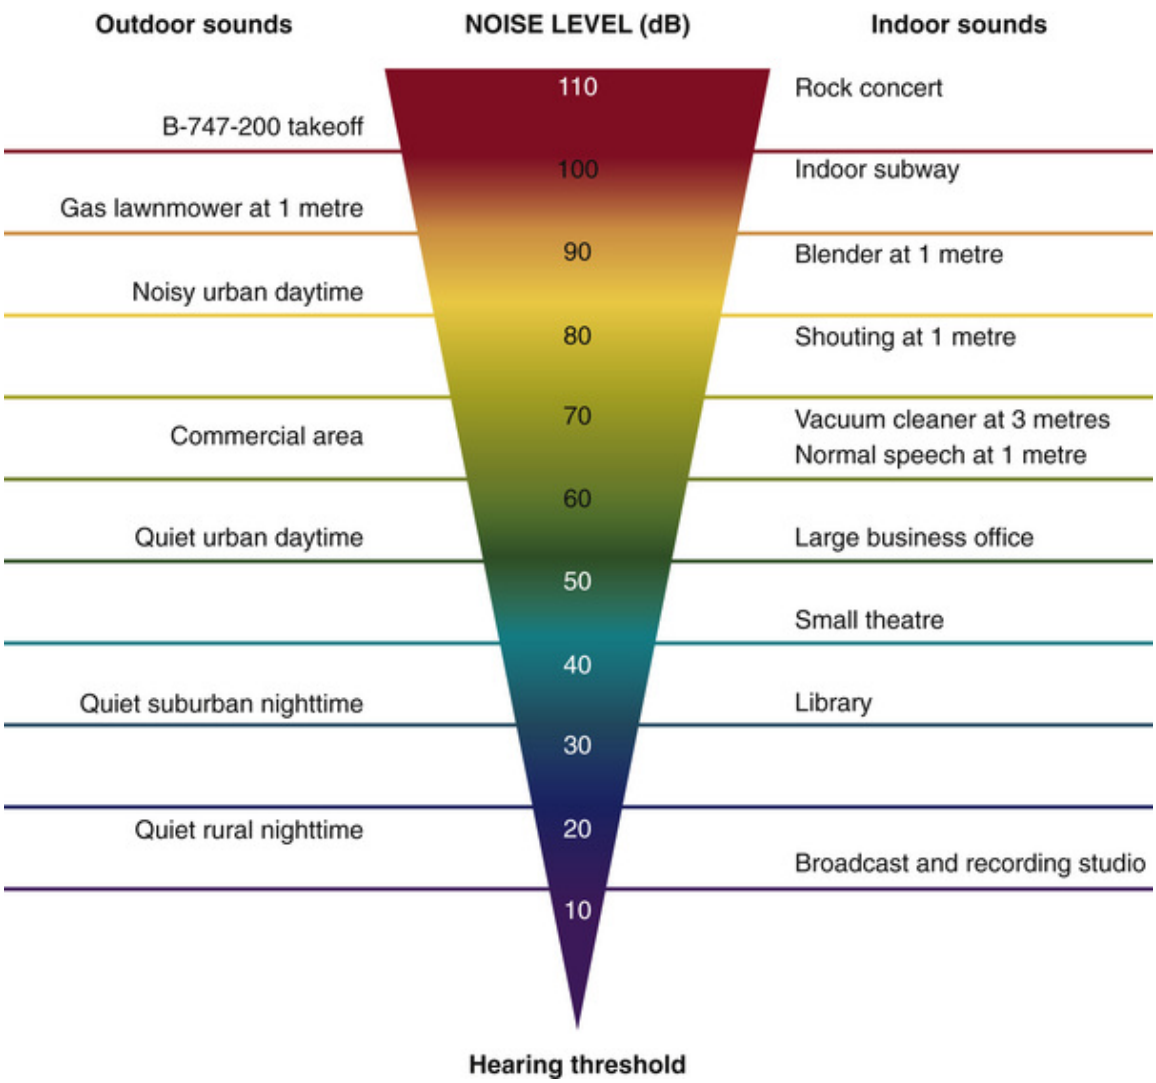

FIGURE 24-13 Levels of common environmental sounds.

In work environments known to have high noise levels (>85 dB), ear protection should be worn. Canadian Occupational Health and Safety regulations Part VII, Sections 7.1 to 7.8, deal with workplace noise (Department of Justice Canada, 2011). A variety of protectors that are worn over the ears or in the ears to prevent hearing loss are available. Periodic audiometric screening should be part of the health maintenance policies of industry. This provides baseline data on hearing to measure subsequent hearing loss.

Employees should participate in hearing conservation programs in work environments. Such programs should include noise exposure analysis, provision for control of noise exposure (hearing protectors), measurements of hearing, and employee–employer notification and

education. Young adults should be encouraged to keep amplified music at a reasonable level and limit their exposure time. Hearing loss caused by noise is irreversible.

Immunizations.

Various viruses in utero can cause deafness as a result of damage and malformations affecting the ear. The nurse should promote childhood and adult immunizations, including the measles-mumps-rubella (MMR) vaccine. Rubella infection during the first 8 weeks of gestation is associated with an 85% incidence of congenital rubella syndrome, which causes sensorineural deafness. Women of child-bearing age should be tested for antibodies to these viral diseases. Women should avoid pregnancy for at least 3 months after being immunized. Immunization must be delayed if the woman is pregnant. Women who are susceptible to rubella can be vaccinated safely during the postpartum period.

Ototoxic Substances.

Drugs commonly associated with ototoxicity include salicylates, loop diuretics, chemotherapy drugs, and antibiotics. Chemicals used in industry (e.g. toluene, carbon disulphide, mercury) may damage the inner ear. Patients who are receiving ototoxic drugs or are exposed to ototoxic chemicals should be monitored for signs and symptoms associated with ototoxicity, including tinnitus, diminished hearing, and changes in equilibrium. If these symptoms develop, immediate withdrawal of the drug may prevent further damage and may cause the symptoms to disappear.

Assistive Devices and Techniques

Hearing Aids.

The patient with a suspected hearing loss should have a hearing assessment by a qualified audiologist. If a hearing aid is indicated, it should be fitted by an audiologist or by a speech and hearing specialist. Many types of hearing aids are available, each with advantages and disadvantages (see Table 24-17). The conventional hearing aid serves as a simple amplifier.

TABLE 24-17
TYPES OF HEARING AIDS

Type	Advantages	Disadvantages
Completely in the canal (mild to moderate hearing loss) 	Smallest and least visible aid Protected from sounds such as wind noise	Costly No space for add-ons such as directional microphones or volume controls Small, short-lived batteries
In the canal (mild to severe hearing loss) 	More powerful than aids completely in the canal Has adjustable features such as noise reduction	Small size of aid with its additional features may be difficult to operate for patients with visual loss or arthritis

Type	Advantages	Disadvantages
In the ear (mild to severe hearing loss) 	Powerful amplification Inserts and adjusts easily Longer-lasting batteries	Visible May pick up wind noise readily
Behind the ear (all types of hearing loss) 	Most powerful aid Adjusts easily Longest battery life	Largest, most visible aid Newer models may be smaller and less obvious

For patients with bilateral hearing impairment, binaural hearing aids provide the best sound lateralization and speech discrimination. The nurse must give careful instruction on its use and maintenance and must assist the patient during the period of adjustment. The goal of hearing aid therapy is improved hearing with consistent use. Patients who are motivated and optimistic about using a hearing aid are more successful users. The nurse should determine the patient's readiness for hearing aid therapy, including acknowledgement of a hearing problem, the patient's feelings about wearing a hearing aid, the degree to which

hearing loss affects life, and any difficulties the patient has manipulating small objects such as putting a battery in a hearing aid.

Initially, use of the hearing aid should be restricted to quiet situations in the home. The patient must first adjust to voices (including the patient's own) and household sounds. The patient should also experiment by increasing and decreasing the volume, as situations require. As the patient adjusts to the increase in sounds and background noise, he or she can progress to situations in which several people are talking simultaneously. Next, the environment can be expanded to the outdoors and then to such environments as a shopping mall or grocery store. Adjustment to different environments occurs gradually, depending on the individual patient.

When the hearing aid is not being worn, it should be placed in a dry, cool area where it will not be inadvertently damaged or lost. The battery should be disconnected or removed when not in use. Battery life averages 1 week, and patients should be advised to purchase only a month's supply at a time. Ear moulds should be cleaned weekly or as needed. Toothpicks or pipe cleaners may be used to clear a clogged ear tip.

Speech Reading.

Speech reading, commonly called *lip reading,* can be helpful in increasing communication. It enables patients to achieve approximately 40% understanding of the spoken word. Patients are able to use visual cues associated with speech, such as gestures and facial expression, to help clarify the spoken message. In speech reading, many words look alike to the patient (e.g., “rabbit” and “woman”). If a patient wears glasses, the glasses should be used to facilitate speech reading. The nurse can help the patient by using and teaching verbal and nonverbal communication techniques as described in Table 24-18.

TABLE 24-18

COMMUNICATION WITH PATIENTS WHO HAVE HEARING IMPAIRMENTS

Nonverbal Aids	Verbal Aids
• Draw attention with hand movements. • Have speaker's face in good light. • Avoid covering mouth or face with hands. • Avoid chewing, eating, and smoking while talking. • Maintain eye contact. • Avoid distracting environments. • Avoid careless expression that the patient may misinterpret. • Use touch. • Move close to better ear. • Avoid light behind speaker.	• Speak normally and slowly. • Do not overexaggerate facial expressions. • Do not overenunciate. • Use simple sentences. • Rephrase sentence; use different words. • Write name or difficult words. • Do not shout. • Speak in normal voice directly into better ear.

Sign Language.

Sign language is used as a form of communication for people with profound hearing impairment. It involves gestures and facial features such as eyebrow motion and lip-mouth movements.

There is no one universal sign language. American Sign Language is used in the United States and the English-speaking parts of Canada. Quebec Sign Language, known in French as *Langue des signes québécoise* or *Langue des signes du Québec (LSQ),* is the sign language of deaf communities in francophone Canada, primarily in Quebec.

Cochlear Implant.

The *cochlear implant* is used as a hearing device for people with severe to profound sensorineural hearing loss in one or both ears. The system consists of an external microphone placed behind the ear, a speech processor and a transmitter implanted under the skin that change sounds into electrical impulses, and a group of electrodes placed within the cochlea that stimulate the auditory nerves in the ear (Figure 24-14). Cochlear implants send information that covers the entire range of sound frequencies. The cochlear implant electrodes are inserted as far as possible into the cochlea to send both high- and low-frequency information. For patients with conductive and mixed hearing loss, the cochlear Baha system may be surgically implanted. The system works through direct bone conduction and becomes integrated with the skull bone over time.

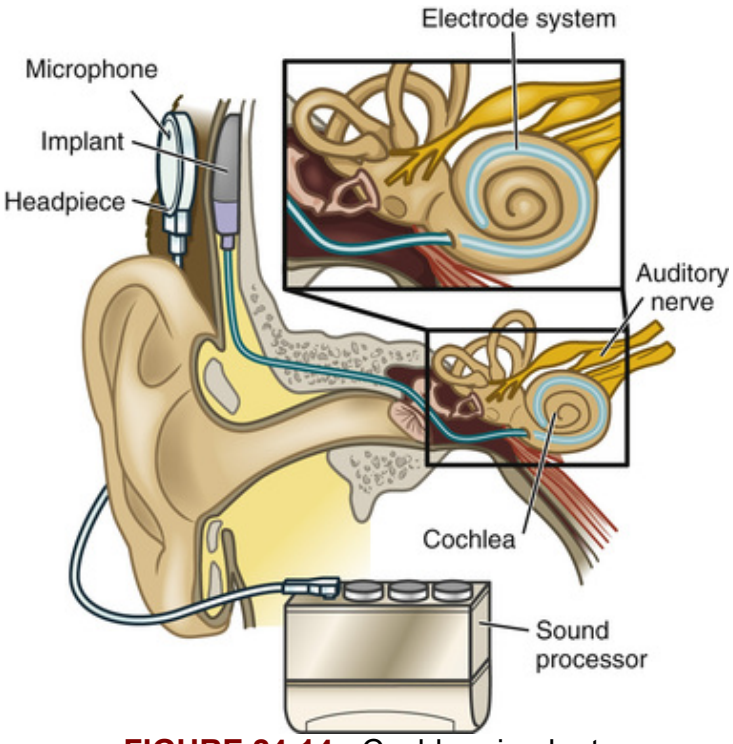

FIGURE 24-14 Cochlear implant.

Extensive training and rehabilitation are essential in order to receive maximum benefit from these implants. The positive aspects of a cochlear implant include providing sound to the person who heard none, improving lip-reading ability, monitoring the loudness of the person's own speech, improving the sense of security, and decreasing feelings of isolation. With continued research, the cochlear implant may offer the possibility of aural rehabilitation for a wider range of hearing-impaired individuals.

The U.S. Food and Drug Administration has created an informational website on cochlear implants (see the Resources at the end of this chapter). The site includes an animated movie to help visualize the implants and how they work.

Assisted Listening Devices.

Numerous devices are now available to assist hearing-impaired persons. Direct amplification devices, amplified telephone receivers, alerting systems that flash when activated by sound, an infrared system for amplifying the sound of the television, and a combination FM receiver and hearing aid are all devices that the nurse can explore on the basis of

the patient's needs. People with profound deafness may be assisted by text-telephone alerting systems that flash when activated by sound, by closed captioning on television, and by specially trained dogs. Such dogs are trained to alert their owners to specific sounds within the environment, which thus increases the person's safety and independence.

Age-Related Considerations

Hearing Loss

Presbycusis, hearing loss associated with aging, includes the loss of peripheral auditory sensitivity, a decline in word recognition ability, and associated psychological and communication issues. Because consonants (high-frequency sounds) are the letters by which spoken words are recognized, an older adult with presbycusis has a diminished ability to understand the spoken word. Vowels are heard, but some consonants fall into the high-frequency range and cannot be differentiated. This may lead to confusion and embarrassment because of the difference in what was said and what was heard (Óberg, 2015).

The cause of presbycusis is related to degenerative changes in the inner ear. Noise exposure is thought to be a common factor. Table 24-19 describes the classification of specific causes and associated hearing changes of presbycusis. Many patients have more than one type of presbycusis. The prognosis for hearing depends on the cause of the loss. Sound amplification with the appropriate device is often helpful in improving the understanding of speech. In other situations, an audiological rehabilitation program can be valuable.

TABLE 24-19
CLASSIFICATION OF PRESBYCUSIS

Type	Hearing Change	Prognosis
Sensory		
Atrophy of auditory nerve; loss of sensory hair cells	Loss of high-pitched sounds	Little effect on speech understanding; good response to sound amplification
Neural		
Degenerative changes in cochlea and spinal ganglion	Loss of speech discrimination	Amplification alone not sufficient
Metabolic		
Degenerative changes in cochlea and spinal ganglion	Uniform loss for all frequencies accompanied by recruitment*	Good response to hearing aid
Cochlear		
Stiffening of basilar membrane, which interferes with sound transmission in the cochlea	Range of hearing loss increases from low to high frequencies; speech discrimination affected with higher frequency losses	Ameliorated by appropriate forms of amplification

*Abnormally rapid increase in loudness as sound intensity increases.

Many older adults are reluctant to use a hearing aid for sound amplification. Reasons cited most often include cost, appearance, insufficient knowledge about hearing aids, amplification of competing noise, and unrealistic expectations. Most hearing aids and batteries are small, and neuro-muscular changes such as stiff fingers, enlarged joints, and decreased sensory perception often make the care and handling of a hearing aid a difficult and frustrating experience for an older person. Some older persons may also tend to accept their losses as part of aging and believe there is no need for improvement.

Case Study

Glaucoma and Diabetic Retinopathy

Source: Blend Images/Shutterstock.com.

Patient Profile

Lena Andrews is a 68-year-old woman who has osteoarthritis and type 2 diabetes mellitus, diagnosed 15 years earlier. She now has diabetic retinopathy. She returns to the eye clinic for continued evaluation and care of the primary open-angle glaucoma (POAG) and re-examination for changes in diabetic retinopathy. Her current medical regimen for POAG includes topical timolol maleate, 0.5% extended (Timoptic XE), once daily in each eye, and latanoprost (Xalatan), 0.005%, in each eye, at bedtime. At her last examination it was noted that she had microaneurysms and hard exudates of the retina.

Subjective Data

- She can no longer read the newspaper and reports that medication labels are difficult to read.
- States that she is not always successful in getting the eye drops instilled because her hands are gnarled and painful from osteoarthritis.

Objective Data

- Distant and near visual acuity are stable at 20/60 in the right eye and 20/50 in the left eye. This is a reduction from 20/40 in both eyes at her last visit.
- Intraocular pressures are stable at 20 mm Hg in both eyes. Visual field testing in the left eye reveals a new scotoma.
- Fluorescein angiography reveals diabetic macular edema in both eyes.

Collaborative Care

- Brimonidine (Alphagan), 0.15%, in left eye 15 min before and immediately after argon laser trabeculoplasty (ALT)
- Argon laser treatment in left eye to seal leaking microaneurysym from macular edema
- Checking intraocular pressure (IOP) after ALT
- Continuing previous glaucoma drop regimen
- Follow-up examination for glaucoma in 2 weeks for possible ALT in right eye
- Follow-up examination for diabetic macular edema in 8 weeks

Discussion Questions

1. What is the cause of Ms. Andrews's new nonproliferative retinopathy?
2. Why might laser photocoagulation be an appropriate therapy for macular edema?
3. What is the purpose of the fluorescein angiography?
4. ***Priority decision:*** What priority topics should be discussed in discharge teaching?
5. In what way could glaucoma cause vision loss if Ms. Andrews's eye pressures are not properly monitored?
6. ***Priority decision:*** What are the priority nursing interventions for Ms. Andrews?
7. ***Priority decision:*** On the basis of the assessment data, what are the priority nursing diagnoses? Are there any collaborative problems?
8. ***Evidence-informed practice:*** Ms. Andrews wants to know if her glaucoma is related to her diabetes. How should the nurse respond to her question?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Why does presbyopia occur in older individuals?
   a. The retina degenerates.
   b. The lens becomes inflexible.
   c. The corneal curvature becomes irregular.
   d. It is associated with cataract development.
2. What is the most important nursing intervention for clients with epidemic keratoconjunctivitis?
   a. Applying patches to the affected eyes.
   b. Accurately measuring intraocular pressure.
   c. Monitoring near visual acuity every 4 hours.
   d. Teaching client and family members good hygiene techniques.
3. What should clients with eye inflammation or an eye infection be taught?
   a. Wear dark glasses to prevent irritation from ultraviolet light.
   b. Acute conditions commonly lead to chronic problems.
   c. Apply a cold compress with pressure to the inflamed area frequently.
   d. Regular, careful hand hygiene may prevent the infection from spreading.
4. Which of the following client behaviours would the nurse promote for healthy eyes and ears? *(Select all that apply)*
   a. Wearing protective sunglasses when bicycling.
   b. Supplemental intake of B vitamins and magnesium
   c. Playing amplified music at 75% of maximum volume.
   d. Notifying the health care provider if tinnitus occurs during antibiotic therapy.
   e. For women, avoiding pregnancy for 4 weeks after receiving measles-mumps-rubella (MMR) immunization.

5. What should the nurse do to prepare clients for retinal detachment surgery?
   a. Explain how to care for an ocular prosthesis.
   b. Assure clients that they can expect 20/20 vision after surgery.
   c. Teach the family how to recognize when the client is hallucinating.
   d. Assess the client's level of knowledge about retinal detachment and provide information appropriate to the situation.
6. What should be included in the nursing plan for a client who needs to administer antibiotic eardrops?
   a. Cool the drops so that they decrease swelling in the canal.
   b. Be careful to avoid touching the tip of the dropper bottle to the ear.
   c. Placement of a cotton wick to assist in administering the drops is not recommended.
   d. Keep the head tilted for 5 to 7 minutes after administering the drops to prevent them from running out of the ear canal.
7. The nurse would suspect otosclerosis from assessment findings of hearing loss in which of the following clients?
   a. A 26-year-old woman with three biological children younger than 5 years of age.
   b. A 52-year-old man whose hearing loss is accompanied by vertigo and tinnitus.
   c. A 42-year-old woman who has a history of serous otitis media.
   d. A 63-year-old man who can hear high-pitched sounds more effectively than low-pitched sounds.
8. Which of the following statements best describes a client who has a sensorineural hearing loss?
   a. The client has difficulty understanding speech.
   b. The client experiences clearer sounds with the use of a hearing aid.
   c. The client may have a reversal of damage caused by ototoxic drugs.
   d. The client hears low-pitched sounds better than high-pitched sounds.
9. Which of the following would the nurse tell the client who is newly fitted with bilateral hearing aids? *(Select all that apply)*

a. Replace the batteries monthly.

b. Clean the ear moulds weekly or as needed.

c. Clean ears with cotton-tipped applicators daily.

d. Disconnect or remove the batteries when not in use.

e. Initially restrict usage to quiet listening in the home.

10. Which strategies would best assist the nurse in communicating with a client who has a hearing loss? *(Select all that apply)*

a. Overenunciate speech.

b. Exaggerate facial expression.

c. Raise the voice to a higher pitch.

d. Write out names or difficult words.

e. Speak normally and slowly.

11. Which of the following statements best describes clients with permanent visual impairment?

a. They feel most comfortable with other visually impaired persons.

b. They may feel threatened when others make eye contact during a conversation.

c. They usually need others to speak louder so they can communicate appropriately.

d. They may experience the same grieving process that is associated with other losses.

1. b; 2. d; 3. d; 4. a, d; 5. d; 6. b; 7. a; 8. a; 9. b, d, e; 10. d, e; 11. d.

CHAPTER 25

Nursing Assessment

Integumentary System

Written by, Diana L. Gallagher

Adapted by, Susannah McGeachy

LEARNING OBJECTIVES

1. Describe the structures and the functions of the integumentary system.
2. Link the age-related changes in the integumentary system to differences in assessment findings.
3. Identify the significant subjective and objective data related to the integumentary system that should be obtained from a patient.
4. Describe specific assessments to be made during the physical examination of the skin and the appendages.
5. Compare the critical components for describing primary and secondary lesions.
6. Identify appropriate techniques used in the physical assessment of the integumentary system.
7. Differentiate normal from common abnormal findings of a physical assessment of the integumentary system.
8. Summarize the structural and assessment differences in lighter- and darker-skinned individuals.

9. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the integumentary system.

KEY TERMS

alopecia, p. 494
dermis, p. 494
epidermis, p. 493
erythema, p. 501, Table 25-7
hirsutism, p. 501, Table 25-7
intertriginous, p. 500
keratinocytes, p. 493
melanocytes, p. 494
mole (nevus), p. 501, Table 25-7
pruritus, p. 498
sebaceous glands, p. 495
vitiligo, p. 501, Table 25-7

The integumentary system is the largest body organ and comprises skin, hair, nails, and glands. The skin is further divided into two layers: the epidermis and the dermis. The subcutaneous tissue is immediately under the dermis (Figure 25-1).

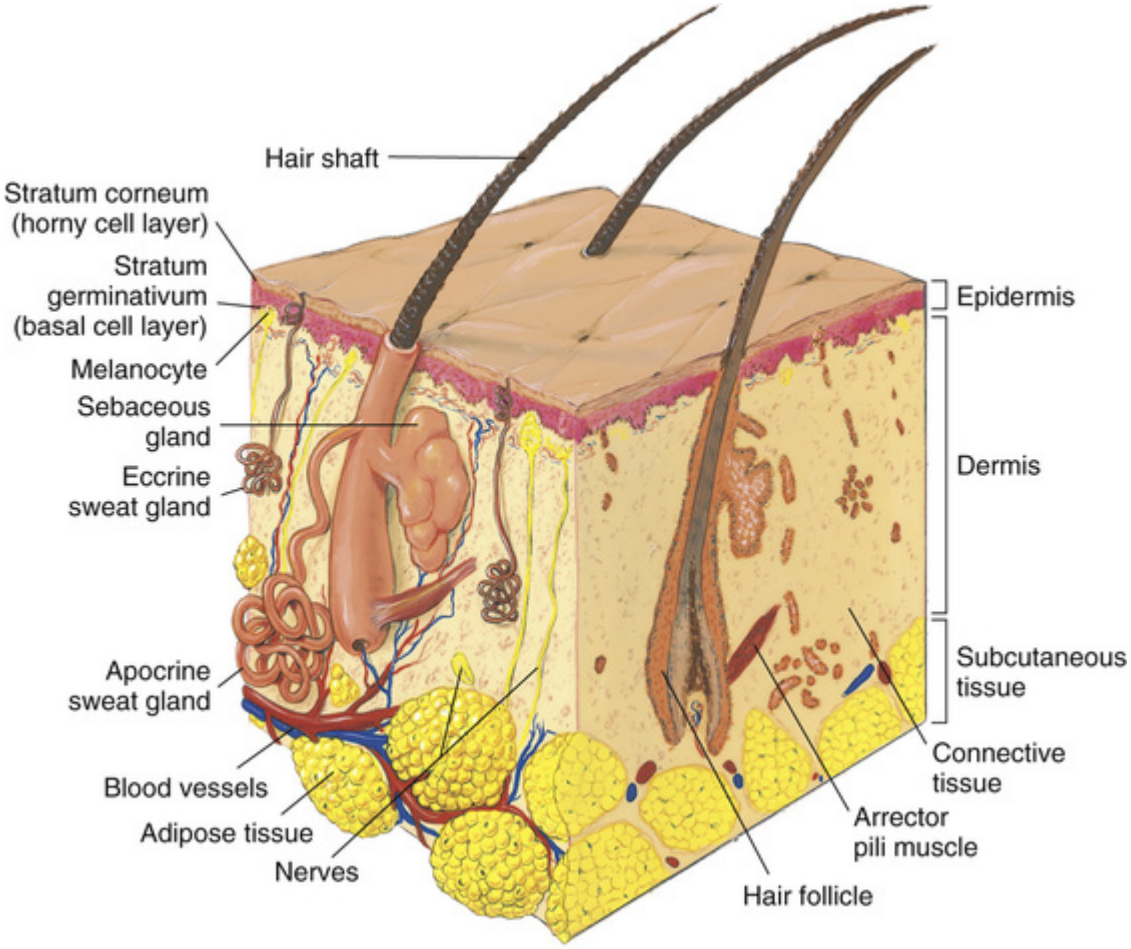

FIGURE 25-1 Microscopic view of the skin in longitudinal section. Source: Jarvis, C., Browne, A. J., MacDonald-Jenkins, J. et al. (2014). *Physical examination and health assessment* (2nd Canadian ed., p. 220). Toronto: Elsevier.

Structures and Functions of the Skin and Appendages

Structures

The epidermis is the outermost layer of the skin. The dermis, the second skin layer, contains collagen bundles and supports the nerve and vascular network. Subcutaneous tissue lies below the dermis and is composed primarily of fat and loose connective tissue.

Epidermis.

The **epidermis,** the thin avascular superficial layer of the skin, is made up of an outer dead portion that serves as a protective barrier and a deeper, living portion that folds into the dermis. Together these layers measure 0.05 to 0.1 mm in thickness. The epidermis is nourished by blood vessels in the dermis. The epidermis regenerates with new cells every 28 days and is composed of two main types of cells: keratinocytes and melanocytes (Woodford & Yao, 2013).

Keratinocytes are synthesized from epidermal cells in the basal layer and outnumber melanocytes ten to one (Woodford & Yao, 2013). Initially, these cells are undifferentiated. As they mature *(keratinize)*, they move to the surface, where they flatten and die to form the outer skin layer *(stratum corneum)*. Keratinocytes produce a fibrous protein, called *keratin*, which is vital to the skin's protective barrier function. The upward movement of keratinocytes from the basement membrane to the stratum corneum takes approximately 4 weeks. If dead cells slough off too rapidly, the skin will appear thin and eroded. If new cells form faster than old cells are shed, the skin becomes scaly and thickened. Changes in this cell cycle account for many skin problems, such as psoriasis.

Melanocytes are contained in the deep, basal layer *(stratum germinativum)* of the epidermis. They contain melanin, a pigment that gives colour to the skin and hair and protects the body from damaging ultraviolet (UV) sunlight. Sunlight and hormones stimulate these cells to produce melanin. The wide range of skin and

hair colours are a result of varying amounts of melanin produced; more melanin results in darker skin colour (Marks & Miller, 2013).

Dermis.

The **dermis** is the connective tissue below the epidermis. The dermis is highly vascular, with a thickness varying from 1 to 4 mm. The dermis is divided into two layers: an upper, thin papillary layer and a deeper, thicker reticular layer (Woodford & Yao, 2013). The papillary layer is folded into ridges, which form congenital patterns called *fingerprints* and *footprints*. The reticular layer contains collagen, elastic, and reticular fibres.

Collagen forms the greatest part of the dermis and is responsible for the mechanical strength of the skin. The primary cell type in the dermis is the fibroblast. Fibroblasts produce collagen and elastin and are important in wound healing. Nerves, lymphatic vessels, hair follicles, and sebaceous and sweat glands are also found in the dermis.

Subcutaneous Tissue.

While not part of the skin, the subcutaneous tissue is often discussed with the integument because it attaches the skin to underlying tissues such as the muscle and bone. The subcutaneous tissue contains loose connective tissue and fat cells, which store lipids, regulate temperature, and provide shock absorption. The anatomical distribution of subcutaneous tissue varies according to gender, heredity, age, and nutritional status.

Skin Appendages.

Appendages of the skin include the hair, the nails, and glands (sebaceous, apocrine, and eccrine). These structures develop from the epidermal layer and receive nutrients, electrolytes, and fluids from the dermis. Hair and nails form from specialized keratin that becomes hardened.

Hair grows on most of the body except for the lips, the palms of the hands, and the soles of the feet (Patton & Thibodeau, 2013). The

colour of the hair is a result of heredity and is determined by the type and the amount of melanin in the hair shaft. Hair grows approximately 1 cm per month. People lose an average of 25 to 100 hairs each day (Marks & Miller, 2013). When hair is not replaced, for example, due to normal aging, an endocrine disorder, a medication reaction, anticancer medication, or a skin disease, baldness, or **alopecia** (partial or complete lack of hair), results.

Fingernails and toenails are made of heavily keratinized cells. The part of the nail that you can see is the nail body. The rest is the nail root. A fold of skin hides most of the nail root. The cuticle borders this skin fold. Nail growth begins in the nail root. The portion of the nail root you can see is called the *lunula*. This white, crescent-shaped area is the site of mitosis and nail growth (Figure 25-2). Under the nail is an area of epidermis called the *nail bed*. The nail bed contains many blood vessels. Fingernails grow at a rate of 0.7 to 0.84 mm per week, with toenail growth 30% to 50% slower (Patton & Thibodeau, 2013). A lost fingernail usually regenerates in 3 to 6 months, while a lost toenail may require 12 months or longer to regenerate. Nail growth varies based on a person's age and health. Nails grow faster in men and in warm weather. Nail colour ranges from pink to yellow or brown depending on skin colour. Colour and texture variations in the nails may represent normal or abnormal conditions. Pigmented longitudinal bands *(melanonychia striata)* occur in the nail bed of most people with dark skin (Figure 25-3).

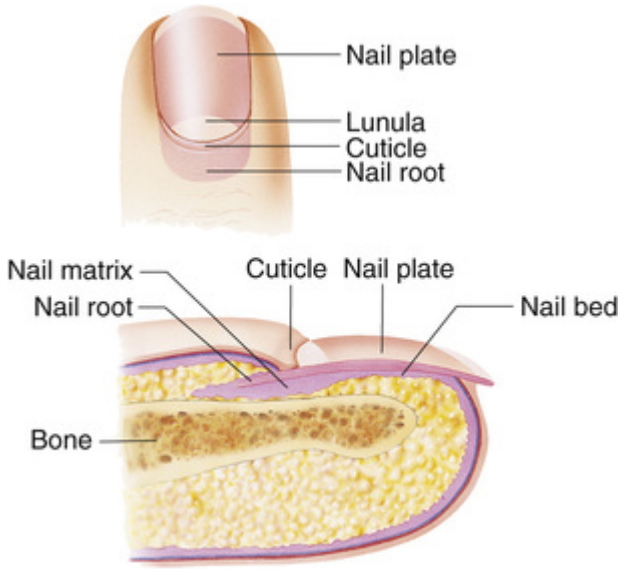

FIGURE 25-2 Structure of a nail. Source: Patton, K. T., & Thibodeau, G. A. (2016). *Essentials of anatomy and physiology* (9th ed., p. 196). St. Louis: Mosby.

FIGURE 25-3 Pigmented nail bed normally seen with dark skin colour. Source: Habif, T. P. (2016). *Clinical dermatology: A color guide to diagnosis and therapy* (6th ed., p. 766). St. Louis: Mosby.

Two major types of glands are associated with the skin: sebaceous and sweat glands. The **sebaceous glands** secrete *sebum,* a lipid-rich substance that waterproofs and lubricates the skin and hair and inhibits bacterial and fungal growth. These glands depend on sex

hormones, particularly testosterone, to regulate sebum secretion and production. Sebum production varies depending on age, sex, and hormone levels. Sebaceous glands are present on all areas of the skin except the palms and soles and are most abundant on the face, the scalp, the upper chest, and the back.

There are two varieties of sweat glands: apocrine and eccrine. The apocrine sweat glands are located mainly in the axillae, breast areolae, umbilical and anogenital areas, external auditory canals, and eyelids. These glands become active at puberty due to reproductive hormones. They secrete a milky, odourless substance, which interacts with skin surface bacteria to produce adult body odour (Jarvis, Browne, MacDonald-Jenkins, et al., 2014). In contrast, eccrine sweat glands are widely distributed over the body. Two square centimetres of skin contains about 1 000 of these sweat glands. Sweat is a transparent watery solution composed of salts, ammonia, urea, and other wastes. The main function of these glands is to cool the body by evaporation, excrete waste products through the pores of the skin, and moisturize surface cells.

Functions of the Integumentary System

The skin's primary function is to protect the underlying tissues of the body from the external environment. The skin acts as a barrier against invasion by bacteria and viruses and prevents excessive water loss. The fat in the subcutaneous layer insulates the body and provides protection from trauma. Melanin screens and absorbs ultraviolet radiation. Nerve endings and receptors located within the skin provide sensory information on environmental stimuli to the brain related to pain, heat and cold, touch, pressure, and vibration. In addition, the skin regulates heat loss by responding to changes in internal and external temperature with vasoconstriction, vasodilation, and excretion of sweat. Evaporation of water from the lungs and skin results in the loss of 600 to 900 mL of water daily. Sebum and sweat lubricate the skin surface. Furthermore, endogenous synthesis of vitamin D, which is critical to calcium and phosphorus balance, occurs in the epidermis.

The skin is also a delivery system for drugs. An increasing number of systemic drugs are effectively delivered via patches or creams applied directly to the skin.

Age-Related Considerations

Effects of Aging on the Integumentary System

Skin changes related to aging include decreased turgor, thinning, dryness, wrinkling, vascular lesions, increased skin fragility, and benign neoplasms. Although many changes are only of cosmetic concern, others can be serious and need careful evaluation. Age-related changes of the integumentary system and differences in assessment findings are listed in Table 25-1.

TABLE 25-1

AGE-RELATED DIFFERENCES IN ASSESSMENT
Integumentary System

Changes	Differences in Assessment Findings
Skin	
• Decreased subcutaneous fat, muscle laxity, degeneration of elastic fibres, collagen stiffening	Increased wrinkling, sagging breasts and abdomen, redundant flesh around eyes, slowness of skin to flatten when pinched (tenting)
• Decreased extracellular water, surface lipids, and sebaceous gland activity	Dry, flaking skin with possible signs of excoriation caused by scratching
• Decreased activity of apocrine and sebaceous glands	Dry skin with minimal to no perspiration, uneven skin coloration
• Increased capillary fragility and permeability	Bruising
• Increased focal melanocytes in basal layer with pigment accumulation	Solar lentigines on face and backs of hands
• Diminished blood supply	Decrease in rosy appearance of skin and mucous membranes; skin cool to touch; diminished awareness of pain, touch, temperature, and peripheral vibration
• Decreased proliferative capacity	Diminished rate of wound healing
• Decreased immuno-competence	Increase in neoplasms
Hair	
• Decreased melanin and melanocytes	Grey or white hair
• Decreased oil	Dry, coarse hair; scaly scalp
• Decreased density of hair	Thinning and loss of hair
• Cumulative androgen effect; decreasing estrogen levels	Facial hirsutism, baldness
Nails	
• Decreased peripheral blood supply	Thick, brittle nails with diminished growth
• Increased keratin	Longitudinal ridging
• Decreased circulation	Prolonged return of blood to nails on blanching

With advancing age, the junction between the dermis and the epidermis becomes flattened, and the epidermis contains fewer melanocytes. In addition, the dermis loses volume and has fewer blood vessels. Scalp, pubic, and axillary hair becomes depigmented and thinner. A loss of melanin results in grey or white hair. The nail plate thins, and nails become brittle, thicker, and more prone to splitting and yellowing.

Chronic UV exposure is the major contributor to photoaging and wrinkling of the skin (Canadian Dermatology Association [CDA], 2015a). Sun damage to the skin is cumulative (Figure 25-4). The wrinkling of sun-exposed areas such as the face and hands is more marked than in sun-shielded areas such as the buttocks. Poor

nutrition, with decreased intake of protein, calories, and vitamins, further contributes to aging of the skin. With aging, collagen fibres stiffen, elastic fibres degenerate, and the amount of subcutaneous tissue decreases. These changes, with the added effects of gravity, lead to wrinkling.

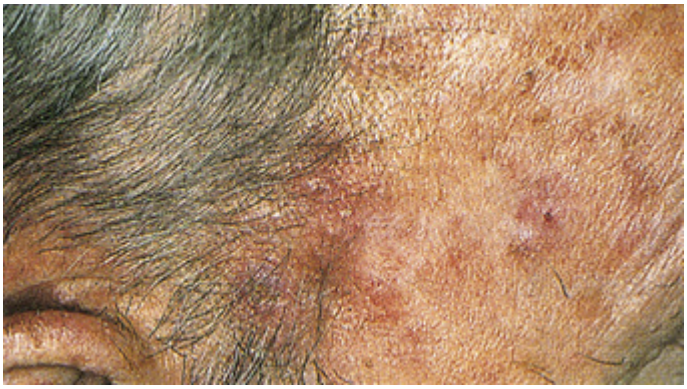

FIGURE 25-4 Photoaging. Irregular pigmentation and keratoses occur on sun-damaged skin on the forehead.

Source: Gawkrodger, D., & Ardern-Jones, M. R. (2012). *Dermatology* (5th ed.). Edinburgh: Churchill Livingstone.

Benign neoplasms related to the aging process can occur. These growths include seborrheic keratoses, vascular lesions such as cherry angiomas, and skin tags. Actinic keratoses appear on areas of chronic sun exposure, especially in people with a fair complexion. These premalignant cutaneous lesions place an individual at increased risk for squamous cell and basal cell carcinomas. The photoaged person is more susceptible to skin cancers because of decline in the capacity to repair cellular deoxyribonucleic acid (DNA) damage caused by UV exposure (CDA, 2015b). Chronic UV exposure from tanning beds causes the same damage as UV from the sun.

Subcutaneous fat decreases with age, leading to increased risk of traumatic injury, hypothermia, and skin shearing, which may lead to pressure injuries. With aging, the apocrine and eccrine sweat glands atrophy, causing dry skin and decreased body odour. The growth rate of the hair and nails decreases as a result of atrophy of the

involved structures. Hormonal and vitamin deficiencies can cause dry, thin hair and alopecia.

The visible effects of aging on the skin and hair may have a profound psychological effect on many people. Although fine wrinkling of the skin, thinning hair, and brittle nails are normal changes with aging, they may result in an altered self-image (Jarvis, Browne, MacDonald-Jenkins, et al., 2014).

Assessment of the Integumentary System

A general assessment of the skin begins at the initial contact with the patient and continues throughout the examination. Specific areas are examined during examination of other body sites unless the reason for seeking care is a dermatological problem. Record a general statement about the physical condition of the patient's skin (Table 25-2). When a skin problem is noted, investigate by gathering further subjective data. Health history questions are presented in Table 25-3.

TABLE 25-2

NORMAL PHYSICAL ASSESSMENT OF THE INTEGUMENTARY SYSTEM

Skin: Evenly pigmented; no petechiae, purpura, lesions, or excoriations; warm; good turgor. *Nails:* Pink; oval; adhere to nail base with 160° angle. *Hair:* Shiny and full; amount and distribution appropriate for age and gender; no flaking of scalp, forehead, or pinna.

TABLE 25-3

HEALTH HISTORY
Integumentary System: Questions for Obtaining Subjective Data

Past History
• Do you have any history of previous trauma, surgery, or prior disease that involves the skin?*
• Do you have any dermatological manifestations of systemic problems such as jaundice (liver disease), delayed wound healing (diabetes mellitus), cyanosis (respiratory disorder), or pallor (anemia)?*
• Do you have a history of chronic or unprotected exposure to UV light such as use of tanning beds or history of radiation treatments?*
• Have you had any skin-related problems that occurred as a result of taking prescription or OTC medications?*
• Have you ever taken vitamins, hormones, antibiotics, corticosteroids, or antimetabolites?
• Are you taking any complementary or alternative medicines?*
• Are you using any medications to treat hair loss?*
• Have you used prescription or OTC medications to treat a primary skin problem, such as acne, or a secondary skin problem, such as itching? If so, please state the name, length of use, method of application, and effectiveness of the medication.
• Have you ever had surgery on your skin, including cosmetic surgery?*
• Do you have any body art, piercings, or tattoos?* Did you experience any complications such as skin infections, allergic reactions, dental problems, or MRI burns?
• Have you ever had a skin biopsy?* If so, what were the results?
• Have you had any treatments specifically for a skin problem (e.g., phototherapy, radiation therapy, cosmetic "peels")?
Family History
• Do you have a family history of any skin diseases, including congenital and familial diseases (e.g., alopecia and psoriasis) and systemic diseases with dermatological manifestations (e.g., diabetes, thyroid disease, cardiovascular diseases, immune disorders)?
• Do you have any family or personal history of skin cancer, particularly melanoma?
Self-Care History
• Describe your daily hygiene practices.
• What skin products are you currently using?
• Do you do anything to protect yourself from the sun?* How frequently do you use sun protection, and what is the SPF number of your sunscreen products?
• Has your birth control method, if used, caused a skin problem?*
Nutritional History
• Are there any changes in the condition of your skin, hair, nails, and mucous membranes that might be related to dietary changes?*
• Do you have food allergies that cause a skin reaction?
Social, Environment, or Occupational History
• Do you have any pets?
• Do you have any food, pet, or drug allergies?*
• Do you have any unusual skin reactions to insect bites and stings?*
• Are there any environmental skin irritants at your current or previous workplace or home?*
• Do your leisure activities involve the use of any chemicals that are potentially toxic to the skin?*
Cognitive–Perceptual
• Do you have any unusual sensations of heat, cold, or touch?*
• Do you have any pain associated with your skin condition?*
• Do you have any joint pain?*
Coping Abilities
• Does stress play a role in the onset of your skin condition, or does stress exacerbate the condition?
• What strategies have you used to manage your skin condition?
General

- Describe any current skin condition, including onset, course, and treatment (if any).
- Describe any changes in the condition of your skin, hair, nails, and mucous membranes.
- Have you noticed any changes in skin pigmentation? Any changes in the size or shape or colour of a mole? Any excessive bruising? Any unusual hair loss? Any change in the strength, colour, or nature of your nails? Any itching?
- Have you noticed any changes in the way sores or lesions heal?*
- Have you noticed changes in your skin related to excessive sweating, dryness, or swelling?*
- Does your skin condition keep you awake or awaken you after you have fallen asleep?*

*If yes, describe.

MRI, magnetic resonance imaging; *OTC,* over-the-counter; *SPF,* sun protection factor; *UV,* ultraviolet.

Case Study

Patient Introduction

Source: DGLimages/Shutterstock.com.

Ms. Danielle Arquette is a 74-year-old woman who comes to her primary care clinic with concerns related to various "spots" on her face. She says they have been there for a while, and she thought they were just "age spots" but got concerned after her friend was diagnosed with a malignant melanoma.

Critical Thinking

The following questions should be kept in mind while studying this assessment chapter:

1. What are the possible causes of Ms. Arquette's facial lesions?
2. What questions should the patient be asked to determine the possible causes?
3. What should be included in the physical assessment? What specific characteristics of the skin lesions should the nurse look for?
4. What diagnostic studies might be ordered?

See pp. 498 and 503 for more information on Ms. Arquette.

Subjective Data

Past Medical History.

Past medical history (PMH) reveals previous trauma, surgery, or disease that involves the skin. Many diseases have dermatological manifestations. The nurse needs to determine if the patient has noticed any problems such as jaundice, delayed wound healing, cyanosis, or pallor. It is important to obtain specific information related to sensitivities, allergies, and skin reactions to insect bites and stings. Any history of chronic or unprotected exposure to UV light should be noted.

Medications.

Many vitamins, hormones, antibiotics, corticosteroids, and antimetabolites have adverse effects that are manifested in the skin, so the patient should be asked about any skin-related changes that occurred after taking medications. Additionally, it is important to document the use of medications (i.e., drug's name, length of use, method of application, and effectiveness) to treat a primary or secondary skin problem.

Surgery or Other Treatments.

The nurse should determine if any surgical procedures, including cosmetic surgery, were done on the skin. Any previous biopsy results should be recorded, as should any treatments done

specifically for a skin problem or for another health problem. Any treatments undergone for cosmetic purposes should also be documented.

Family History.

The nurse should obtain information about any family history of skin diseases or systemic diseases with dermatological manifestations. Any family or personal history of skin cancer, particularly melanoma, must also be noted.

Self-Care History.

The patient should be questioned about health and hygiene practices related to the integumentary system, including the brand name, quantity, and frequency of use of personal care products (e.g., shampoos, moisturizing agents, cosmetics). Any current skin problems, including onset, symptoms, course, and treatment, should be recorded, as well as the frequency of use and the sun protection factor (SPF) of sunscreen products.

Nutritional History.

A diet history reveals the adequacy of nutrients essential to healthy skin such as vitamins A, D, E, and C; dietary fat; and protein. The nurse should question the patient regarding recent dietary changes; any food allergies that cause a skin reaction; and conditions of the skin such as dehydration, edema, and **pruritus** (itching), which can indicate alterations in fluid balance. If urinary or fecal incontinence is a problem, the nurse should determine the condition of the skin in the anal and perineal areas.

Social, Environmental, and Occupational Health History.

The patient should be questioned about environmental factors that affect the skin such as occupational exposure to chemicals, irritants, sun, and unusually cold or unhygienic conditions. Contact

dermatitis caused by allergies and irritants is a common problem associated with occupation, as well as with some hobbies. The patient's participation in any recreational activities involving significant sun exposure should be determined and documented, as should any changes in the skin during exercise or other activities.

Cognitive–Perceptual.

The patient's perception of the sensations of health, cold, pain, and touch should be determined. The nurse should note any discomfort associated with a skin condition, especially when observed in intact skin. As well, joint pain and the mobility of joints should be assessed and recorded, since a skin condition may cause alterations in mobility.

Coping Abilities.

The patient should be asked about the role that stress may play in creating or exacerbating the skin condition. The nurse should determine what coping strategies the patient uses to manage the skin condition. For example, pruritus can be distressing and cause major alterations in normal sleep patterns, while acne can be disfiguring and lead to significant threat to self-image.

Case Study

Subjective Data

Source: DGLimages/Shutterstock.com.

A focused subjective assessment of Danielle Arquette reveals the following:

- *PMH:* Negative except for an appendectomy at age 16.
- *Medications:* None at present. No known allergies.
- *Self-care:* Currently washes her face with a skin cleanser in the morning and at nighttime. After cleansing, she applies a moisturizer with SPF 15. She has used these facial products for the past 3 years, since she first started noticing small age spots appearing. Before that, she used just soap and water.
- *Nutritional:* Ms. Arquette reports that her skin seems to be drier as she ages but otherwise no changes besides the "age spots or whatever they are." Denies any changes in the way cuts or sores heal. No weight loss. Takes 400 IU of vitamin D daily; does not take any other supplemental vitamins or minerals.
- *Elimination:* Although skin is a little dry, she does not perceive it to be excessively dry. Denies excessive sweating or any swelling.
- *Social, environmental, and occupational:* Loves to garden and go for walks outdoors. Reports a history of frequent, sometimes severe, sunburns as a child. No use of sunscreen growing up but does remember her mother making her wear T-shirts over her bathing suits to help prevent sunburn. Has used sunscreen for the past 20 years when outdoors. Reapplies as needed.
- *Coping abilities:* Denies any pain or discomfort associated with skin lesions. Fearful that she might have skin cancer.

See p. 503 for more information on Ms. Arquette.

Genetics in Clinical Practice

Skin Malignancies

- The primary risk factor leading to skin cancers, including melanoma, is environmental exposure to UV radiation. UV radiation damages DNA, causing an error in the genetic code and resulting in abnormal skin cells (Han, Chien, & Kang, 2014).
- However, inherited genetic factors can increase the risk for skin cancer. A person who has a first-degree relative (e.g., parent, full sibling) who had a melanoma has an increased risk for developing melanoma (CDA, 2015b).
- The risk for skin cancer is also increased in people who have a fair complexion (light-coloured skin that easily freckles, red or blond hair, and blue or light-coloured eyes).

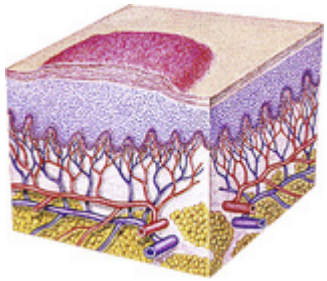
Objective Data

Physical Examination.

A physical examination of the skin begins with a systematic, general inspection and then a more specific assessment of problem areas. The nursing assessment should note changes in the colour, turgor, temperature, dryness, thickness, and vascularity of the skin. The findings may be normal, relative to age, genetic factors, and environmental exposures, or may represent primary or secondary skin lesions (Tables 25-3 and 25-4). General principles when conducting an assessment of the skin are as follows:

TABLE 25-4
PRIMARY SKIN LESIONS

Lesion	Description
Macule 	Circumscribed, flat area with a change in skin colour; <0.5 cm in diameter; if lesion >0.5 cm, it is a *patch* *Examples:* freckles, petechiae, measles, flat mole (nevus), café-au-lait spots, vitiligo (complete depigmentation)
Papule 	Elevated, solid lesion; <0.5 cm in diameter; if lesion is >0.5 cm in diameter, it is a *nodule* *Examples:* wart (verruca), elevated moles, lipoma, basal cell carcinoma
Vesicle 	Circumscribed, superficial collection of serous fluid; <0.5 cm in diameter *Examples:* varicella (chicken pox), herpes zoster (shingles) (Figure 25-6), second-degree burn
Plaque	Circumscribed, elevated, superficial, solid lesion; >0.5 cm in diameter *Examples:* psoriasis, seborrheic and actinic keratoses

Lesion	Description
	


Wheal 	Firm, edematous, irregularly shaped area; diameter variable *Examples:* insect bite, urticaria
Pustule 	Elevated, superficial lesion filled with purulent fluid *Examples:* acne, impetigo

1. Use a private examination room of moderate temperature with good lighting; a room with exposure to daylight is preferred.
2. Ensure that the patient is comfortable and in a gown that allows easy access to all skin areas.
3. Be systematic and proceed from head to toe.
4. Compare symmetrical parts.
5. Perform a general inspection followed by a lesion-specific examination.

6. Use the metric system when taking measurements.
7. Use appropriate terminology and nomenclature when reporting or documenting.

Photographs are useful to accurately capture findings and to monitor skin lesions over time. Follow clinical agency protocol regarding obtaining a patient's consent to photograph skin lesions for inclusion in the medical record.

Inspection.

The skin should be inspected for general colour and pigmentation, vascularity, bruising, and the presence of lesions or discolorations. The critical factor in assessment of skin colour is change. A skin colour that is normal for a particular patient can be a sign of a pathological condition in another patient. The most reliable areas in which to assess erythema, cyanosis, pallor, and jaundice are the areas of least pigmentation, such as sclerae, conjunctivae, nail beds, lips, and buccal mucosa. The true skin colour is best observed in photoprotected areas, such as the buttocks. Activity, sun (UV) exposure, emotions, cigarette smoking, and edema, as well as respiratory, renal, cardiovascular, and hepatic disorders, can all directly affect the colour of the skin.

In the general inspection, the nurse should note the presence of body art such as piercings and tattoos. The nose, ears, eyebrows, lips, navel, and nipples are common sites of piercing. Tattoos and needle track marks should be identified, and their location and the characteristics of the surrounding skin area noted. Tattoo pigments deposited in the skin may cause itching, pain, and sensitivity for several weeks after the tattoo is placed.

The skin should be examined for possible problems related to vascularity, such as areas of bruising, and vascular and purpuric lesions, such as *angiomas* (benign tumours of blood or lymph vessels), *petechiae* (tiny purple-red macules on skin), ecchymoses (bruises, larger than petechiae), or *purpuras* (purple patches characterized by ecchymoses or other small hemorrhages) (Figure 25-5). Placing direct pressure on a lesion can provide important information. If the lesion blanches on direct pressure and then refills,

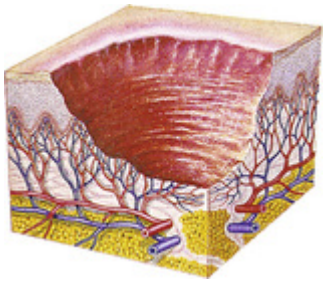
the redness is caused by dilated blood vessels. If the discoloration remains, it is the result of subcutaneous or intradermal bleeding or the presence of a nonvascular lesion. Bruising that has a pattern—for example, in the shape of a hand or fingers—should be documented, as should bruises at different stages of resolution. These may be indications of other health problems or abuse and require further investigation.

FIGURE 25-5 Purpura as seen in acute meningococcemia.
Source: Dr. François Bricaire/ScienceSource.

If lesions are found on the skin, their colour, size, height, distribution, location, and shape should be recorded. Lesions may be primary or secondary. Primary skin lesions develop on previously unaltered skin. The common characteristics of primary skin lesions are shown in Table 25-4. Secondary skin lesions are lesions that change with time or occur because of factors such as scratching or infection. Secondary skin lesions are shown in Table 25-5.

TABLE 25-5
SECONDARY SKIN LESIONS

Lesion	Description
Fissure 	Linear crack or break from the epidermis to the dermis; dry or moist *Examples:* athlete's foot, cracks at corner of the mouth
Scale 	Excess, dead epidermal cells produced by abnormal keratinization and shedding *Examples:* flaking of skin after a drug reaction or sunburn
Scar 	Abnormal formation of connective tissue that replaces normal skin *Examples:* surgical incision, healed wound
Ulcer	Loss of the epidermis, extending into the dermis; crater-like, irregular shape *Examples:* pressure injury, chancre

Lesion	Description
	


Atrophy 	Depression in skin resulting from thinning of the epidermis or dermis *Examples:* aged skin, striae
Excoriation 	Area in which epidermis is missing, exposing the dermis *Examples:* abrasion, scratch

Skin lesions are usually described in terms of their configuration (shape, whether solitary or forming a pattern in relation to other lesions) and distribution (arrangement of lesions over an area of skin) (Table 25-6). For example, herpes zoster (shingles) lesions are characteristically vesicular and have a linear distribution clustered along one or more dermatomes (Figure 25-6). Any unusual odours should also be noted. Skin sites with lesions, such as rashes, may be colonized with yeast or bacteria, which can be associated with distinctive odours in intertriginous areas (Figure 25-7).

Intertriginous areas are where skin surfaces overlap and rub on each other (e.g., below the breasts, axillae, and groin).

TABLE 25-6

LESION DISTRIBUTION TERMINOLOGY

Term	Description
Asymmetric	Unilateral distribution
Confluent	Merging together
Diffuse	Wide distribution
Discrete	Separate from other lesions
Generalized	Diffuse distribution over large area of body surface
Grouped	Cluster of lesions
Localized	Limited areas of involvement that are clearly defined
Satellite	Single lesion in proximity to a large grouping
Solitary	A single lesion
Symmetrical	Bilateral distribution
Zosteriform	Bandlike distribution along a dermatome area

FIGURE 25-6 Herpes zoster (shingles) on the anterior chest, classic dermatomal distribution. Source: James, W. D., Berger, T. G., & Elston, D. M. (2011). *Andrews' diseases of the skin* (11th ed.). Philadelphia: Saunders.

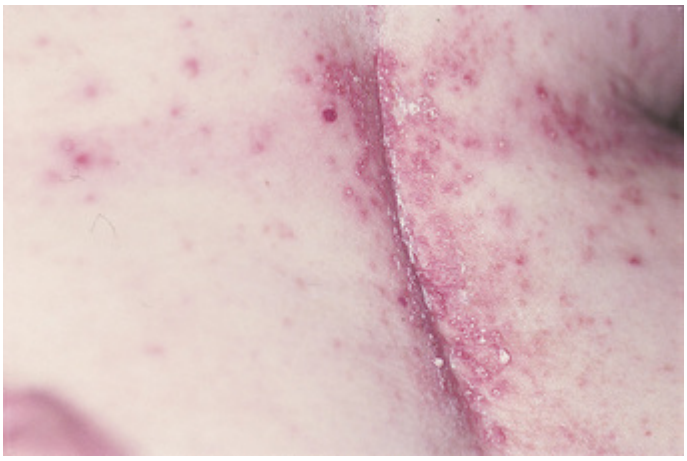


FIGURE 25-7 Intertrigo. Candidal rash in body folds. Source: Graham-Brown, R., Bourke, J., & Cunliffe, T. (2008). *Dermatology: Fundamentals of practice*. Edinburgh: Mosby.

The nurse's inspection should include all body hair, noting the distribution, texture, and quantity of hair. Changes in the normal distribution of body hair and growth may indicate an endocrine or vascular disorder. The nails should be observed for shape, thickness, curvature, and surface, and any grooves, pitting, ridges, or detachment from nail bed should be noted. Changes in nail smoothness or thickness can occur with anemia, psoriasis, thyroid problems, decreased vascular circulation, and some infections.

Palpation.

Palpating the skin provides information about temperature, turgor and mobility, moisture, and texture. The nurse should use the back of her or his own hand to gauge skin temperature, since the skin on the back of the examiner's hand is thinner than on the palm and therefore more sensitive to temperature changes. The patient's skin should be warm, not hot. Skin temperature increases with increased blood flow to the dermis. Localized temperature increase occurs with burns and local inflammation. A generalized increase will result from fever. A decreased skin temperature may occur when shock or other circulatory problems, chilling, or infection is present.

Turgor refers to the elasticity of the skin. The nurse should assess turgor by gently pinching an area of skin under the clavicle or on the back of the hand. Skin with good turgor should move easily when

lifted and should immediately return to its original position when released (see Figure 19-13). Dehydration and aging may cause loss of turgor, leading to skin tenting (Table 25-7).

TABLE 25-7

assessment abnormalities
Integumentary System

Finding	Description	Possible Etiology and Significance
Alopecia	Loss of hair (localized or general; especially the head, but there can be hair loss on other parts of the body as well, from patches to total body hair loss) (see Figure 25-8)	Heredity, friction, rubbing, traction, trauma, stress, infection, inflammation, chemotherapy, pregnancy, emotional shock, tinea capitis, immunological factors or unknown causation
Angioma	Tumour consisting of blood or lymph vessels	Increased incidence normal with aging, liver disease, pregnancy, varicose veins
Carotenemia (carotenosis)	Yellow discoloration of skin, no yellowing of sclerae, most noticeable on palms and soles	Excessive ingestion of vegetables containing carotene (e.g., carrots, squash), hypothyroidism
Comedone (acne lesion)	Enlarged hair follicle plugged with sebum, bacteria, and skin cells; can be open (blackhead) or closed (whitehead)	Heredity, certain drugs, hormonal changes with puberty and pregnancy
Cyanosis	Slightly bluish-grey or dark purple discoloration of the skin and mucous membranes caused by presence of excessive amounts of reduced hemoglobin in capillaries	Cardiorespiratory problems; vasoconstriction, asphyxiation, anemia, leukemia, and malignancies
Cyst	Sac containing fluid or semisolid material	Obstruction of a duct or gland, parasitic infection
Ecchymosis	Large, bruiselike lesion caused by collection of extravascular blood in dermis and subcutaneous tissue	Trauma, bleeding disorders
Erythema	Redness occurring in patches of variable size and shape	Heat, certain drugs, alcohol, ultraviolet rays, any problem that causes dilation of blood vessels to the skin
Hematoma	Extravasation of blood of sufficient size to cause visible swelling	Trauma, bleeding disorders
Hirsutism	Male-pattern distribution of hair in women	Abnormality of ovaries or adrenal glands, decrease in estrogen level, heredity
Hypopigmentation	Congenital or acquired loss of melanin resulting in lighter depigmented areas	Heredity, chemical or pharmacological agents, nutritional factors, burns, inflammation and infection, vitiligo (patchy loss of skin pigment common on hands, face, and genital region) (Figure 25-9)
Intertrigo	Dermatitis of overlying surfaces of the skin	Moisture, irritation, obesity; may be complicated by *Candida* infection (see Figure 25-7)
Jaundice	Yellow (in White people) or yellowish-brown (in Black people) discoloration of the skin, best observed in the sclera; secondary to increased bilirubin in the blood	Liver disease, red blood cell hemolysis, pancreatic cancer, common bile duct obstruction
Keloid	Hypertrophied scar beyond margin of incision or trauma (see Figure 14-8)	Predisposition more common in dark-skinned individuals
Lichenification	Thickening of the skin with accentuated skin markings	Repeated scratching, rubbing, and irritation usually due to pruritus or neurosis

Finding	Description	Possible Etiology and Significance
Mole (nevus)	Benign overgrowth of melanocytes	Defects of development; excessive numbers of large, irregular moles; sometimes hereditary
Petechiae	Pinpoint, discrete deposit of blood <1–2 mm in the extravascular tissues; visible through the skin or mucous membrane	Inflammation, marked dilation, blood vessel trauma, blood dyscrasia that results in bleeding tendencies (e.g., thrombo-cytopenia)
Telangiectasia	Visibly dilated, superficial, cutaneous small blood vessels, commonly found on face and thighs	Aging, acne, sun exposure, alcohol use, liver failure, corticosteroids, radiation, certain systemic diseases, skin tumours
Tenting	Failure of skin to return immediately to normal position after gentle pinching	Aging, dehydration, cachexia
Varicosity	Increased prominence of superficial veins	Interruption of venous return (e.g., from tumour, incompetent valves, inflammation), commonly found on lower legs with aging
Vitiligo	Complete absence of melanin (pigment) resulting in chalky white patch (see Figure 25-9)	Autoimmune, heredity, thyroid disease

Skin moisture (level of dampness or dryness of the skin) increases in intertriginous areas and with high humidity. Skin moisture varies with environmental temperature, muscular activity, body weight, and body temperature. The skin should be intact with no flaking, scaling, or cracking. Skin generally becomes drier with increasing age. *Texture* refers to the fineness or coarseness of the skin. The skin should feel smooth and firm, with the surface evenly thin in most areas. Thickened callous areas are normal on the soles and palms and relate to weight bearing. Increased thickness is often work related and a result of excessive pressure. Excessive calluses on the soles of patients with neuropathy or diabetes predispose them to developing lesions. Common assessment abnormalities of the skin are described in Table 25-7.

Risk assessment to predict a patient's pressure injury risk should be done using a validated assessment tool such as the Braden Scale. (See Chapter 14, Table 14-14, for the Braden Scale for Predicting Pressure Sore Risk.)

A focused assessment is used to evaluate the status of previously identified integumentary problems and to monitor for signs of new problems. A focused assessment of the integumentary system is presented in the box on the following page.

Focused Assessment

Integumentary System

This checklist can be used to make sure the key assessment steps have been done.

Subjective

The patient should be asked about any of the following and responses noted:

Hair loss (unusual or rapid)	Y	N
Changes in the skin (e.g., lesions, bruising)	Y	N
Nail discoloration	Y	N

Objective: Diagnostic

The following should be checked for results and critical values:

Biopsy results	✓
Albumin	✓

Objective: Physical Examination

The following should be inspected:

Skin for colour, integrity, scars, lesions, signs of breakdown	✓
Facial and body hair for distribution, colour, quantity, and hygiene	✓
Nails for shape, contour, colour, thickness, and cleanliness	✓
Dressings if present	✓

Palpation is used to determine the following:

Skin for temperature, texture, moisture, thickness, turgor, and mobility	✓

Assessment of Dark Skin Colour

The structures of dark skin are no different than those of lighter skin, but they are often more difficult to assess (Table 25-8). Colour variation is easiest to assess in parts of the body where the epidermis is thin and pigmentation is not influenced by sun exposure, such as

the lips, mucous membranes, nail beds, and protected areas such as the buttocks. As well, palmar and plantar surfaces are lighter than other skin areas.

TABLE 25-8

ASSESSMENT VARIATIONS IN LIGHTER- AND DARKER-SKINNED INDIVIDUALS

Lighter Skin	Darker Skin
Cyanosis	
Greyish-blue tone, especially in nail beds, earlobes, lips, mucous membranes, and palms and soles of feet	Ashen or greyish colour most easily seen in the conjunctiva of the eye, mucous membranes, and nail beds
Ecchymosis	
Dark red, purple, yellow, or green colour, depending on age of bruise	Purple to brownish-black; difficult to see unless occurring in an area of light pigmentation
Erythema	
Reddish tone, possibly accompanied by increased skin temperature secondary to localized inflammation	Deeper brown or purple skin tone with evidence of increased skin temperature secondary to inflammation
Jaundice	
Yellowish colour of skin, sclera, fingernails, palms of hands, and oral mucosa	Yellowish-green colour most obviously seen in sclera of eye (do not confuse with yellow eye pigmentation, which may be evident in darker-skinned individuals), palms, and soles
Pallor	
Pale skin colour that may appear white or ashen; also evident on lips, nail beds, and mucous membranes	Underlying red tone in brown or black skin is absent, causing the skin to appear yellowish, ashen, or grey
Petechiae	
Lesions appear as small, reddish purple pinpoints, best observed on abdomen and buttocks	Difficult to see; may be evident in the buccal mucosa of the mouth or the conjunctiva of the eye
Rash	
May be visualized as well as felt with light palpation	Not easily visualized, but may be felt with light palpation
Scar	
Generally heals, showing narrow scar line	Higher incidence of keloid development, resulting in a thickened, raised scar (see Chapter 14, Figure 14-8)

Rashes are often difficult to observe in darker-skinned individuals and may need to be palpated (Jarvis, Browne, MacDonald-Jenkins, et al., 2014). Wrinkling also is less apparent among this population.

People with dark skin are predisposed to certain skin and hair conditions. *Keloid* is a protrusion of scar tissue that extends beyond the wound edges and may form tumour-like masses (e.g., ear piercing) (see Chapter 14, Figure 14-8). Vitiligo is total loss of

pigment in the affected area (Figure 25-9). In *dermatosis papulosa nigra*, the person has small, pigmented wartlike papules, commonly on the face. *Nevus of Ota* is a slate-grey or blue-grey birthmark located on the forehead and face around the eye area. It may also involve the sclera (Figure 25-10). *Traction alopecia* may be the result of trauma from hair rollers or from tight braiding of the hair (see Figure 25-8). The hair loss may be temporary or permanent. *Pseudofolliculitis* is an inflammatory response to ingrown hairs that may occur after shaving, which results in pustules and papules.

FIGURE 25-8 Traction alopecia. Hair loss in scalp because of prolonged tension from hair roller, braiding, or straightening combs. Source: Hurwitz, S. (1993). *Clinical pediatric dermatology: A textbook of skin disorders of childhood and adolescence* (2nd ed.). Philadelphia: Saunders.

FIGURE 25-9 Vitiligo. Total loss of pigment in the affected area. Source: Graham-Brown, R., Bourke, J., & Cunliffe, T. (2008). *Dermatology: Fundamentals of practice*. Edinburgh: Mosby.

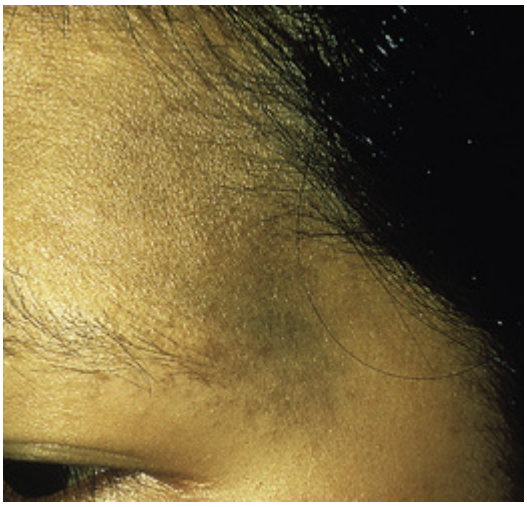

FIGURE 25-10 Nevus of Ota. Flat grey to blue pigmentation in the upper trigeminal area, which is more common in darker-skinned individuals. Source: Gawkrodger, D., & Ardern-Jones, M. R. (2012). *Dermatology* (5th ed.). Edinburgh: Churchill Livingstone.

In patients with darker skin, colour may not be a reliable indicator of systemic conditions (e.g., flushed skin with fever). Cyanosis may be difficult to determine because a normal bluish hue occurs in dark-

skinned people. Dark skin rarely shows a blanch response, making it more difficult to identify pressure injuries.

Case Study

Objective Data

Source: DGLimages/Shutterstock.com.

Physical Examination

Physical examination findings of Danielle Arquette's skin are as follows:

- Complexion fair. Wrinkles around eyes, above upper lip, and on sides of cheeks bilaterally. Normal skin temperature and turgor.
- Lesions on upper right forehead measuring 2 × 3 mm; on left forehead near hairline measuring 1 × 2 mm; and on left lower cheek measuring 2 × 2.5 mm.
- All lesions are slightly erythematous but do not blanch when direct pressure is applied. Borders distinct. Minimal elevation noted on palpation.
- No skin lesions noted on rest of body.

Throughout this chapter, consider which diagnostic studies would likely be performed for Ms. Arquette and also identify patient problems and the appropriate nursing interventions for her while she is in the clinic.

Diagnostic Studies

Ms. Arquette's primary care provider examines the lesions via dermatoscopy and also uses a Wood's lamp to rule out a fungal infection. She suspects basal cell carcinoma, which is confirmed by a shave biopsy.

See pp. 496 and 498 for more information on Ms. Arquette.

Diagnostic Studies of the Integumentary System

Diagnostic studies provide the nurse important information for monitoring the patient's condition and planning appropriate interventions. These studies are considered to be objective data. Table 25-9 presents diagnostic studies common to the integumentary system.

TABLE 25-9
DIAGNOSTIC STUDIES
Integumentary System

Study	Description and Purpose	Nursing Responsibility
Biopsy		
Punch	Special punch biopsy instrument of appropriate size is used. Instrument is rotated to appropriate level to include dermis and some fat. Suturing may or may not be done. Provides full-thickness skin for diagnostic purposes.	Verify that consent form is signed (if needed). Assist with preparation of site, anaesthesia, procedure, and hemostasis. Apply dressing, and give postprocedure instructions to patient. Properly identify specimen.
Excisional	Useful when good cosmetic results or entire removal or both are desired. Skin closed with subcutaneous and skin sutures.	Same as above.
Incisional	Wedge-shaped incision made in lesion too large for excisional biopsy. Useful when larger specimen than shave biopsy is needed.	Same as above.
Shave	Single-edged razor blade used to shave off superficial lesions or small sample of a large lesion. Provides thin specimen for diagnostic purposes.	Same as above.
Microscopic Tests		
Potassium hydroxide (KOH)	Hair, scales, or nails are examined for superficial fungal infection. Specimen is put on a glass slide, and potassium hydroxide solution of 10%–20% concentration added.	Instruct patient regarding purpose of test. Prepare slide.
Culture	The test identifies fungal, bacterial, and viral organisms. For *fungi*, scraping or swab of skin is performed. For *bacteria*, material is obtained from intact pustules, bullae, or abscesses. For *viruses*, vesicle or bulla is scraped and exudate taken from base of lesion.	Instruct patient regarding purpose and procedure. Properly identify specimen. Follow instructions for storage of specimen if not immediately sent to laboratory.
Mineral oil slides	The test checks for infestations. Scrapings are placed on slide with mineral oil and viewed microscopically.	Instruct patient about purpose of test. Prepare slide.
Immuno-fluorescent studies	Some cutaneous diseases have specific, abnormal antibody proteins that can be identified by fluorescent studies. Both skin and serum can be examined.	Inform patient about purpose of test. Assist in obtaining specimen. For punch biopsy of tissue, place specimen in special fixative (e.g., Michel's), and not formalin.
Miscellaneous		
Wood's lamp (black light)	Examination of skin with long-wave ultraviolet light causes specific substances to fluoresce (e.g., *Pseudomonas* organisms, fungal infections, vitiligo).	Explain purpose of examination and that it is not painful. Room is darkened for examination.
Patch test	Used to determine whether patient is allergic to specific testing material. Small amount of potentially allergenic material is applied, usually to skin on back.	Explain purpose and procedure to patient. Instruct patient to return in 48–72 hr for removal of allergens and evaluation. Inform patient if re-evaluation is needed at 96 hr (see Figure 25-11).

The main diagnostic techniques related to skin problems are inspection of an individual lesion and the taking of a careful history related to the problem. If a definitive diagnosis cannot be made through these techniques, additional tests may be indicated such as dermatoscopy (examination of the skin through a lighted instrument with optical magnification) (Marchetti & Marghoob, 2014).

Biopsy is one of the most common diagnostic tests used in the evaluation of a skin lesion. A biopsy is indicated in all conditions in which a malignancy is suspected or a specific diagnosis is questionable. Techniques include punch, incisional, excisional, and shave biopsies. The method used is related to factors such as the site of the biopsy, the cosmetic result desired, and the type of tissue to be obtained.

Other diagnostic procedures used include stains and cultures for fungal, bacterial, and viral infections. *Direct immuno-fluorescence* is a technique used on skin biopsy specimens and may be indicated in certain conditions such as bullous diseases and systemic lupus erythematosus. In contrast, *indirect immuno-fluorescence* is performed on a blood sample. Patch testing (Figure 25-11) and photopatch testing may be used in the evaluation of allergic contact dermatitis and photoallergic reactions (Goldsmith, Katz, Gilchrest, et al., 2012).

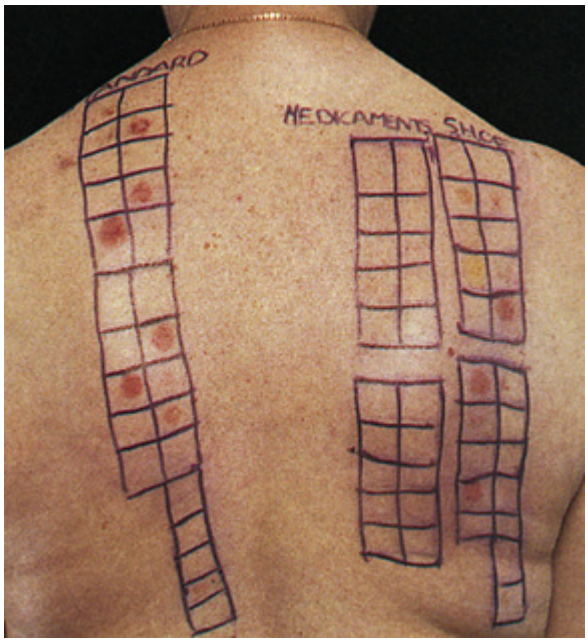

FIGURE 25-11 Patch test. Results from an application of possible allergens to the skin show positive reactions in the sites labelled “standard” and “shoe.” Source: Graham-Brown, R., Bourke, J., & Cunliffe, T. (2008). *Dermatology: Fundamentals of practice*. Edinburgh: Mosby.

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. What is the primary function of the skin?
   a. Insulation
   b. Protection
   c. Sensation
   d. Absorption
2. Which of the following are age-related changes in the hair and nails? *(Select all that apply)*
   a. Oily scalp
   b. Scaly scalp
   c. Thinner nails
   d. Thicker, brittle nails
   e. Longitudinal nail ridging
3. When assessing self-care habits in relation to the skin, what does the nurse question the client about?
   a. Joint pain
   b. Use of sunscreen products
   c. Recent changes in exercise tolerance
   d. Family history of melanoma
4. During the physical examination of a client's skin, which of the following would the nurse do?
   a. Use a flashlight if the room is poorly lit.
   b. Note cool, moist skin as a normal finding.
   c. Pinch up a fold of skin to assess for turgor.
   d. Perform a lesion-specific examination first and then a general inspection.
5. The nurse assessed the client's skin lesions as firm, edematous, and irregularly shaped with variable diameter. What would these

lesions be called?

a. Wheals

b. Papules

c. Pustules

d. Plaques

6. What is the *most* appropriate technique for the nurse to use in assessing the skin for temperature and moisture?

a. Palpation

b. Inspection

c. Percussion

d. Auscultation

7. On inspection of the client's skin, the nurse notes the complete absence of melanin pigment in patchy areas on the client's hands. What is this assessment finding called?

a. Vitiligo

b. Nevus of Ota

c. Telangiectasia

d. Lichenification

8. Individuals with dark skin are more likely to develop which of the following?

a. Keloids

b. Wrinkles

c. Rashes

d. Skin cancer

9. Under what circumstance is diagnostic testing recommended for skin lesions?

a. When a health history cannot be obtained

b. When a more definitive diagnosis is needed

c. When percussion reveals an abnormal finding

d. When treatment with prescribed medication has failed

1. b; 2. b, d, e; 3. b; 4. c; 5. a; 6. a; 7. a; 8. a; 9. b

CHAPTER 26

Nursing Management

Integumentary Problems

Written by, Diana L. Gallagher

Adapted by, Susannah McGeachy

LEARNING OBJECTIVES

1. Specify health-promotion practices related to the integumentary system.
2. Explain the etiology, clinical manifestations, and nursing and collaborative management of common acute dermatological problems.
3. Explain the etiology, clinical manifestations, and collaborative management of malignant dermatological disorders.
4. Explain the etiology, clinical manifestations, and collaborative management of bacterial, viral, and fungal infections of the integument.
5. Explain the etiology, clinical manifestations, and collaborative management of infestations and insect bites.
6. Explain the etiology, clinical manifestations, and collaborative management of allergic dermatological disorders.
7. Explain the etiology, clinical manifestations, and collaborative management care related to benign dermatological disorders.

8. Summarize the psychological and physiological effects of chronic dermatological conditions.
9. Explain the indications and nursing management related to common cosmetic procedures and skin grafts.

Health Promotion

Health-promotion practices related to the skin often parallel practices appropriate for general good health. The skin reflects both physical and psychological well-being. Specific health-promotion activities appropriate to good skin health include avoidance of

environmental hazards; adequate rest, hygiene, and nutrition; and skin self-examination.

Environmental Hazards

Sun Exposure.

Years of exposure to the sun cause cumulative skin damage. The ultraviolet (UV) rays of the sun cause degenerative changes in the dermis, resulting in premature aging (e.g., loss of elasticity, thinning, wrinkling, and drying of the skin). Prolonged and repeated sun exposure is a major factor in precancerous and cancerous lesions (Health Canada, 2013). Actinic keratoses, basal cell carcinoma (BCC), squamous cell carcinoma (SCC), and malignant melanoma are dermatological problems associated directly or indirectly with sun exposure. The earth's ozone layer, which protects the world's creatures from excessive exposure to UV radiation, continues to thin because of environmental pollutants, leading to increased risk for sun damage and skin cancer.

It is important for the nurse to emphasize safe sun practices to patients. Specific wavelengths of the sun (Table 26-1) have different effects on the skin. Sunlight is composed of visible light and UV light; UV light may be further divided into UVA and UVB. Both types can damage the skin and increase the risk for skin cancer. When sun exposure is excessive, the turnover time of the skin is shortened and results in peeling. Individuals with fair skin should be especially cautious about excessive sun exposure because they have less melanin and, thus, less natural protection.

TABLE 26-1
WAVELENGTHS OF THE SUN AND EFFECTS ON SKIN

Wavelength	Effect
Long (UVA)	• Causes elastic tissue damage and actinic skin damage • Is responsible for tanning due to increased melanin production • Contributes to formation of skin cancer
Middle (UVB)	• Is responsible for sunburn • Is a major factor in development of skin cancer
Short (UVC)	• Does not reach earth; is blocked by atmosphere

UVA, ultraviolet A light; *UVB*, ultraviolet B light; *UVC*, ultraviolet C light.

Nurses play an important role in educating patients on sun-safety strategies including sun avoidance, protective clothing, and sunscreen. The greatest risk of damaging sun exposure is between the hours of 10:00 a.m. and 4:00 p.m., so avoiding the sun or using protection is paramount during these hours (Health Canada, 2014). Even on overcast days, serious sunburn can occur, because up to 80% of UV rays can penetrate the clouds. Other factors that increase sunburn risk include being at high altitudes, where atmospheric protection from UV rays is decreased, being in snow, and being in or near water, as water and snow reflect a significant portion of the sun's rays back toward the skin. The UV index is a scale used by Environment Canada to communicate the risk for harmful UV exposure; it is regularly included in local weather forecasts and is available online. At an index of 3 (moderate) or higher, Health Canada (2014) recommends using sun-protective measures.

Eye protection is important to consider when spending time in the sun, as UV rays can potentially cause retinal damage and may be a contributing factor in cataract development. The nurse should advise patients to use sunglasses with UVA and UVB protection, particularly when the UV index is 3 or above (Government of Canada [GOC], 2012a).

Sun-protective measures for the skin include carrying an umbrella, wearing a large-brimmed hat and long-sleeved clothing, and applying sunscreen to exposed skin. Two types of sunscreens filter both UVA and UVB wavelengths: chemical and physical. Chemical sunscreens are light creams, lotions, or sprays that absorb or filter UV light, resulting in diminished UV light penetration. In contrast,

physical sunscreens (e.g., titanium dioxide, zinc oxide) are thick, opaque, heavy creams that reflect UV radiation, blocking all UVA and UVB radiation. Sunscreen products are rated according to their **sun protection factor (SPF)** (GOC, 2012b). SPF measures the effectiveness of a sunscreen in filtering and absorbing UVB radiation. "Broad-spectrum" products offer protection against UVA radiation as well (GOC, 2012b) (Table 26-2).

TABLE 26-2

SUNSCREEN INGREDIENTS AND ULTRAVIOLET LIGHT PROTECTION

Sunscreen Ingredients	Ultraviolet Light Protection
Chemical	
Benzophenones	UVA and UVB
PABA and PABA esters (Removed from many sunscreen products because of clothing staining and allergic reactions, including contact dermatitis)	UVB
Cinnamates	UVB
Salicylates	UVB
Miscellaneous	
Methyl anthranilate	UVB
Parsol (Avobenzone)	UVA
Physical Sunscreens	
Titanium dioxide	UVA and UVB
Zinc oxide	UVA and UVB

PABA, para-aminobenzoic acid; *UVA*, long wavelength of ultraviolet light; *UVB*, middle wavelength of ultraviolet light.

In general, a sunscreen with a minimum SPF of 15 should be used daily (GOC, 2012b). Sunscreens with an SPF of 15 or more filter 92% of the UVB responsible for erythema and make sunburn unlikely in most individuals when applied appropriately. The Canadian Dermatology Association (CDA, 2017a) recommends a broad-spectrum sunscreen with an SPF of 30 or higher to prevent premature aging of the skin and skin cancer, particularly for outdoor workers, athletes, and spectators. Sunscreen should be applied 20 to 30 minutes before going outside. It must be reapplied after swimming or profusely sweating to maintain good sun protection even if the product is "waterproof." Sunscreens with physical filters

such as zinc oxide or titanium dioxide that scatter and reflect both UVA and UVB rays are recommended for prominent parts like the nose, cheeks, shoulders, and ears (GOC, 2012b). Tanning booths and sun lamps are still commonly used to artificially tan skin, despite well-known associated risks including photoaging (premature aging of the skin due to UV exposure) and skin cancers. Indoor tanning increases a person's risk of developing melanoma by 75% if used before the age of 35 and increases the risk of developing other skin malignancies such as SCC and BCC (GOC, 2012c). Indoor tanning especially increases cancer risk for individuals who are younger than 18 years of age, have fair or freckled skin, burn easily, have lots of moles, have had previous skin cancer or a family history of skin cancer, or use medication that increases sensitivity to UV (CDA, 2017b). Sunless tanning creams are cosmetic creams absorbed by the epidermis only to give the appearance of tan (GOC, 2012d). In 2000, the CDA published a position statement that self-tanning products are safe. However, it is important to note that these products provide *no* sun protection and must be used in conjunction with appropriate SPF products and sun-avoidance strategies.

Evidence-Informed Practice

Research Highlight

Is Sun-Protective Counselling Effective?

Clinical Question

In adults (P) does sun-protective counselling (I) improve safe sun behaviours (O)?

Best Available Evidence

Systematic review of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence

- Five RCTs (n = 6 949) of middle-aged white men and women and three RCTs (n = 897) of young adults examined the effect of counselling on sun-protective behaviours. Trials ranged from one to several sessions of in-person counselling, phone counselling, or tailored written feedback according to risk.
- Counselling with tailored feedback influenced sun-protective behaviours in older adults.
- Appearance-focused counselling reduced indoor tanning use among young women.

Conclusion

- Relevant counselling by primary health care providers can increase sun-protective behaviours and decrease indoor tanning.

Implications for Nursing Practice

- Promote safe sun behaviours for patients to decrease ultraviolet exposure, including sunscreen use, sun-avoidance hours, and protective clothing.
- Emphasize the dangers of tanning booth use among college students.
- Tailor sun-safety interventions to the target population.

P, Patient population of interest; *I,* intervention or area of interest; *O,* outcomes of interest (see Chapter 1).

Reference for Evidence

Evidence-Informed Practice

Translating Research Into Practice

A nurse is helping in a skin cancer screening clinic. Sara Walters, a 24-year-old woman with a fair skin type (blond hair and blue eyes), is completing her health history before her screening examination. She indicates that she visits an indoor tanning salon every other week because being tan makes her feel "more attractive." The nurse spends time explaining the increased risk for skin cancer associated with the use of tanning booths.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
Canadian Dermatology Association and International Agency for Cancer Research report a strong link between exposure to indoor tanning devices and development of skin cancer and melanoma.	The nurse notes that Ms. Walters has the following skin cancer risk factors: fair skin, blond hair, blue eyes, frequent use of tanning booths.	After listening, the patient tells the nurse that she will consider reducing the frequency of her visits—going only when she has an important event to attend.

Decision and Action

The nurse accepts Ms. Walters's decision, tells her that this is a step in the right direction, and encourages her to consider completely stopping her use of the tanning booth.

References for Evidence

Certain topical and systemic medications potentiate the effect of the sun, even with brief exposure. Categories of drug therapy that may contain common photosensitizing medications are listed in Table 26-3. Many drugs are included in these categories, and the photosensitivity of each individual drug should be examined. The chemicals in these medications absorb light and release energy that harms cells and tissues. The clinical manifestations of drug-induced photosensitivity (Figure 26-1) are similar to those of exaggerated sunburn. These include swelling, erythema, vesicles, and papular, plaquelike lesions. Skin that is at risk for photosensitivity reactions can be protected by the use of sunscreen products. Educating patients about photosensitizing effects of their medications is an important nursing role.

TABLE 26-3

DRUG THERAPY
Categories of Drugs That May Cause Photosensitivity

Categories	Examples
Anticancer drugs	Methotrexate (Metoject), vinorelbine
Antidepressants	Amitriptyline (Elavil), clomipramine (Anafranil), doxepin (Silenor)
Antidysrhythmics	Quinidine, amiodarone
Antifungals	Ketoconazole (Ketoderm, Nizoral)
Antihistamines	Diphenhydramine (Benadryl), chlorpheniramine (Chlor-Tripolon)
Antimicrobials	Tetracycline, sulfamethoxazole-trimethoprim (Septra), azithromycin (Zithromax), ciprofloxacin (Cipro)
Antipsychotics	Chlorpromazine, haloperidol
Diuretics	Furosemide (Lasix), hydrochlorothiazide
Hypoglycemics	Tolbutamide, chlorpropamide
Nonsteroidal anti-inflammatory drugs	Diclofenac (Arthrotec, Voltaren), piroxicam, sulindac (Apo-Sulin)

FIGURE 26-1 Intense eruption in areas exposed to sunlight after patient started on hydrochlorothiazide. Source: Habif, T. P. (2016). *Clinical dermatology: A color guide to diagnosis and therapy* (6th ed., p. 454). St. Louis: Mosby.

Cold Exposure.

Excessive or prolonged exposure to cold can cause damage to the skin and underlying tissue, or frostbite. Assessment and management of frostbite are discussed further in Chapter 71.

Irritants and Allergens.

Patients may seek treatment for irritant or allergic dermatitis, which are two types of contact dermatitis. *Irritant contact dermatitis* is produced by direct chemical injury to the skin. *Allergic contact dermatitis* is an antigen-specific, type IV delayed hypersensitivity response. This response requires sensitization and occurs only in individuals who are predisposed to react to a particular antigen (see Chapter 16).

The nurse should counsel patients to avoid known irritants (e.g., ammonia, harsh detergents). Skin patch testing (application of allergens) can sometimes be helpful in determining the most likely sensitizing agent. Sometimes the health care provider is the first to detect a contact allergy to various metals, gloves (latex), and adhesives. The nurse must also be aware that prescribed and over-the-counter (OTC) topical and systemic drugs used to treat a variety of conditions may contain fragrances and preservatives that cause dermatological reactions. Health Canada (2016) maintains a database (called MedEffect) of suspected adverse reactions, including dermatological problems, to Canadian-marketed health products. Consumers and health care providers may report suspected reactions online, by phone, or by mail.

Radiation.

Although most radiology departments are extremely cautious in protecting both themselves and their patients from the effects of excessive radiation, the nurse should support the patient in making informed decisions by ensuring the patient understands the benefits and risks of proposed radiological procedures. Discussing the purpose of the procedure, common adverse effects, and rare adverse effects can assist patients in their decision and increase patient engagement in the plan of care. Radiographic studies are invaluable in both diagnosis and therapy, but they can cause serious adverse

effects to the skin, including erythema, dry and moist desquamation, edema, and changes in pigmentation.

Rest and Sleep

Sleep is restorative to the skin. Pruritic skin diseases often interfere with sleep. Helping patients obtain high-quality sleep is an important health-promotion consideration. Adequate rest increases the patient's ability to tolerate itching, thereby decreasing skin damage from scratching.

Exercise

Exercise has numerous psychological and physiological benefits, including dilation of the blood vessels and improved perfusion of the dermis. However, caution must be used to avoid or protect from overexposure to heat, cold, and sun during outdoor exercise.

Hygiene

The patient's skin type, lifestyle, culture, age, and gender influence hygiene practices. The normal acidity of the skin and perspiration protect against bacterial overgrowth. Most soaps are alkaline and neutralize the skin surface, leading to loss of protection. Using mild, moisturizing soaps or “nonsoap” lipid-free cleansers, and avoiding hot water and vigorous scrubbing can noticeably decrease local skin irritation. Skin piercings where jewellery has been inserted can be cared for with antibacterial soaps that do not contain sulfites.

In general, the skin and hair should be washed often enough to remove excess oil and excretions and to prevent odour. Older people should avoid the use of harsh, heavily scented soaps and shampoos (such as Dial or Irish Spring) because of the increasing dryness of their skin and scalp; unscented products marketed “for sensitive skin” are generally preferable. Cold weather and indoor heating systems further contribute to dry and pruritic skin conditions, particularly during winter months. Patients should be advised that applying moisturizers immediately after bathing while the skin is still damp helps seal in moisture.

Nutrition

A well-balanced diet adequate in all food groups can produce healthy skin, hair, and nails (see *Canada's Food Guide* in Chapter 42). Important elements of skin nutrition appear in Table 26-4.

TABLE 26-4

NUTRITIONAL THERAPY
Nutrients Essential for Healthy Skin, Hair, and Nails

Nutrient	Supportive Function	Impact of Nutrient Deficiency
Vitamin A	• Maintenance of normal epithelial cell structure • Wound healing	• Conjunctival dryness • Poor wound healing
Vitamin B complex (niacin, pyroxidine, biotin)	• Complex metabolic functions	• Erythema/rashes • Bullae • Seborrhea-like lesions • Alopecia

Vitamin C (ascorbic acid)	• Connective tissue formation
	• Wound healing
		• Symptoms of scurvy (severe deficiency):
		  • Petechiae
		  • Bleeding gums
		  • Purpura

Vitamin D3 (cholecalciferol)	• Bone health • Produced in skin cells after UVB exposure	• Decreased bone mineral density • Muscle weakness and pain
Vitamin K	• Blood clotting cascade	• Decreased prothrombin synthesis • Easy bruising
Protein	• Cell growth and maintenance • Wound healing	• Poor wound healing • Dry, flaky skin • Brittle nails and hair
Unsaturated fatty acids (e.g., linoleic acid, arachidonic acid)	• Integrity of cellular and subcellular membranes	• Decreased tissue metabolism

Obesity has an adverse effect on the skin. The increase in subcutaneous fat can lead to stretching and overheating. Overheating secondary to the greater insulation provided by fat causes an increase in sweating, which inflames and dries the skin. Obesity is a risk factor for poor wound healing and type 2 diabetes mellitus. Increased skin folds contribute to skin problems. Skin in these intertriginous (skin on skin) areas is predisposed to skin tags *(acrochordons),* candidiasis (yeast), intertrigo (bacteria, fungi, yeast), and erythrasma (bacteria) infections.

Self-Treatment

Self-diagnosis and treatment of skin problems can be dangerous; and the wide variety of OTC skin preparations, confusing.

In general, the nurse should stress the duration of the treatment and the need to follow package directions closely. Skin problems may be slow to produce symptoms and slow to resolve. If the package insert of an OTC drug says its use should not exceed 7 days, patients should heed this warning. If any systemic signs of inflammation or extension of the skin problem (e.g., an increased number of lesions or increased erythema or swelling) develop, self-care should be stopped and the patient should seek the help of a health care provider.

Malignant Skin Neoplasms

Skin cancer is the most common cancer diagnosed in Canada and worldwide, with incidence in Canada steadily increasing since the early 1980s (GOC, 2015). Skin cancers are either nonmelanoma or melanoma. The fact that skin lesions are so visible increases the likelihood of early detection and diagnosis; a marked majority of cancerous skin lesions are first detected by patients or their family members (CDA, 2017c).

Teach patients to self-examine their skin at least monthly. The cornerstone of the skin self-examination is the "ABCDE rule." Examine skin lesions for **a**symmetry, **b**order irregularity, **c**olour change or variation, **d**iameter of 6 mm or more, and an **e**volving appearance (Figure 26-2). The nurse should emphasize to patients that persistent skin lesions that do not heal, lesions once flat and now raised, or lesions once small and recently growing or changing in appearance are warning signs. These should be examined by a health care provider. Skin malignancies generally grow slowly, and early detection and treatment often leads to a highly favourable prognosis.

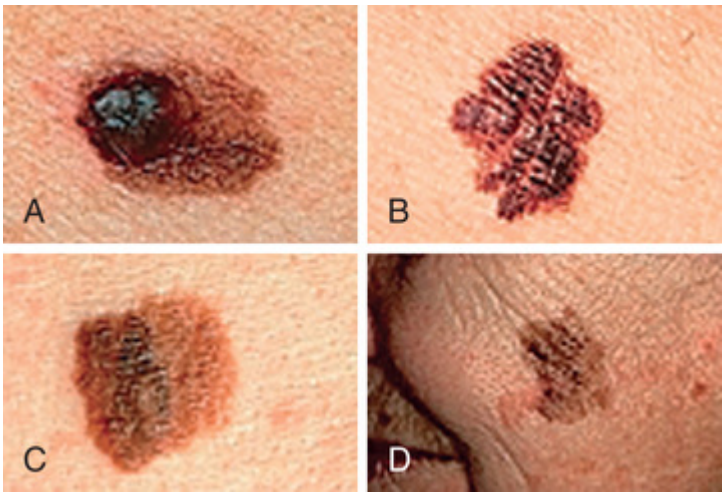

FIGURE 26-2 The ABCDEs of melanoma. **A,** Asymmetry: one half is unlike the other half. **B,** Border irregularity: edges are ragged, notched, or blurred. **C,** Colour: varied pigmentation; shades of tan, brown, and black. **D,** Diameter: greater than 6 mm (diameter of a pencil eraser). **E,** Evolving; changing appearance (not pictured; change in shape, size, colour, or other characteristic is noted over a length of time).

Risk Factors

Risk factors for skin malignancies include having fair skin, blond or red hair, light eye colour, history of chronic sun exposure, family or personal history of skin cancer, outdoor occupations, frequent outdoor recreational activities, indoor tanning, and smoking (Canadian Cancer Society, 2015). Patients treated with photochemotherapy, which is called *PUVA* and is a combination of oral methoxsalen (**p**soralen) and **UVA** radiation, may be at greater risk for melanoma. Individuals with darker skin are less susceptible to skin cancer because of naturally occurring increased melanin, an effective sunscreen. Melanoma may still occur in these patients, however, most often on the palms, the soles, and the mucous membranes.

Nonmelanoma Skin Cancers

Nonmelanoma skin cancers (basal cell and squamous cell carcinomas) are the most common forms of skin cancer, with a projected 78 000 diagnoses in Canada in 2015 alone (GOC, 2015). Nonmelanoma skin cancers do not develop from melanocytes. They develop in the basement membrane of the skin. Although there are few deaths from nonmelanoma skin cancers, they have the potential for severe local destruction, permanent disfigurement, and disability.

Nonmelanoma skin cancers usually develop in sun-exposed areas, such as the face, head, neck, back of the hands, and arms, and are more common in patients over age 50. The most common causative factor is sun exposure. There are some differences between basal and squamous cell cancers. SCCs usually occur on the head and neck, where there is the highest degree of UV radiation. BCCs do not follow that pattern and may occur in sun-protected areas.

Actinic Keratosis

Actinic keratosis, also known as *solar keratosis*, consists of hyperkeratotic papules and plaques occurring on sun-exposed areas. Actinic keratoses are premalignant skin lesions that affect nearly all older individuals with light skin. They are the most common precancerous skin lesion. The clinical appearance of actinic keratoses can be highly varied. The typical lesion is an irregularly shaped, flat, slightly erythematous papule with indistinct borders and an overlying hard keratotic scale or horn (Table 26-5). Because actinic keratosis is impossible to differentiate from squamous cell carcinoma, treatment should be aggressive. Nonsurgical procedures are the first-line treatment (see Table 26-5). Any lesion that persists should be evaluated for a possible biopsy.

TABLE 26-5
PREMALIGNANT AND MALIGNANT CONDITIONS OF THE SKIN

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Actinic Keratosis		
Actinic (sun) damage. Premalignant skin lesion, precursor of squamous cell carcinoma.	Flat or elevated, dry, hyperkeratotic scaly papule; felt more than seen. Adherent rough scale on red base, which returns when removed. Often multiple. Often on erythematous sun-exposed areas; increase in number with age.	Cryosurgery, chemical caustics, topical application of 5-FU over entire area for 14–28 days or topical application of imiquimod (Aldara) over ≥16 wk. Photodynamic or later therapies. Recurrence possible even with adequate treatment.
Dysplastic Nevi		
Morphologically between common acquired nevi and melanoma. May be precursor of cutaneous malignant melanoma.	Often >5 mm; irregular border, possibly notched. Variegated colour of tan, brown, black, red, or pink with single mole. Presence of at least one flat portion, often at edge of mole. Frequently multiple. Most common site is the back, but possible in uncommon mole sites such as scalp or buttocks.	Increased risk for melanoma. Careful monitoring of people suspected of familial tendency to melanoma or dysplastic nevi. Excisional biopsy for suspicious lesions.
Basal Cell Carcinoma		
Change in basal cells. No maturation or normal keratinization. Continuing division of basal cells and formation of enlarging mass. Related to excessive sun exposure, genetic skin type, radiographic radiation, scars, and some types of nevi.	*Nodular and ulcerative:* Small, slowly enlarging papule. Borders semitranslucent or "pearly," with overlying telangiectasia. Erosion, ulceration, and depression of centre. Normal skin markings lost (see Figure 26-3). *Superficial:* Erythematous, pearly, sharply defined, barely elevated multinodular plaques; similar to eczema but nonpruritic.	Excisional surgery, chemosurgery, electrosurgery, Mohs (microscopically controlled) surgery, cryosurgery; 90% cure rate; slow-growing tumour that invades local tissue; metastasis rare; 5-FU and imiquimod (Aldara) for superficial lesions.
Squamous Cell Carcinoma		
Frequent occurrence on previously damaged skin (e.g., from sun, radiation, scar). Malignant tumour of squamous cell of epidermis. Invasion of dermis, surrounding skin.	*Superficial:* Thin, scaly, erythematous plaque without invasion into the dermis. *Early:* Firm nodules with indistinct borders, scaling, and ulceration. *Late:* Covering of lesion with scale or horn from keratinization. Most common on sun-exposed areas such as face and hands.	Surgical excision, cryosurgery, radiation therapy, chemotherapy, Mohs surgery, or electrodessication and curettage. Untreated lesion may metastasize to regional lymph nodes. High cure rate with early detection and treatment.
Cutaneous T-Cell Lymphoma (Mycosis Fungoides)		

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Origination in skin. Localized, chronic, slowly progressing disease. Possible etiologies of environmental toxins and chemical exposure.	Classic presentation involving three stages—patch (early), plaque, and tumour (advanced). History of persistent macular eruption followed by gradual appearance of indurated erythematous plaques on the trunk that appear similar to psoriasis. Pruritus, lymphadenopathy.	Treatment usually controls symptoms, not curative. UVB, PUVA, corticosteroids, topical nitrogen mustard, radiation therapy, systemic chemotherapy, extracorporeal photopheresis. Disease course is unpredictable; 10% will have progressive disease.
Malignant Melanoma		
Neoplastic growth of melanocytes anywhere on skin, eyes, or mucous membranes. Classification according to major histological mode of spread. Potential invasion and widespread metastases.	Irregular colour, surface, and border. Varying colour including red, white, blue, black, grey, and brown. Flat or elevated. Eroded or ulcerated. Often <1 cm in size. Most common sites are back, chest, and legs.	Wide surgical excision and possible sentinel lymph node evaluation depending on depth. Correlation of survival rate with depth of invasion. Poor prognosis unless diagnosis and treatment early. Spreading by local extension, regional lymphatic vessels, and bloodstream. Adjuvant therapy after surgery may be indicated if lesion >1.5 mm in depth.

5-FU, 5-fluorouracil; *PUVA*, psoralen plus ultraviolet A light (phototherapy); *UVB*, ultraviolet B light.

Basal Cell Carcinoma

Basal cell carcinoma (BCC) is a locally invasive malignancy arising from epidermal basal cells. It is the most common type of skin cancer but the least deadly. BCC usually occurs in middle-aged to older adults. It commonly develops at the site of earlier trauma, such as scarring, thermal burns, and injuries (Habif, 2011).

Clinical manifestations are described in Table 26-5. Some BCCs are pigmented, with curled borders and an opaque appearance. They may be hard to distinguish from melanoma. A tissue biopsy is needed to confirm the diagnosis. BCCs rarely metastasize (Figure 26-3). However, if BCC is left untreated, massive tissue destruction may result.

FIGURE 26-3 Basal cell carcinoma. Note rolled border and central erosion. Pearly papule with slight erythema. Source: Swartz, M. H. (2010). *Textbook of physical diagnosis: History and examination* (6th ed., p. 159). Philadelphia: Saunders.

Treatment depends on the tumour location and histological type, history of recurrence, and patient characteristics (see Table 26-5). Location and size are important factors in determining the best treatment.

Squamous Cell Carcinoma

Squamous cell carcinoma (SCC) is a malignant neoplasm of keratinizing epidermal cells. It frequently occurs on sun-exposed skin. While less common than BCC, SCC can be aggressive, has the potential to metastasize, and may lead to death if not treated early and correctly. Pipe, cigar, or cigarette smoking contributes to the formation of SCC on the mouth and lips. Immuno-suppression leads to a dramatic increase in the incidence of SCC.

Manifestations and treatment of SCC are described in Table 26-5. A biopsy should always be performed when a lesion is suspected to be SCC. There is a high cure rate with early detection and treatment.

Malignant Melanoma

Malignant melanoma is a tumour arising in melanocytes, the cells producing melanin. Melanoma causes the majority of skin cancer

deaths. Estimates in 2016 were that nearly 6 800 new cases would be diagnosed in Canada in that calendar year, and over 1 200 Canadians would die from the disease (Canadian Cancer Society's Advisory Committee on Cancer Statistics, 2016). Since 2001, the incidence of Canadians diagnosed with melanoma has risen steadily at 2% to 3% per year. Melanoma can occur in the eyes, ears, gastro-intestinal tract, leptomeninges, and oral and genital mucous membranes. When it begins in the skin, it is called *cutaneous melanoma*. Melanoma has the ability to metastasize to any organ, including the brain and heart.

Although the exact cause of melanoma is unknown, a combination of environmental and genetic factors is involved. Excessive exposure to UV radiation from the sun plays a leading role in the development of melanomas, but artificial sources of UV radiation, such as sun lamps and tanning booths, also play a role. UV radiation damages the deoxyribonucleic acid (DNA) in skin cells, causing mutations in their genetic code and altering the cells. Although anyone can develop melanoma, the risk is greatest for people who have red or blond hair, blue or light-coloured eyes, and light-coloured skin that freckles easily. These individuals have less melanin and thus less protection from UV radiation. The use of immuno-suppressive drugs and a history of dysplastic nevi also increase a person's risk.

Additionally, a person may have a genetic predisposition toward getting melanoma. Between 5% and 10% of people with melanoma have a first-degree relative (e.g., parent, full sibling) who had melanoma. This risk increases significantly if multiple relatives have a history of melanoma. Mutated genes have been identified in some families who have a high familial incidence of melanoma. Furthermore, having multiple and atypical moles, particularly atypical dysplastic nevi, increases individual risk for melanoma (CDA, 2017c). Other factors that affect a person's likelihood for developing melanoma are listed in the "Determinants of Health" box.

Determinants of Health

Melanoma

Biology and Genetic Endowment

- There are genetic links associated with the development of melanoma (e.g., xeroderma pigmentosum, Werner syndrome).
- There is an increased risk if a first-degree relative has been diagnosed with melanoma.

Personal Health Practices and Coping Skills

- Individuals who have had more than one blister sunburn in youth have a higher risk of developing melanoma, a risk that increases with each successive sunburn.
- Radiation exposure (i.e., environmental or occupational) increases an individual's risk for developing melanoma.

Gender

- Melanoma is more common in men than in women.

Source: Canadian Cancer Society. (2016). *Risk factors for melanoma*. Retrieved from *http://www.cancer.ca/en/cancer-information/cancer-type/skin-melanoma/risks/?region=on#possible*.

Clinical Manifestations

About 25% of melanomas occur in existing nevi or moles; about 20% occur in dysplastic nevi (see Table 26-5). Melanomas frequently occur on the lower legs and on the back in women and on the trunk, the head, and the neck in men. Because most melanoma cells continue to produce melanin, melanoma tumours are often dark brown or black. Individuals should consult their health care provider immediately if their moles or lesions show any of the clinical signs (ABCDEs) of melanoma (see Figure 26-2). Any sudden

or progressive increase in the size, the colour, or the shape of a mole should be evaluated.

Collaborative Care

One of the initial steps in correctly diagnosing a suspicious lesion is dermoscopic examination. Dermatoscopes use magnification to see patterns and structures not visible with the naked eye and can assist the health care provider in determining if a lesion without the obvious ABCDE signs should be biopsied. Biopsy is a critical tool for identifying a lesion. All suspicious lesions should be biopsied using an excisional biopsy technique. They should not be shave-biopsied, shave-excised, or electrocauterized. These techniques fail to provide an accurate measurement of depth.

The most important prognostic factor is tumour thickness at the time of the diagnosis. Two methods to determine thickness are currently being used. The *Breslow measurement* indicates tumour depth in millimetres (Figure 26-4), and the *Clark level* indicates the number of skin layers involved (one to five); the higher the number, the deeper the melanoma.

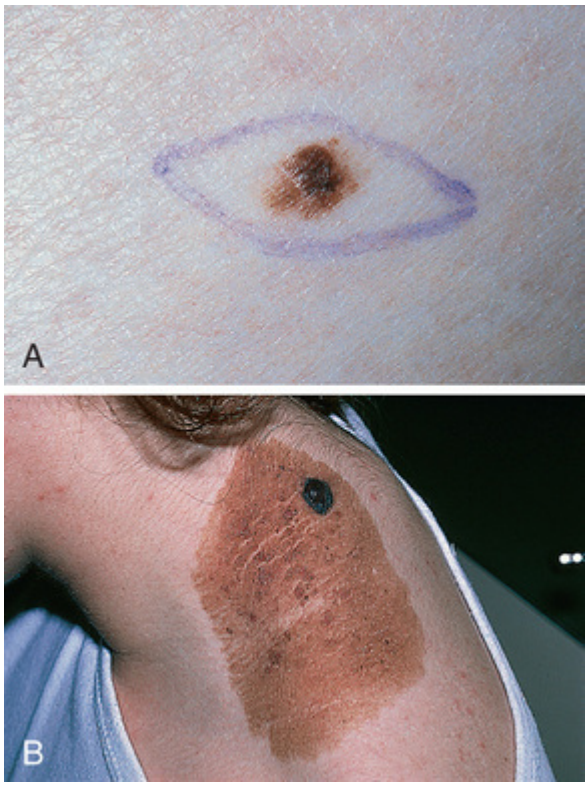

FIGURE 26-4 Breslow measurement of tumour thickness. **A,** Thin (0.08-mm) superficial spreading melanoma, good prognosis. **B,** Thick nodular melanoma with lymph node involvement, poor prognosis. Source: Gawkrodger, D., & Ardern-Jones, M. R. (2012). *Dermatology* (5th ed.). Edinburgh: Churchill Livingstone.

Treatment depends on the site of the original tumour, stage of the cancer, and the patient's age and general health. The staging of melanoma (stages 0–4) is based on tumour size, nodal involvement, and presence of metastasis. In stage 0, the melanoma is confined to one place (in situ) in the epidermis. Melanoma is nearly 100% curable by excision if diagnosed at stage 0. The 5-year survival rate depends on the sentinel node biopsy results, which indicate whether metastasis has occurred. If spread to regional lymph nodes has occurred (stage 3), the patient has a 61.7% chance of 5-year survival (Howlader, Noone, Krapcho, et al., 2015). If metastasis to other organs occurs (stage 4), treatment then is palliative.

The initial treatment of malignant melanoma is wide surgical excision. Melanoma that has spread to the lymph nodes or nearby sites usually requires additional (adjuvant) therapy such as chemotherapy, immunotherapy, targeted therapy, radiation therapy,

or a combination of therapies. Examples of chemotherapeutic drugs that are used include dacarbazine and temozolomide. These may be given alone or in combination with other drugs, such as cisplatin, carmustine, carboplatin, or vincristine, to improve the response rate.

Immunotherapy can include cytokines (interferon alfa, interleukin-2), programmed cell death protein 1 (PD-1) inhibitors, or cytotoxic T-lymphocyte antigen 4 (CTLA-4) inhibitors. PD-1 inhibitors include nivolumab (Opdivo) and pembrolizumab (Keytruda). These drugs block PD-1, a protein on T cells that normally keeps these cells from attacking other cells in the body. By blocking PD-1, these drugs boost the immune response against melanoma cells. Ipilimumab (Yervoy), a CTLA-4 inhibitor, also boosts the immune system, but it has a different target. It blocks CTLA-4, a protein that normally helps keep T cells in check. By blocking the action of CTLA-4, ipilimumab boosts the immune response against melanoma cells (Kim, Trinh, & Hwu, 2014).

Targeted therapy for melanoma includes BRAF and MEK inhibitors. About half of all melanomas have mutations in the *BRAF* gene, which makes an altered BRAF protein that signals melanoma cells to proliferate. Vemurafenib (Zelboraf) and dabrafenib (Tafinlar) are BRAF-inhibitor drugs that attack the BRAF protein directly. The *MEK* gene is involved in the activation of the BRAF pathway. Therefore, a MEK-inhibitor drug, trametinib (Mekinist), can be used to treat melanomas with *BRAF* gene changes.

Atypical/Dysplastic Nevus

An abnormal nevus pattern called *dysplastic nevus syndrome* places a person at increased risk for melanoma. Approximately 2% to 8% of the white population has moles classified as **dysplastic nevi (DNs)**. DNs, or atypical moles, are moles that are larger than usual (>5 mm across) and have irregular borders and various shades of colour. These nevi may have the same ABCDE characteristics as melanoma, but they are less pronounced. The earliest clinically detectable abnormality associated with DNs is an increase in the number of morphologically normal-looking nevi that occur in children between 2 and 6 years of age. Another proliferation occurs around

adolescence, and new nevi continue to appear throughout the person's life. The average number of normal nevi in adults is about 40; individuals with DNs may have over 100 normal-appearing nevi. The nurse should obtain a detailed family history related to melanoma and DNs. The risk of developing melanoma doubles with the presence of one DN, and having multiple DNs increases the risk up to twelve-fold.

Skin Infections and Infestations

Bacterial Infections

The skin provides an ideal environment for bacteria growth because of its abundant supply of nutrients and water and its warm temperature; it is home to numerous microorganisms, including bacteria. Bacterial infection occurs when the balance between the host and the microorganisms is altered. Infection can be primary, following a break in the skin, or it can be secondary, appearing in already damaged skin or as a sign of a systemic disease. *Staphylococcus aureus* and group A β-hemolytic streptococci are the major types of bacteria responsible for primary and secondary skin infections, including impetigo (Figure 26-5), erysipelas, cellulitis (Figure 26-6), lymphangitis, and furuncles (Table 26-6).

FIGURE 26-5 Impetigo. Superficial pustules covered by a thick, honey-coloured crust. Source: Habif, T. P. (2016). *Clinical dermatology: A color guide to diagnosis and therapy* (6th ed., p. 329). St. Louis: Mosby.

FIGURE 26-6 Cellulitis with characteristic erythema, tenderness, and edema. Source: Habif, T. P. (2011). *Clinical dermatology: A color guide to diagnosis and therapy* (5th ed., p. 274). St. Louis: Mosby.

TABLE 26-6
COMMON BACTERIAL INFECTIONS OF THE SKIN

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Impetigo		
Group A β-hemolytic streptococci, staphylococci, or combination of both. Associated with poor hygiene. Primary or secondary infection. Contagious.	Vesiculo-pustular lesions that develop a thick, honey-coloured crust surrounded by erythema. Pruritic. Most common on face as primary infection (Figure 26-5).	Systemic Antibiotics Oral penicillin, benzathine penicillin G by IM route, erythromycin. Local Treatment Warm saline or aluminum acetate soaks followed by soap-and-water removal of crusts. Topical antibiotic cream or ointment (mupirocin [Bactroban], fusidic acid [Fucidin]). Meticulous hygiene essential. With no treatment, glomerulonephritis is possible when streptococcal strain is nephritogenic.
Folliculitis		
Usually staphylococci; present in areas subjected to friction, moisture, oiliness, or shaving. Increased incidence in patients with diabetes mellitus.	Small pustule at hair follicle opening with minimal erythema. Development of crusting; most common on scalp, beard, extremities in men. Tender to touch.	Warm compresses of water or aluminum acetate solution. Antistaphylococcal soap (e.g., Hibiclens, Lever 2000, Dial) and water cleansing. Topical antibiotics (e.g., mupirocin [Bactroban], fusidic acid [Fucidin]). Heals usually without scarring. If lesions are extensive and deep, with possible scarring and loss of involved hair follicles, treatment with systemic antibiotics is necessary.
Furuncle		
Deep infection with staphylococci around hair follicle, often associated with severe acne or seborrheic dermatitis.	Tender erythematous area around hair follicle. Draining pus and core of necrotic debris on rupture. Most common on face, back of neck, axillae, breasts, buttocks, perineum, thighs. Painful.	Incision and drainage, possibly with packing. Antibiotics. Meticulous care of involved skin including frequent application of warm, moist compresses.
Furunculosis		
Increased incidence in patients with obesity, diabetes, chronic illness, or those regularly exposed to moisture or pressure.	Lesions as above. Malaise, regional adenopathy, fever.	Incision and drainage of painful nodules. Warm, moist compresses. Systemic antibiotic after culture and sensitivity study of drainage (usually semisynthetic, penicillinase-resistant oral penicillin such as cloxacillin. Measures to reduce surface staphylococci include antimicrobial cream to nares, armpits, and groin and antiseptic to entire skin. Often recurrent with scarring. Prevention or correction of predisposing factors. Meticulous personal hygiene.
Carbuncle		

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Multiple, interconnecting furuncles.	Many pustules appearing in erythematous area, most commonly at nape of neck.	Treatment same as for furuncles. Often recurrent despite production of antibodies. Slow healing with scar formation.
Cellulitis		
Inflammation of subcutaneous tissues; possibly secondary complication or primary infection. Often following break in skin. *Staphylococcus aureus* and streptococci usual causative agents. Deep inflammation of subcutaneous tissue from enzymes produced by bacteria.	Hot, tender, erythematous, and edematous area with diffuse borders (Figure 26-6). Chills, malaise, and fever.	Moist heat, immobilization and elevation, systemic antibiotic therapy, hospitalization if severe. Progression to gangrene possible if untreated.
Erysipelas		
Superficial cellulitis primarily involving the dermis. Group A β-hemolytic streptococci.	Red, hot, sharply demarcated plaque that is indurated and painful. Bacteremia possible. Most common on face and extremities. Toxic signs, such as fever, ↑ WBC count, headache, malaise.	Systemic antibiotics, usually penicillin. Hospitalization often required.

IM, intramuscular; *WBC*, white blood cell.

Healthy people can develop bacterial skin infections. Predisposing factors such as moisture, obesity, atopic dermatitis, systemic corticosteroids and antibiotics, and chronic disease such as diabetes mellitus all increase the likelihood of infection. Good hygiene practices and general good health inhibit bacterial infections. If an infection is present, the resulting drainage is infectious. Good skin hygiene and infection-control practices are necessary to prevent the spread of infection.

Viral Infections

Similar to viral infections elsewhere in the body, viral infections of the skin are difficult to treat. When a virus infects a cell, a skin lesion may develop. Lesions can also result from an inflammatory response to the viral infections. Herpes simplex (Figure 26-7), herpes zoster

(see Chapter 25, Figure 25-6), and warts (Figure 26-8) are the most common viral infections affecting the skin (Table 26-7).

FIGURE 26-7 Herpes viral infection on the lips. Typical presentation with vesicles on the lips and extending onto the skin. Source: Habif, T. P. (1996). *Clinical dermatology: A color guide to diagnosis and therapy* (3rd ed.). St. Louis: Mosby.

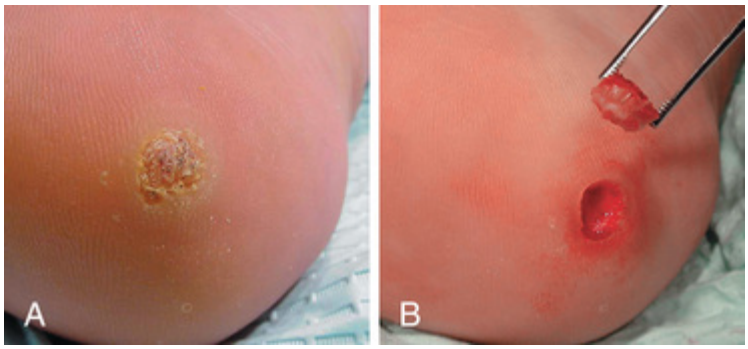

FIGURE 26-8 Plantar wart. **A,** Keratotic lesion. **B,** After excision. Source: Swartz, M. H. (2010). *Textbook of physical diagnosis: History and examination* (6th ed.). Philadelphia: Saunders.

TABLE 26-7
COMMON VIRAL INFECTIONS OF THE SKIN

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Herpes Simplex Virus (HSV) Types 1 and 2		
Oral or genital HSV infections can be serotyped as either HSV-1 or HSV-2; both are recurrent, lifelong viral infections. Exacerbated by sunlight, trauma, menses, stress, and systemic infection. Contagious to those not previously infected. Transmission by respiratory droplets or virus-containing fluid (e.g., saliva, cervical secretions). Infection in one area readily transmitted to another area by contact.	First Episode Symptoms occurring 3–7 days or more after contact. Painful local reaction. Single or grouped vesicles on erythematous base. Systemic symptoms (e.g., fever, malaise) possible or asymptomatic presentation possible (see Figure 26-7). Recurrent Episodes Typically milder and shorter; recur in similar spot; characteristic grouped vesicles on erythematous base.	Soothing, moist compresses; petroleum jelly to lesions. Usually not scarring. Antiviral agents (e.g., acyclovir [Zovirax], famciclovir [Famvir], and valacyclovir [Valtrex]) depending on location, frequency of outbreaks.
Herpes Zoster (Shingles)		
Activation of the varicella-zoster virus. Incidence increases with age and in immuno-suppressed patients. Potentially contagious to anyone who has not had varicella.	Linear distribution along dermatome of grouped vesicles on erythematous base. Usually unilateral on trunk, face, and lumbosacral areas. Burning, pain, and neuralgia preceding outbreak. Mild to severe pain during outbreak (see Chapter 25, Figure 25-6).	Symptomatic. Antiviral agents (e.g., acyclovir [Zovirax], famciclovir [Famvir], and valacyclovir [Valtrex]) effective for prevention of postherpetic neuralgia (PHN) if given within 72 hours of lesion appearance. Wet compresses, silver sulfadiazine (Flamazine) to ruptured vesicles. Analgesia. Gabapentin (Neurontin) to treat PHN. Usually heals without complications, but scarring and PHN possible. Vaccine (Zostavax II) to reduce risk for shingles and PHN is available for adults 60 years or older who previously had chicken pox.
Verruca Vulgaris		

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Caused by human papilloma virus (HPV). Spontaneous disappearance in 1–2 yr possible. Mildly contagious by autoinoculation. Specific response dependent on body part affected. Prevalence greater in youth and immuno-suppressed.	Circumscribed, hypertrophic, flesh-coloured papule limited to epidermis. Painful on lateral compression.	Multiple treatments, including surgery: blunt dissection with scissors or curette, liquid nitrogen therapy keratolytic agents (e.g., cantharidin/salicylic acid [Cantharone Plus]), podophyllin (Podofilm), CO_2 laser destruction. Possibility of scarring.
Plantar Warts		
Caused by human papilloma virus (HPV).	Wart on bottom surface of foot, growing inward because of pressure of walking or standing. Painful when pressure applied. Interrupted skin markings. Cone-shaped with black dots (thrombosed vessels) when wart removed (Figure 26-8).	Topical immunotherapy (imiquimod [Vyloma]), cryotherapy, salicylic acid, duct tape.

Fungal Infections

Because of the large number of identified fungi, it is almost impossible to avoid exposure to some pathological varieties. However, some fungi, including candidiasis and tinea unguium (Figure 26-9), can cause infections of the skin, hair, and nails. Common fungal infections of the skin are presented in Table 26-8. Most infections are relatively harmless in healthy adults, but they can be embarrassing and distressing to the patient.

FIGURE 26-9 Tinea unguium (onychomycosis). Fungal infection of toenails. Crumbly, discoloured, and thickened nails. Source: Gawkrodger, D., & Ardern-Jones, M. R. (2012). *Dermatology: An illustrated colour text* (5th ed.). Edinburgh: Churchill Livingstone.

TABLE 26-8

COMMON FUNGAL INFECTIONS OF THE SKIN AND THE MUCOUS MEMBRANES

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Candidiasis		
Caused by *Candida albicans*; also known as *moniliasis*. 50% of adults are symptom-free carriers. Appears in warm, moist areas such as groin area, oral mucosa, and submammary folds. HIV infection, chemotherapy, radiation, and organ transplantation related to depression of cell-mediated immunity that allows yeast to become pathogenic.	Mouth: White, cheesy plaque, resembles milk curds. Vagina: Vaginitis, with red, edematous, painful vaginal wall, white patches, vaginal discharge, pruritus, and/or pain on urination and intercourse. Skin: Diffuse papular erythematous rash with pinpoint satellite lesions around edges of affected area.	Microscopic examination and culture. Azole antifungals (e.g., fluconazole [Canesoral, Diflucan], ketoconazole [Ketoderm, Nizoral]) or other specific medication, such as vaginal suppository or oral mouthwash. Abstinence from intercourse or use of condom. Skin hygiene to keep area clean and dry. Powder effective on nonmucosal skin surfaces to prevent reinfection.
Tinea Corporis		
Various dermatophytes, commonly referred to as *ringworm*.	Typical annular (ringlike), scaly appearance; well-defined margins. Erythematous.	Cool compresses. Topical antifungals for isolated patches (e.g., miconazole [Monistat], clotrimazole [Canasten], ketoconazole [Ketoderm, Nizoral]).
Tinea Cruris		
Various dermatophytes, commonly referred to as *jock itch*.	Well-defined, scaly plaques in groin area. Does not affect mucous membranes.	Topical antifungal cream or solution.
Tinea Pedis		

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Various dermatophytes, commonly referred to as *athlete's foot*.	Interdigital scaling and maceration. Scaly plantar surfaces sometimes with erythema and blistering. May be pruritic. Less commonly painful.	Topical antifungal cream, gel, solution, spray, or powder (e.g., tolnaftate [Tinactin], clotrimazole [Canasten]).
Tinea Unguium (Onychomycosis)		
Various dermatophytes. Incidence increases with age.	Toenails more commonly affected than fingernails. Scaliness under distal nail plate. Brittle, thickened, broken, or crumbling nails with yellowish discoloration (see Figure 26-9).	Oral antifungal (terbinafine [Lamisil], itraconazole [Sporanox]). Topical antifungals (e.g., ciclopirox [Penlac], efinaconazole [Jublia]) minimally effective but an option if unable to tolerate system drug. Thinning of toenails if needed. Nail avulsion (removal) is an option.

HIV, human immunodeficiency virus.

Microscopic examination of the scraping of suspicious skin lesions in 10% to 20% potassium hydroxide (KOH) is an easy, inexpensive diagnostic measure to determine the presence of fungus. The appearance of hyphae (threadlike structures) is indicative of a fungal infection.

Infestations and Insect Bites

The possibilities for exposure to infestations (harbouring insects or worms) and insect bites are numerous (Table 26-9). In many instances, an allergy to the venom plays a major role in the reaction. In other cases, the clinical manifestations are a reaction to eggs, feces, or body parts of the invading organism. Some individuals react with a severe hypersensitivity (anaphylaxis), which can be life-threatening. (Anaphylaxis is discussed in Chapter 16).

TABLE 26-9
COMMON INFESTATIONS AND INSECT BITES

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Bees and Wasps		
Hymenoptera species.	Intense, burning, local pain. Swelling and itching. Severe hypersensitivity, possibly leading to anaphylaxis.	Cool compresses. Local application of antipruritic lotion. Antihistamines if indicated. Usually uneventful recovery.
Bedbugs		
Cimicidae species. Usually feed at night. Present in furniture, clothing, walls during day.	Wheal surrounded by vivid flare. Firm urticaria transforming into persistent lesion. Severe pruritus. Often grouped in threes appearing on noncovered parts of body.	Bedbug controlled by chlorocyclohexane. Lesions usually requiring no treatment. Severe itching possibly necessitating use of antihistamines or topical corticosteroids.
Pediculosis (Head Lice, Body Lice, Pubic Lice)		
Pediculus humanus, var. *capitis*; *Pediculus humanus,* var. *corporis*; *Phthirus pubis*. Obligate parasites that suck blood, leave excrement and eggs on skin, live in seams of clothing (if body lice) and in hair as nits. Transmission of pubic lice often by sexual contact.	Minute, red, noninflammatory. Points flush with skin. Progression to papular wheal-like lesions. Pruritus with secondary excoriation, especially parallel linear excoriations in intrascapular region. Firmly attached to hair shaft in head and body lice.	Pyrethrins (R&C Shampoo), permethrin 1% (Nix Crème Rinse), isopropyl myristate/cyclomethicone (Resultz) to treat various parts of body. Apply as directed. Screen and treat all possible close contacts: bed partners, playmates. Do not share head gear.
Scabies		
Sarcoptes scabiei. Mite penetrates stratum corneum, deposits eggs. Allergic reaction resulting from presence of eggs, feces, mite parts. Transmission by direct physical contact, only occasionally by shared personal items. Rarely seen in dark-skinned people.	Severe itching, especially at night, usually not on face. Presence of burrows, especially in interdigital webs, flexor surface of wrists, genitalia, and anterior axillary folds. Erythematous papules (may be crusted), possible vesiculation, interdigital web crusting.	5% permethrin topical lotion, one overnight application with second application 1 wk later, may yield 95% eradication. Treat all cohabitants and sexual partners. Treat environment with plastic covering for 5 days, launder all clothes and linen with bleach. Antibiotics if secondary infections present. Residual pruritus possible up to 4 weeks after treatment. Recurrence possible if inadequately treated.
Ticks		

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Borrelia burgdorferi (spirochete transmitted by ticks in certain areas) causes Lyme disease. Distribution shifts yearly, but generally endemic in Nova Scotia, southern and eastern Ontario, southeast Manitoba, and southern British Columbia, with isolated occurrences in the southern part of the provinces bordering the United States.	Spreading, ringlike rash 3–4 wk after bite. Rash commonly in groin, buttocks, axillae, trunk, and upper arms and legs. May be warm, itchy, or painful. Flulike symptoms. Cardiac, arthritic, and neurological manifestations possible. Unreliable laboratory test. No acquired immunity.	Oral antibiotics such as doxycycline or tetracycline. Intravenous antibiotics for arthritic, neurological, and cardiac symptoms. Rest and healthy diet. Most patients recover (see discussion of Lyme disease in Chapter 67).

Prevention of insect bites by avoidance or by the use of repellents is somewhat effective. Meticulous hygiene related to personal articles, clothing, bedding, and examination and care of pets, as well as careful selection of sexual partners, can reduce the incidence of infestations. Routine inspection is necessary in geographical areas where there is a risk of tick bites and Lyme disease.

Allergic Dermatological Problems

Dermatological problems associated with allergies and hypersensitivity reactions may present a challenge to the clinician (Table 26-10). The pathophysiology related to allergic and contact dermatitis is discussed in Chapter 16. A careful family history and discussion of exposure to possible offending agents can provide valuable data. Patch testing involves the application of allergens to the patient's skin (usually on the back) for 48 hours and evaluation of the test sites for signs of reaction; this is useful in determining possible causative agents. The best treatment of allergic dermatitis is avoidance of the causative agent. The extreme pruritus of contact dermatitis and its potential for chronicity make it a frustrating problem for clinicians and patients, especially if the offending agent cannot be identified.

TABLE 26-10
COMMON ALLERGIC CONDITIONS OF THE SKIN

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Allergic Contact Dermatitis		
Manifestation of delayed hypersensitivity, absorbed agent acting as antigen, sensitization after one or more exposures, appearance of lesions 2–7 days after contact with allergen.	Red papules and plaques, sharply circumscribed with occasional vesicles. Usually pruritic. Area of dermatitis frequently takes shape of causative agent (e.g., metal allergy and bandlike dermatitis on ring finger).	Elimination of contact allergen. Topical or systemic corticosteroids. Antihistamines. Skin lubrication.
Urticaria		
Usually allergic phenomenon. Erythema and edema in upper dermis resulting from a local increase in permeability of capillaries (histamine response).	Spontaneously occurring, raised or irregularly shaped wheals. Varying size; usually multiple. May occur anywhere on the body.	Removal of triggering agent, if known. Oral antihistamine. Cool compresses. Systemic corticosteroids if severe.
Drug Reaction		
May be caused by any drug that acts as antigen and causes hypersensitivity reaction. Certain drugs (e.g., penicillin) more prone to reactions. Not all reactions are allergic; some are intolerance (e.g., gastric upset).	Rash of any morphology. Often red, macular and papular, semiconfluent, generalized rash with abrupt onset. Appearance as late as 14 days after cessation of drug. Possibly pruritic. Some reactions may be life-threatening, requiring immediate and intensive care.	Withdrawal of drug if possible. Antihistamines, topical or systemic corticosteroids may be necessary depending on severity of symptoms.
Atopic Dermatitis		
Exaggerated cutaneous response to environmental allergens. Genetically influenced, chronic, relapsing disease associated with immunological irregularity involving inflammatory mediators. Associated with allergic rhinitis and asthma. Most severe in childhood.	Multiple presentations include acute, subacute, and chronic stages. All are pruritic. Common in an antecubital and popliteal space in adults. Acute stage with bright erythema, oozing vesicles, with extreme pruritus. Subacute stage with scaly, light red to red-brown plaques. Chronic stage with thickened skin and accentuation of skin markings (lichenification), possible hypopigmentation or hyperpigmentation. Dry skin.	Lubrication of dry (xerotic) skin; restoration of skin barrier function. Topical immuno-modulators (pimecrolimus [Elidel], tacrolimus [Protopic]). Corticosteroids. Phototherapy for severe inflammation and pruritus. Reduction of stress reduces flares. Antibiotics for secondary infection as needed.

Benign Dermatological Problems

The list of benign dermatoses is extensive; nonetheless, some of the most commonly seen and distressing problems include psoriasis, acne vulgaris, and seborrheic keratoses. Benign problems are summarized in Table 26-11.

TABLE 26-11
COMMON BENIGN CONDITIONS OF THE SKIN

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Acne Vulgaris		
Inflammatory disorder of sebaceous glands. More common in teenagers but possible development and persistence in adulthood. Flare can occur before menses, with use of corticosteroids, or with use of androgen-dominant oral contraceptives.	Noninflammatory lesions, including open comedones (blackheads) and closed comedones (whiteheads). Inflammatory lesions, including papules, pustules, and cysts. Most common on face, neck, and upper back. Nodular or inflammatory acne produces deeper lesions and can lead to significant scarring (see Figure 26-11).	Mechanical removal of multiple lesions with comedo extractor. Topical benzoyl peroxide or other antimicrobial. Topical retinoids. Systemic antibiotics if severe. Aim of treatment is to suppress new lesions and minimize scarring. Spontaneous remission possible. Use of isotretinoin (Accutane) for severe nodulocystic acne to possibly provide lasting remission (see "Drug Alert" box for contraindications). Pregnancy testing and monitoring of liver function, lipids, and depression essential.
Nevi (Moles)		
Grouping of normal cells derived from melanocyte-like precursor cells.	Hyperpigmented areas that vary in form and colour. Flat, slightly elevated, verrucoid, dome-shaped, sessile, or papillomatous. Preservation of normal skin markings. Hair growth possible.	No treatment necessary except for cosmetic reasons. Skin biopsy for suspicious or changing nevi.
Psoriasis		

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Autoimmune chronic dermatitis, which involves excessively rapid turnover of epidermal cells. Genetic predisposition. Usually develops before age 40.	Sharply demarcated, silvery, scaling plaques on the scalp, elbows, knees, palms, soles, and fingernails. Itching, burning pain. Localized or general, intermittent or continuous. Symptoms vary from mild to severe (see Figure 26-10).	Goal is to reduce inflammation and suppress rapid turnover of epidermal cells. No cure, but control is possible. Topical treatments including corticosteroids, tar, anthralin, intralesional injection of corticosteroids for chronic plaques, sunlight, natural or artificial UVB, PUVA, UVA (alone or with topical or systematic potentiation [psoralen]) and clobetasol propionate 0.05% spray (Clobex). Systemic treatments include antimetabolites (e.g., methotrexate), immuno-suppressants (e.g., cyclosporin [Apo-Cyclosporine]), and biological therapies (e.g. adalimumab [Humira], etanercept [Enbrel], infliximab [Remicade], ustekinumab [Stelara]) for moderate to severe plaque form of disease.
Seborrheic Keratoses		
Benign growths. Exact etiology unknown. Increasing number with age; no association with sun exposure.	Irregularly round or oval, often verrucous, flat-topped papules or plaques. Well-defined shape, appearance of being "stuck on." Increase in pigmentation with time. Usually multiple and possibly itchy (Figure 26-12).	Removal by curettage or cryosurgery for cosmetic reasons or to eliminate source of irritation. Biopsy if unable to differentiate from melanoma.
Acrochordons (Skin Tags)		
Common after midlife. Appearance on neck, axillae, and upper trunk secondary to mechanical friction or redundant skin (correlated with obesity).	Small, skin-coloured, soft, pedunculated papules, irregularly round or oval. May become irritated.	Surgical removal for cosmetic reasons or to eliminate source of irritation only. Usually just "clipping off" without anaesthesia.
Lipoma		
Benign tumour of adipose tissue, often encapsulated. Most common in 40- to 60-yr-old age group.	Rubbery, compressible, round mass of adipose tissue. Single or multiple. Variable in size, possibly extremely large. Most common on trunk, back of neck, and forearms.	Usually no treatment; biopsy to differentiate from liposarcoma; excision only when indicated.
Vitiligo		

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Unknown cause; genetically influenced, often precipitated by an event such as illness or a crisis. Most noticeable in dark-skinned people and those with a tan; complete absence of melanocytes. Noncontagious.	Focal amelanosis (complete loss of pigment). Macular. Wide variation in size and location. Usually symmetrical and may be permanent.	Topical steroids often successful in small areas. Attempts at repigmentation of larger areas with exposure to PUVA. Depigmentation of pigmented skin with extensive disease (>50% of body involved). Cosmetics and stains to conceal vitiliginous areas.
Lentigo		
Increased number of normal melanocytes in basal layer of epidermis related to sun exposure and aging. Also called *liver spots* or *age spots*.	Hyperpigmented, brown to black, flat macule or patch. Single or multiple. Typically on sun-exposed areas.	Evaluate carefully for progression. Treatment (only for cosmetic purposes) is liquid nitrogen or laser resurfacing. May recur. Biopsy if suspicious of melanoma.

PUVA, psoralen plus ultraviolet A light; *UVA*, ultraviolet A light; *UVB*, ultraviolet B light.

Psoriasis is a common inherited benign disorder that is characterized by the eruption of reddish, silver-scaled maculopapules, predominantly on the elbows, knees, scalp, and trunk. It currently affects 1 million people in Canada (CDA, 2017d) and usually develops in individuals between 15 and 35 years old. One-third of people with psoriasis have at least one relative with the disease. Diagnosis is often based on the skin's appearance (Figure 26-10). Lesions merge to form plaques. The affected area is normally rounded, with adherent silver scales that bleed easily when removed.

FIGURE 26-11 Acne vulgaris. Papules and pustules. Source: James, W. D., Berger, T., & Elston, D. (2011). *Andrews' diseases of the skin: Clinical dermatology* (11th ed.). Philadelphia: Saunders.

FIGURE 26-12 Seborrheic keratoses. Deeply pigmented, rough, and warty surface. Source: Callen, J. P., & Greer, K. E. (1993). *Color atlas of dermatology*. Philadelphia: Saunders.

While most people with psoriasis have mild disease, many with severe disease often have a weakened immune system, diabetes mellitus, depression, and cardiovascular disease. Psoriatic arthritis affects 10% to 30% of all people with psoriasis (CDA, 2017d). (Psoriatic arthritis is discussed in Chapter 67.) The chronicity of psoriasis can be severe and disabling. People withdraw from social contacts because of visible lesions, and quality of life can diminish.

Drug Alert

Isotretinoin (Accutane)

- Used to treat acne
- Can cause serious damage to fetus
- Contraindicated in women who are pregnant or want to become pregnant while on the drug
- Blood donation prohibited for those taking the drug and for 1 month after treatment ends
- Linked to liver function test abnormalities

Collaborative Care: Dermatological Problems

Diagnostic Studies

A careful history is of prime importance in the diagnosis of skin problems. The health care provider must be skilled at detecting evidence that could reveal the cause of a large number of skin diseases and conditions. Individual lesions must be inspected as part of the physical examination. Thorough history, physical examination, and appropriate diagnostic tests guide therapy.

Collaborative Care

Many different treatment methods are used in dermatology. Advances in this field have brought relief to patients with previously chronic, untreatable conditions. Many therapies require specialized equipment and are usually reserved for use by a dermatologist.

Phototherapy.

Ultraviolet light (UVL) of different wavelengths may be used to treat many dermatological conditions, including psoriasis, cutaneous T-cell lymphoma, atopic dermatitis, vitiligo, and pruritus. Light sources available include broadband UVB, narrowband UVB, and long-wave UV (UVA). One form of phototherapy involves the use of psoralen plus UVA light (PUVA). Psoralen is a photosensitizing drug given to patients for a prescribed amount of time before exposure to UVA.

Treatments are generally given two to four times a week. Adverse effects of oral psoralen include nausea and vomiting, sunburn, and persistent pruritus. Nurses should perform frequent skin assessments on all patients receiving phototherapy since erythema is an adverse effect of treatment. Topical corticosteroids may reduce painful erythema. Psoralen is used with extreme caution in patients with liver or renal disease because slower metabolism and excretion can lead to prolonged photosensitivity.

Prior to initiating phototherapy, the patient should understand the risks and benefits associated with UV exposure. Patients should be cautioned about the potential hazards of using photosensitizing

chemicals and of further exposure to UV rays from sunlight or artificial UVL during therapy. Because the lens of the eye absorbs psoralen, patients receiving PUVA need prescription protective eyewear that blocks 100% of UVL to prevent cataract formation. Patients should be instructed to use the eyewear for 24 hours after taking the medication when outdoors or even when near a bright window because UVA penetrates glass. Ongoing monitoring is essential because of the immuno-suppressive effects of PUVA, including an increased risk of SCC, BCC, and melanoma.

Photodynamic therapy is a special type of phototherapy used to treat actinic keratosis and some malignant skin tumours. This therapy uses a photosensitizing agent in a different way than other phototherapy treatments. The patient receives the photosensitizing agent intravenously or topically, depending on the area being treated. Time is allowed for the drug to be absorbed by the target cells, and light is then applied to the area, causing the drug to react with oxygen. This starts a reaction that kills the cells (Rkein & Ozog, 2014).

Radiation Therapy.

The use of radiation for the treatment of cutaneous malignancies varies greatly according to local practice and availability. Even if radiation therapy is planned, a biopsy must first be performed to obtain a pathological diagnosis. One of the advantages of radiation treatment is that it produces minimal damage to surrounding tissue, which is a prime consideration for such areas as the nose, eyelids, and canthal areas. It is a useful treatment for the older adult or the debilitated patient who cannot tolerate minor surgical procedures.

Radiation therapy usually requires multiple visits to a radiology department. It can produce permanent hair loss *(alopecia)* in the irradiated areas. Other adverse effects, depending on anatomical location and dose of radiation delivered, include telangiectasia, atrophy, hyperpigmentation, depigmentation, ulceration, hearing loss, ocular damage, atrophy, and mucositis. Careful shielding is necessary to prevent ocular lens damage if the irradiated area is around the eyes. (Radiation therapy is discussed in Chapter 18.)

Total-body skin irradiation (in which the body is bombarded with high-energy electrons) is one treatment for cutaneous T-cell lymphoma. Treatment follows a lengthy course. Patients experience varying degrees of hair loss and radiation dermatitis with transient loss of sweat gland function. This treatment causes premature aging of the skin.

Laser Technology.

Laser treatment is an efficient surgical tool for many types of dermatological problems (Table 26-12). Lasers are able to produce measurable, repeatable, consistent zones of tissue damage. They can cut, coagulate, and vaporize tissue to some degree. The wavelength determines the type of delivery system used and the intensity of the energy delivered.

TABLE 26-12

SKIN CONDITIONS TREATED BY LASER

• Acne scars	• Port wine stain
• Skin lesions	• Vascular lesions
• Hemangiomas	• Tattoos
• Spider veins or telangiectasias	• Rough or scarred skin
• Rosacea	• Psoriasis
• Pigmented nevi	• Wrinkles
• Hair removal	• Pigment discoloration in epidermis

The surgical use of laser energy requires a focusing device to produce a small, high-density spot of energy. Several types of lasers are available. The CO_2 laser, the most common, has numerous applications as a vaporizing and cutting tool for most tissues. The argon laser emits light that is primarily absorbed by hemoglobin. It helps in the treatment of vascular and other pigmented lesions. Other, less common lasers include copper and gold vapours and neodymium: yttrium–aluminum–garnet (Nd:YAG). Written policies and procedures should cover laser safety and be reviewed by all personnel working with laser equipment.

Laser technology is increasingly being used for cosmetic treatments. The effectiveness of the treatment depends on a variety of factors, including choice of the correct laser equipment, training

and skills of the laser operator, beam wavelength, power settings, duration of the energy pulse, and colour of the skin or hair. The patient must be informed about the risks of laser treatments, which include pain; reddened, bruised, and swollen skin; burns; infection; and temporary scarring and discoloration if the wrong equipment or technique is used (CDA, 2017e).

Drug Therapy.

Antibiotics.

Antibiotics are used both topically and systemically to treat dermatological problems, and they are often used in combination. If used, topical antibiotics should be applied lightly in a thin film to clean skin. Examples of common OTC topical antibiotics are polymyxin B sulphate–neomycin sulphate and bacitracin zinc (Polysporin). Prescription topical antibiotics include mupirocin (Bactroban; used for superficial *Staphylococcus* such as impetigo), gentamicin (used for *Staphylococcus* and most Gram-negative organisms), and erythromycin (used for Gram-positive cocci [staphylococci and streptococci] and Gram-negative cocci and bacilli). Topical erythromycin (e.g., erythromycin–benzoyl peroxide [Benzamycin]) and clindamycin (e.g., clindamycin phosphate–benzoyl peroxide [Clindoxyl, BenzaClin]) are used in combination with other agents for the treatment of acne vulgaris. Topical metronidazole (Metrogel) is used to treat rosacea and bacterial vaginosis.

If there are manifestations of systemic infection, a systemic antibiotic should be used. Systemic antibiotics are useful in the treatment of bacterial infections and acne vulgaris. The most frequently used are synthetic sulphur, penicillin, erythromycin (Eryc), minocycline, tetracycline, or doxycycline. These drugs are particularly useful for erysipelas, cellulitis, carbuncles, and severe, infected eczema. Culture and sensitivity of the lesion can guide the choice of antibiotic. Patients require drug-specific instructions on the proper technique of taking or applying antibiotics.

Corticosteroids.

Corticosteroids are particularly effective in treating a wide variety of dermatological conditions and can be used topically, intralesionally, or systemically. Topical corticosteroids are used for their local anti-inflammatory action as well as for their antipruritic effects. Attempts to diagnose a lesion should be made before a corticosteroid preparation is applied because corticosteroids may alter the clinical manifestations. Once a sufficient amount of medication is dispensed, limits should be set on the duration and the frequency of application.

The potency of a particular preparation is related to the concentration of active drug in the preparation. With prolonged use, the more potent corticosteroid formulations can cause adrenal suppression, especially if a large surface area is covered and occlusive dressings are used. High-potency corticosteroids may produce adverse effects when their use is prolonged, including atrophy of the skin resulting from impaired cell mitosis and capillary fragility and susceptibility to bruising. In general, dermal and epidermal atrophy does not occur until a corticosteroid has been used for 2 to 3 weeks. If drug use is discontinued at the first sign of atrophy, recovery usually occurs in several weeks. Rosacea eruptions, severe exacerbations of acne vulgaris, and dermatophyte infections may also occur. Rebound dermatitis is not uncommon when therapy is stopped; this can be reduced by tapering the use of high-potency topical corticosteroids when the patient improves.

Low-potency corticosteroids such as hydrocortisone act more slowly but can be used for a longer period without producing serious adverse effects. Low-potency corticosteroids are safe to use on the face and intertriginous areas, such as the axillae and groin. The ointment form represents the most efficient delivery system. Creams and ointments should be applied in thin layers and slowly massaged into the site one to three times a day as prescribed. Accurate and adequate topical therapy is often the key to a successful outcome.

Intralesional corticosteroids are injected directly into or just beneath the lesion. This method provides a reservoir of medication with an effect lasting several weeks to months. Intralesional injection is commonly used in the treatment of psoriasis, alopecia areata

(patchy hair loss), hypertrophic scars, and keloids. Triamcinolone acetonide (Kenalog) is the most common drug used for intralesional injection.

Systemic corticosteroids can have remarkable results in the treatment of dermatological conditions. However, they often have undesirable systemic effects (see Chapter 51). Corticosteroids can be administered as short-term therapy for acute conditions such as contact dermatitis caused by poison ivy. Long-term corticosteroid therapy for dermatological conditions is reserved for chronic bullous (blistering) disorders.

Antihistamines.

Oral antihistamines are helpful in treating urticaria, angioedema, and pruritus that can occur with problems such as atopic dermatitis, contact dermatitis, and other allergic cutaneous reactions. Antihistamines compete with histamine for the receptor site, thus preventing its effects. Antihistamines may have anticholinergic or sedative effects or both. Several different antihistamines may have to be tried before the satisfactory therapeutic effect is achieved. Sedating antihistamines such as hydroxyzine (Atarax) and diphenhydramine (Benadryl) are often preferred for pruritus because the tranquilizing and sedative effects offer symptomatic relief. The patient should be warned about sedative effects, a particular problem when driving or operating heavy machinery. Antihistamines such as fexofenadine (Allegra), cetirizine (Reactine), and loratadine (Claritin) bind to peripheral histamine receptors, providing antihistamine action without sedation. These nonsedating antihistamines are generally not effective for controlling pruritus. Antihistamines should be used with caution in older adults because of their long half-life and their anticholinergic effects.

Topical Fluorouracil.

Fluorouracil (5-FU) is a topical cytotoxic agent with selective toxicity for sun-damaged cells. It is used for the treatment of premalignant (especially actinic keratosis) and some malignant skin diseases. Because systemic absorption of the drug is minimal, systemic adverse effects are virtually nonexistent. Patient compliance can be a

problem because 5-FU causes erythema and pruritus within 3 to 5 days and painful, eroded areas over the damaged skin within 1 to 3 weeks, depending on skin thickness of site. Treatment must continue with applications one to two times a day for 2 to 4 weeks. Healing may take up to 4 weeks after medication is stopped (Micali, Lacarrubba, Nasca, et al., 2014). Low-potency topical steroids are often prescribed and increase patient compliance with therapy. Because 5-FU is a photosensitizing drug, the patient must be educated to avoid sunlight during treatment. Patients should also be educated about the effect of the medication, including a warning that they will look worse before they look better. Adherence depends on thoroughness of the instruction, which should include a written handout. After effective treatment, treated skin is smooth and free of actinic keratosis. Recurrence in treated areas is possible and multiple courses of chemotherapy may be necessary over the years for individuals with severely sun-damaged skin.

Immuno-Modulators.

Topical immuno-modulators, such as pimecrolimus (Elidel) and tacrolimus (Protopic), are used to treat atopic dermatitis. They work by suppressing an overreactive immune system. The adverse effects are minimal and may include a transient burning or feeling of heat at the application site. An increased risk of skin cancer and precancerous lesions may be associated with long-term use of these drugs. Another topical immuno-modulator, imiquimod (Aldara), acts to stimulate the production of interferon alfa and other cytokines to enhance cell-mediated immunity. It boosts the immune response only where applied and is safe for transplant patients. This medication is used for external genital warts, actinic keratoses, and superficial BCC. Most patients using this cream experience skin reactions including redness, swelling, blistering, excoriations, peeling, itching, and burning. Dosing varies depending on the type of lesion treated and the strength of medication prescribed (Micali, Lacarrubba, Nasca, et al., 2014).

Diagnostic and Surgical Therapy

Skin Scraping.

Scraping is done with a scalpel blade to obtain a sample of surface cells (stratum corneum) for microscopic inspection and diagnosis. The most common tests of skin scrapings are potassium hydroxide (KOH) for fungus and mineral oil examination for scabies.

Electrodesiccation and Electrocoagulation.

Electrical energy can be converted to heat by the tip of an electrode. This results in tissue being destroyed by burning. The major uses of this type of therapy are point coagulation of bleeding vessels to obtain hemostasis and destruction of small *telangiectasias* (dilation of groups of superficial capillaries and venules). *Electrodesiccation* uses a monopolar electrode and usually involves more superficial destruction. *Electrocoagulation* uses a dipolar electrode and has a deeper effect, with better hemostasis but an increased possibility of scarring. While minor electrosurgery on patients with a pacemaker poses minimal risk, both pacemakers and internal defibrillators can be affected by the electrical energy being used.

Curettage.

Curettage is the removal and scooping away of tissue using an instrument with a circular cutting edge attached to a handle. Although the curette is not usually strong enough to cut normal skin, it is useful for scooping many types of small skin tumours and superficial lesions, such as warts, actinic keratoses, and small BCCs and SCCs. The area to be curetted is anaesthetized before the procedure. Hemostasis is obtained by use of one of several methods: electrocoagulation, ferric subsulphate (Monsel's solution), gelatin foam, aluminum chloride, or a gauze pressure dressing. Specimens are usually sent for biopsy. A small scar and hypopigmentation may form.

Punch Biopsy.

Punch biopsy is a common dermatological procedure used to obtain a tissue sample for histological study or to remove small lesions. Its use is generally reserved for lesions smaller than 0.5 cm. Before local anaesthesia is used, the biopsy area is outlined so that landmarks

will not be obscured by the anaesthetizing agent. The biopsy punch instrument cores out a small cylinder of skin when its sharp edge is twirled between the fingers (Figure 26-13). The core of skin is snipped from the subcutaneous fat and appropriately preserved for examination in a fixative solution. Hemostasis is achieved by using methods as used with curettage, but sites of 4 mm or larger are often closed with sutures.

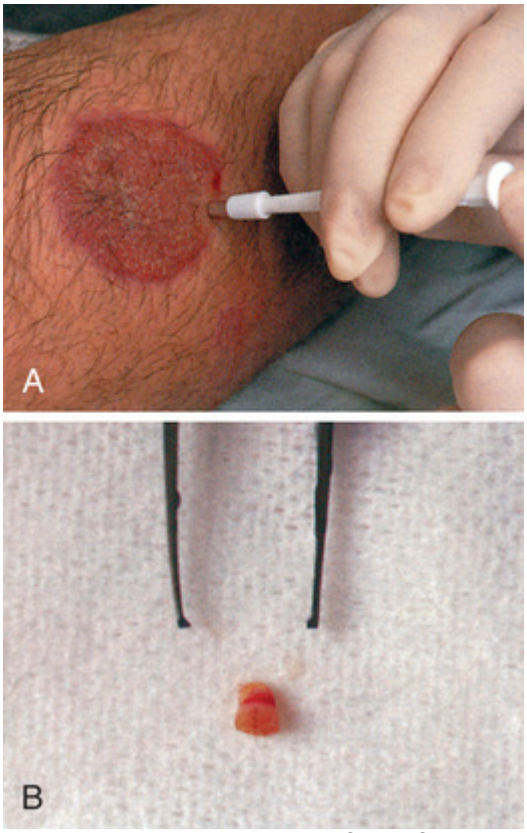

FIGURE 26-13 **Punch biopsy. A, Removal of skin for diagnostic purposes. B, Specimen obtained. Source: Graham-Brown, R., Bourke, J., & Cunliffe, T. (2008). *Dermatology: Fundamentals of practice*. Edinburgh: Mosby.**

Cryosurgery.

Cryosurgery is the use of subfreezing temperatures to destroy epidermal lesions. Cryosurgery is a useful treatment for common benign, precancerous conditions including common and genital warts, cutaneous tags, thin seborrheic keratoses, lentigines, actinic keratoses, BCC, and SCC. Topical liquid nitrogen is the agent most

commonly used for cryosurgery (Marks & Miller, 2013). The mechanism of injury involves direct cellular freezing as well as vascular stasis (stoppage or slowdown in the flow of blood), which develops after thawing. Intracellular ice formation causes the cell to rupture during thaw, leading to cell death and necrosis of the treated tissue.

Liquid nitrogen can be applied topically (directly onto the lesion) with a direct spray or cotton-tipped applicator. Patients usually feel a stinging cold sensation. The lesion will first become swollen and red, and it may blister. A scab forms and falls off in 1 to 3 weeks. The skin lesion is sloughed off along with the scab. Growth of new skin follows. The low temperature of the liquid nitrogen easily destroys melanocytes, leaving an area of hyperpigmentation resembling a scar. The size of the area to be treated may limit the use of cryotherapy. The major disadvantages of this treatment are lack of a tissue specimen for histological confirmation of cell type before destruction and potential for destruction of adjacent healthy tissue.

Excision.

Excision is an option if the lesion involves the dermis. Complete closure of the excised area usually results in a good cosmetic outcome. One type of excision is *Mohs surgery* (Figure 26-14), which is a microscopically controlled removal of a cutaneous malignancy. In this procedure, the health care provider removes tissue sections in thin horizontal layers. All of the specimen's margins are examined to determine whether any malignant cells remain. Any residual tumour not removed by the first surgical excision is removed in serial excisions performed the same day. Benefits of Mohs surgery are preserving normal tissue, producing the smallest possible wound, and completely removing the cancer before surgical closure. Although this can become a lengthy procedure, it is done in an outpatient setting using local anaesthesia.

Nursing Management Dermatological Problems

Ambulatory and Home Care

Dermatological conditions are not usually a primary reason for hospitalization. Nevertheless, many hospitalized patients will exhibit concurrent skin problems that warrant nursing intervention and patient education. Nursing interventions related to dermatological conditions fall into broad categories. They are applicable to many skin problems in both inpatient and outpatient settings. A nursing care plan for the patient with chronic skin lesions is available on the Evolve website.

Wet Dressings.

For superficial skin problems that involve inflammation, itching, and infection, wet compresses (dressings) are commonly used. They are appropriate for damaged, oozing skin. Wet compresses are an excellent way to remove crusts and scabs that are adhering to the wound surface. Wet compresses provide comfort and treatment of conditions such as poison ivy, insect bites, and skin infections.

It is important to understand how to do a wet dressing correctly. Unless there is a concern about water quality, tap water at room temperature is the best choice. If drinkable water is not available, filtered, bottled, or sterile water may be used. Depending on the skin problem, additives may be used. Antibacterial solutions may contain aluminum acetate (Domeboro powder), silver nitrate, or acetic acid. Close attention to appropriate concentrations is critical when additives are used. Wet compresses should generally be tepid. However, when an anti-inflammatory effect is desired, the wet dressing should be cool.

The material for wet compresses should be four to eight layers thick and slightly larger than the area being treated. Gauze or any clean material (e.g., thin cotton sheeting, thermal underwear, tube socks) may be used. Ingenuity is sometimes required when covering odd-shaped body parts. Gauze sponges with fillers (abdominal pads) should be avoided for this purpose, because they will retain too much solution, and fibres can be left in the wound if the skin is open. Compress material is placed into fresh solution and excess liquid squeezed out. The goal is a *wet* compress—not simply damp and not dripping.

Wet compresses are applied continuously or intermittently. When used continuously, new solution should be used as needed but no additional solution added since doing so can alter the concentration and damage the skin. Depending on the desired effect, intermittent compresses are placed for 10 to 30 minutes two to four times a day, always using clean materials. Careful monitoring of the skin is important. If the skin appears *macerated* (softens and turns white), the dressings should be discontinued for 2 to 3 days. The patient should be protected from discomfort and chilling. A water-resistant pad will help protect the mattress, linens, and furniture.

Baths.

Baths are appropriate when large body areas need to be treated. They also have sedative and antipruritic effects. Some medications, such as oilated oatmeal (Aveeno) and sodium bicarbonate, can be added directly to the bath water. The tub should be filled enough to cover affected areas. Both the bath water and the prescribed solution should be at a lukewarm (tepid) temperature. The patient can soak for 15 to 20 minutes three or four times a day, depending on the severity of the dermatitis and the patient's discomfort. It is important to stress to the patient that the skin must not be rubbed dry with a towel but gently patted to prevent increasing irritation and inflammation. The addition of oils makes a bathtub extremely slippery and should be avoided. If oils *are* used in the tub, the utmost caution must be used in transferring patients to prevent accidents. Applying scent-free cream or emollients (moisturizer) or topical agents to the skin directly after the bath helps sustain the hydrating effect by helping to seal moisture into hydrated cells.

Topical Medications.

Topical medications are commonly used to treat cutaneous problems. The effectiveness of topical therapy depends on which base the medication is prepared in. Table 26-13 summarizes the common agents used as bases for topical preparations and their therapeutic considerations. The base selected depends on the properties needed.

TABLE 26-13

DRUG THERAPY
Common Bases for Topical Medications

Agent	Therapeutic Considerations
Powder	Promotion of dryness. Lubrication of skin fold areas to prevent irritation. Increase in evaporation, absorbing of moisture possible. Common base for antifungal preparations. Patient must be protected from inhalation.
Lotion	Oil and water emulsions. Cooling and drying effect, with residual powder film after evaporation of water. Useful in subacute pruritic eruptions.
Cream	Oil and water emulsions. Most common base for topical medications. Affords lubrication and protection.
Ointment	Oil with differing amounts of water added in suspension. Lubrication and prevention of dehydration. Petrolatum most common.
Paste	Mixture of powder and ointment. Useful when drying effect necessary because moisture is absorbed.
Gel	Nongreasy combination of propylene glycol and water. May contain alcohol. Used for acute exudative inflammation (e.g., poison ivy contact dermatitis).

Creams are very versatile and most commonly prescribed. They are a mix of organic oils, water, and usually a preservative. Ointments are primarily organic oils with little or no water. Many are preservative free. They are more lubricating than creams and offer enhanced potency of the active ingredient. They may be too occlusive for conditions with high levels of exudate or in body creases. Gels work well on the scalp, where other compounds may mat the hair, and for acute exudative conditions such as poison ivy. Lotions can be a mix of water, alcohols, and oils. They are also appropriate for the scalp but may cause stinging and drying when used in skin folds. Pastes are a compound of 50% or more powder in an ointment base. They are good for protecting the skin but are messy. A limited number of foams are available.

Some of these medications are very costly. Proper administration, as directed, will yield best results, maintain consistency, and avoid waste. As a general rule, topical medication should be applied in a thin film to clean skin and spread evenly in a downward motion in the direction of hair growth, using a gloved hand. Thick creams will spread more easily if the skin is still damp. If a secondary dressing is going to be used, the medication may be applied directly onto a dressing. The patient and caregiver will need to be taught proper dosing, application technique, anticipated results, and common

reactions. Patients and caregivers should be reminded to wash hands with soap and water after applying topical medications at home.

Occlusion with a plastic wrap is an effective way of increasing the absorption of topical corticosteroids or simple emollients. The plastic wrap traps perspiration against the outer layer of the epidermis. Applying preparations to moist skin increases absorption ten-fold. Tape or stretch wraps can keep the plastic wrap in place. For conditions on the feet or lower legs, socks can be worn over the plastic wrap. Wraps applied multiple times daily are kept in place for 2 to 8 hours. Some patients choose to use the occlusion technique at bedtime. Occlusion is recommended with discretion because it is not appropriate in areas prone to infection, such as skin creases, or when high-potency corticosteroids or antibiotics are used.

Control of Pruritus.

Pruritus (itching) can be caused by almost any physical or chemical stimulus to the skin (e.g., drugs, insects), dry skin, or any scaling skin disorder. The itch sensation is carried by the same nonmyelinated nerve fibres as pain. If the epidermis is damaged or absent, the sensation will be felt as pain rather than itch.

The itch/scratch cycle must be broken to prevent excoriation and lichenification. Control of pruritus is also important because it is difficult to diagnose a lesion that is excoriated and inflamed. Certain circumstances make itching worse. Anything that causes vasodilation, such as heat or rubbing, should be avoided. Dryness of the skin lowers the itch threshold and increases the itch sensation.

There are several approaches to help break the itch/scratch cycle. A cool environment may cause vasoconstriction and decrease itching. Hydration, wet compresses, and moisturizers (including antipruritic lotions) are normally helpful. Topical and injectable corticosteroids are occasionally ordered. Topically applied menthol, camphor, or phenol can be used to numb the itch receptors. Systemic antihistamines may provide relief while the underlying cause of the pruritus is diagnosed and treated. The principal adverse effect of most antihistamines is sedation. This may be desirable because pruritus is often worse at night and can interfere with sleep.

Lichenification is a thickening of epidermis with exaggerated markings resembling a washboard. It is caused by chronic scratching or rubbing of the skin. Lichenification is often associated with atopic dermatoses and other pruritic conditions. Although any area of the body may be affected, the hands, forearms, shins, and nape of the neck are common sites. Itching may become habitual. The persistent scratching can cause excoriations. Treating the cause of the itching is the key to preventing lichenification.

Prevention of Spread.

Although most skin problems are not contagious, infection-control precautions indicate wearing gloves when working with any open wounds or lesions with drainage. Procedures should be explained to avoid demoralizing patients who may be sensitive about skin lesions. Careful handwashing and proper disposal of soiled dressings are the best means of preventing the spread of infections or infestations. The most common contagious lesions include impetigo, streptococcal infections, staphylococcal infections (e.g., methicillin-resistant *S. aureus* [MRSA]), fungal infections, primary chancre, scabies, and pediculosis.

Prevention of Secondary Infections.

Open skin lesions are susceptible to invasion by other viral, bacterial, or fungal organisms. Meticulous hygiene, handwashing, and dressing changes are important to minimize potential for secondary infections. Patients should be warned against scratching lesions, which can cause excoriations and create a portal of entry for pathogens. The patient's nails should be kept short to minimize trauma from scratching.

Specific Skin Care.

Nurses are often in a position to advise patients regarding care of the skin following simple dermatological surgical procedures, such as skin biopsy, excision, and cryosurgery. Patient follow-up should be individualized. In general, instructions include dressing changes, use of topical antibiotics, and the signs and symptoms of infection. After a dermatological procedure, any oozing wound should be

cleansed twice a day with a saline solution or as ordered by the health care provider. Soap and water can be used to clean a non-oozing wound. An antibiotic ointment or plain petroleum jelly may then be applied with a dressing that is both absorbent and nonadherent.

Wounds that are kept moist and covered heal more rapidly and with less scarring. The initial crust that forms should be left undisturbed as a protective coating for the damaged skin beneath. Healing crusts that have been moisturized and protected will separate naturally from healed epidermis.

A sutured wound may be covered with a variety of dressings. Sutures are generally removed within 4 to 14 days depending on the site. Sometimes alternating sutures are removed after the third day. Incision lines may require daily cleansing, usually with plain tap water. If necessary, a topical antibiotic is applied and the wound either covered with a dry sterile dressing or left open to air. The patient may experience some swelling and discomfort in the first 24 hours during the first phase of wound healing. Intermittent application of cold (ice packs) over the surgical dressing may reduce edema and promote comfort. Mild analgesics such as acetaminophen or a nonsteroidal anti-inflammatory medication should control discomfort. The patient should learn to differentiate normal inflammation from an infection. A slight red border during the first few days after a procedure is normal inflammation. Redness that persists longer than a week or extends beyond a 1 cm border, a fever above 38°C, increased pain, pronounced swelling, and purulent drainage are all signs and symptoms of a possible infection. If these occur, they should be promptly reported to the health care provider.

Psychological Effects of Chronic Dermatological Problems

Emotional stress can occur for people who suffer from chronic skin problems such as psoriasis, atopic dermatitis, or acne. The sequelae of chronic skin problems can include social and employment problems with subsequent financial implications, a poor self-image, problems with sexuality, and increasing and progressive frustration.

The usual lack of overt systemic illness coupled with the visibility of the skin lesions often presents a real problem to the patient.

Nurses are positioned to help the patient remain optimistic and adhere to the prescribed regimen. The patient must be allowed to verbalize the "Why me?" question, even though there is no ready answer. Dermatology patient support groups are listed on the CDA website (see the Resources at the end of this chapter). These groups are extremely helpful in providing patient support and accurate educational materials.

The location of lesions and scars is the determining factor with respect to cosmetic implications. Facial scars are the most damaging psychologically because they are so visible. Creative use of cosmetics can do much to mask lesions and scarring. Individual sensitivity to product ingredients must be considered when selecting cosmetics. Oil-free, hypoallergenic cosmetics are available and may be beneficial for the allergic patient. Rehabilitative cosmetics are available to help camouflage and de-emphasize such lesions as *vitiligo* (loss of pigmentation), *melasma* (tan to brown patches on the face), or healed postoperative wound sites. These commercially available products are opaque, smudge resistant, and water resistant.

Physiological Effects of Chronic Dermatological Problems

Scarring and lichenification are the result of chronic dermatological problems. Scars occur when ulceration takes place and reflect the pattern of healing in the area. Scars are pink and vascular at first. With time, in lighter-skinned people, they become avascular and white, and in individuals with darker skin, they may become hyperpigmented. Different regions of the body scar differently, such as the face and neck, which heal fairly well because they are well vascularized. Scar formation is described in Chapter 14.

Cosmetic Procedures

A vast array of cosmetic procedures is available, including chemical peels, toxin injections, collagen fillers, laser surgery, breast augmentation and reduction (see Chapter 54), laser surgery, facelift, eyelid lift, and liposuction. Common cosmetic topical procedures are presented in Table 26-14. Other types of common cosmetic injection procedures include the injection of botulinum toxins (Botox) and collagen (Xiaflex, Santyl). Transitory adverse effects such as mild redness, pain, swelling, and bruising may occur.

TABLE 26-14
COMMON COSMETIC TOPICAL PROCEDURES

Procedure	Indications	Description	Adverse Effects	Patient Teaching
Tretinoin (Retin-A)	Improves appearance of photodamaged skin, especially fine wrinkling. Reduces actinic keratosis.	Applied initially every other day, nightly as tolerated. Treatment stopped if inflammation is severe. Maximum response in 8–12 mo.	Erythema, swelling, flaking, photosensitivity, hypopigmentation. Teratogenic. Increases phototoxicity if also taking other photosensitive drugs (see Table 26-3).	Apply emollients, use sunscreen (SPF 15 or higher), use sun-avoidance measures, avoid use of abrasive or drying facial cleanser if severe sensitivity.
Chemical peels	Improves appearance of aged and photodamaged skin, acne scarring, freckles, actinic and seborrheic keratoses.	Solution applied (e.g., trichloracetic acid, phenol) in varying amounts to the skin, causing a controlled burn. Loss of melanin occurs.	Moderate swelling and crusting for 1 wk. Redness persisting 6–8 wk. Pink tone possible for several months. Photosensitivity.	Use sunscreen; avoid sun for 6 mo to prevent hyperpigmentation.
Microdermabrasion	Smoothes appearance of photodamaged and wrinkled skin, acne scarring.	Removal of the epidermis and top dermal layer by application of aluminum oxide or baking soda crystals. Re-epithelialization of abraded surface then occurs.	Light pink tone that resolves within 24 hr. Photosensitivity.	Generous application of emollients and sunscreen.
Alpha-hydroxy acids (e.g., glycolic acid, lactic acid)	Similar indications as for microdermabrasion. Also called a *minipeel* or *light chemical peel*.	Low concentrations (<10%) found in many skin care products that patients can self-administer. Higher concentrations (50%–70%) given only by a health care provider.	Photosensitivity, irritation at lower concentrations. Severe redness, oozing, and flaking skin possible for 1–4 wk with higher concentrations.	Sunscreen and sun avoidance.

SPF, sun protection factor.

The reasons for undergoing these procedures are as varied as the techniques. The most common reason that people suffer the discomfort and financial expense (most are not covered by insurance) of a cosmetic procedure is to improve their body image. If

patients feel better about themselves after having cosmetic procedures, they will often act more confident and self-assured. Often social position and economic considerations are part of the decision. Increased longevity provides a larger population to whom cosmetic procedures are especially appealing.

Regardless of the patient's reasons, the nurse should maintain a supportive, nonjudgemental attitude about these cosmetic procedures. If the patient wishes to change or enhance a body feature perceived as unattractive and has realistic expectations about the outcome, it is reasonable to support this decision.

Body Art and Tattoos

Body art through tattoos and skin piercings are popular means of self-expression. A tattoo is a permanent design that is made by injecting dyes into the skin's epidermal layer via a machine that creates tiny skin pricks. Patients should ensure tattoo and piercing establishments are certified through the local public health unit and that artists use new, sterile equipment and good hand hygiene and gloves. These measures minimize the risk of contracting a bloodborne disease (e.g., human immunodeficiency virus, hepatitis C) or skin infection. Tattoo dye contains metal, so a magnetic resonance imaging scan may not be able to be done over a tattooed site. Patients should be educated on how to care for tattoos and piercings at home in order to minimize infection risk. Important points include washing hands thoroughly before applying lotions or ointments to the tattooed or pierced area and before rotating jewellery and observing for signs of infection (pain, swelling, redness, or high temperature) and allergic reactions. Oral piercings require specific care: careful mouth hygiene (ideal bacterial breeding ground), plastic jewellery because metal chips the teeth, checking for loose pieces that could be a choking risk, and a mouth guard when playing sports (Simcoe Muskoka District Health Unit, n.d.).

Elective Surgery

Laser Surgery.

When a laser beam enters the skin, the light can affect skin structures by scattering, being absorbed, or passing through different layers. The spectrum of clinical application for each laser depends on the depth of the wavelength emitted and the operator technique. Laser surgery is used to treat congenital and acquired vascular lesions (cherry angiomas, spider leg veins, hemangiomas, port wine stains, and tattoo removal) and for skin resurfacing and hair removal. Lasers can reduce scarring and fine wrinkles around the lips or eyes and remove facial lesions (see Table 26-12). Swelling, redness, and bruising are common after treatment. The treated areas usually are kept moist with ointment or occlusive dressings for the first few days. The patient must protect treated skin from the sun.

Facelift.

A facelift *(rhytidectomy)* is the lifting and repositioning of the lower two-thirds of the face and neck to improve appearance (Figure 26-15). Indications for this procedure include the following:

FIGURE 26-15 Facelift. **A,** Before surgery. **B,** After surgery.

Source: Reprinted from *Facial Plastic Surgery Clinics of North America,* 13(3), Pastorek, N., & Bustillo, A. Deep Plane Face-Lift, Pages 433–449, Copyright 2005, with permission from Elsevier.

1. Redundant soft tissue resulting from disease (e.g., acne scarring).
2. Asymmetrical redundancy of soft tissues (e.g., facial palsy).
3. Redundant soft tissue resulting from trauma.
4. Preauricular lesions.
5. Redundant soft tissues resulting from solar elastosis (sagging of the skin as a result of sun damage), changes in body weight, and the effects of gravity.
6. Restoration of body image.

The surgical approach and the lines of incisions vary according to the nature of the deformity and the position of the hairline. Eyelid lifts *(blepharoplasty)* with similar indications are performed to remove redundant tissue and possibly improve the field of vision. Preventing hematoma formation is the most important postoperative consideration. Ice packs are usually applied during the first 24 to 48 hours to reduce swelling and decrease the possibility of hematoma formation. Usually pain is minimal. Antibiotics are used at the surgeon's discretion. Infection is not a common problem. Complications can occur if the person smokes or is involved in vigorous exercise.

Liposuction.

Liposuction is a technique for removing subcutaneous fat to improve facial and body contours. Although not a substitute for diet and exercise, it can be successful in removing areas of fat from virtually any body area that is resistant to other techniques.

Liposuction is relatively free of complications. Possible contraindications include use of anticoagulants, uncontrolled hypertension, diabetes mellitus, and poor cardiovascular status. People younger than 40 years of age with good skin elasticity are the best candidates, but those over 40 can be treated successfully.

The procedure is usually performed on an outpatient basis under local anaesthesia. One or more sessions may be necessary, depending on the size of the area to be treated. A blunt-tipped cannula is inserted through a 1.3-cm incision and pushed into the fat to break it loose from the fibrous stroma. Multiple repeated thrusts

disrupt the fat and create tunnels. The loosened fat is removed with a powerful suction. Afterwards, firm pressure is applied to the wounds, and compression garments are worn for 3 to 4 weeks (Afrooz, Pozner, & DiBernardo, 2014). Bandaging also helps to contour the skin. It may take several months for the results to be evident.

Nursing Management Cosmetic Surgery

Many cosmetic surgical procedures are performed in well-equipped day-surgery units or in office surgery suites. Nursing interventions are important, regardless of where the surgery was done.

Preoperative Management

A major preoperative management consideration relates to informed consent and realistic expectations of what cosmetic surgery can accomplish. Although this information is usually provided by the surgeon, the nurse should reinforce this information and answer questions and concerns. For instance, a facelift has little or no effect on deep wrinkling of the forehead and temples, deep nasolabial grooves, or vertical lip wrinkles. Before- and after-treatment photographs of similar cases are often useful in helping the patient to set realistic expectations.

The nurse's teaching plan should include the time frame for healing. The oozing, crusting stage of the abrasive procedure must be explained so the patient can plan time off from work if necessary. Since the third phase of wound healing does not become complete for 1 year, the patient should not anticipate complete results immediately. The final results of the cosmetic procedure are affected by the patient's age, general state of health, extent of procedure, and skin type. Efforts should be made to correct or control any existing health problem before the procedure.

Postoperative Management

Most cosmetic procedures are not extremely painful. Usually, mild analgesics are sufficient to keep the patient comfortable. Although

infection is not a common problem after cosmetic surgery, the nurse should assess surgical sites for signs of infection. The patient should be educated on signs of infection and know to report any such signs and symptoms immediately so that appropriate antibiotic intervention can be started.

If the surgery involved alteration to the skin's circulation, such as in a facelift, careful monitoring for adequate circulation is necessary. In light-skinned individuals, warm pink skin that blanches with pressure indicates that adequate circulation is present in the surgical area. Blanching does not occur in dark-skinned patients, so it is necessary to check for areas that are darker than surrounding skin and to check for local changes in skin texture and skin temperature. Supportive compression dressings and ice packs may be necessary early in the postoperative period.

Skin Grafts

Uses

Skin grafts may be necessary to provide protection to underlying structures or to reconstruct areas for functional or cosmetic purposes. They may be used to facilitate rapid closure and minimize complications. Ideally, wounds heal by primary intention. However, large wounds, surgically created wounds, trauma, and chronic wounds can result in extensive tissue destruction, making primary intention healing impossible. In these cases, skin grafting may be necessary to close the defect. Improved surgical techniques make it possible to graft skin, bone, cartilage, fat, fascia, muscles, and nerves. For cosmetically pleasing results, the colour, thickness, texture, and hair-growing nature of skin used for grafting should match the recipient site. (See Chapter 27 for further discussion of skin grafting.)

Types

The two types of skin grafts are free grafts and skin flaps. Free grafts are further classified according to the method of providing a blood supply to the grafted skin. One method is to transfer the graft (epidermis and part or all of the dermis) to the recipient site from the

donor site. If the graft is an *autograft* (from the patient's own body) or an *isograft* (from an identical twin), it will revascularize and become fixed to the new site. Chapter 27 discusses full- and split-thickness skin grafts in detail. Another method of free skin grafting is by *reconstructive microsurgery.* An operating microscope is used to immediately establish circulation in the graft by anastomosis of the blood vessels from the skin flap to the vessels in the recipient site.

Skin flaps involve moving a section of skin and subcutaneous tissue from one part of the body to another without terminating the vascular attachment *(pedicle).* Skin flaps are used to cover wounds with a poor vascular bed, to provide padding when needed, and to cover wounds over cartilage and bone. The patient may need intermediate flap placement if the recipient site is far removed from the donor site. For instance, a skin flap from the thigh to the head would require an intermediate graft. The flap is advanced to the recipient site when circulation is well established at the intermediate site. The patient's needs and the type of defect to be repaired determine the type of flap and the route of transfer. Soft tissue expansion is a technique for providing skin (1) for resurfacing a defect, such as a burn scar; (2) for removing a disfiguring mark (e.g., a tattoo); or (3) as a preliminary step in breast reconstruction. A subcutaneous tissue expander of an appropriate size and shape is placed under the skin, usually as an outpatient procedure. Weekly expansion with saline solution can be done in a health care setting or by the patient at home. This expansion procedure is repeated until the skin reaches the size needed for the repair. This may take from several weeks to 4 months. Once sufficient skin is available, the old incision is opened, the expander is removed, and the soft tissue is ready to be used as an advancement flap. The tissue expander next to a defect retains the primary tissue characteristics such as colour and texture.

Newer engineered skin substitutes (e.g., Dermagraft, Alloderm) are gaining popularity. There are a number available, and each offers its own benefits. Some are two-layered membranes with both dermal and epidermal components. Others are only one layer. The skin is engineered from neonatal foreskins and cadavers. Because the tissue is engineered, Langerhans cells are removed, reducing the risk for

rejection (Nathoo, Howe, & Cohen, 2014). Engineered skin grafts have an extended shelf life. Some are cryopreserved; others, shipped overnight as they are needed. Advantages include ready availability, the avoidance of a donor site, application in outpatient settings, minimal scarring, and less pain.

Case Study

Malignant Melanoma and Dysplastic Nevi

Source: tmcphotos/Shutterstock.com.

Patient Profile

Gordon Lindquist is a 46-year-old fair-skinned man who is a contract safety officer supervising large industrial construction sites. In his leisure time, he enjoys fishing and kayaking. He comes to the clinic for evaluation of a changing lesion on his left arm.

Subjective Data

- History of a basal cell carcinoma (BCC) on his left ear in the past 4 years
- Father treated for metastatic malignant melanoma in the past 2 years
- First noted the lesion 5 months ago, when it started changing size
- Anxious the lesion might have spread and require extensive, disfiguring surgery

Objective Data

Physical Examination

- Has a 4-mm lesion, dark brown/black, scalloped with vaguely defined borders to dorsum of left forearm just distal to the elbow
- Has a large number of small nevi (>50) on back, legs, and arms
- Has four dysplastic nevi on back

Diagnostic Studies

- Excisional biopsy confirmed malignant melanoma.
- Sentinel node biopsy results were negative.
- Diagnostic tests indicate melanoma stage 1.

Discussion Questions

1. What risk factors for malignant melanoma does Mr. Lindquist have?
2. What are the usual clinical manifestations associated with malignant melanoma?
3. What is the prognosis for a patient with this stage of malignant melanoma?
4. What treatment options are available for him?
5. ***Priority decision:*** What is the priority of care for Mr. Lindquist?
6. How would the nurse address Mr. Lindquist's anxiety over the treatment outcomes?
7. What should the nurse include in the patient teaching plan to address future sun exposure?
8. ***Priority decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?

9. ***Evidence-informed practice:*** Mr. Lindquist wants to know whether regularly applying sunscreen will reduce his risk for developing a second melanoma. How should the nurse reply?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Which sun-safety practices would the nurse include in the teaching plan for a client who has photosensitivity? *(Select all that apply)*
   a. Wear protective clothing.
   b. Apply sunscreen liberally and often.
   c. Use tanning booths only for short durations.
   d. Avoid exposure to the sun, especially during midday.
   e. Wear any sunscreen as long as it is purchased at a drugstore.
2. In teaching a client who is using topical corticosteroids to treat acute dermatitis, what information should the nurse include? *(Select all that apply)*
   a. The cream form is the most efficient system of delivery.
   b. Short-term use of topical corticosteroids usually does not cause systemic adverse effects.
   c. Apply creams and ointments with a glove in small amounts to prevent further infection.
   d. Abruptly discontinuing the use of topical corticosteroids may cause a reappearance of the dermatitis.
   e. Malnourishment is a risk factor for systemic adverse effects from topical corticosteroids.
3. What measurement is the prognosis of a client with malignant melanoma most dependent on?
   a. The thickness of the lesion
   b. The degree of asymmetry in the lesion
   c. How much the lesion has spread superficially
   d. The amount of ulceration in the lesion
4. The nurse determines that a client with a diagnosis of which disorder is most at risk for spreading the disease?

a. Tinea pedis
b. Impetigo on the face
c. Candidiasis of the nails
d. Psoriasis on the palms and soles

5. A mother and her two children have been diagnosed with pediculosis corporis at a health centre. Which of the following is an appropriate measure in treating this condition?
   a. Application of pyrethrins to the body
   b. Topical application of an antifungal ointment
   c. Moist compresses applied frequently
   d. Administration of systemic antibiotics
6. What is a common site for the lesions associated with atopic dermatitis?
   a. Buttocks
   b. Temporal area
   c. Antecubital space
   d. Plantar surface of the feet
7. During assessment of a client, the nurse notes on the client's knee and elbow red, sharply defined plaques covered with silvery scales that the client reports as mildly itchy. What should the nurse recognize this finding to be?
   a. Lentigo
   b. Psoriasis
   c. Actinic keratosis
   d. Seborrheic keratosis
8. A patient with acne vulgaris tells the nurse that she has quit her job as a receptionist because she feels her appearance is disgusting to customers. Which of the following nursing diagnoses best describes this patient's response?
   a. *Ineffective coping* related to *insufficient social support*
   b. *Impaired skin integrity* related to *inadequate nutrition*

c. *Anxiety* related to *unmet needs* (lack of knowledge about the disease process)

d. *Social isolation* related to *alteration in physical appearance*

9. What important point should client teaching after a chemical peel include?

a. Avoidance of sun exposure

b. Application of firm bandages

c. Limitation of vigorous exercise

d. Use of moist heat to prevent discomfort

1. a, b, d; 2. b, d; 3. a; 4. b; 5. a; 6. c; 7. b; 8. d; 9. a.

CHAPTER 27

Nursing Management

Burns

Written by, Judy Knighton

LEARNING OBJECTIVES

1. Explain the causes of burn injuries and prevention strategies.
2. Differentiate between partial- and full-thickness burns.
3. Apply the parameters used to determine the severity of burns.
4. Compare the pathophysiological processes, clinical manifestations, complications, and collaborative management throughout the three burn phases.
5. Compare the fluid and electrolyte shifts during the emergent and the acute burn phases.
6. Differentiate the nutritional needs of the patient with a burn injury throughout the three burn phases.
7. Compare the various burn wound care techniques and surgical options for partial-thickness versus full-thickness burn wounds.
8. Prioritize nursing interventions in the management of the physiological and psychosocial needs of the patient throughout the three burn phases.
9. Examine the various physiological and psychosocial aspects of burn rehabilitation.
10. Design a plan of care to prepare the burn patient and family for discharge.

thermal burns, p. 531

A **burn** is an injury to the tissues of the body caused by heat, chemicals, electric current, or radiation. The resulting effects are influenced by the temperature of the burning agent, the duration of contact time, and the type of tissue that is injured.

While there is a lack of precise data on the number of Canadians burned each year, there is some consistency between two existing data sources. The Institute for Clinical Evaluative Sciences (ICES, 2005) found that, in one year in Ontario, there were 157 emergency department visits for hot object/scald (115) and fire/flame (42) per 100 000 people. Based on a population of 35 million people in Canada, it could then be estimated that approximately 54 950 Canadians are burned each year, severely enough to require a visit to an emergency department. According to Statistics Canada (2011), 44 450 Canadians over the age of 12 years stated that they had an activity-limiting injury due to a burn, scald, or chemical burn in the previous 12 months. The highest incidence occurred within the 20–64 years age group, and treatment predominantly occurred in the emergency department.

An estimated 486 000 Americans seek medical care each year for burns (American Burn Association [ABA], 2016). Accounting for the 2016 population difference between the United States and Canada (324 million versus 36 million), the burn incidence data appear similar. Around the world, nearly 11 million people need medical attention annually for burn injuries, and about 265 000 die as a result of burns (World Health Organization, 2016).

Although burn incidence has decreased over the past 20 years, burn injuries still occur too frequently, mainly to those in a lower socioeconomic

level and with histories of substance abuse or mental illness. Most burn incidents are preventable (Taira, Cassara, Meng, et al., 2011). The focus of burn prevention has shifted from blaming individuals and changing behaviours to making legislative changes and collecting global burn data to address the unique prevention needs of low- and middle-income countries (Peck, 2012).

Coordinated national programs in developed countries have focused on child-resistant lighters, nonflammable children's clothing, tap water anti-scald devices, stricter building codes, hard-wired smoke detectors and alarms, and fire sprinklers. Nurses can advocate for and teach about burn risk–reduction strategies in the home and at work (Tables 27-1 and 27-2).

TABLE 27-1
COMMON LOCATIONS AND SOURCES OF BURN INJURY*

Home Hazards
Kitchen and Bathroom
• Microwaved food • Steam, hot grease, or liquids from cooking • Hot water heaters set at 60°C or higher
General Household
• Heat lamps • Fireplaces (e.g., gas, wood) • Open space heaters • Radiators (e.g., home, automobile) • Outdoor grills (e.g., propane, charcoal) • Frayed or defective wiring • Multiple extension cords per outlet
• Flammables (e.g., starter fluid, gasoline, kerosene) • Carelessness with cigarettes, matches, candles
Occupational Hazards
• Tar • Cement • Chemicals • Hot metals • Steam pipes • Combustible fuels • Fertilizers, pesticides • Electricity from power lines • Sparks from live electric sources

*List is not all-inclusive.

TABLE 27-2

TYPES OF BURN INJURY AND BURN RISK–REDUCTION STRATEGIES

Flame or Contact
• Never smoke in bed. • Use child-resistant lighters. • Hold regular fire exit drills in the home. • Never leave hot oil unattended while cooking. • Never use gasoline or other flammable liquids to start a fire. • Never leave candles unattended or near open windows or curtains. • Consider a flame-retardant smoking apron for older or at-risk people. • Exercise caution when microwaving food and beverages as they can get very hot. **Scald** • Lower hot water temperature to the "lowest point" or 40°C. • Use "anti-scald" devices with showerhead or faucet fixtures. • Supervise bathing of small children, older adults, or anyone with impaired physical movement, physical sensation, or judgement. • After running bath water, check temperature with back of hand or bath thermometer.
Inhalation
• Install smoke and carbon monoxide detectors and change batteries annually (if appropriate). **Chemical** • Store chemicals safely in approved containers, and label clearly. • Ensure safety of workers and students handling chemicals (e.g., provide education, protective eyewear, gloves, masks, clothing). **Electrical** • Avoid or repair frayed wiring. • Avoid outdoor activities during electrical (i.e., lightning) storms. • Ensure electrical power source is shut off before beginning repairs. • Wear protective eyewear and gloves when making electrical repairs.

Types of Burn Injury

Thermal Burns

Thermal burns are caused by flame, flash fire, scald, or contact with hot objects. They are the most common type of burn injury (Figure 27-1; see Table 27-2). The severity depends on the temperature of the burning agent and duration of contact time. Scald injuries can occur in the bathroom or while cooking. Flash, flame, or contact burns can occur while cooking, smoking, burning leaves in the backyard, or using gasoline or hot oil.

FIGURE 27-1 Types of burn injury. **A,** Superficial, partial-thickness scald burn to thigh. **B,** Deep partial-thickness flame burn to hand. **C,** Full-thickness flame burn secondary to posterior chest and arm.

Source: Courtesy Judy A. Knighton, RN, MScN, Toronto.

Chemical Burns

Chemical burns are the result of contact with acids, alkalis, and organic compounds. Acids are found in the home and at work and include hydrochloric, oxalic, and hydrofluoric acid. Alkali burns can be more difficult to manage than acid burns since alkalis adhere to tissue, causing protein hydrolysis and liquefaction. Alkalis are found in cement, oven and drain cleaners, and heavy industrial cleansers (Summers, 2013). Organic compounds, including phenols (chemical disinfectants) and petroleum

products (creosote and gasoline), produce contact burns and systemic toxicity.

Smoke and Inhalation Injury

Smoke and inhalation injuries from breathing noxious chemicals or hot air can cause damage to the tissues of the respiratory tract. Fortunately, gases are cooled to body temperature before they reach the lung tissue. The vocal cords and glottis close as a protective mechanism, so damage to the respiratory mucosa occurs less often. Smoke inhalation injuries are a major predictor of mortality in burn patients. Rapid initial and ongoing assessment are critical (Table 27-3). Assess for signs and symptoms of airway compromise and pulmonary edema that can develop over the first 12 to 48 hours (Jeschke, 2013).

TABLE 27-3

MANIFESTATIONS OF RESPIRATORY INJURY ASSOCIATED WITH BURNS

Upper Airway Injury
Edema, hoarseness, difficulty swallowing, copious secretions, stridor, substernal and intercostal retractions, total airway obstruction
Lower Airway Injury
Strongly assumed if patient was trapped in a fire in an enclosed space or clothing caught fire and if patient has facial burns or singed nasal or facial hair; symptoms include dyspnea, carbonaceous sputum, wheezing, hoarseness, altered mental status

There are three types of smoke and inhalation injuries:

1. *Carbon monoxide poisoning.* Carbon monoxide poisoning and asphyxiation account for the majority of deaths at a fire scene. Carbon monoxide is produced by the incomplete combustion of burning materials. It is subsequently inhaled and displaces oxygen (O_2) on the hemoglobin molecule, causing carboxyhemoglobinemia, hypoxia, and, when the carbon monoxide levels exceed 20%, death. With severe carbon monoxide poisoning, skin colour is often described as "cherry red" in appearance. Carbon monoxide poisoning may occur in the absence of burn injury to the skin (e.g., smoke inhalation during a fire).
2. *Inhalation injury above the glottis.* In general, an inhalation injury above the glottis *(upper airway injury)* is thermally produced and may be caused by the inhalation of hot air, steam, or smoke. Mucosal burns of the oropharynx and larynx are manifested by

redness, blistering, and edema. Mechanical obstruction can occur quickly, which represents a true medical emergency. Clues to the occurrence of this injury include the presence of facial burns, singed nasal hair, hoarseness, painful swallowing, darkened oral and nasal membranes, carbonaceous sputum, history of being burned in an enclosed space, and clothing burns around the chest and neck.

3. *Inhalation injury below the glottis.* An inhalation injury below the glottis *(lower airway injury)* is usually chemically produced. Tissue damage is related to the duration of exposure to smoke or toxic fumes. Clinical manifestations such as pulmonary edema may not appear until 12 to 24 hours after the burn, and then they may manifest as acute respiratory distress syndrome (see Chapter 70).

Electrical Burns

Electrical burns result from intense heat generated from an electric current. Direct damage to nerves and vessels, causing tissue anoxia and death, can also occur. The severity of the electrical injury depends on the amount of voltage, tissue resistance, current pathways, surface area in contact with the current, and length of time that the current flow was sustained (Figure 27-2). Tissue density affects the amount of resistance to electric current. For example, fat and bone offer the most resistance, whereas nerves and blood vessels offer the least resistance. Current that passes through vital organs (e.g., brain, heart, kidneys) produces more life-threatening sequelae than that which passes through other tissues. In addition, electric sparks may ignite the patient's clothing, causing a flame injury.

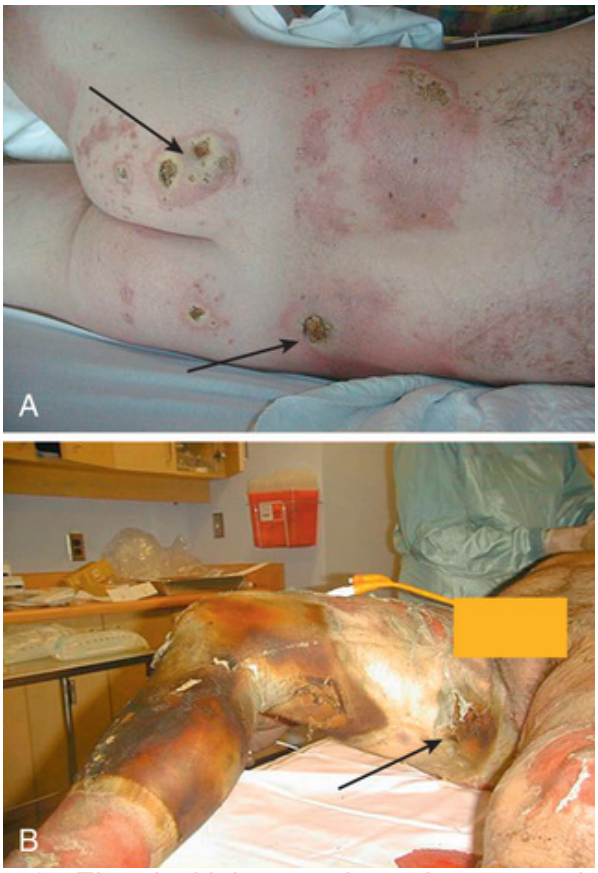

FIGURE 27-2 Electrical injury produces heat coagulation of the blood supply and contact area as electric current passes through the skin. **A,** Back and buttock *(arrows).* **B,** Leg *(arrow).* Source: Courtesy Judy A. Knighton, RN, MScN, Toronto.

As with inhalation injury, a rapid assessment of the patient with an electrical injury should be performed. Transfer to a burn centre is indicated. The severity of an electrical injury can be difficult to determine since most of the damage is below the skin (known as the *iceberg effect*). Determination of electric current contact points and history of the injury may help reveal the likely path of the current and potential areas of injury. Contact with electric current can cause muscle contractions strong enough to fracture the long bones and vertebrae. Another reason to suspect long bone or spinal fractures is a fall resulting from the electrical injury. For this reason, consider all patients with electrical burns at risk for a cervical spine injury. Use cervical spine immobilization during transport and subsequent diagnostic testing until injury is ruled out.

Electrical injury puts the patient at risk for dysrhythmias or cardiac arrest, severe metabolic acidosis, and myoglobinuria (Saracogli, Kuzucuoglu, Yakupoglu, et al., 2014). Electric shock can cause immediate

asystole or ventricular fibrillation. Delayed dysrhythmias or arrest can also occur without warning during the first 24 hours after injury. Myoglobin from injured muscle and hemoglobin from damaged red blood cells (RBCs) are released into the circulation whenever massive muscle and blood vessel damage occurs. The released myoglobin travels to the kidneys and can block the renal tubules. This can result in acute tubular necrosis (ATN) and acute kidney injury (see Chapter 49).

Cold Thermal Injury

Cold thermal injury, or frostbite, is discussed in Chapter 71.

Classification of Burn Injury

Treatment of burns is related to the severity of the injury. Severity is determined by (a) depth of burn, (b) extent of burn calculated in percentage of total body surface area (TBSA), (c) location of burn, and (d) patient risk factors (e.g., age, past medical history). Health Canada uses referral criteria to determine which burn injuries should be treated in burn centres (Table 27-4). Critical Care Services Ontario (CCSO) has adapted American Burn Association (ABA) "Burn Center Referral Criteria" to develop "Burns Centre Consultation Guidelines" (see Table 27-4). A list of provincial burn units and centres across Canada is found in Table 27-5. The majority of patients with minor burn injuries can be managed in community hospitals or on an outpatient basis (Payne & Cole, 2012).

TABLE 27-4

CRITERIA FOR TRANSFER OF THE PATIENT WITH BURN INJURIES*

Consider transfer to a major burn centre:

- ≥20% TBSA partial- and/or full-thickness at any age
- ≥10% TBSA partial- and/or full-thickness for ages ≤10 and ≥50
- Full-thickness burns ≥5% TBSA at any age
- Burns to face, hands, feet, joints, genitalia, perineum
- Electrical burns [including lightning injury]
- Chemical burns
- Inhalation injury
- Burns with comorbidity
- Burns with patients who require special social, emotional, or rehabilitation care

Consider transfer to a minor burn centre:

- Burns >10% but <20% TBSA in adults

Remain at base site:

- Burns <10% TBSA in adults who do not require transfer but seek medical advice or an ambulatory burns clinic referral for assessment

Special considerations:

High-risk considerations which may warrant transfer at a lower clinical threshold. These considerations include:

- ≥50 years of age
- Anticoagulation
- Immuno-suppression
- Pregnancy
- Diabetes
- Other significant medical problems

Source: Developed by Judy Knighton, RN, MScN, clinical nurse specialist—burns. (2015, April). Data collected for Canadian Special Interest Group Meeting, American Burn Association Meeting, Chicago.

Goals of care include wound healing, prevention of infection, pain management, prevention of complications, and return to preinjury function.

Depth of Burn

Burn injury involves the destruction of the integumentary system. The skin is divided into three layers: epidermis, dermis, and subcutaneous tissue (Figure 27-3). The *epidermis,* or nonvascular outer layer of the skin, is approximately as thick as a sheet of paper. It is composed of many layers of nonliving epithelial cells that provide a protective barrier to the skin, hold in fluids and electrolytes, help regulate body temperature, and keep harmful agents in the external environment from injuring or invading the

body. The *dermis,* which lies below the epidermis, is approximately 30 to 45 times thicker than the epidermis. The dermis contains connective tissues with blood vessels and highly specialized structures consisting of hair follicles, nerve endings, sweat glands, and sebaceous glands. Under the dermis lies *subcutaneous tissue,* which contains major vascular networks, fat, nerves, and lymphatic vessels. The subcutaneous tissue acts as a heat insulator for underlying structures, which include the muscles, tendons, bones, and internal organs.

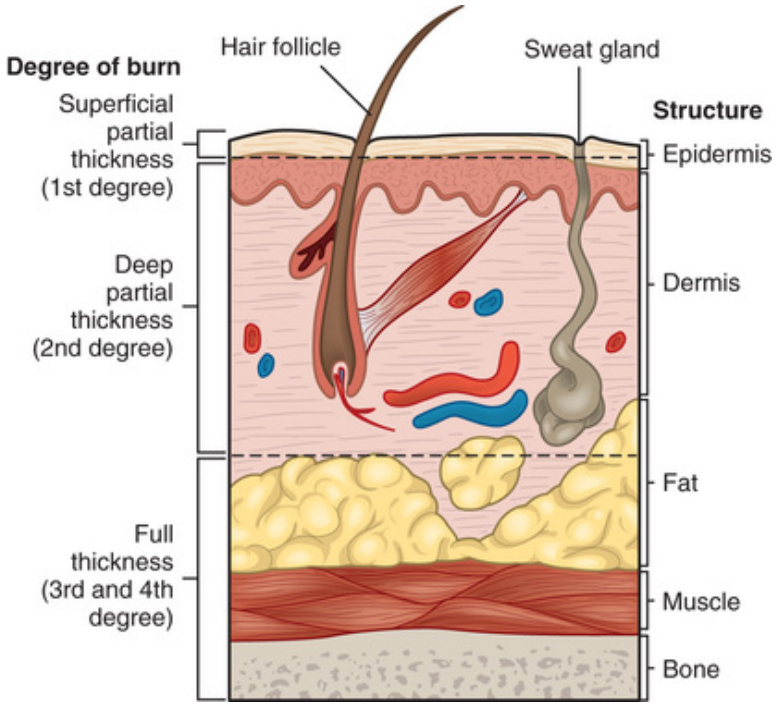

FIGURE 27-3 Cross-section of skin indicating the depth of burn and structures involved.

Burns continue to be defined by degrees: first-, second-, third-, and fourth-degree. The ABA recommends a more precise definition, classifying them according to depth of skin destruction: **partial-thickness burn** and **full-thickness burn** (see Figure 27-3). Partial-thickness burns have varying degrees of epidermal and dermal skin injury, with some skin elements remaining viable for regeneration. Full-thickness burns involve the destruction of all skin elements and subcutaneous tissues, with the possible involvement of muscles, tendons, and bones. Skin-reproducing (re-epithelializing) cells are located along the shafts of the hair follicles, sweat glands, and sebaceous glands. If there is significant damage to the dermis (e.g., a full-thickness burn), not enough skin cells remain to

regenerate new skin. A permanent, alternative source of skin is then needed. In Table 27-6, the various burn classifications are compared according to depth of injury.

TABLE 27-6
CLASSIFICATION OF BURN INJURY DEPTH

Classification	Clinical Appearance	Possible Cause	Structures Involved
Partial-Thickness Skin Destruction			
Superficial: first-degree burn	Erythema, blanching on pressure, pain and mild swelling, no vesicles or blisters (although after 24 hr, skin may blister and peel)	Superficial sunburn Quick heat flash	Superficial epidermal damage with hyperemia; tactile and pain sensation intact
Deep: second-degree burn	Fluid-filled vesicles that are red, shiny, wet (if vesicles have ruptured); severe pain caused by nerve injury; mild to moderate edema	Flame Flash Scald Contact Chemical Tar Electrical current	Epidermis and dermis involved to varying depth; skin elements, from which epithelial regeneration occurs, remain viable
Full-Thickness Skin Destruction			
Third- and fourth-degree burns	Dry, waxy-white, leathery, or hard skin; visible thrombosed vessels; insensitivity to pain because of nerve destruction; possible involvement of muscles, tendons, and bones	Flame Scald Chemical Tar Electrical current	All skin elements and local nerve endings destroyed; coagulation necrosis present; surgical intervention advisable for healing

Extent of Burn

Two commonly used guides for determining the TBSA affected or the extent of a burn wound are the adult Lund–Browder chart (Figure 27-4, A) and the adult rule of nines chart (Figure 27-4, B). (First-degree burns, equivalent to a sunburn, are not included when TBSA burned is calculated.) The Lund–Browder chart is considered more accurate because the patient's age, in proportion to relative body-area size, is taken into account. The rule of nines, which is easy to remember, is considered adequate for initial assessment of an adult patient with burn injury. For irregular or odd-shaped burns, the size of the patient's hand (including the fingers) is approximately 1% TBSA.

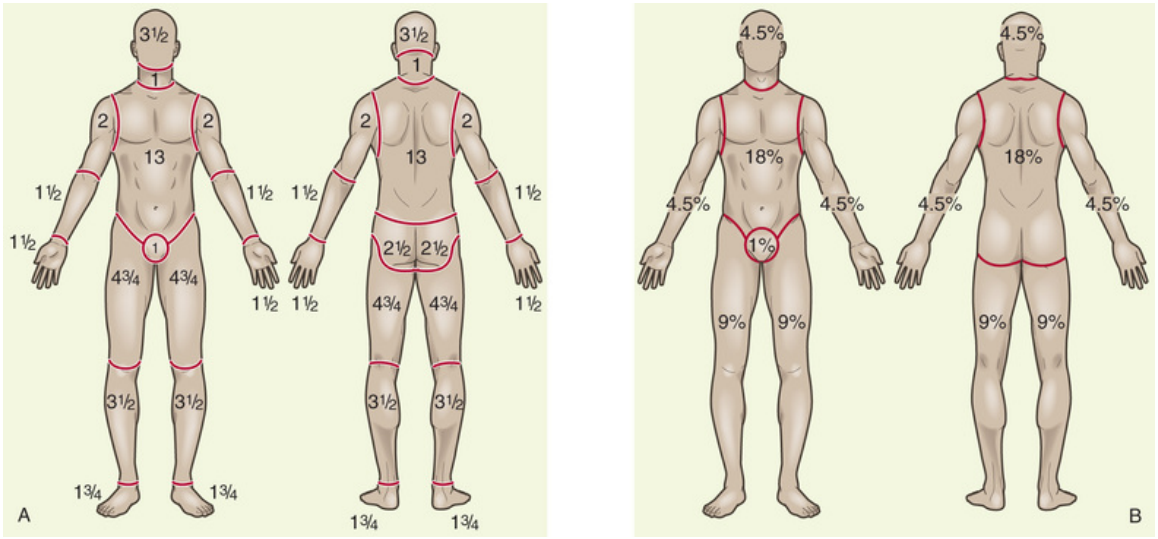

FIGURE 27-4 **A,** Adult Lund–Browder chart. By convention, areas of partial-thickness injury are coloured in blue, and areas of full-thickness in red. Superficial partial-thickness burns are not calculated. **B,** Adult rule of nines chart.

An additional tool is the Sage Burn Diagram, a free, Internet-based tool available for estimating TBSA burned (see the Resources at the end of this chapter). There are also mobile applications (e.g., uBurn, Mersey Burns) available to estimate the percentage of burn and fluid resuscitation needs (Faraklas, Ghanem, Brown, et al., 2013). The extent of a burn is often revised after edema has subsided and demarcation of the zones of injury has occurred.

Location of Burn

The severity of the burn injury is related to the location of the burn wound. Burns to the face and neck and circumferential burns to the trunk or back can result in mechanical obstruction, secondary to edema, and leathery, devitalized tissue formation *(eschar),* both of which may inhibit respiratory function. These injuries may also include possible inhalation injury and respiratory mucosal damage.

Burns to the hands, feet, joints, and eyes are of concern because they make self-care very difficult and may jeopardize future function. Burns to the hands and feet are challenging to manage because of superficial vascular and nerve supply systems that must be protected and because of the need to maintain hand function during healing.

Burns to the ears and nose are susceptible to infection because the skin is very thin and the underlying skeleton frequently exposed. Burns to the

buttocks or perineum are at high risk for infection from urine or feces contamination. Circumferential burns to the extremities can cause circulatory compromise distal to the burn and, subsequently, neurological impairment of the affected extremity. Patients may also develop compartment syndrome (see Chapter 65) from direct heat damage to muscles; edema may result, and preburn vascular problems can be exacerbated.

Patient Risk Factors

The older adult heals more slowly and usually experiences more difficulty with rehabilitation than a younger adult. Any patient with pre-existing cardiovascular, respiratory, or renal disease has a poorer prognosis for recovery because of the tremendous demands placed on the body by a burn injury. The patient with diabetes mellitus or peripheral vascular disease is at high risk for poor healing especially with leg and foot burns (Somerset, Coffey, Jones, et al., 2014) General physical debilitation from any chronic disease—including alcoholism, drug abuse, or malnutrition—renders the patient less physiologically able to recover from a burn injury. In addition, the patient with a burn injury who has concurrently sustained other injuries—fractures, head injuries, or other trauma—has a poorer prognosis for recovery.

Phases of Burn Management

Historically, burn management has been organized chronologically into three phases that correspond to the key priority of each particular phase: emergent (resuscitative), acute (wound healing), and rehabilitative (restorative). Care overlaps from one phase to another. For example, although the emergent phase is seen as beginning in the emergency department, care often begins in the prehospital phase, depending on the skill level of paramedics at the scene. Planning for rehabilitation begins on the day of the burn injury or admission to the burn unit. Formal rehabilitation begins as soon as functional assessment can be performed. Wound care is the primary focus of the acute phase, but it also takes place in both the emergent and rehabilitative phases.

Prehospital Care

At the injury scene, priority is given to removing the person from the source of the burn and stopping the burning process. Rescuers must also protect themselves from being injured. In the case of electrical and chemical injuries, initial management involves removal of the patient from the electrical or chemical source.

Small thermal burns (<10% of TBSA) should be covered with a clean, cool, tap water–dampened towel for the patient's comfort and protection until definitive medical care is instituted. Cooling of the injured area (if small) within 1 minute helps minimize the depth of the injury. If the burn area is large (>10% TBSA) or an electrical or inhalation burn is suspected and the patient is unresponsive, attention needs to be focused first on CAB (**c**irculation, **a**irway, **b**reathing):

- *Circulation:* Check for presence of pulses and elevate the burned limb(s) above the heart to decrease pain and swelling.
- *Airway:* Check for patency, soot around nares and on the tongue, singed nasal hair, darkened oral or nasal membranes.
- *Breathing:* Check for adequacy of ventilation.

If the patient is responsive, the nurse's priorities would follow the order of the ABCs: **a**irway, **b**reathing, and **c**irculation.

To prevent hypothermia, large burns should be cooled for no more than 10 minutes. Do not immerse the burned body part in cold water because doing so might lead to extensive heat loss. Never cover a burn with ice because this can cause hypothermia and vasoconstriction of blood vessels, further reducing blood flow to the injury. Gently remove as much burned clothing as possible to prevent further tissue damage. Adherent clothing should be left in place until the patient is transferred to a hospital. The patient should be wrapped in a dry, clean sheet or blanket to prevent further contamination of the wound and to provide warmth.

Chemical burns are best treated by quickly removing the solid particles and powder from the skin. (For information on handling specific agents, refer to a hazardous materials text.)

Watch patients with inhalation injuries closely for signs of respiratory distress or compromise. Patients who have both body burns and inhalation injury must be transferred to the nearest burn unit.

Patients with burns may also have sustained other injuries that take priority over the burn wound. It is important for individuals involved in the prehospital phase of burn care to adequately communicate the circumstances of the injury to hospital-based health care providers. This is especially important when the patient's injury involves entrapment in a closed space, hazardous chemicals, electricity, or possible trauma (e.g., fall).

Prehospital management and emergency management are described for chemical burns in Table 27-7, for inhalation injury in Table 27-8, for electrical burns in Table 27-9, and for thermal burns in Table 27-10.

TABLE 27-7

EMERGENCY MANAGEMENT
Chemical Burns

Cause	Assessment Findings	Interventions
• Acids • Alkalis • Organic compounds	• Burning • Redness, swelling of injured tissue • Degeneration of exposed tissue • Discoloration of injured skin • Localized pain • Edema of surrounding tissue • Degeneration of exposed tissue (tissue destruction continuing for up to 72 hr) • Respiratory distress if chemical inhaled • Decreased muscle coordination (if organophosphate is involved) • Paralysis	**Initial** 1. If unresponsive, assess circulation, airway, and breathing before decontamination procedures are done. 2. If responsive, monitor airway, breathing, and circulation before decontamination procedures are done. 3. Stabilize cervical spine. 4. Provide supplemental oxygen as needed. 5. Anticipate intubation with significant inhalation injury, circumferential full-thickness burns to the neck and trunk, or large TBSA burn. 6. Brush dry chemical from skin before irrigation. 7. Remove nonadherent clothing, shoes, watches, jewellery, and, if face was exposed, glasses or contact lenses. 8. Flush chemical from wound and surrounding area with copious amounts of saline solution or water. 9. For chemical burn of the eye, flush from inner to outer corner of eye with water unless lactated Ringer's solution is available. 10. Cover burned areas with dry dressings or clean sheet. 11. Establish IV access with two large-bore catheters if burn >15% TBSA. 12. Begin fluid replacement. 13. Insert urinary catheter if adult burn >15% TBSA. 14. Elevate burned limb above level of heart to decrease edema. 15. Administer IV analgesic drug and assess effectiveness frequently. 16. Contact poison control centre for assistance. **Ongoing Monitoring** • Monitor airway if patient was exposed to chemicals. • Monitor urine output. • Consider possibility of systemic effect of identified chemical, and monitor and treat accordingly. • Monitor pH of eye if eye was exposed to chemicals. • Monitor pain level.

IV, intravenous; *TBSA,* total body surface area.

TABLE 27-8

EMERGENCY MANAGEMENT
Inhalation Injury

Cause	Assessment Findings	Interventions
• Exposure of respiratory tract to intense heat or flames • Inhalation of noxious chemicals, smoke, or carbon monoxide	• History of being trapped in an enclosed space, of being in an explosion, or of clothing catching fire • Rapid, shallow respirations • Increasing hoarseness • Coughing • Singed nasal or facial hair • Darkened oral or nasal membranes • Smoky breath • Carbonaceous sputum • Productive cough with black, grey, or bloody sputum • Irritation of upper airways or burning pain in throat or trunk • Difficulty swallowing • Cherry-red skin colour (carbon monoxide levels >20%) • Restlessness, anxiety • Altered mental status, including confusion, coma • Decreased oxygen saturation • Dysrhythmias	**Initial** 1. If unresponsive, assess circulation, airway, and breathing. 2. If responsive, monitor airway, breathing, and circulation. 3. Stabilize cervical spine. 4. Assess for inhalation injury. 5. Assess for concurrent thermal burn. 6. Provide 100% humidified oxygen. 7. Monitor vital signs, level of consciousness, oxygen saturation, and cardiac rhythm. 8. Remove nonadherent clothing, jewellery, and, if face was exposed, glasses or contact lenses. 9. Establish IV access with two large-bore catheters if burn >15% TBSA. 10. Begin fluid replacement. 11. Insert urinary catheter if burn >15% TBSA. 12. Elevate burned limb(s) above level of heart to decrease edema. 13. Measure arterial blood gas and carboxyhemoglobin levels, and obtain chest radiograph. 14. Administer IV analgesic drug and assess effectiveness frequently. 15. Identify and treat other associated injuries (e.g., fractures, pneumothorax, head injury). 16. Cover burned areas with dry dressings or clean sheet if TBSA is large or patient is hypothermic; can cover with normal saline–moistened gauze and clean sheet if TBSA is small. 17. Anticipate need for fibre-optic bronchoscopy or intubation. **Ongoing Monitoring** • Monitor airway, breathing, and circulation. • Monitor urine output. • Monitor vital signs, level of consciousness, respiratory status, oxygen saturation, and cardiac rhythm. • Monitor pain level.

IV, intravenous; *TBSA,* total body surface area.

TABLE 27-9

EMERGENCY MANAGEMENT
Electrical Burns

Cause	Assessment Findings	Interventions
Alternating Current • Electrical wires • Utility wires **Direct Current** • Lightning • Defibrillator	• Leathery, white, or charred skin • Burn odour • Loss of consciousness • Impaired touch sensation • Minimal or no pain • Dysrhythmias • Cardiac arrest • Location of contact points • Diminished peripheral circulation in injured extremity • Thermal burns if clothing ignited • Fractures or dislocations from force of current • Head or neck injury if fall occurred • Depth and extent of wound difficult to visualize (injury should be presumed more severe than what is seen)	**Initial** 1. Remove patient from electric source while protecting rescuer. 2. If unresponsive, assess circulation, airway, and breathing. 3. If responsive, monitor airway, breathing, and circulation. 4. Stabilize cervical spine. 5. Provide supplemental oxygen as needed. 6. Monitor vital signs, level of consciousness, respiratory status, oxygen saturation, and cardiac rhythm. 7. Check pulses distal to burns. 8. Remove nonadherent clothing, shoes, watches, jewellery, and, if face was exposed, glasses or contact lenses. 9. Cover burned areas with dry dressing or clean sheet if TBSA is large or patient is hypothermic; can cover with normal saline–moistened gauze and dry sheet if TBSA is small. 10. Establish IV access with two large-bore catheters if burn >15% TBSA. 11. Begin fluid replacement. 12. Measure arterial blood gas to assess acid–base balance. 13. Insert urinary catheter if burn >15% TBSA. 14. Elevate burned limb(s) above level of heart to decrease edema. 15. Administer IV analgesic drug and assess effectiveness frequently. 16. Identify and treat other associated injuries (e.g., fractures, pneumothorax, head injury). **Ongoing Monitoring** • Monitor airway, breathing, and circulation. • Monitor vital signs, cardiac rhythm, level of consciousness, respiratory status, oxygen saturation, and neuro-vascular status of injured limbs. • Monitor urine output. • Monitor serum creatine kinase for development of myoglobinuria secondary to muscle breakdown and urine for hemoglobinuria secondary to RBC breakdown. • Anticipate possible administration of $NaHCO_3$ to alkalinize the urine and maintain serum pH >6.0. • Monitor pain level.

IV, intravenous; *$NaHCO_3$,* sodium bicarbonate; *RBC,* red blood cell; *TBSA,* total body surface area.

TABLE 27-10

EMERGENCY MANAGEMENT
Thermal Burns

Cause	Assessment Findings	Interventions
• Hot liquids or solids • Flash flame • Open flame • Steam • Hot surface • UV rays	**Partial-Thickness Burn** ***Superficial; First-Degree Burn***	**Initial** 1. If unresponsive, assess circulation, airway, and breathing. If responsive, monitor airway, breathing, and circulation. 2. Stabilize cervical spine. 3. Assess for inhalation injury. 4. Provide supplemental oxygen as needed. 5. Anticipate endotracheal intubation and mechanical ventilation with circumferential, full-thickness burns to the neck, trunk, or both or with large TBSA. 6. Monitor vital signs, level of consciousness, respiratory status, oxygen saturation, and cardiac rhythm. 7. Remove nonadherent clothing, shoes, watches, jewellery, and, if face was exposed, glasses or contact lenses. 8. Cover burned areas with dry dressings or clean sheet if TBSA is large or patient is hypothermic; cover with normal saline–moistened gauze and dry sheet if TBSA is small. 9. Establish IV access with two large-bore catheters if burn >15% TBSA. 10. Begin fluid replacement. 11. Insert urinary catheter if burn >15% TBSA. 12. Elevate burned limb(s) above level of heart to decrease edema. 13. Administer IV analgesic drug and assess effectiveness frequently. 14. Identify and treat other associated injuries (e.g., fractures, pneumothorax, head injury).
	• Redness • Pain • Moderate to severe tenderness • Minimal edema • Blanching with pressure	
	Deep; Second-Degree Burn	
	• Moist blebs, blisters • Mottled white, pink to cherry red • Hypersensitive to touch or air • Moderate to severe pain • Blanching with pressure	
	Full-Thickness; Third- or Fourth-Degree Burn	
	• Dry, leathery eschar • White, waxy, dark brown, or charred appearance • Strong burn odour • Impaired sensation when touched • Absence of pain with severe pain in surrounding tissues • Lack of blanching with pressure	**Ongoing Monitoring** • Monitor airway, breathing, and circulation. • Monitor vital signs, cardiac rhythm, level of consciousness, respiratory status, and oxygen saturation. • Monitor urine output. • Monitor pain level.

IV, intravenous; *TBSA*, total body surface area; *UV*, ultraviolet.

Emergent Phase

The *emergent (resuscitative) phase* is the period of time required to resolve the immediate, life-threatening problems resulting from the burn injury (Hampson, Piantadosi, Thom, et al., 2012). This phase usually lasts up to 72 hours from the time of the burn. Primary concerns are the onset of hypovolemic shock and formation of edema. The phase ends when fluid mobilization and diuresis begin.

Pathophysiological Changes

Fluid and Electrolyte Shifts.

The greatest initial threat to a patient with a major burn is hypovolemic shock. It is caused by a massive shift of fluids out of the blood vessels as a result of increased capillary permeability and can begin as early as 20 minutes after the burn injury. As the capillary walls become more permeable, water, sodium, and, later, plasma proteins (especially albumin) move into interstitial spaces and other surrounding tissue (Figure 27-5). The colloidal osmotic pressure decreases with progressive loss of protein from the vascular space. This results in the shifting of more fluid out of the vascular space into the interstitial spaces (Figure 27-6). (Fluid accumulation in the interstitium is termed *second spacing*.) Fluid also moves to areas that normally have minimal to no fluid, a phenomenon termed *third spacing*. Examples of third spacing in burn injury are exudate and blister formation, as well as edema in nonburned areas.

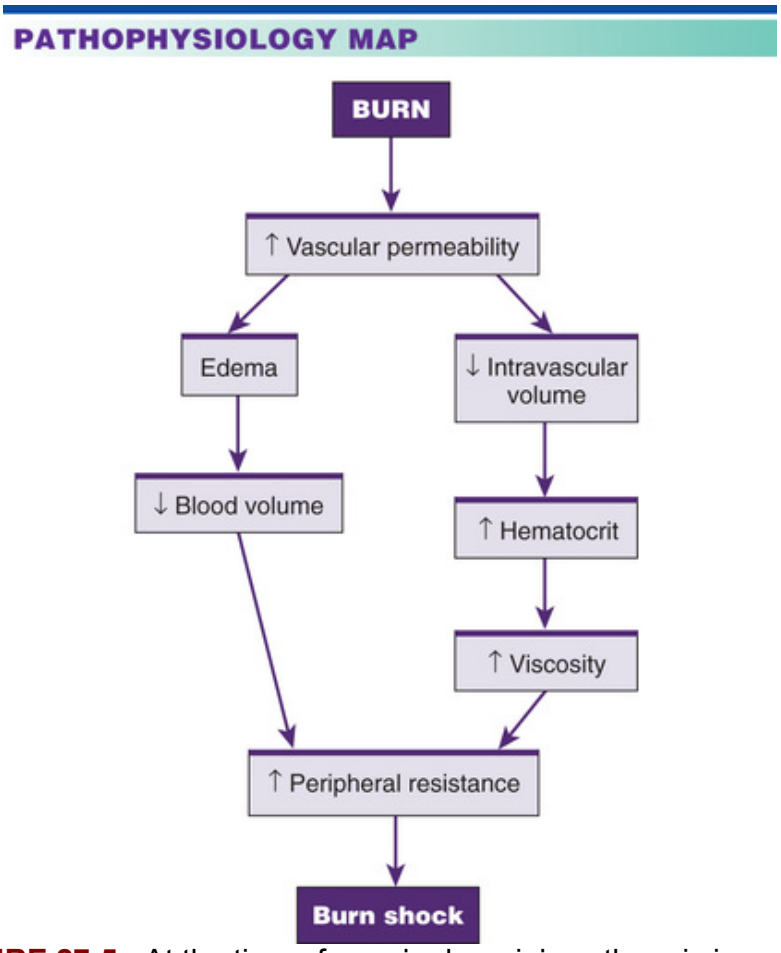

FIGURE 27-5 At the time of a major burn injury, there is increased capillary permeability. All fluid components of the blood begin to leak into the interstitium, causing edema and a decrease in blood volume. Hematocrit increases, and the blood becomes more viscous. The combination of decreased blood volume and increased viscosity produces increased peripheral resistance. Burn shock, a type of hypovolemic shock, rapidly ensues, and, if it is not corrected, death can result.

FIGURE 27-6 **A,** Facial edema before fluid resuscitation. **B,** Facial edema after 24 hours. Source: Courtesy Judy Knighton, Toronto, Canada.

Other sources of fluid loss during this period are insensible losses by evaporation from large, denuded body surfaces and the respiratory system. The normal insensible loss of 30 to 50 mL per hour is increased in severely burned patients. The net result of the fluid shifts and losses is intravascular volume depletion. Decreased blood pressure (BP), increased heart rate, and other manifestations of hypovolemic shock are clinically detectable signs of intravascular volume depletion (see Chapter 69). If it is not corrected, irreversible shock and death may result. The circulatory status is also impaired because of hemolysis of RBCs. The RBCs are hemolyzed by circulating factors (e.g., oxygen free radicals) released at the time of the burn, as well as by the direct insult of the burn injury. Thrombosis in the capillaries of burned tissue causes an additional loss of circulating RBCs. Elevation of the hematocrit is commonly caused by hemoconcentration, which results from fluid loss. After fluid balance has been restored, hematocrit levels lower as a result of dilution.

Major shifts in sodium and potassium also occur during this phase. Sodium rapidly shifts to the interstitial spaces and remains there until edema formation ceases (Figure 27-7). A potassium shift develops initially because injured cells and hemolyzed RBCs release potassium into the circulation. (Fluid and electrolyte shifts are discussed in Chapter 19.)

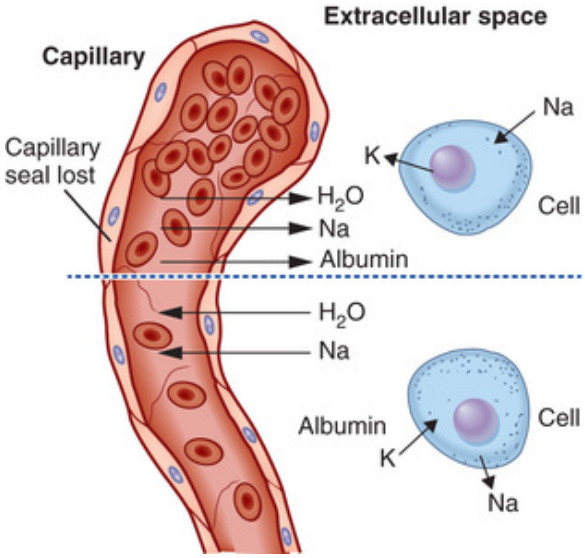

FIGURE 27-7 The effects of burn shock are shown above the dotted line. As the capillary seal is lost, interstitial edema develops. The cellular integrity is also altered, with sodium *(Na)* moving into the cell in abnormal amounts and potassium *(K)* leaving the cell. The shifts after the resolution of burn shock are shown below the dotted line. The water and sodium move back into the circulating volume through the capillary. The albumin remains in the interstitium. Potassium is transported into the cell, and sodium is transported out as the cellular integrity returns.

Toward the end of the emergent phase, capillary membrane permeability is restored if fluid replacement is adequate. Fluid loss and edema formation cease. Interstitial fluid gradually returns to the vascular space (see Figure 27-7). Clinically, diuresis is noted with low urine specific gravities.

Inflammation and Healing.

Burn injury causes coagulation necrosis, in which tissues and vessels are damaged or destroyed. Neutrophils and monocytes accumulate at the site of injury. Fibroblasts and newly formed collagen fibrils appear and begin wound repair within the first 6 to 12 hours after injury. (The inflammatory response is discussed in Chapter 14.)

Immunological Changes.

Burn injury causes widespread impairment of the immune system. The skin barrier to invading organisms is destroyed, bone marrow depression occurs, and circulating levels of immunoglobulins decrease. The function of white blood cells (WBCs) becomes defective. The inflammatory cytokine

cascade triggered by tissue damage impairs the function of lymphocytes, monocytes, and neutrophils. This impaired function increases the patient's risk for infection.

Clinical Manifestations

Patients with burns are likely to be in shock from hypovolemia. In many cases, areas of full-thickness and deep partial-thickness burns are initially anaesthetic because nerve endings have been destroyed. Superficial to moderate partial-thickness burns are painful. Blisters, filled with fluid and protein, may develop in partial-thickness burns. Fluid is not actually lost from the body as much as it is sequestered in the interstitium and third spaces. Patients with a larger burn area may have signs of adynamic ileus, such as absent or decreased bowel sounds, as a result of the body's response to massive trauma and potassium shifts. Shivering may occur as a result of chilling caused by heat loss, anxiety, or pain. Ongoing nursing assessment of the ABCs, vital signs, cardiac rhythm, oxygenation, and level of consciousness are priorities during the emergent phase of burn care.

Most patients with burn injuries are quite alert and can provide answers to questions shortly after the injury or until they are intubated. They are often frightened and benefit from calm reassurance and simple explanations by all health care providers. Unconsciousness or altered mental status in a patient with burn injury is usually not a result of the burn. The most common reason for unconsciousness or altered mental status is hypoxia associated with smoke inhalation. Other possibilities include head trauma, history of substance abuse, or excessive amounts of sedation or pain medication.

Complications

The three major organ systems most susceptible to complications during the emergent phase of burn injury are the cardiovascular, respiratory, and urinary systems.

Cardiovascular System.

Cardiovascular system complications include dysrhythmias and hypovolemic shock, which may progress to irreversible shock. Circulation to the extremities can be severely impaired by deep, circumferential burns and subsequent edema formation. These processes occlude the blood supply by acting like a tourniquet. If they are untreated, ischemia,

paresthesias, and necrosis can occur. To restore circulation to compromised extremities, an **escharotomy** (a scalpel or electrocautery incision into necrotic tissue) is frequently performed after the patient's transfer to a burn unit (Figure 27-8).

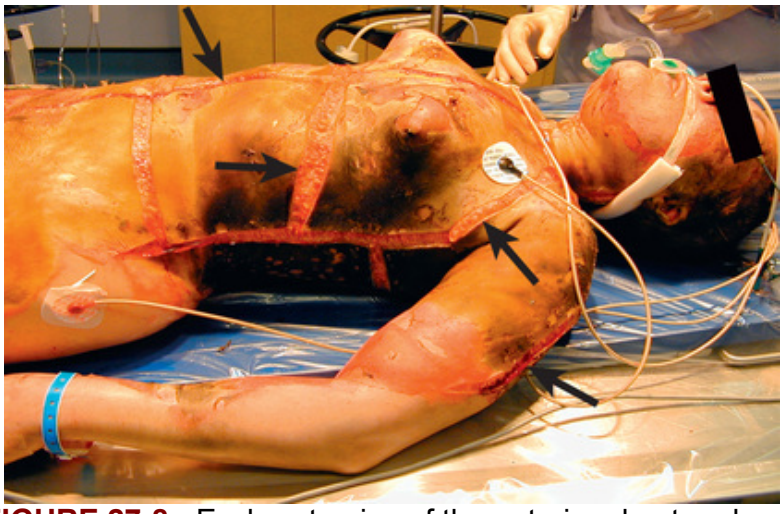

FIGURE 27-8 Escharotomies of the anterior chest and arm (indicated by *arrows*). Source: Courtesy Judy A. Knighton, RN, MScN, Toronto.

Initially, blood viscosity increases with burn injuries because of fluid loss occurring in the emergent period. Microcirculation is impaired because of damage to skin structures containing small capillary systems. These two events result in a phenomenon termed *sludging*. Sludging can be corrected by adequate fluid replacement.

Respiratory System.

The respiratory system is especially vulnerable to two types of injury: (a) upper airway burns, which cause edema formation and obstruction of the airway, and (b) lower airway injury (see Table 27-3). Upper airway distress may occur with or without smoke inhalation, and airway injury at either level may occur in the absence of burn injury to the skin.

Upper Airway Injury.

Upper airway injury results from an inhalation injury to the mouth, oropharynx, or larynx. The injury may be caused by thermal burns or the inhalation of hot air, steam, or smoke. Mucosal burns of the oropharynx and larynx are manifested by redness, blistering, and edema. The swelling can be massive, and the onset rapid. Flame burns to the neck and chest

may make breathing more difficult because of burn eschar, which becomes tight and constricting from underlying edema. Swelling from scald burns to the face and neck can also be lethal, as can external pressure from edema pressing on the airway. Mechanical obstruction can occur quickly, presenting a true airway emergency.

Carefully assess the patient for facial burns, singed nasal hair, hoarseness, painful swallowing, darkened oral and nasal membranes, carbonaceous sputum, history of being burned in an enclosed space, and clothing burns around the neck and trunk.

Lower Airway Injury.

An inhalation injury to the trachea, bronchioles, and alveoli is usually caused by breathing in toxic chemicals or smoke. Tissue damage is related to the duration of exposure to toxic fumes or smoke. Clinical manifestations of lower airway lung injury are presented in Table 27-3. Pulmonary edema may not appear until 12 to 48 hours after the burn and may manifest as acute respiratory distress syndrome (ARDS) (see Chapter 70).

Other Cardiopulmonary Problems.

Burn-injured patients with pre-existing heart disease (e.g., myocardial infarction) or lung disease (e.g., chronic obstructive pulmonary disease) are at risk for complications. If fluid replacement is too vigorous, these patients can develop heart failure or pulmonary edema. Invasive measures (e.g., hemodynamic monitoring) may be necessary to monitor fluid resuscitation.

Burn-injured patients with pre-existing respiratory problems are more likely to develop a respiratory infection. Pneumonia is a common complication of major burns and the leading cause of death in patients with inhalation injury. Debilitation, abundant microbial flora, and relative immobility predispose such patients to the development of pneumonia.

Urinary System.

The most common complication of the urinary system in the emergent phase is ATN. If the patient becomes hypovolemic, blood flow to the kidneys decreases, causing renal ischemia. If the decreased flow rate continues, acute kidney injury may develop.

With full-thickness and electrical burns, myoglobin (from muscle cell breakdown) and hemoglobin (from RBC breakdown) are released into the bloodstream and occlude renal tubules. Adequate fluid replacement and

diuretics can counteract myoglobin and hemoglobin obstruction of the tubules.

Nursing and Collaborative Management Emergent Phase

In the emergent phase, patient survival depends on rapid and thorough assessment and intervention (Fahlstrom, Boyle, & Makic, 2013). The nurse and physician make the initial assessment of depth and extent of the burn and coordinate the actions of the health care team. In a community hospital, decisions must be made as to whether the patient requires inpatient or outpatient care and, in the case of inpatient care, whether the patient remains in that hospital or is transferred to the closest regional burn unit (see Table 27-5). From the onset of the burn event until the patient is stabilized, nursing and collaborative management consist predominantly of airway management, fluid therapy, and wound care (Table 27-11).

TABLE 27-11

COLLABORATIVE CARE
Patient With Burn Injury

Emergent Phase	Acute Phase	Rehabilitation Phase
Fluid Therapy • Assess fluid needs.* • Begin IV fluid replacement. • Insert urinary catheter. • Monitor intake and output. **Wound Care** • Start daily shower/cleansing and wound care. • Debride as necessary. • Assess extent and depth of burns. • Administer tetanus toxoid or tetanus antitoxin. **Pain and Anxiety** • Assess and manage pain and anxiety. **Psychosocial Care** • Provide support to patient and family during initial crisis phase. **Respiratory Therapy** • Assess oxygenation needs. • Provide supplemental oxygen as needed. • Intubate if necessary. • Monitor respiratory status. **Physiotherapy and Occupational Therapy** • Place patient in position that prevents contracture formation and reduces edema. • Assess need for splints or devices such as pressure relief/reduction mattresses to decrease tissue ischemia and potential for skin breakdown. • Turn and reposition patient frequently to allow for appropriate circulation to tissues. **Nutritional Therapy** • Assess nutritional needs and begin feeding patient by most appropriate route as soon as possible.	**Fluid Therapy** • Continue to monitor intake and output. • Continue to replace fluids, depending on patient's clinical response. **Wound Care** • Continue daily shower and wound care. • Assess wound daily and adjust dressing protocols as necessary. • Observe for complications (e.g., infection). • Continue debridement (if necessary). **Pain and Anxiety** • Continue to assess for and treat pain and anxiety. **Psychosocial Care** • Continue to provide ongoing support, counselling, and education to patient and family about physical and emotional aspects of care and recovery. • Begin to anticipate discharge needs. **Respiratory Therapy** • Continue to assess oxygenation needs. • Continue to monitor respiratory status. • Monitor for signs of complications (e.g., pneumonia). **Physiotherapy and Occupational Therapy** • Have patient begin daily therapy program for maintenance of range of motion. • Assess need for splints and anticontracture positioning. • Encourage and assist patient with self-care as possible. **Nutritional Therapy** • Continue to assess diet to support wound healing. **Other TherapyEarly Excision and Grafting*** • Provide temporary homografts. • Provide permanent autografts. • Care for donor sites. **Drug Therapy*** • Assess need for medications.	• Continue to counsel and teach patient and caregiver about wound care. • Discuss possible need for home care to continue wound care in the community. • Continue to counsel and teach patient and family. • Continue to encourage and assist patient in resuming self-care. • Continue to prevent or minimize contractures (surgery, physiotherapy and occupational therapy, splinting, or pressure garments), and assess likelihood for scarring. • Discuss possible reconstructive surgery. Prepare for discharge home or transfer to rehabilitation unit or hospital.

Emergent Phase	Acute Phase	Rehabilitation Phase
	• Continue to monitor effectiveness of and necessity for medications. • Titrate medications and discontinue as appropriate.	

*See Tables 27-12, 27-13, and 27-14.

IV, intravenous.

Although burn management can be chronologically categorized as emergent, acute, and rehabilitative, overall care requirements are not so easily classified. Depending on the severity of the patient's condition, the duration of time spent in each phase varies greatly, and conditions improve and worsen unpredictably on a daily basis. Care changes accordingly. Whereas physiotherapy and occupational therapy are a focus of the acute and rehabilitative phases, proper positioning and splinting begin at the time of admission. Support and teaching of patients and caregivers begin on admission and intensify in the rehabilitative phase. See the accompanying nursing care plan NCP 27-1 (Patient With a Thermal Burn Injury) on the Evolve website.

Airway Management

Airway management frequently involves early endotracheal (preferably orotracheal) intubation. Early intubation eliminates the necessity for emergency tracheostomy after respiratory problems have become apparent. In general, patients with major injuries that include burns to the face and neck require intubation within 1 to 2 hours after burn injury. (Intubation is discussed in Chapter 68.) After intubation, such patients are placed on ventilatory assistance, and the delivered oxygen concentration is determined from an assessment of arterial blood gas (ABG) values. Extubation may be indicated when the edema resolves, usually 3 to 6 days after burn injury, unless severe inhalation injury is involved. Escharotomies of the trunk may be needed to relieve respiratory distress secondary to circumferential, full-thickness burns to the neck and trunk (see Figure 27-8).

Within 6 to 12 hours after injury in which smoke inhalation is suspected, a fibre-optic bronchoscopy should be performed to assess the lower airway. Significant findings include the appearance of carbonaceous material, mucosal edema, vesicles, erythema, hemorrhage, and ulceration.

When intubation is not performed, treatment of inhalation injury includes administration of 100% humidified oxygen as needed. Patients should be placed in a high Fowler's position unless it is contraindicated

(e.g., because of spinal injury), and coughing and deep breathing every hour should be encouraged. Patients should be repositioned every 1 to 2 hours, and chest physiotherapy and suctioning performed as necessary. If respiratory failure develops, intubation and mechanical ventilation are initiated. Positive end-expiratory pressure may be used to prevent collapse of the alveoli and progressive respiratory failure (see Chapter 68). Bronchodilators may be administered to treat severe bronchospasm. Carbon monoxide poisoning is treated by administering 100% oxygen until carboxyhemoglobin levels return to normal. The use of hyperbaric oxygen therapy to treat carbon monoxide poisoning is contraindicated in the presence of a body burn as it delays important burn care.

Fluid Therapy

Establishing IV access that can accommodate large volumes of fluid is critical for fluid resuscitation and medication administration. At least two large-bore IV access routes must be obtained for patients with burns over more than 15% TBSA. For patients with burns over more than 30% TBSA, a central line for fluid and medication administration, as well as a line for blood sampling, should be considered if frequent ABGs or invasive BP monitoring is needed.

A standardized chart is used to assess the extent of the burn wound (see Figure 27-4), allowing for accurate estimation of fluid resuscitation requirements.

The type of fluid replacement is determined by size and depth of burn, age of the patient, and individual considerations, such as pre-existing chronic illness. Fluid replacement is accomplished with crystalloid solutions (usually lactated Ringer's solution), colloids (albumin), or a combination of the two. Paramedics generally administer IV saline until the patient's arrival at the hospital.

The Parkland (Baxter) formula for fluid replacement is the formula most commonly used to estimate fluid replacement (Table 27-12; see also the Parkland Formula for Burns calculator in the Resources for this chapter). It is important to remember that all formulas yield estimates, which must be titrated on the basis of the patient's physiological response. For example, in patients with an electrical injury or inhalation injury, fluid requirements may be greater than normal and include an osmotic diuretic (mannitol) and sodium bicarbonate to alkalize the urine. Too much fluid and overestimation of TBSA contribute to the development of fluid over-resuscitation or “fluid creep” (Fahlstrom, Boyle, & Makic, 2013).

TABLE 27-12
FLUID RESUSCITATION WITH THE PARKLAND (BAXTER) FORMULA*

Formula		
4 mL of lactated Ringer's solution per kilogram of body weight per percentage of TBSA burned = Total fluid requirements for first 24 hr after burn**Application** 50% of total in first 8 hr 25% of total in second 8 hr 25% of total in third 8 hr		
Example		
For a 70-kg patient with a burn on 50% of TBSA:		
4 mL × 70 kg × 50% of TBSA burned	=	14 000 mL, or 14 L, in 24 hr
50% of total in first 8 hr	=	7 000 mL (875 mL/hr)
25% of total in second 8 hr	=	3 500 mL (438 mL/hr)
25% of total in third 8 hr	=	3 500 mL (438 mL/hr)

*Formulas are guidelines. Fluid is administered at a rate to produce 0.5–1.0 mL/kg/hr of urine output.

TBSA, total body surface area.

Colloidal solutions (e.g., albumin) may be given. However, administration is recommended in the first 12 to 24 hours after the burn injury, when capillary permeability returns to normal or near normal. After this time, the plasma remains in the vascular space and expands the circulating volume. The replacement volume is calculated on the basis of the patient's body weight and TBSA burned (e.g., 0.3 to 0.5 mL/kg per percentage of TBSA burned).

The adequacy of fluid replacement is best assessed according to clinical parameters. Urine output, the most commonly used parameter, and cardiac parameters are defined as follows:

1. *Urine output:* The goal is generally 0.5 to 1 mL/kg/hour for most patients with burn injuries but increases to 75 to 100 mL/hour for patients with an electrical burn and evidence of hemoglobinuria or myoglobinuria.
2. *Cardiac factors:* Mean arterial pressure is greater than 65 mm Hg, systolic BP is greater than 90 mm Hg, and heart rate is less than 120 beats/minute. Mean arterial pressure and BP are most appropriately measured by means of an arterial line. Peripheral measurement is often invalid because of vasoconstriction and edema.

Wound Care

Once a patent airway, adequate circulation, and adequate fluid replacement have been established, the priority is care of the burn wound. Full-thickness burn wounds are dry and waxy white to dark brown or black and have only minor, localized sensation because nerve endings have largely been destroyed. Partial-thickness burn wounds appear pink to cherry red and are wet and shiny with serous exudate. These wounds may or may not have intact blisters and are painful when touched or open to air due to exposed nerve endings.

Cleansing and gentle debridement, with the use of scissors and forceps, can occur on a cart shower (Figure 27-9), a regular shower, or the patient's bed or stretcher. Extensive, surgical debridement is performed in the operating room (Figure 27-10). During **debridement,** necrotic skin is removed from the wound to prevent infection and promote healing. Releasing escharotomies and fasciotomies can be carried out in the emergent phase, usually in burn units by burn physicians.

FIGURE 27-9 Cart shower. Showering presents an opportunity for wound care and physiotherapy. Source: Courtesy Judy A. Knighton, RN, MScN, Toronto.

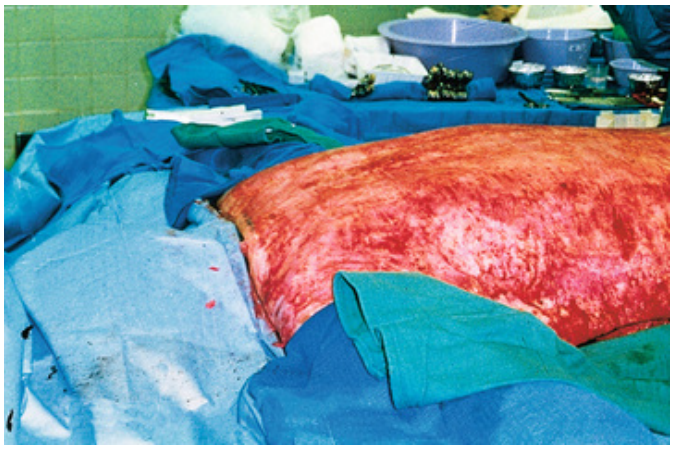

FIGURE 27-10 Surgical debridement of full-thickness burns is necessary to prepare the wound for grafting. Source: Courtesy Judy Knighton, Toronto, Canada.

Patients find the initial wound care to be both physically and psychologically demanding. Patients are showered with tap water not exceeding 40°C. A once-daily shower and dressing change in the morning, followed by a dressing change in the patient's room in the evening, are part of a common routine in many burn units. Some of the newer antimicrobial dressings can be left in place from 3 to 14 days, thereby decreasing the frequency of dressing changes.

Infection is the most serious risk, leading to further tissue injury and possible sepsis (Shahrokhi, 2014). The source of infection in burn wounds is the patient's own flora, predominantly from the skin (burned and unburned), respiratory tract, and gastro-intestinal tract. The prevention of cross-contamination between one patient and another is a priority for all members of the health care team.

Two approaches to burn wound treatment are the open method and the closed method, using multiple dressing changes. In the *open method*, the patient's burn is covered with a topical antimicrobial and has no dressing over the wound. In the *multiple–dressing change* or *closed method*, sterile gauze dressings are impregnated with or laid over a topical antimicrobial. These dressings are changed at various intervals, from every 12 to 24 hours to once every 14 days, depending on the product. Most burn units support the concept of moist wound healing and use dressings to cover the burned areas, except for the burned face.

When the patient's open burn wounds are exposed, staff must wear personal protective equipment (e.g., disposable hats, masks, gowns, gloves). When removing contaminated dressings and washing the dirty wound, the nurse may use nonsterile, disposable gloves. Sterile gloves,

however, are used when applying ointments and sterile dressings. In addition, the room must be kept warm (approximately 30°C) to prevent the patient from using up valuable calories through shivering. When finished treating one patient, the nurse removes all personal protective equipment and dons new personal protective equipment before treating another patient to avoid transmitting organisms from one patient to another. Careful handwashing and the use of alcohol-based hand rub, both inside and outside each patient room, is also necessary to prevent cross-contamination. After the dressing change is completed, the equipment and immediate environment are thoroughly cleaned and disinfected. The use of plastic liners on equipment is helpful in reducing the potential contamination of the equipment and facilitates cleaning.

Coverage is the primary goal for burn wounds. In the major burn wound (>50% TBSA), there is rarely enough unburned skin for immediate grafting. This necessitates the use of other temporary wound closure methods. *Allograft (homograft) skin* (from a cadaver skin bank) is used, along with newer biosynthetic options, with varying frequency among burn units (Table 27-13).

TABLE 27-13

SOURCES OF GRAFTS

Source	Graft Name	Coverage
Porcine skin	Heterograft or xenograft (different species)	Temporary (3 days to 2 wk)
Cadaveric skin	Homograft or allograft (same species)	Temporary (3 days to 2 wk)
Patient's own skin	Autograft	Permanent
Patient's own skin and cell cultures	Cultured epithelial autograft (CEA)	Permanent
Porcine collagen bonded to silicone membrane	Biobrane	Temporary (10–21 days)
Bovine collagen and glycosaminoglycan bonded to silicone membrane	Integra	Permanent
Acellular dermal matrix derived from donated human skin	AlloDerm	Permanent
Donated neonatal foreskin fibroblasts and keratinocytes in bovine collagen sponge	OrCel	Permanent
Donated neonatal foreskin fibroblasts and keratinocytes in bovine collagen gel	Apligraf	Permanent
Bovine collagen and elastin matrix	MatriDerm	Permanent

Other Care Measures

For certain parts of the body (e.g., face, eyes, hands, arms, ears, perineum), nursing care must be particularly meticulous. The face is highly vascular

and subject to a great amount of edema. It is often covered with ointments and gauze but not wrapped, to limit pressure on delicate facial structures. Eye care for corneal burns or edema includes antibiotic ointments. All patients with facial burns should undergo an ophthalmological examination soon after admission. Periorbital edema can prevent opening of the eyes and be frightening to the patient. The nurse should provide assurance that the swelling is not permanent. Instillation of methyl cellulose drops or artificial tears into the eyes for moisture provides additional comfort for patients.

Burned hands and arms should be extended and elevated on pillows to minimize edema. Splints may need to be applied to maintain them in positions of function. Ears should be kept free of pressure because of their poor vascularization and predisposition to infection. A patient with ear burns should not rest the head on pillows because pressure on the cartilage may cause chondritis and the ear may stick to the pillowcase, causing pain and bleeding. The patient's head can be elevated with a rolled towel placed under the shoulders, with care to avoid pressure necrosis. The same holds true for a patient with neck burns. Pillows are removed and a rolled towel is placed under the shoulders to hyperextend the neck and prevent neck wound contracture.

The perineum must be kept as clean and dry as possible. In addition to providing hourly urine outputs, an in-dwelling catheter prevents urine contamination of the perineal area.

Routine laboratory tests are performed to monitor fluid and electrolyte balance. ABGs are measured to determine adequacy of ventilation and perfusion in all patients with suspected or confirmed inhalation or electrical injury.

Physiotherapy is begun immediately, sometimes during showering and dressing changes and before new dressings are applied. Early range-of-motion exercises are necessary to facilitate mobilization of the extravasated fluid back into the vascular bed. Exercise also maintains function, prevents contracture, and reassures the patient that movement is still possible.

Drug Therapy

Analgesics and Sedatives.

Analgesics are ordered to promote patient comfort. Early in the postburn period, pain medications should be given intravenously because (a) onset of action is fastest with this route; (b) gastro-intestinal function is slowed or impaired as a result of shock or paralytic ileus; and (c) medications

injected intramuscularly are not absorbed adequately in burned or edematous areas, and so medications pool in the tissues. When fluid mobilization begins, interstitial accumulation of previous intramuscular medications could cause inadvertent overdose.

Opioids commonly used for pain control are listed in Table 27-14. The need for analgesia must be re-evaluated frequently because patients' needs may change and tolerance to medications may develop over time. Initially, opioids are the drugs of choice for pain control. Sedative–hypnotics and antidepressant drugs can also be given with analgesics to control the anxiety, insomnia, or depression that patients may experience (see Table 27-14). Analgesic requirements can vary tremendously from one patient to another. The extent and depth of burn may not be correlated with pain intensity. Hospital pharmacists, psychiatrists, and multidisciplinary pain services are valuable resources for the more complex patient situations. Effective pain control depends on assessment, prompt analgesia with dosages titrated to achieve effect, and regular evaluation.

TABLE 27-14

DRUG THERAPY
Drugs Commonly Used in Burn Treatment

Types and Names of Drugs	Purpose
Nutritional Support	
Vitamins A, C, E, and multivitamins	Promote wound healing
Minerals: zinc, iron (ferrous sulphate)	Promote cell integrity and hemoglobin formation
Analgesia	
Morphine (Statex) Sustained-release morphine (MS Contin) Hydromorphone (Dilaudid) Sustained-release hydromorphone (Dilaudid) Fentanyl Acetaminophen (Tylenol) Ibuprofen (Advil) Adjuvant analgesics (e.g., gabapentin [Neurontin], pregabalin [Lyrica])	Promote pain control
Sedation–Hypnosis	
Quetiapine (Seroquel) Haloperidol (Haldol)	Produce antipsychotic and sedative effects
Lorazepam (Ativan)	Diminish anxiety
Midazolam Ketamine (Ketalar)	Provide short-acting amnestic effects
Antidepressant Therapy	
Venlafaxine (Effexor XR) Citalopram (Celexa)	Reduce depression; improve mood
Anticoagulation Therapy	
Enoxaparin (Lovenox) Heparin	Prevent venous thrombo-embolism
Gastro-Intestinal Support	
Ranitidine (Zantac) Esomeprazole (Nexium)	Decrease stomach acid and risk for Curling's ulcer
Aluminum/magnesium hydroxide (Diovol)	Neutralize stomach acid

Tetanus Immunization.

Tetanus toxoid is given routinely to all patients with burn injuries because of the likelihood of anaerobic contamination of the burn wound. If the patient has not received an active immunization in the 10 years before the burn injury, tetanus immunoglobulin should be considered.

Antimicrobial Agents.

After the wound is cleansed, topical agents are applied and covered with a light dressing. Systemic antibiotics are not routinely used to control burn wound flora because there is little or no blood supply to the burn eschar and, consequently, little delivery of the antibiotic to the wound. In

addition, the routine use of systemic antibiotics increases the chance of developing multidrug-resistant organisms. Some topical burn agents penetrate the eschar, thereby inhibiting bacterial invasion of the wound. Silver-impregnated dressings (e.g., Acticoat Flex, Aquacel Ag Burn, Exsalt T7) can be left in place anywhere from 3 to 14 days and are effective against many organisms. Silver sulphadiazine (Flamazine) and mafenide acetate (Sulfamylon) creams are also used (Sheckter, Van Vliet, Krishnan, et al., 2014). Sepsis remains a leading cause of death in patients with major burns because it may lead to multiple organ dysfunction syndrome (see Chapter 69). Systemic antibiotic therapy is initiated when invasive burn wound sepsis is clinically diagnosed or when some other source of infection (e.g., pneumonia) is identified.

Fungal infections may develop in the patient's mucous membranes (mouth and genitalia) as a result of systemic antibiotic therapy and low resistance in the host. The offending organism is usually *Candida albicans*. Oral infection is treated with nystatin mouthwash. When a normal diet is resumed, yogourt or *Lactobacillus* may be given by mouth to reintroduce the normal intestinal flora that have been destroyed by antibiotic therapy.

Venous Thrombo-Embolism Prophylaxis.

For burn-injured patients at risk for venous thrombo-embolism (e.g., those with lower extremity burns, obese patients), if there are no contraindications, it is recommended that low-molecular-weight heparin (enoxaparin [Lovenox]) or low-dose unfractionated heparin be started as soon as it is considered safe to do so (see Table 27-14). For burn-injured patients who are at high risk for bleeding, it is recommended that mechanical prophylaxis against venous thrombo-embolism, with sequential compression devices or graduated compression stockings, or both, be used until the bleeding risk decreases and heparin can be started (Faraklas, Ghanem, Brown, et al., 2013) (see Table 27-14).

Nutritional Therapy

Early and aggressive nutritional support within several hours of the burn injury can decrease mortality risks and complications, optimize healing of the burn wound, and minimize the negative effects of hypermetabolism and catabolism (Jeschke, 2014). Nonintubated patients with a burn over less than 20% TBSA are generally able to eat enough to meet their nutritional requirements. Intubated patients and those with larger burns require additional support. Enteral feedings (gastric or intestinal) have

almost entirely replaced parenteral feeding. Early enteral feeding, usually with smaller-bore tubes, preserves gastro-intestinal function, increases intestinal blood flow, promotes optimal conditions for wound healing, and prevents complications (e.g., Curling's ulcer). The patient with a large burn (>20% TBSA) can develop paralytic ileus within a few hours as a result of the body's response to major trauma. If a large nasogastric tube is inserted on admission, gastric residuals should be checked frequently to detect delayed gastric emptying. Bowel sounds should be assessed every 8 hours. In general, feedings can begin slowly at 20 to 40 mL/hour and be increased to the goal rate within 24 to 48 hours.

A *hypermetabolic state* proportional to the size of the wound occurs after a major burn injury. Resting metabolic expenditure may increase by 50% to 100% above normal in patients with major burns. Core temperature is elevated. Catecholamines, which stimulate catabolism and heat production, increase. Massive catabolism can occur and is characterized by protein breakdown and increased gluconeogenesis. Failure to supply adequate calories and protein leads to malnutrition and delayed healing. Calorie-containing nutritional supplements and milkshakes are often administered because of the great need for calories. Protein powder can also be added to food and liquids. Supplemental vitamins may be given as early as the emergent phase, with iron supplements often started in the acute phase (Nordlund, Pham, & Gibran, 2014; see Table 27-14).

Acute Phase

The *acute phase* begins with mobilization of extracellular fluid and subsequent diuresis. This phase concludes when the burned area is completely covered by skin grafts or when the wounds are healed. This may take weeks or many months.

Pathophysiological Changes

Burn injury involves pathophysiological changes in many body systems. Diuresis from fluid mobilization occurs, and the patient becomes less edematous. Areas that are full- or partial-thickness burns are more evident than in the emergent phase. Bowel sounds return. The patient may now become aware of the enormity of the situation and benefit from additional psychosocial support. Some healing begins as WBCs surround the burn wound and phagocytosis occurs. Necrotic tissue begins to slough. Fibroblasts lay down matrices of the collagen precursors that eventually form granulation tissue. A partial-thickness burn wound heals from the

edges and the dermal bed below if kept free from infection and *desiccation* (dryness). However, full-thickness burn wounds, unless extremely small, must be covered by skin grafts. In some cases, healing time and length of hospitalization are decreased by early excision and grafting.

Clinical Manifestations

Partial-thickness wounds form eschar, which begins separating fairly soon after injury. Once the eschar is removed, re-epithelialization begins at the wound margins and appears as red or pink scar tissue. Epithelial buds from the dermal bed eventually close in the wound, which then heals spontaneously without surgical intervention, usually within 10 to 21 days.

Margins of full-thickness eschar take longer to separate. As a result, full-thickness wounds necessitate surgical debridement and skin grafting for healing.

Laboratory Values

Because the body is attempting to re-establish fluid and electrolyte homeostasis in the initial acute phase, it is important to monitor serum electrolyte levels closely.

Sodium.

Hyponatremia can develop from excessive gastro-intestinal suction, diarrhea, and excessive water intake. Manifestations of hyponatremia include weakness, dizziness, muscle cramps, fatigue, headache, tachycardia, and confusion. The patient with burn injuries may also develop *water intoxication*, a dilutional form of hyponatremia. To avoid this condition, the patient should drink fluids other than water, such as juice or nutritional supplements.

Hypernatremia may occur after successful fluid replacement if copious amounts of hypertonic solutions were required. Other causes may be related to tube-feeding therapy or inappropriate fluid administration. Manifestations of hypernatremia include thirst; dry, coated tongue; lethargy; confusion; and possibly seizures.

Potassium.

Hyperkalemia is noted if the patient has renal failure, adrenocortical insufficiency, or massive deep muscle injury (e.g., electrical burn) and if large amounts of potassium are being released from damaged cells. Cardiac dysrhythmias and ventricular failure can occur with elevated

potassium levels. Muscle weakness and electrocardiographic changes are observed clinically (see Chapter 19).

Hypokalemia occurs with vomiting, diarrhea, prolonged gastro-intestinal suction, and prolonged IV therapy without potassium supplementation. Constant potassium loss occurs through the burn wound.

Manifestations of hypokalemia include fatigue, muscle weakness, leg cramps, paresthesias, and decreased reflexes (see Chapter 19).

Complications

Infection.

The body's first line of defence, the skin, is destroyed by burn injury. Pathogens often proliferate before phagocytosis has adequately begun. The burn wound becomes colonized with organisms. If the bacterial density at the junction of the eschar with underlying viable tissue rises to greater than 10^5/g of tissue, the burn wound is considered infected. In the presence of an infection, localized inflammation, induration, and sometimes suppuration can occur at the burn wound margins. Partial-thickness burns can convert to full-thickness wounds when the infecting organisms invade viable, adjacent, unburned tissue. Invasive wound infections may be treated with systemic antibiotics on the basis of culture results.

Burn wound infection may progress to transient bacteremia and sepsis as a result of burn wound manipulation (e.g., after showering and debridement). Manifestations of sepsis include hypothermia or hyperthermia, increased heart and respiratory rates, decreased BP, and decreased urine output. Patients may exhibit mild confusion, chills, malaise, and loss of appetite. The WBC count is usually between 10 and 20 $\times 10^9$/L.

There are functional deficits in the WBCs, and the patient remains immuno-suppressed for a time after the burn injury. The causative organisms of sepsis are usually Gram-negative bacteria (e.g., *Pseudomonas, Proteus* organisms), which increase the risk for septic shock.

When sepsis is suspected, cultures are immediately obtained from all possible sources, including the burn wound, blood, urine, sputum, oropharynx, perineal regions, and any invasive line or tube sites. However, treatment should not be delayed pending results of the culture and sensitivity studies. Therapy begins with antibiotics appropriate for the usual residual flora of the particular burn unit. The topical antibiotic in use may be continued or changed to another medication. At this stage, the

patient's condition is critical, and vital signs must be monitored closely. Collaboration with infectious disease specialists is important to ensure appropriate antibiotic coverage.

Cardiovascular and Respiratory Systems.

The same cardiovascular and respiratory system complications present in the emergent phase may continue into the acute phase of care. In addition, new problems might arise, necessitating timely intervention.

Neurological System.

Neurologically, the patient usually has no physical symptoms, unless severe hypoxia from respiratory injuries or complications from electrical injuries occur. However, some patients may demonstrate certain behaviours that are not completely understood. A patient can become extremely disoriented, become withdrawn or combative, or have hallucinations and nightmare-like episodes. Delirium is more acute at night and occurs more often in older patients. Consultation with psychiatric or geriatric services is helpful in quickly diagnosing and treating delirium or similar behaviours. The nurse can then focus on strategies to orient and reassure a confused or agitated patient. Delirium is a transient state, lasting from a day or two to several weeks. Various causes have been considered, including electrolyte imbalance, stress, cerebral edema, sepsis, sleep disturbances, and the use of analgesics and antianxiety drugs.

Musculo-Skeletal System.

The musculo-skeletal system is prone to complications during the acute phase. As the burns begin to heal and scar tissue forms, the skin is less supple and pliant. Range of motion may be limited, and contractures can occur. The muscles in the body tend to shorten in a flexed position. The patient should be encouraged to stretch and move the burned body parts as much as possible. Splinting can be beneficial in preventing or reducing contracture formation. Attention to repositioning and the use of devices such as pressure-redistribution mattresses may also be necessary to decrease the potential for tissue ischemia and skin breakdown.

Gastro-Intestinal System.

The gastro-intestinal system may also exhibit complications during this phase. Paralytic ileus results from sepsis. Diarrhea may be caused by the use of enteral feedings or antibiotics. Constipation can occur as an adverse

effect of opioid analgesics, decreased mobility, and a low-fibre diet. *Curling's ulcer* is a type of gastro-duodenal ulcer characterized by diffuse superficial lesions (including mucosal erosion). It is caused by a generalized stress response to decreased blood flow to the gastro-intestinal tract during the emergent phase; this response results in decreased production of mucus and increased secretion of gastric acid. The best measure for preventing Curling's ulcer is feeding the patient soon after the injury. Antacids, H_2-histamine blockers (e.g., ranitidine [Zantac]), and proton pump inhibitors (e.g., esomeprazole [Nexium]) are used prophylactically to neutralize stomach acids and inhibit the secretion of histamine and hydrochloric acid (see Table 27-14).

Endocrine System.

A transient increase in blood glucose levels may occur because of stress-mediated cortisol and catecholamine release, which results in increased mobilization of glycogen stores, gluconeogenesis, and subsequent production of glucose. Insulin production and release also increase. However, insulin's effectiveness decreases because of relative insulin insensitivity; consequently, the blood glucose level becomes elevated. Later, hyperglycemia can be caused by the increased caloric intake necessary to meet metabolic requirements. When hyperglycemia occurs, the treatment is supplemental intravenous insulin, not decreased feeding. Serum glucose levels are checked frequently, and an appropriate amount of insulin is given if hyperglycemia is present. Glucometers may be used to assess blood glucose at the patient's bedside; however, serum glucose samples yield more accurate results. As the patient's metabolic demands are met and less stress is placed on the entire system, this stress-induced condition may be reversed before or at time of discharge.

Nursing and Collaborative Management Acute Phase

The predominant therapeutic interventions in the acute phase are (a) wound care, (b) excision and grafting, (c) pain management, (d) physiotherapy and occupational therapy, (e) nutritional therapy, and (f) psychosocial care.

Wound Care

The goals of wound care are to (a) prevent infection by cleansing and debriding the area of necrotic tissue that would promote bacterial growth and (b) promote wound re-epithelialization, successful skin grafting, or both.

Wound care consists of daily observation, assessment, cleansing, debridement, and dressing reapplication. Nonsurgical debridement, dressing changes, topical antimicrobial therapy, graft care, and donor site care are performed as necessary, depending on the topical cream or dressing ordered. Wounds are cleansed with soap and water or with normal saline–moistened gauze to gently remove the old antimicrobial agent and any loose necrotic tissue, scabs, or dried blood. During the debridement phase, the wound is covered with topical antimicrobial agents (e.g., silver sulphadiazine, silver-impregnated dressings). When partial-thickness burn wounds have been fully debrided, a protective greasy (paraffin or petroleum) gauze dressing is applied to protect the re-epithelializing cells as they resurface and close the open wound bed. If grafting is necessary, the meshed, split-thickness skin graft may be protected with the same greasy gauze dressings, followed by middle and outer dressings. With facial grafts, the unmeshed sheet graft is left open, so it is possible for *blebs* (serosanguinous exudate) to form between the graft and the recipient bed. Blebs prevent the graft from permanently attaching to the wound itself. The evacuation of blebs is best performed by aspiration with a tuberculin syringe and only by professionals who have received instruction in this specialized skill. (Dressings are discussed in Chapter 14 and Table 14-11.)

Excision and Grafting

Current management of full-thickness burn wounds involves early removal of the necrotic tissue, followed by application of split-thickness autograft skin (Kamolz, 2014). In the past, patients with major burns had low rates of survival because healing and wound coverage took so long that patients usually died of sepsis or malnutrition. Currently, as a result of earlier intervention, mortality and morbidity rates have been greatly reduced. Many patients, especially those with major burns, are taken to the operating room for wound excision on day 1 or 2 (resuscitation phase). The wounds are covered with a biological dressing or allograft for temporary coverage until permanent grafting can be accomplished (see Table 27-13).

During the procedure of **excision and grafting**, devitalized tissue (eschar) is removed down to the subcutaneous tissue or the fascia, depending on the degree of injury. Surgical excision can result in massive blood loss. Topical application of epinephrine or thrombin, application of extremity tourniquets, or application of a fibrin sealant (ARTISS) all work to decrease surgical blood loss.

Once hemostasis has been achieved, a graft is then placed on clean, viable tissue to achieve good adherence. Whenever possible, the freshly excised wound is covered with *autograft* (the person's own) skin (see Table 27-13). Fibrin sealant has been used to attach skin grafts to the wound bed. Grafts can also be stapled or sutured into place (Figure 27-11, A). Negative pressure wound therapy dressings are often placed on top of skin grafts to optimize adherence to the excised bed (Waltzman & Bell, 2014). A temporary allograft (from a cadaver skin bank) can be used to test how the recipient site will accept a graft. The allograft is then removed several days later in the operating room, and an autograft applied.

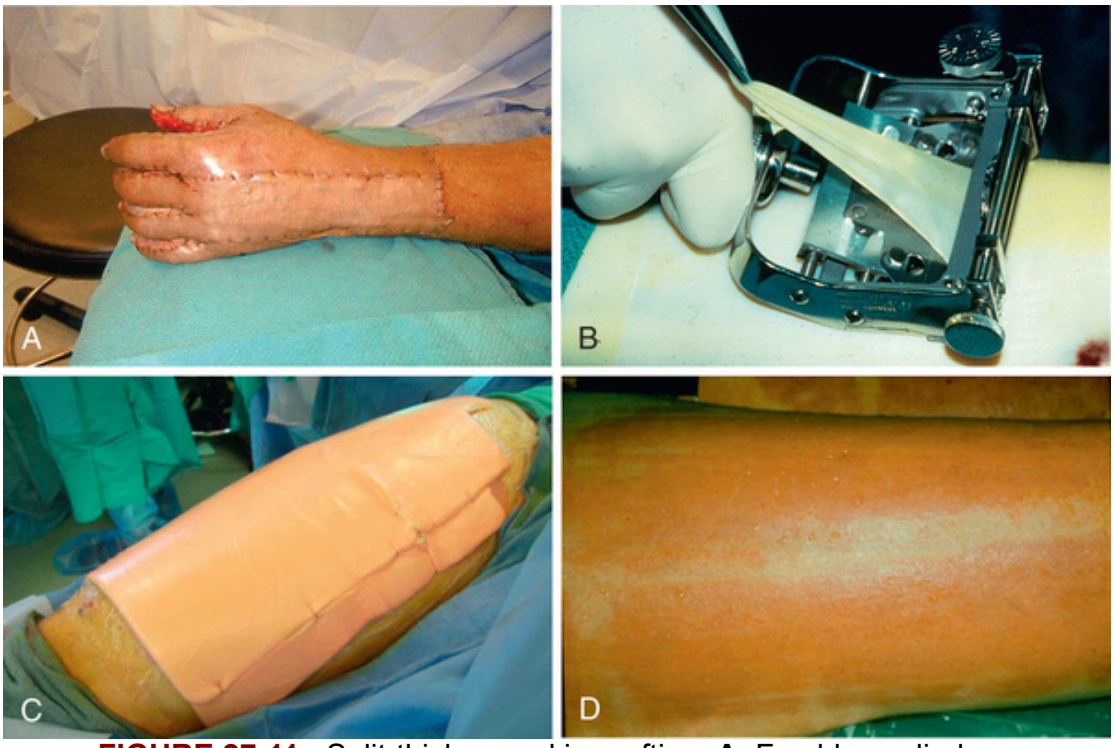

FIGURE 27-11 Split-thickness skin grafting. **A,** Freshly applied split-thickness sheet skin graft to the hand. **B,** Split-thickness skin graft is harvested from a patient's thigh using a dermatome. **C,** Donor site is covered with a hydrophilic foam dressing after harvesting. **D,** Healed donor site. Source: Courtesy Judy A. Knighton, RN, MScN, Toronto.

With early excision, function is restored, and scar tissue formation is minimized. Frequent observation for bleeding and circulation problems and appropriate nursing interventions can help identify and manage complications that would interfere with graft survival. Facial, neck, and hand burns require skillful nursing care to identify and manage clots quickly for the best functional and aesthetic outcomes.

Donor skin from another area of the patient's body is harvested for grafting by means of a dermatome, which removes a thin (14/1000 to 16/1000) split-thickness layer of skin from an unburned site (see Figure 27-11, B). This sample of skin can be meshed (usually a ratio of 1.5 : 1) to allow for greater wound coverage, or it may be applied as an unmeshed sheet graft for a better cosmetic result when grafting the face, neck, and hands. The site from which this skin was taken now becomes a new open wound.

The goals of donor site care are to promote rapid moist wound healing, decrease pain at the site, and prevent infection. The choices of dressings

vary among burn centres and include greasy gauze dressings, silver-impregnated dressings, and hydrophilic foam dressings (see Figure 27-11, C). Nursing care of the donor site is specific to the dressing selected. Several of the newer dressing materials offer decreased healing time, which facilitates earlier reharvesting of skin at the same site. The average healing time for a donor site is 10 to 14 days (see Figure 27-11, D).

Cultured Epithelial Autografts.

In the patient with large body surface area burns, only a limited amount of unburned skin may be available as donor sites for grafting, and some of that available skin may be unsuitable for harvesting. **Cultured epithelial autograft (CEA)** is a method of obtaining permanent skin from a person with limited available skin for harvesting. CEA is grown from biopsy specimens obtained from the patient's own unburned skin. The specimens are sent to a commercial laboratory, where the keratinocytes from the biopsy sample are grown in a culture medium containing epidermal growth factor. After approximately 18 to 25 days, the keratinocytes have expanded up to 10 000 times and form confluent sheets that can be used as skin grafts. The cultured skin is returned to the burn unit, where it is placed on the patient's excised burn wounds. Because CEA tissue is made only of epidermal cells, meticulous care is required to prevent shearing injury or infection (Figure 27-12). Problems related to CEA include infection, contracture development, and poor graft take as a result of loss of thin epidermal skin during healing.

Artificial Skin.

To be successful, artificial skin must perform all functions of natural skin and consist of both dermal and epidermal elements (Jeschke, Finerty, Shahrokhi, et al., 2013). The Integra dermal regeneration template is an example of a successful skin replacement system available in burn care today. As with CEA, it is indicated for use in the treatment of life-threatening full-thickness or deep partial-thickness burn wounds when conventional autograft is not available or advisable, as in older-adult patients or those at high risk for complications from anaesthesia. It has also been successfully used in surgical burn reconstructive procedures. As with CEA, it needs to be applied within a few days of admission for greatest success.

Integra artificial skin has a bilayer membrane composed of acellular dermis and silicone. The wound is debrided, the bilayer membrane is placed dermal layer down, and the wound is wrapped with dressings in the operating room. The dermal layer functions as a biodegradable template that induces organized regeneration of new dermis by the body. The silicone layer remains intact for 3 weeks as the dermal layer degrades and epidermal autografts become available. At this point, the silicone is removed during a second surgical procedure and replaced by the patient's own epidermal autografts. In some situations, burn units use CEA as the source of epidermis.

Another currently available dermal replacement is AlloDerm, a cryopreserved allogenic dermis. Human allograft dermis, harvested from

cadavers, is decellularized to render it immunogenic, and then it is freeze-dried. Once thawed, AlloDerm is rehydrated with ultrathin epidermal autografts immediately before placement on a newly excised wound.

Pain Management

One of the most critical functions a nurse performs on behalf of a patient with burn injuries is individualized and ongoing pain assessment and management. Many aspects of burn care cause pain. However, patients experience moments of relative comfort if they receive adequate analgesia. A coordinated understanding of both physiological and psychological aspects of pain is essential if the nurse is to intervene with actions that are beneficial. (General pain management is discussed in Chapter 10.) Patients with burn injuries experience two kinds of pain: (a) continuous, background pain that might be present throughout the day and night and (b) treatment-induced pain associated with dressing changes, ambulation, and rehabilitation activities. Initial treatment is pharmacological (see Table 27-14). With background pain, a continuous intravenous infusion of an opioid allows for a steady, therapeutic level of medication. If an intravenous infusion is not present, slow-release twice-a-day opioid medications (e.g., MS Contin, sustained-release hydromorphone [Dilaudid]) are indicated. Around-the-clock oral analgesics can also be used (ibuprofen, acetaminophen). Breakthrough doses of pain medication need to be available regardless of the regimen selected. Anxiolytics (e.g., lorazepam [Ativan]), which frequently potentiate analgesics, are also indicated.

For treatment-induced pain, premedication with an analgesic and perhaps an anxiolytic via the IV or oral route, is required. For patients with an IV infusion, a potent, short-acting analgesic, such as fentanyl, is useful. During treatment or activity, doses should be low but high enough to keep the patient as comfortable as possible. Elimination of all pain is difficult to achieve, and most patients indicate satisfaction with "tolerable" levels of discomfort.

Pain can also be managed through nonpharmacological strategies. Mind–body interventions such as relaxation, hypnosis, guided imagery, biofeedback, and music therapy are considered adjuncts to traditional pharmacological treatment of pain. They are not meant to be used exclusively to control pain but may help some patients cope with the painful aspects of care, both in the hospital and after discharge (see Chapter 8).

An important point to remember is that the more control the patient has in managing the pain, the more successful the chosen strategies are. Patient-controlled analgesia (PCA) is used in some burn units, with varying degrees of success. (PCA is discussed in Chapters 10 and 22.) Active patient participation has been found to be effective also for some patients in anticipating and coping with treatment-induced pain.

Physiotherapy and Occupational Therapy

Rigorous physiotherapy throughout burn recovery is imperative to maintain muscle strength and optimal joint function. A good time for exercise is during and after wound cleansing, when the skin is softer and bulky dressings are removed. Passive and active range-of-motion exercises should be performed on all joints. The patient with neck burns must sleep without pillows or with the head hanging slightly over the top of the mattress to encourage hyperextension. Custom-fitted splints are designed to keep joints in a functional position. These must be re-examined frequently to ensure an optimal fit with no undue pressure that might lead to skin breakdown or nerve damage.

Nutritional Therapy

The goal of nutritional therapy during the acute burn phase is to provide adequate calories and protein to promote healing. The patient with burn injury is in a hypermetabolic and highly catabolic state. Decreasing catecholamine release by minimizing pain, fear, anxiety, and cold can maximize the patient's comfort and conserve energy. Infection also increases the metabolic rate.

Meeting daily caloric requirements is crucial and should begin within the first 1 to 2 days after the burn injury. The daily estimated caloric needs must be regularly calculated by a dietitian and readjusted as the patient's condition changes (e.g., wound healing, sepsis).

If the patient is on a mechanical ventilator or unable to consume adequate calories by mouth, a small-bore feeding tube is placed and enteral feedings are initiated. When the patient is extubated, a swallowing assessment should be performed by a speech–language pathologist before oral feeding is commenced. The alert patient should be encouraged to eat high-protein, high-carbohydrate foods to meet increased caloric needs. Family members should be encouraged to bring in favourite foods from home. Ideally, weight loss should not be more than 10% of preburn

weight. Daily calorie counts and weekly weights are monitored by the dietitian to evaluate progress.

Evidence-Informed Practice

Research Highlight

Does the Type of Enteral Feeding Affect Outcomes in Burn Patients?

Clinical Question

In patients with burns (P), what is the effect of high-carbohydrate enteral feeding (I) versus high-fat enteral feeding (C) in reducing mortality, days on ventilator, and incidence of pneumonia (O)?

Best Available Evidence

Systematic review of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence

- Two RCTs (n = 93) were done in the immediate postburn period involving hospitalized patients with burns covering ≥10% of the total body surface area (TBSA).
- Two types of enteral feeding were compared: high-carbohydrate, high-protein, low-fat feeding (high-carbohydrate formula) and low-carbohydrate, high-protein, high-fat feeding (high-fat formula).
- High-carbohydrate enteral feeding resulted in a reduced incidence of pneumonia compared with high-fat enteral feeding.
- Results on type of enteral feeding as it related to patient outcomes of mortality and days on ventilator were inconclusive.

Conclusion

- High-carbohydrate enteral feedings may be of benefit in reducing the risk for pneumonia.

Implications for Nursing Practice

- Further research is needed to determine if type of enteral feeding produces significantly different patient outcomes.

P, Patient population of interest; *I*, intervention or area of interest; *C*, comparison of interest or comparison group; *O*, outcomes of interest (see Chapter 1).

Psychosocial Care

The patient and family have many needs for psychosocial support during the often lengthy, unpredictable, and complex course of care. The social worker and nursing staff have important support and counselling roles to play. (Patient and family emotional needs are discussed later in this chapter and in Chapter 6.)

Rehabilitation Phase

The formal *rehabilitation phase* begins when the patient's burn wounds have healed and the patient is able to resume a level of self-care activity. This can occur as early as 2 weeks or as long as 7 to 8 months after the burn injury. Goals for this period are (a) to assist the patient in resuming a functional role in society and (b) rehabilitation after functional and cosmetic reconstructive surgery (Stergiou-Kita, Grigorovich, & Gomez, 2014). Rehabilitation-focused activities that were taking place during the earlier emergent and acute phases begin in earnest once the patient's wounds have healed.

Pathophysiological Changes and Clinical Manifestations

Burn wounds can heal on their own or through skin grafting. Through epithelialization, the tissue structure destroyed by the burn injury begins to rebuild. Collagen fibres, present in the new scar tissue, assist with healing and add strength to weakened areas. The new skin appears flat and pink. In approximately 4 to 6 weeks, the area may become raised and hyperemic. If adequate range of motion is not instituted, the new tissue shortens, which causes a contracture. Mature healing is reached in about 12 months, by which time suppleness has returned and, in lighter-skinned people, the pink or red colour has faded to a slightly lighter hue than the

surrounding unburned tissue. More heavily pigmented skin takes longer to regain its dark colour because many of the melanocytes have been destroyed. In many cases, the skin does not regain its original colour. Paramedical cosmetic camouflage—the topical application of pigment onto the skin—can help even out unequal skin tones and improve the patient's overall appearance and self-image.

Scarring has two components: discoloration and contour. The discoloration of scars fades somewhat with time. However, scar tissue tends to develop altered contours; that is, it is no longer flat or slightly raised but becomes elevated and enlarged above the original burned area. It is believed that pressure can help keep a scar flat. Gentle pressure can be maintained on the healed burn with custom-fitted pressure garments, worn up to 24 hours a day for as long as 12 to 18 months. They should never be worn over unhealed wounds and are removed for bathing.

Patients typically experience discomfort from itching where healing is occurring. Application of water-based moisturizers and use of oral antihistamines (e.g., diphenhydramine [Benadryl]) help reduce the itching. Massage, silicone gel sheeting (e.g., Cica-Care), gabapentin (Neurontin)/pregabalin (Lyrica), and injectable steroids may also be helpful (Carrougher, Martinez, McMullen, et al., 2013). As "old" epithelium is replaced by new cells, flaking occurs. Newly formed skin is extremely sensitive to trauma. Blisters and skin tears are likely to develop from slight pressure or friction. In addition, newly healed areas can be hypersensitive or hyposensitive to cold, heat, and touch. Grafted areas are more likely to be hyposensitive until peripheral nerve regeneration occurs. Healed burn areas must be protected from direct sunlight for 3 to 6 months to prevent hyperpigmentation and sunburn.

Complications

The most common complications during the rehabilitative phase are skin and joint contractures and hypertrophic scarring (Godleski, Oeffling, Bruflat, et al., 2013). A **contracture** (an abnormal, usually permanent condition of a joint, characterized by flexion and fixation) develops as a result of the shortening of scar tissue in the flexor tissues of a joint. Areas most susceptible to contracture formation include anterior and lateral neck areas, axillae, antecubital fossae, fingers, groin areas, popliteal fossae, knees, and ankles (Figure 27-13). Not only does the skin over these areas develop contractures, but also the underlying tissues, such as the ligaments and tendons, have a tendency to shorten in the healing process.

FIGURE 27-13 Contractures. **A,** Foot. **B,** Neck. Source: Courtesy Judy A. Knighton, RN, MScN, Toronto, and Linda Bucher, RN, PhD.

Because of pain, patients with burn injuries prefer to assume a flexed position for comfort. This position predisposes wounds to contracture formation. Proper positioning, splinting, and exercise should be instituted to minimize this complication while the skin matures. Burned legs may be wrapped with elastic (e.g., tensor [ACE]) bandages to assist with circulation to leg graft and donor sites before ambulation. This additional pressure prevents blister formation, promotes venous return, and decreases pain and itchiness. Once the skin is completely healed and less fragile, interim tubular gauze (Tubigrip, Coban) and then custom-fitted pressure garments can replace the elastic bandages.

Nursing and Collaborative Management Rehabilitation Phase

During the rehabilitation phase, both the patient and the family are actively encouraged to participate in care. Because the patient may go home with small, unhealed wounds, education and "hands-on" instruction in dressing changes and wound care are needed. If necessary, home care nursing services may be arranged to assist with wound care for the first few weeks after discharge. An emollient, water-based cream (e.g., Vaseline Intensive Care Extra Strength) that penetrates into the dermis should be used routinely on healed areas to keep the skin supple and well moisturized, thereby decreasing itching and flaking. Reconstructive surgery is frequently required after a major burn. It is important for the patient to understand the need for or possibility of further surgery before leaving the hospital.

The continuous role of exercise and physiotherapy or occupational therapy cannot be overemphasized. Computerized gaming devices can provide patients with a break from exercise routines (Parry, Carbullido, Kawada, et al., 2014). Constant encouragement and reassurance are necessary to maintain morale, particularly once the patient realizes that recovery can be slow and rehabilitation may need to be a primary focus for at least the next 12 months.

Because of the tremendous psychological effect of burn injury, health care providers should be particularly sensitive and attuned to the patient's emotions and concerns. It is essential that patients be encouraged to discuss their fears regarding loss of their lifestyle as they once knew it, loss of function, temporary or permanent deformity and disfigurement, return to work and home life, and financial burdens resulting from a long and potentially costly hospitalization and rehabilitation. Patients may benefit from being assisted toward a realistic and positive appraisal of their particular situation, emphasizing what they can do instead of what they cannot do.

A person's self-esteem may be impacted by a burn injury. In some individuals, an overwhelming fear may be the loss of relationships because of perceived or actual physical disfigurement. In a society in which physical beauty is valued, alterations in body image may result in psychological distress. Encouraging appropriate independence, an eventual return to preburn activities, and interactions with other burn

survivors will involve the patient in familiar activities that may bring comfort and help restore self-esteem. Counselling, which may have started in the acute phase of care, can be offered after discharge. Patients appreciate reassurance that their emotions during this period of adjustment are normal and that frustration is to be expected as they attempt to resume a normal lifestyle.

Age-Related Considerations

Burns

Older-adult patients with burns present many challenges for the burn team. The normal aging process puts such patients at risk for injury because of the possibility of an unsteady gait, limited eyesight, and diminished hearing. As people age, skin becomes drier, more wrinkled, and looser. The dermal layer thins, there is a loss of elastic fibres, the amount of subcutaneous adipose tissue lessens, and vascularity decreases. As a result, the thinner dermis, with reduced blood flow, sustains deeper burns with poorer rates of healing.

Once injured, older adults have more complications in the emergent and acute phases of burn resuscitation because of pre-existing medical conditions. For example, among older patients with diabetes, heart failure, or chronic obstructive pulmonary disease, morbidity and mortality rates exceed those of healthy, younger patients. Pneumonia is a frequent complication, burn wounds and donor sites take longer to heal, and surgical procedures are not as well tolerated. Weaning from a ventilator can be a challenge, and delirium from medication and anaesthesia may be a distressing, although usually self-limiting, outcome. It usually takes longer for older patients to become rehabilitated to the point at which they can safely return home. For some, a return home to independent living may not be possible. As the population ages, developing strategies to prevent burn injuries in this age group is a priority.

Emotional Needs of the Patient and Caregivers

For the nurse to adequately manage the enormous range of emotional responses that the patient with burn injury may exhibit, it is important to have an understanding of the circumstances of the burn, family relationships, and previous coping experiences with stressful stimuli (Kornhaber, Wilson, Abu-Kumar, et al., 2014). At any time, emotions of fear, anxiety, anger, guilt, and depression may be experienced (Table 27-15).

TABLE 27-15
EMOTIONAL RESPONSES OF PATIENTS WITH BURN INJURY*

Emotion	Possible Verbal Expression
Fear	"Will I die?" "What will happen next?" "Will I be disfigured?" "Will my family and friends still love me?"
Anxiety	"I feel out of control." "What's going to happen to me?" "When will I look normal again?"
Anger	"Why did this happen to me?" "The nurses enjoy hurting me." "I hope the person who did this to me dies."
Guilt	"If only I'd been more careful." "I'm being punished because I did something wrong."
Depression	"It's no use going on like this." "I don't care what happens to me." "I wish people would leave me alone."

*List is not all-inclusive.

A common emotional response is regression. The patient may revert to behaviour that helped with stressful situations in the past. This response can be healthy and is usually short-lived. As more and more independence is expected from the patient, new fears must be confronted: "Can I do it?" "Am I a desirable partner or parent?" Open and frequent communication among the patient, family members, close friends, and burn team members is essential.

Burn survivors frequently experience thoughts and feelings that are frightening and disturbing, such as guilt about the burn accident, reliving the experience, fear of death, concern about future therapy and surgery, frustrations with ongoing discomfort and wound breakdown, and, perhaps, hopelessness about the future. Families may share some or all of these feelings. At times, family members may feel helpless to assist their loved one. Continued support from trusted and familiar burn team members is essential. Assisting with aspects of care helps family members reconnect with their loved one and assists with the transition home. Many burn survivors and their families remark on the powerful learning experience of the burn and a renewed appreciation for life, despite the ongoing challenges of a prolonged and challenging recovery (Stavrou, Weissman, Tessone, et al., 2014). Acknowledgement that such feelings are normal and valid can be therapeutic for patients and their families.

The stress of the burn injury occasionally precipitates a time-limited psychiatric or psychological crisis. Many patients realize that coping with this experience is beyond their ability. Assessment by a psychiatrist who

can prescribe appropriate medication, if needed, and begin short-term counselling is frequently helpful. Early psychiatric intervention is essential if the patient has been previously treated for a psychiatric illness or if the injury resulted from a suicide attempt. The diagnosis of post-traumatic stress disorder is made in a number of patients with burn injuries. However, it has been noted that distress and trauma symptoms can act as a catalyst for positive post-traumatic growth. Coping styles and social support appear to assist in these positive changes postburn (Baillie, Sellwood, & Wisely, 2014). Treatment typically begins in the hospital, but links to community resources must be made before discharge to ensure continuity of psychological care. Once the patient is discharged, referral to a psychiatrist, psychologist, mental health counsellor, social worker, or psychiatric clinical nurse specialist may be helpful if concerns are raised at burn clinic follow-up.

Patients with burn injuries benefit from information about sexuality and intimacy (Gonçalves, Melo, Caltran, et al., 2014). Physical appearance is altered in patients who have sustained a major burn, and acceptance of any changes is difficult at first for both the patient and the significant other. The nature of skin injury causes modifications in processing sexual stimuli. Touch is an important part of sexuality, and immature scar tissue may make the sensation of touch unpleasant or may dull it. This effect is usually transient, but the patient and partner need to know that it is normal, so they will benefit from anticipatory guidance from the health care team to avoid undue emotional strain.

Patient and family support groups may assist patients and families with their emotional needs at any phase of the recovery process. Speaking with other people who have experienced burn trauma can be beneficial, both in terms of reaffirming that their feelings are normal and allowing for sharing of helpful advice (Tolley & Foroushani, 2014). The Phoenix Society (see the Resources at the end of this chapter) is an international and highly respected burn survivors' support group that has been offering invaluable support and resources to burn survivors, family members, and burn team personnel for many years.

Special Needs of the Nursing Staff

Warm, trusting, mutually satisfying relationships frequently develop between patients with burn injuries and nursing staff, not only during hospitalization but also during the long-term rehabilitation period. The frequency and intensity of family contact can also be rewarding, as well as

draining, for the nurse. Those new to burn nursing often find it difficult at first to cope with not only the deformities caused by burn injury but also the odours, the unpleasant sight of wounds, and the reality of the pain that accompanies the burn and its treatment. With time and positive experiences, those reactions diminish.

Many nurses come to know that the care they provide makes a critical difference in helping patients not only to survive but also to cope with and triumph over a challenging and multifaceted injury. It is this belief that allows and inspires nurses to provide meaningful care to patients with burn injury and their families.

Ongoing support services for the burn nurse or critical incident stress debriefings led by a psychiatrist, psychologist, psychiatric clinical nurse specialist, or social worker may be helpful. Professional burn nursing groups (e.g., American Burn Association, Canadian Association of Burn Nurses, International Society for Burn Injuries) can serve a similar purpose by helping nursing staff cope with difficult feelings they may experience when caring for patients with burn injuries. Burn nursing is physically, psychologically, and intellectually demanding and immensely rewarding (Leggett, Wasson, Sinacore, et al., 2013). Attention to self-care helps to maintain a positive attitude and healthy work–life balance. Time with family and friends and rest and relaxation at home are essential parts of self-care and living a life with purpose and fulfillment.

Case Study

Burn Injury

Source: Billion Photos/Shutterstock.com.

Patient Profile

Elliott Curtis, a 65-year-old married man, is brought to the emergency department with burns to his face, neck, torso, right arm and hand, and right foot from a kitchen grease fire. He arrives with an 18-gauge IV line with lactated Ringer's solution infusing at 100 mL/hour, and he is receiving 100% humidified oxygen by mask.

Subjective Data

- Complains of impaired vision and swallowing difficulties
- States his burns are painful and that he is scared
- States he has “diabetes and high blood pressure”

Objective Data

Physical Examination

- Patient is awake, alert, and oriented but in some distress
- Eyes are red and irritated
- Voice is hoarse; nasal hair is singed
- Face is reddened, with blisters noted on the nose and forehead
- Right arm, right hand, anterior torso, neck, and right foot have shiny, bright red, wet wounds
- Patient is shivering

Discussion Questions

1. ***Priority decision:*** What are the priorities of care in the prehospital setting and emergency department? How should Mr. Curtis's airway, breathing, and circulation be managed?
2. ***Priority decision:*** What signs and symptoms indicate that Mr. Curtis likely has an inhalation injury? What priority interventions can be anticipated?
3. What pain medications might be considered to relieve his pain?
4. Which of the criteria for admission to the hospital burn unit does Mr. Curtis meet?
5. What metabolic disturbances would be expected soon after Mr. Curtis's admission? Explain the physiological basis for these changes.

6. How might Mr. Curtis's comorbidities affect his burn care and rehabilitation?
7. What measures should be taken to support Mr. Curtis's family?
8. ***Priority decision:*** What three priority nursing diagnoses and any collaborative problems can be identified based on the assessment data presented?
9. ***Evidence-informed practice:*** What are the most effective wound care strategies to manage Mr. Curtis's burn wounds?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Knowing the most common causes of household fires, which prevention strategy would the nurse focus on when teaching about fire safety?
   a. Set hot water temperature at 60°C.
   b. Use only hard-wired smoke detectors.
   c. Encourage regular home fire exit drills.
   d. Never permit older adults to cook unattended.
2. Which of the following injuries is least likely to result in a full-thickness burn?
   a. Sunburn
   b. Scald injury
   c. Chemical burn
   d. Electrical injury
3. When assessing a client with a partial-thickness burn, what would the nurse expect to find? *(Select all that apply)*
   a. Blisters
   b. Exposed fascia
   c. Exposed muscles
   d. Intact nerve endings
   e. Red, shiny, wet appearance
4. A client is admitted to the burn centre with burns on his head and neck, chest, and back after an explosion in his garage. On assessment, the nurse auscultates the lung fields and hears wheezes throughout. On reassessment, the wheezes are gone and the breath sounds are greatly diminished. Which action is the most appropriate for the nurse to take next?
   a. Obtain vital signs and an immediate arterial blood gas
   b. Encourage the client to cough and auscultate the lungs again
   c. Document the findings and continue to monitor the client's breathing
   d. Anticipate the need for endotracheal intubation and notify the physician

5. Which of the following fluid and electrolyte shifts occurs during the early emergent phase?
   a. Adherence of albumin to vascular walls
   b. Movement of potassium into the vascular space
   c. Sequestering of sodium and water in interstitial fluid
   d. Hemolysis of RBCs from large volumes of rapidly administered fluid
6. Which of the following must the client with a major burn do in order to maintain a positive nitrogen balance?
   a. Eat a high-protein, low-fat, high-carbohydrate diet
   b. Increase normal adult caloric intake by about three times
   c. Eat at least 1 500 calories per day in small, frequent meals
   d. Eat rice and whole wheat for their chemical effect on nitrogen balance
7. A client has 25% of TBSA burned in a car fire. His wounds have been debrided and covered with a silver-impregnated dressing. What should the nurse's priority intervention for wound care be?
   a. To reapply a new dressing without disturbing the wound bed
   b. To observe the wound for signs of infection during dressing changes
   c. To apply cool compresses for pain relief in between dressing changes
   d. To wash the wound aggressively with soap and water three times a day
8. Which of the following is most effective in terms of pain management for the client with burn injuries? (*Select all that apply*)
   a. A pain rating tool is used to monitor the client's level of pain.
   b. Painful dressing changes are delayed until the client's pain is completely relieved.
   c. The client is educated about pain management and has some control over its management.
   d. A multimodal approach is used (e.g., sustained-release and short-acting opioids, nonsteroidal anti-inflammatory drugs, adjuvant analgesics).
   e. Nonpharmacological therapies (e.g., music therapy, distraction) replace opioids in the rehabilitation phase of a burn injury.
9. Which of the following therapeutic measures is used to prevent hypertrophic scarring during the rehabilitative phase of burn recovery?
   a. Applying pressure garments

b. Repositioning the patient every 2 hours

c. Performing active range of motion at least every 4 hours

d. Massaging the new tissue with water-based moisturizers

10. A client is recovering from second- and third-degree burns over 30% of his body and is now ready for discharge. What is the first action that the nurse should take when meeting with the client?

a. Arrange a return-to-clinic appointment and prescription for pain medications

b. Teach the client and the caregiver proper wound care to be performed at home

c. Review the client's current health care status and readiness for discharge to home

d. Give the client written discharge information and websites for additional information for burn survivors

1. c, 2. a, 3. a, d, e, 4. d, 5. c, 6. a, 7. b, 8. a, c, d, 9. a, 10. c.

SECTION 5

Problems of Oxygenation: Ventilation

OUTLINE

Introduction

Source: Pictureguy/Shutterstock.com.

CHAPTER 28

Nursing Assessment

Respiratory System

Written by, Eugene E. Mondor

Adapted by, Lesley MacMaster, Micki Puksa

LEARNING OBJECTIVES

1. Describe the structures and functions of the upper respiratory tract, the lower respiratory tract, and the chest wall.
2. Describe the process that initiates and controls inspiration and expiration.
3. Describe the process of gas diffusion within the lungs.
4. Identify the respiratory defence mechanisms.
5. Describe the significance of arterial blood gas values and the oxygen–hemoglobin dissociation curve in relation to respiratory function.
6. Identify the signs and symptoms of inadequate oxygenation and the implications of these findings.
7. Describe age-related changes in the respiratory system and differences in assessment findings.
8. Identify the significant subjective and objective data related to the respiratory system that should be obtained from a patient.
9. Describe the techniques used in physical assessment of the respiratory system.
10. Differentiate normal from common abnormal findings in a physical assessment of the respiratory system.
11. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the respiratory system.

wheezes, p. 569

Structures and Functions of the Respiratory System

The primary purpose of the respiratory system is gas exchange, which involves the transfer of oxygen and carbon dioxide from the atmosphere to the blood. The respiratory system is divided into two parts: the upper respiratory tract and the lower respiratory tract (Figure 28-1). The upper respiratory tract includes the nasal cavity, the pharynx, the adenoids, the tonsils, the epiglottis, the larynx, and the trachea. The major structures of the lower respiratory tract are the bronchi, the bronchioles, the alveolar ducts, and the alveoli. With the exception of the right and left mainstem bronchi, all lower airway structures are contained within the lungs. The right lung is divided into three lobes (upper, middle, and lower) and the left lung into two lobes (upper and lower; Figure 28-2). The structures of the chest wall (ribs, pleura, muscles of respiration) are also essential for respiration.

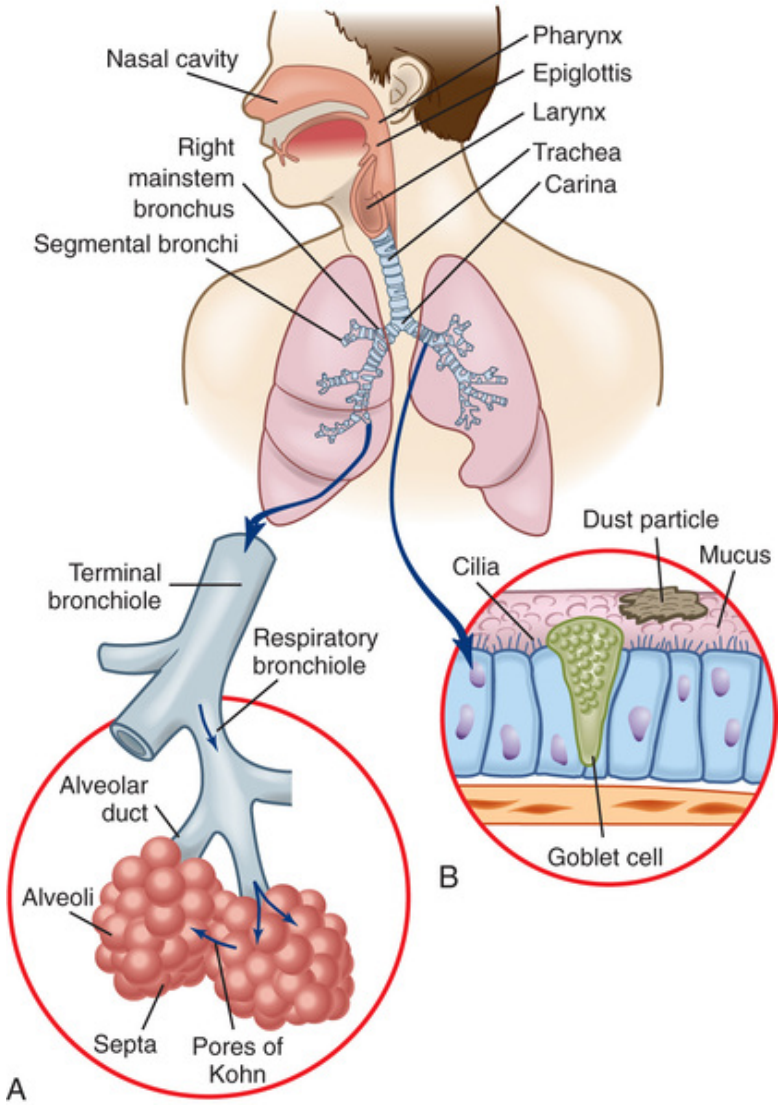

FIGURE 28-1 Structures of the respiratory tract. **A,** Pulmonary functional unit. **B,** Ciliated mucous membrane. Source: Redrawn from Price, S. A., & Wilson, L. M. (2003). *Pathophysiology: Clinical concepts of disease processes* (6th ed.). St. Louis: Mosby.

Upper Respiratory Tract

The nose, made of bone and cartilage, is divided into two nares by the nasal septum. The interior of the nose is shaped into rolling projections called *turbinates* that increase the surface area for warming and moistening air. The internal portion of the nose opens directly into the sinuses. The nasal cavity is connected to the pharynx, a tubular passageway that is subdivided into three parts: in descending order, they are the nasopharynx, the oropharynx, and the laryngopharynx.

Breathing through the narrow nasal passages (rather than mouth breathing) provides protection for the lower airway. The nose is lined with mucous membrane and small hairs. Air entering the nose is warmed to near body temperature, humidified to nearly 100% water saturation, and filtered to remove particles larger than 10 mcm (e.g., dust, bacteria).

The olfactory nerve endings (receptors for the sense of smell) are located in the roof of the nose. The adenoids and the tonsils, which are small masses of lymphatic tissue, are found in the nasopharynx and the oropharynx, respectively.

The epiglottis is a small flap of tissue at the base of the tongue. During swallowing, the epiglottis covers the larynx, preventing solids and liquids from entering the lungs. A condition such as a stroke that alters swallowing ability may impair the function of the epiglottis, thus predisposing the affected person to aspiration.

After passing through the oropharynx, air moves through the laryngopharynx and the larynx, where the vocal cords are located, and then down into the trachea. The trachea is a cylindrical tube about 10 to 12 cm long and 1.5 to 2.5 cm in diameter. The support of U-shaped cartilages keeps the trachea open but allows the adjacent esophagus to expand for swallowing. The trachea bifurcates into the right and left mainstem bronchi at a point called the *carina.* The carina is located at the level of the manubriosternal junction, also called the *angle of Louis.* The carina is highly sensitive, and touching it during suctioning causes vigorous coughing (Patton & Thibodeau, 2016).

Lower Respiratory Tract

Once air passes the carina, it is in the lower respiratory tract. The mainstem bronchi, the pulmonary vessels, and nerves enter the lungs through a slit called the *hilum.* The right mainstem bronchus is shorter, wider, and straighter than the left mainstem bronchus. For this reason, aspiration is more likely to occur in the right lung than in the left lung.

The mainstem bronchi subdivide several times to form the lobar, segmental, and subsegmental bronchi. In further divisions, the bronchioles are formed. The most distant bronchioles are called the *respiratory bronchioles.* Beyond these lie the alveolar ducts and the alveolar sacs (Figure 28-3). The bronchioles are encircled by smooth muscles that constrict and dilate in response to various stimuli. The terms *bronchoconstriction* and *bronchodilation* are used to refer to a decrease or increase in the diameter of the airways that is caused by contraction or relaxation of these muscles.

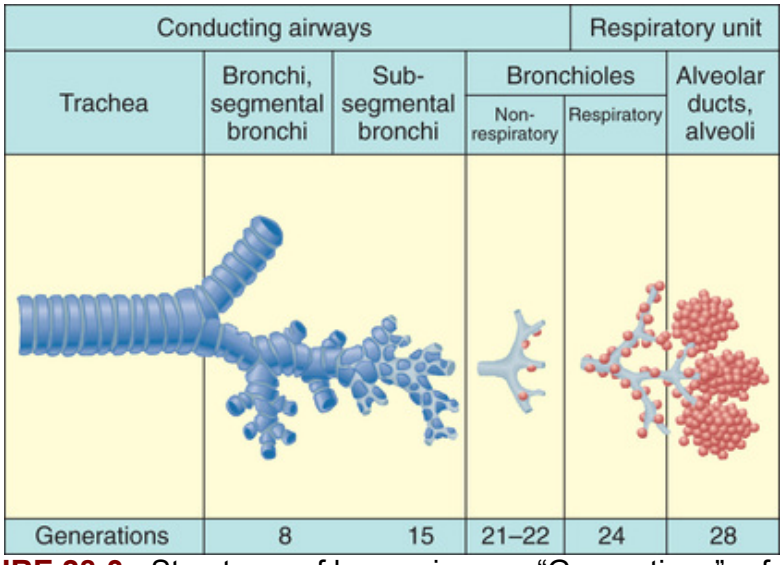

FIGURE 28-3 Structures of lower airways. "Generations" refers to the number of subdivisions of the mainstem bronchus. Source: From Thompson, J. M., McFarland, G., & Tucker, S. (2002). *Mosby's clinical nursing* (5th ed.). St. Louis: Mosby.

No exchange of oxygen or carbon dioxide takes place until air enters the respiratory bronchioles. The area of the respiratory tract from the nose to the respiratory bronchioles serves only as a conducting pathway and is therefore termed the *anatomical dead space* (V_D). This space must be filled with every breath, but the air that fills it is not available for gas exchange. In adults, a normal **tidal volume,** or volume of air exchanged with each breath, is about 500 mL. Of each 500 mL inhaled, about 150 mL is V_D.

After moving through the conducting zone, air reaches the respiratory bronchioles and the alveoli (Figure 28-4). *Alveoli* are small sacs that form the functional unit of the lungs. The alveoli are interconnected by pores of Kohn, which allow movement of air from alveolus to alveolus (see Figure

28-1). Bacteria can also move through these pores; as a result, a respiratory infection can extend to previously noninfected areas. The 300 million alveoli in the adult have a total volume of about 2500 mL and a surface area for gas exchange that is about the size of a tennis court. The alveolar–capillary membrane (Figure 28-5) is very thin—less than 5 mcm thick—and is the site of gas exchange. In conditions such as pulmonary edema, excess fluid fills the interstitial space and the alveoli, markedly impairing gas exchange (Patton & Thibodeau, 2016; Weinberger, Cockrill, & Mandel, 2014).

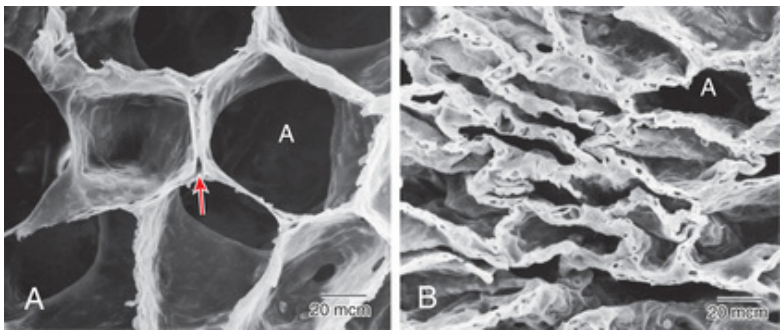

FIGURE 28-4 Scanning electron micrograph of lung parenchyma. **A,** Alveoli *(A)* and alveolar capillary *(arrow).* **B,** Effects of atelectasis. Alveoli *(A)* are partially or totally collapsed. Source: **A,** From Bone, R. C., Dantzker, D. R., George, R. B., et al. (Eds.). (1993). *Pulmonary and critical care medicine* (Vol. 1). St. Louis: Mosby. **B,** From Albertine, K. H., Williams, M. C., & Hyde, D. M. (2005). Anatomy of the lungs. In Mason, R. J., Broaddus, V. C., Murray, J. F., et al. (Eds.), *Murray and Nadel's textbook of respiratory medicine* (4th ed.). Philadelphia: W. B. Saunders.

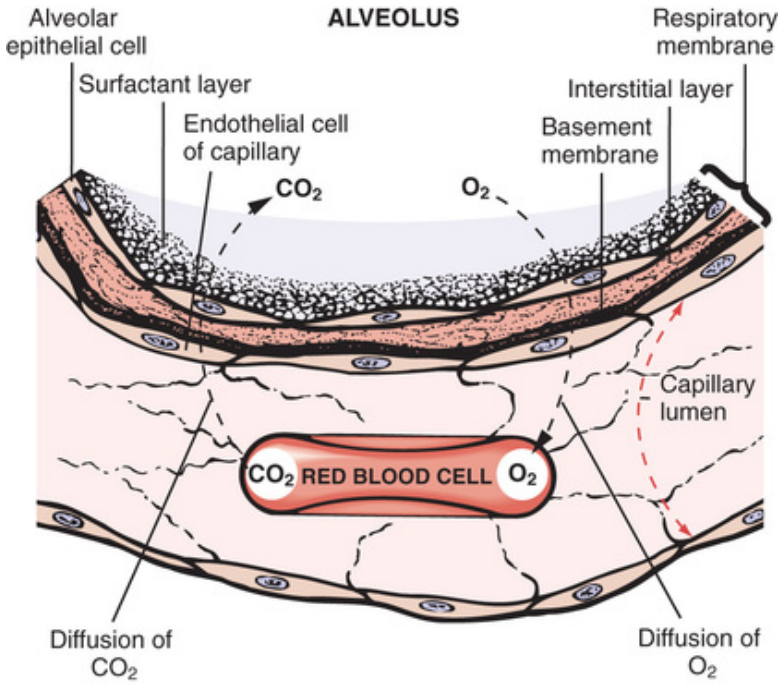

FIGURE 28-5 Illustration of a small portion of the respiratory membrane, greatly magnified. An extremely thin interstitial layer of tissue separates the endothelial cell and basement membrane on the capillary side from the epithelial cell and surfactant layer on the alveolar side of the respiratory membrane. The total thickness of the respiratory membrane is less than 5 mcm.

Surfactant.

The lung can be conceptualized as a collection of 300 million bubbles (alveoli), each 0.3 mm in diameter. Such a structure is inherently unstable and, as a consequence, the alveoli have a natural tendency to collapse. The alveolar surface is composed of cells that provide structure and cells that secrete surfactant (see Figure 28-5). **Surfactant,** a lipoprotein that lowers the surface tension in the alveoli, reduces the amount of pressure needed to inflate the alveoli and decreases the tendency of the alveoli to collapse. Normally, each person takes a slightly larger breath, termed a *sigh,* after every five to six breaths. This sigh stretches the alveoli and promotes surfactant secretion.

When the amount of surfactant is insufficient, the alveoli collapse. The term *atelectasis* refers to collapsed, airless alveoli (see Figure 28-4). The patient who has just undergone surgery is at risk for postoperative atelectasis because of the effects of anaesthesia and restricted breathing with pain (see Chapter 22). In acute respiratory distress syndrome, lack of

surfactant contributes to widespread atelectasis (Huether & McCance, 2017). (Acute respiratory distress syndrome is discussed further in Chapter 70.)

Blood Supply.

The lungs have two different types of circulation: pulmonary and bronchial. The pulmonary circulation provides the lungs with blood for gas exchange. The pulmonary artery receives deoxygenated blood from the right ventricle of the heart and branches so that each pulmonary capillary is directly connected with many alveoli. Oxygen–carbon dioxide exchange occurs at this point. The pulmonary veins return oxygenated blood to the left atrium of the heart.

The bronchial circulation starts with the bronchial arteries, which arise from the thoracic aorta. The bronchial circulation provides oxygen to the bronchi and other pulmonary tissues. Deoxygenated blood returns from the bronchial circulation through the azygos vein into the left atrium.

Chest Wall

The chest wall is shaped, supported, and protected by 24 ribs (12 on each side). The ribs and the sternum protect the lungs and the heart from injury and, collectively, are sometimes called the *thoracic cage.* The structures of the chest wall include the thoracic cage, the pleura, and the respiratory muscles.

The chest cavity is lined with a membrane called the *parietal pleura,* and the lungs are lined with a membrane called the *visceral pleura.* The parietal and visceral pleurae are joined and form a closed, double-walled sac. The visceral pleura does not have any afferent pain fibres or nerve endings. The parietal pleura, however, does have afferent pain fibres. Therefore, irritation of the parietal pleura causes severe pain with each breath.

The space between the pleural layers is termed the *intrapleural space.* In a normal adult, this space is filled with a thin film of fluid, which serves two purposes: it provides lubrication, allowing the layers of pleura to slide over each other during breathing, and it increases cohesion between the pleural layers, thereby facilitating expansion of the pleura and lung during inspiration.

Normally, the pleural space contains 20 to 25 mL of fluid. Fluid is drained from the pleural space by the lymphatic circulation. Several pathological conditions may cause the accumulation of greater amounts of fluid; such accumulations are termed *pleural effusions.* Pleural fluid may

accumulate because malignant cells block lymphatic drainage or because there is an imbalance between intravascular and oncotic fluid pressures, as occurs in heart failure. The presence of purulent pleural fluid with bacterial infection is called *empyema.*

The diaphragm is the major muscle of respiration. During inspiration, the diaphragm contracts, pushing the abdominal contents downward. At the same time, the external intercostal muscles and scalene muscles contract, increasing the lateral and anteroposterior dimension of the chest. This causes the size of the thoracic cavity to increase and intrathoracic pressure to decrease, so that air can enter the lungs.

The diaphragm is made up of two hemidiaphragms, each innervated by the right and left phrenic nerves. The phrenic nerves arise from the spinal cord between the third and fifth cervical vertebrae (C3 and C5). Injury to the phrenic nerve results in hemidiaphragmatic paralysis on the side of the injury. Complete spinal cord injuries above the level of C3 result in total diaphragmatic paralysis, and affected patients are dependent on mechanical ventilation (Herlihy, 2014).

Physiology of Respiration

Ventilation.

Ventilation involves *inspiration* (movement of air into the lungs) and *expiration* (movement of air out of the lungs). Air moves in and out of the lungs because intrathoracic pressure changes in relation to pressure at the airway opening. Contraction of the diaphragm and of the intercostal and scalene muscles increases chest dimensions, thereby decreasing intrathoracic pressure. Gas flows from an area of higher pressure (atmospheric) to one of lower pressure (intrathoracic). When inspiration is difficult, neck and shoulder muscles can assist the effort. Some conditions (e.g., phrenic nerve paralysis, rib fractures, neuro-muscular disease) may limit diaphragm or chest wall movement and cause the patient to breathe with smaller tidal volumes. As a result, the lungs do not fully inflate, and gas exchange is impaired.

In contrast to inspiration, expiration is passive. The elastic recoil of the chest wall and lungs allows the chest to passively return to its normal position. Intrathoracic pressure rises, causing air to move out of the lungs. Exacerbations of asthma or emphysema cause expiration to become an active, laboured process (see Chapter 31). Abdominal and intercostal muscles assist in expelling air during laboured breathing.

Elastic Recoil and Compliance.

Elastic recoil is the tendency for the lungs to recoil after being stretched or expanded. The elasticity of lung tissue is attributable to the elastin fibres that are found in the alveolar walls and that surround the bronchioles and capillaries.

Compliance (distensibility) is a measure of the elasticity of the lungs and the thorax. When compliance is decreased, inflation of the lungs is more difficult. Examples of conditions in which compliance is decreased include those that increase fluid in the lungs (e.g., pulmonary edema, acute respiratory distress syndrome); diseases that make lung tissue less elastic (e.g., pulmonary fibrosis, sarcoidosis); and conditions that restrict lung movement (e.g., pleural effusion). Compliance is decreased as a result of aging and when there is destruction of alveolar walls and loss of tissue elasticity, as in emphysema.

Diffusion.

Oxygen and carbon dioxide move back and forth across the alveolar capillary membrane by diffusion. The overall direction of movement is from the area of higher concentration to the area of lower concentration. Thus oxygen moves from alveolar gas (atmospheric air) into the arterial blood, and carbon dioxide from the arterial blood into the alveolar gas. Diffusion continues until equilibrium is reached (see Figure 28-5).

The ability of the lungs to oxygenate arterial blood adequately is determined by examination of the arterial oxygen tension (PaO_2; also referred to as the *partial pressure of oxygen in arterial blood*) and arterial oxygen saturation (SaO_2). Oxygen is carried in the blood in two forms: dissolved oxygen and hemoglobin-bound oxygen. The PaO_2 represents the amount of oxygen dissolved in the plasma and is expressed in millimetres of mercury. The SaO_2 is the amount of oxygen actually bound to hemoglobin, as opposed to the amount of oxygen that the hemoglobin can carry. The SaO_2 is expressed as a percentage. For example, if the SaO_2 is 90%, this means that 90% of the hemoglobin attachments for oxygen have oxygen bound to them.

Oxygen–Hemoglobin Dissociation Curve.

The affinity of hemoglobin for oxygen is described by the *oxygen–hemoglobin (oxyhemoglobin) dissociation curve* (Figure 28-6). Oxygen delivery to the tissues depends on the amount of oxygen transported to the tissues

and the ease with which hemoglobin gives up oxygen once it reaches the tissues. In the upper flat portion of the curve, fairly large changes in the PaO_2 cause small changes in hemoglobin saturation. For this reason, if the PaO_2 drops from 100 to 60 mm Hg, the saturation of hemoglobin changes only 7% (from the normal 97% to 90%). In other words, the hemoglobin remains 90% saturated despite a 40–mm Hg drop in the PaO_2. This portion of the curve also explains why a patient is considered adequately oxygenated when the PaO_2 is higher than 60 mm Hg. Increasing the PaO_2 above this level does little to improve hemoglobin saturation.

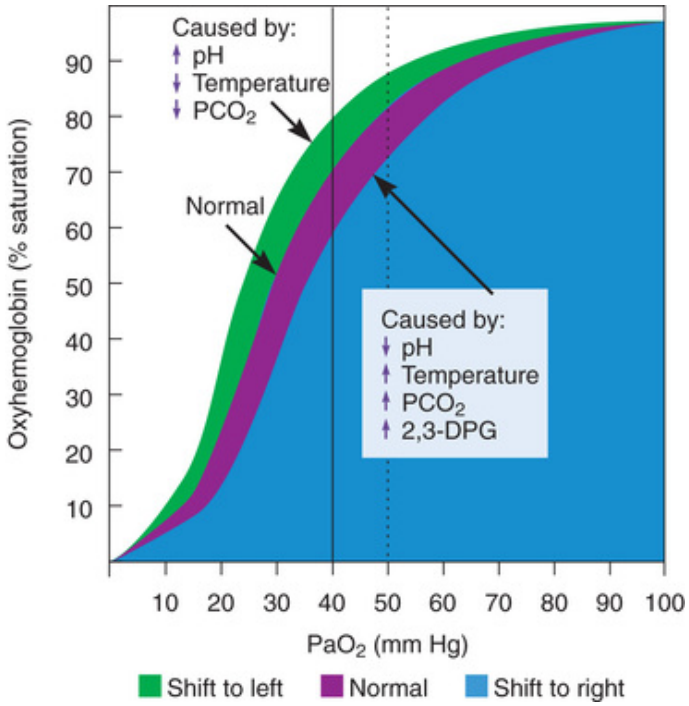

FIGURE 28-6 Oxygen–hemoglobin dissociation curve. A shift to the left indicates the hemoglobin's increased affinity for oxygen. A shift to the right indicates the hemoglobin's decreased affinity for oxygen. *2,3-DPG,* 2,3-diphosphoglycerate; *PaO_2,* partial pressure of oxygen in arterial blood; *PCO_2,* partial pressure of carbon dioxide.

The lower portion of the oxygen–hemoglobin dissociation curve indicates a different type of phenomenon. As hemoglobin is desaturated, larger amounts of oxygen are released for tissue use. This is an important method of maintaining the pressure gradient between the blood and the tissues. It also ensures an adequate oxygen supply to peripheral tissues, even if oxygen delivery is compromised.

Many factors alter the affinity of hemoglobin for oxygen. A shift to the left in the oxygen–hemoglobin dissociation curve indicates that blood picks up oxygen more readily in the lungs but delivers oxygen less readily to the tissues. This occurs in alkalosis, in hypothermia, and with a decrease in arterial carbon dioxide tension ($PaCO_2$; also referred to as the *partial pressure of carbon dioxide in the arterial blood;* see Figure 28-6). A patient with a condition that causes a leftward shift of the curve, such as hypothermia that follows open heart surgery, may be given higher concentrations of oxygen until the body temperature normalizes. This helps compensate for decreased oxygen unloading in the tissues. A shift in the curve to the right indicates the opposite: blood picks up oxygen less rapidly in the lungs but delivers oxygen more readily to the tissues. This occurs in acidosis, in hyperthermia, and when the $PaCO_2$ is increased.

Two methods are used to assess the efficiency of gas transfer in the lung: analysis of arterial blood gas (ABG) values and oximetry. These measures are usually adequate if the patient is stable and not critically ill. Many critically ill patients have a condition that impairs tissue oxygen delivery. In such patients, cardiac output, tissue oxygen consumption, mixed venous oxygen tension (PvO_2), and venous oxygen saturation (SvO_2) may also be assessed (Urden, Stacy, & Lough, 2014; see Chapter 68).

Arterial Blood Gases.

ABGs are measured to determine oxygenation status and acid–base balance. ABG analysis includes measurement of the PaO_2, the $PaCO_2$, the pH, and the amount of bicarbonate (HCO_3^-) in arterial blood. The SaO_2 is either calculated or measured during this analysis. Blood for ABG analysis can be obtained by arterial puncture or from an arterial catheter in the radial or the femoral artery. Both techniques are invasive and allow only intermittent analysis. Continuous intra-arterial blood gas monitoring is also possible via a fibre-optic sensor or an oxygen electrode inserted into an arterial catheter. An arterial catheter enables ABG sampling without repeated arterial punctures.

Normal ABG values are given in Table 28-1, and ABG analysis and interpretation are further discussed in Chapter 19. The normal PaO_2 decreases with advancing age. The normal PaO_2 also varies in relation to the distance above sea level. At higher altitudes, the barometric pressure is lower, and thus the amount of inspired oxygen pressure and the PaO_2 are lower (see Table 28-1). Most airplanes are pressurized to approximate an

altitude of 2400 m above sea level. A normal person can expect a 16– to 32–mm Hg fall in PaO_2 at this altitude (McCance & Huether, 2014). A patient who is already receiving oxygen therapy or whose PaO_2 is lower than 72 mm Hg while he or she is breathing room air needs a careful evaluation before air travel. Supplemental oxygen or a change in litre flow may be required during the flight.

TABLE 28-1

NORMAL ARTERIAL AND VENOUS BLOOD GAS VALUES*

Laboratory Value	Arterial Blood Gases		Mixed Venous Blood Gases
	BP at Sea Level: 760 mm Hg	BP at 1609 m Above Sea Level: 629 mm Hg	
pH	7.35–7.45	7.35–7.45	7.31–7.41
Partial pressure of oxygen	80–100 mm Hg	65–75 mm Hg	40–50 mm Hg
Oxygen saturation	≥95%†	≥95%†	60–80%†
Partial pressure of carbon dioxide	35–45 mm Hg	35–45 mm Hg	SvO_2 is a better indicator for change in acid–base balance
HCO_3^-	21–28 mmol/L	21–28 mmol/L	21–28 mmol/L

*Assumes patient is 60 years of age or younger and breathing room air.

†The same normal values apply to both the venous oxygen saturation value (obtained through mixed venous blood gas sampling or oximetry via catheter) and the oxygen saturation value (obtained through pulse oximetry).

BP, barometric pressure; *HCO_3^-*, bicarbonate.

Mixed Venous Blood Gases.

For patients with normal or near-normal cardiac status, an assessment of PaO_2 or SaO_2 is usually sufficient to determine adequate oxygenation. Patients with impaired cardiac output or hemodynamic instability may have inadequate tissue oxygen delivery or abnormal oxygen consumption. The amount of oxygen delivered to the tissues or consumed can be calculated.

A catheter positioned in the pulmonary artery, termed a *pulmonary artery catheter,* is used for mixed venous sampling (see Chapter 68). Blood drawn from a pulmonary artery catheter is termed a *mixed venous blood gas sample* because it consists of venous blood that has returned to the heart from all tissue beds and "mixed" in the right ventricle. Normal mixed venous values are listed in Table 28-1. When tissue oxygen delivery is

inadequate or when amount of oxygen transported to the tissues by the hemoglobin is inadequate, the PvO_2 and SvO_2 fall.

Oximetry.

ABG values provide accurate information about oxygenation and acid–base balance. However, the tests are invasive, necessitate laboratory analysis, and create the risk of bleeding from an arterial puncture. Arterial oxygen saturation can be monitored continuously by means of a *pulse oximetry* probe on a finger, a toe, an ear, the forehead, or the bridge of the nose (Figure 28-7).

FIGURE 28-7 **A,** Portable pulse oximeter displays oxygen saturation (SpO_2) and pulse rate. **B,** A pulse oximeter displays the oxygen saturation and pulse rate as a digital reading. Sources: *A,* © Can Stock Photo/praisaeng. *B,* © Can Stock Photo/masuti.

A pulse oximeter emits two wavelengths of light, one red and one infrared, which pass from a light-emitting diode (positioned on one side of the probe) to a photodetector (positioned on the opposite side). Well-oxygenated blood absorbs light differently than does deoxygenated blood. The oximeter determines the amount of light absorbed by the vascular bed and calculates the saturation. The oxygen saturation value obtained by pulse oximetry (SpO_2) and heart rate are displayed on the monitor as digital readings (see Figure 28-7, *B*). The normal SpO_2 is higher than 95%.

Pulse oximetry is particularly valuable in intensive care and perioperative areas, in which sedation or decreased consciousness might

mask hypoxia (Table 28-2). SpO_2 is assessed during each routine check of vital signs in many inpatient areas. Changes in SpO_2 can be detected quickly and treated (Table 28-3). Oximetry is also used during exercise testing and when flow rates are adjusted during long-term oxygen therapy. Pulse oximetry alone does not provide information about ventilation status and acid–base balance. Therefore, ABG measurements are also needed periodically.

TABLE 28-2
SIGNS AND SYMPTOMS OF INADEQUATE OXYGENATION

Signs and Symptoms	Onset
Central Nervous System	
Unexplained apprehension	Early
Unexplained restlessness or irritability	Early
Unexplained confusion or lethargy	Early or late
Combativeness	Late
Coma	Late
Respiratory System	
Tachypnea	Early
Dyspnea on exertion	Early
Dyspnea at rest	Late
Use of accessory muscles	Late
Retraction of interspaces on inspiration	Late
Pause for breath between sentences, words	Late
Cardiovascular System	
Tachycardia	Early
Mild hypertension	Early
Dysrhythmias (e.g., premature ventricular contractions)	Early or late
Hypotension	Late
Cyanosis	Late
Cool, clammy skin	Late
Other Body Systems	
Diaphoresis	Early or late
Decreased urinary output	Early or late
Unexplained fatigue	Early or late

TABLE 28-3

CRITICAL VALUES FOR PaO_2 AND SpO_2*

PaO_2	SpO_2	Considerations
≥70%	≥95%	Adequate unless patient is hemodynamically unstable or has O_2 unloading problem. With a low cardiac output, dysrhythmias, a leftward shift of the oxygen–hemoglobin dissociation curve, or carbon monoxide inhalation, higher values may be desirable. Benefits of a higher arterial O_2 level must be balanced against the risk of O_2 toxicity.
60%	90%	Adequate in almost all patients. Values are at steep part of oxygen–hemoglobin dissociation curve. Oxygenation is adequate, but margin of error is less than for higher values.
55%	88%	Adequate for patients with chronic hypoxemia if no cardiac problems occur. These values are also used as criteria for prescription of continuous O_2 therapy.
40%	75%	Inadequate but may be acceptable on a short-term basis if the patient also has CO_2 retention. In this situation, respirations may be stimulated by a low PaO_2. Thus, the PaO_2 cannot be raised rapidly. O_2 therapy at a low concentration (24%–28%) will gradually increase the PaO_2. Monitoring for dysrhythmias is necessary.
<40%	<75%	Inadequate. Tissue hypoxia and cardiac dysrhythmias can be expected.

*The same critical values apply for SpO_2 and arterial oxygen saturation (SaO_2). Values pertain to rest or exertion.

PaO_2, partial pressure of oxygen in arterial blood; *SpO_2*, the oxygen saturation value obtained by pulse oximetry.

Values obtained by pulse oximetry are less reliable if the SpO_2 is lower than 70%. At this level, the oximeter tends to underestimate saturation and may display an artificially low value. Pulse oximetry is also inaccurate if hemoglobin variants (e.g., carboxyhemoglobin, methemoglobin) are present. Other factors that can alter the accuracy of pulse oximetry include motion, low perfusion, anemia, bright fluorescent lights, intravascular dyes, thick acrylic nails, and dark skin colour. If there is doubt about the accuracy of the SpO_2 reading, ABGs should be measured to verify accuracy.

Oximetry can also be used to monitor SvO_2 via a pulmonary artery catheter. A decrease in SvO_2 suggests that less oxygen is being delivered to the tissues or that more oxygen is being consumed. Changes in SvO_2 provide an early warning of a change in cardiac output or tissue oxygen delivery. Normal SvO_2 is 60% to 80%.

Oxygen Delivery.

Information from ABG values or oximetry is used to assess adequacy of oxygenation. Several questions must be asked to determine whether oxygenation is adequate:

1. What is the patient's SpO_2 or PaO_2 in comparison with expected normal values (see Table 28-1)?
2. What is the degree of hypoxemia, and what is the trend? Has SpO_2 or PaO_2 declined rapidly? A sudden drop in blood oxygen level can be life-threatening. A gradual decline is tolerated with fewer symptoms. Critical values for SpO_2 and PaO_2 are given in Table 28-3.
3. Is the patient exhibiting signs or symptoms of inadequate oxygenation? Changes in central nervous system, respiratory, cardiovascular, and renal function occur when tissue oxygen delivery is inadequate (see Table 28-2). Because the brain is highly sensitive to a decrease in tissue oxygen delivery, the first evidence of hypoxemia may be apprehension, restlessness, or irritability. If these signs or symptoms are observed, a change in the management plan is needed.
4. What is the oxygenation status with activity or exercise? To assess for desaturation with activity, pulse oximetry is used to monitor SpO_2 levels during a standardized 6-minute walk distance test or during activities of daily living. An SpO_2 value of 88% or less during exertion indicates the need for supplemental oxygen (McCance & Huether, 2014).

Control of Respiration

In the brain stem, the respiratory centre in the medulla responds to chemical and mechanical signals from the body. Impulses are sent from the medulla to the respiratory muscles through the spinal cord and phrenic nerves.

Chemoreceptors.

A **chemoreceptor** is a receptor that responds to a change in the chemical composition ($PaCO_2$ and pH) of the fluid around it. Central chemoreceptors are located in the medulla and respond to changes in the hydrogen ion (H^+) concentration. An increase in the H^+ concentration *(acidosis)* causes the medulla to increase the respiratory rate and tidal volume. A decrease in H^+ concentration *(alkalosis)* has the opposite effect. Changes in $PaCO_2$ regulate ventilation primarily by their effect on the pH of the cerebro-spinal fluid. When the $PaCO_2$ level is increased, more CO_2 is

available to combine with H_2O and form carbonic acid (H_2CO_3). This lowers the pH of the cerebro-spinal fluid and stimulates an increase in respiratory rate. The opposite process occurs with a decrease in $PaCO_2$ level.

Peripheral chemoreceptors are located in the carotid bodies at the bifurcation of the common carotid arteries and in the aortic bodies above and below the aortic arch. The peripheral chemoreceptors respond to decreases in PaO_2 and pH and to increases in $PaCO_2$. These changes also cause stimulation of the respiratory centre.

In a healthy person, an increase in $PaCO_2$ or a decrease in pH causes an immediate increase in the respiratory rate. The process is extremely precise. The $PaCO_2$ does not vary more than about 3 mm Hg if lung function is normal. Conditions such as chronic obstructive pulmonary disease (COPD) alter lung function and may result in chronic elevation of $PaCO_2$ levels. In these circumstances, patients are relatively insensitive to further increases in $PaCO_2$ as a stimulus to breathe and may be maintaining ventilation largely because of a hypoxic drive from the peripheral chemoreceptors (carbon dioxide narcosis is discussed in Chapter 31).

Mechanical Receptors.

Mechanical receptors (juxtacapillary and irritant) are located in lungs, upper airways, chest wall, and diaphragm. They are stimulated by a variety of physiological factors, such as irritants, muscle stretching, and alveolar wall distortion. Signals from the stretch receptors aid in the control of respiration. As the lungs inflate, pulmonary stretch receptors activate the inspiratory centre to inhibit further lung expansion. This is termed the *Hering–Breuer reflex* and prevents overdistension of the lungs. Impulses from the mechanical sensors are sent through the vagus nerve to the brain. Juxtacapillary (J) receptors are believed to cause the rapid respiration (tachypnea) observed in patients with pulmonary edema. These receptors are stimulated by the entry of fluid into the pulmonary interstitial space.

Respiratory Defence Mechanisms

Respiratory defence mechanisms are efficient in protecting the lungs from inhaled particles, microorganisms, and toxic gases. The defence

mechanisms include filtration of air, the mucociliary clearance system, the cough reflex, reflex bronchoconstriction, and alveolar macrophages.

Filtration of Air.

Nasal hairs filter the inspired air. In addition, the abrupt changes in direction of airflow that occur as air moves through the nasopharynx and larynx increase air turbulence. This causes particles and bacteria to contact the mucosa lining these structures. Most large particles (>5 mcm in diameter) are removed in this manner.

The velocity of airflow slows greatly after it passes the larynx, facilitating the deposition of smaller particles (1–5 mcm in size). They settle like sand in a river, a process termed *sedimentation.* Particles less than 1 mcm in size are too small to settle in this manner and are deposited in the alveoli. One example of small particles that can build up is coal dust, which can lead to pneumoconiosis (see Chapter 30). Particle size is important. Particles larger than 5 mcm are less dangerous because they are removed in the nasopharynx or bronchi and do not reach the alveoli.

Mucociliary Clearance System.

Below the larynx, movement of mucus is accomplished by the mucociliary clearance system, commonly referred to as the *mucociliary escalator.* This term is used to indicate the interrelationship between the secretion of mucus and the ciliary activity. Mucus is continually secreted at a rate of about 100 mL per day by goblet cells and submucosal glands. It forms a mucous blanket that contains the impacted particles and debris from distal lung areas (see Figure 28-1). The small amount of mucus normally secreted is swallowed without being noticed. Collectins (glycoproteins which are part of the innate immune system) are secreted and produced by the lungs and contribute to protection against bacteria and viruses (McCance & Huether, 2014).

Cilia cover the airways from the level of the trachea to the respiratory bronchioles (see Figure 28-1). Each ciliated cell contains approximately 200 cilia, which beat rhythmically about 1 000 times per minute in the large airways, moving mucus toward the mouth. The ciliary beat is slower farther down the tracheobronchial tree. As a consequence, particles that penetrate more deeply into the airways are removed less rapidly. Ciliary action is impaired by dehydration, smoking, inhalation of high oxygen concentrations, infection, and ingestion of drugs such as atropine, anaesthetics, alcohol, and cocaine. Cilia are often destroyed by chronic

bronchitis and cystic fibrosis, which results in impaired secretion clearance, a chronic productive cough, and frequent upper respiratory infections.

Cough Reflex.

The cough is a protective reflex action that clears the airway by a high-pressure, high-velocity flow of air. It is a backup for mucociliary clearance, especially when this clearance mechanism is overwhelmed or ineffective. Coughing is effective in removing secretions only above the subsegmental level (large or main airways). Secretions below this level must be moved upward by the mucociliary mechanism or by interventions such as postural drainage before they can be removed by coughing.

Reflex Bronchoconstriction.

Another defence mechanism is reflex bronchoconstriction. In response to the inhalation of large amounts of irritating substances (e.g., dusts, aerosols), the bronchi constrict in an effort to prevent entry of the irritants. In conditions of hyperreactive airways, such as asthma, bronchoconstriction occurs after inhalation of cold air, perfume, or other strong odours.

Alveolar Macrophages.

Because ciliated cells are not found below the level of the respiratory bronchioles, the primary defence mechanism at the alveolar level is performed by alveolar macrophages. *Alveolar macrophages* rapidly phagocytize inhaled foreign particles such as bacteria. The debris is moved to the level of the bronchioles for removal by the cilia or is removed from the lungs by the lymphatic system. Particles (e.g., coal dust, silica) that cannot be adequately phagocytized tend to remain in the lungs for indefinite periods and can stimulate inflammatory responses (see Chapter 30). Because alveolar macrophage activity is impaired by cigarette smoke, people who are employed in an occupation with heavy dust exposure (e.g., mining, foundries) and smoke are at an especially high risk for lung disease.

Age-Related Considerations

Effects of Aging on the Respiratory System

Age-related changes in the respiratory system and related assessment findings can be divided into alterations in structure, defence mechanisms, and respiratory control (Table 28-4).

TABLE 28-4

AGE-RELATED DIFFERENCES IN ASSESSMENT
Respiratory System

Changes	Differences in Assessment Findings
Structure	
↓ Elastic recoil ↓ Chest wall compliance ↑ Anteroposterior diameter ↓ Functioning alveoli	Barrel shape of chest ↓ Chest wall movement ↓ Respiratory excursion ↓ Vital capacity* ↑ Functional residual capacity* Diminished breath sounds, particularly at lung bases ↓ PaO_2 and SaO_2; normal pH and $PaCO_2$
Defence Mechanisms	
↓ Cell-mediated immunity ↓ Specific antibodies ↓ Cilia function ↓ Cough force ↓ Alveolar macrophage function	↓ Cough effectiveness ↓ Secretion clearance ↑ Risk of upper respiratory infection, influenza, and pneumonia; respiratory infections may be more severe and last longer
Respiratory Control	
↓ Response to hypoxemia ↓ Response to hypercapnia	Greater ↓ in PaO_2 and ↑ in $PaCO_2$ before respiratory rate changes Significant hypoxemia or hypercapnia may develop as a result of relatively minor incidents Retained secretions, excessive sedation, or positioning that impairs chest expansion may substantially alter PaO_2 or SpO_2 values

*See Table 28-14 for definitions of terms related to lung volumes and capacities.

$PaCO_2$, arterial carbon dioxide tension; *PaO_2*, arterial oxygen tension; *SaO_2*, arterial oxygen saturation; *SpO_2*, oxygen saturation value obtained by pulse oximetry.

Within the aging lung, the number of functional alveoli decreases and small airways in the lung bases close earlier in expiration. As a consequence, more inspired air is distributed to the lung apices, and ventilation is less matched to perfusion, which causes a lowering of the

PaO_2. The PaO_2 associated with a given age can be calculated by means of the following equation:

$$PaO_2 \text{ (mm Hg)} = 103.5 - (0.42 \times \text{age in years})$$

For example, the normal PaO_2 for a patient 80 years of age is 70 mm Hg (103.5 − [0.42 × 80]); in comparison, the normal PaO_2 for a 25-year-old person is 93 mm Hg (103.5 − [0.42 × 25]).

The extent of these changes varies among persons of the same age. Older adults—who have experienced many years of exposure to smoking, air pollutants, and other environmental toxins—are at risk for a host of other conditions (Hoffman Wold, 2012; Jarvis, Browne, MacDonald-Jenkins, et al., 2014).

Assessment of the Respiratory System

Correct diagnosis depends on an accurate health history and a thorough physical examination (Table 28-5). A respiratory assessment can be performed as part of a comprehensive physical examination or as a focused evaluation. Whether all or part of the history and physical examination is completed is based on problems presented by the patient and the degree of respiratory distress. If respiratory distress is severe, only pertinent information should be obtained; a thorough assessment should be deferred until the patient's condition stabilizes. Table 28-6 outlines subjective and objective data that may emerge during the assessment that provide clues to the presence of respiratory problems.

TABLE 28-5

HEALTH HISTORY
Respiratory System: Questions for Obtaining Subjective Data

Cough
• Do you have a cough, and if so, when did it start? How often do you cough? Does it wake you up at night? Does activity affect your cough?* What relieves your cough? • Do you cough up sputum?* How much do you expectorate? What colour is your sputum? • Are you coughing up blood?*
Shortness of Breath
• Are you ever short of breath?* What brings it on? • Do you get too short of breath to do the things you want to do?* (Note: To determine the intensity of dyspnea, the Medical Research Council Dyspnea Scale [see Chapter 31, Figure 31-12] or a visual analogue scale may be helpful [Registered Nurses' Association of Ontario, 2010, p. 93]) • Do breathing problems cause you to awaken during the night?* • Can you lie flat at night? If not, how many pillows do you use? Do you need to sleep upright in a chair? • What do you do when you get short of breath?
Chest Pain With Breathing
• Do you experience chest pain with breathing?* Where exactly is the pain located? What brings on the pain? What relieves the pain?
History of Respiratory Infections or Illness
• Do you have any history of breathing trouble or lung disease (e.g. shortness of breath, coughing, blood in your sputum, COPD, bronchitis, emphysema, asthma, pneumonia, sleep apnea)?* • Have you ever been hospitalized or treated for a respiratory illness?* • Do you have frequent colds or very severe colds, or both?* • Do you have any allergies or sensitivities (food, environmental, medications)?* • Do you have a family history of allergies, tuberculosis, or asthma?*
Self-Care History
• Do you use any equipment or take any medications to manage respiratory symptoms (e.g., home oxygen therapy equipment, metered-dose inhaler with spacer or nebulizer for medication administration, positive airway pressure device for relief of sleep apnea)?* • Do you smoke?* If yes, how many packs daily? For how many years? Do you smoke cigarettes or cigars? Have you ever tried to quit? Are you living with someone who smokes? • Are there any environmental conditions at home or work that may have an effect on your respiratory health (e.g., smoke, dust, chemicals)?* If so, do you do anything to protect your lungs or monitor your exposure? • Have you received immunization for influenza (flu), pneumococcal pneumonia (Pneumovax), tuberculosis skin test, and/or chest radiograph? When?

*If the answer is "yes," the patient should describe further.

COPD, chronic obstructive pulmonary disease.

Source: Based on Jarvis, C., Browne, A. J., MacDonald-Jenkins, J., et al. (Eds.). (2014). *Physical examination & health assessment* (2nd Canadian ed., pp. 441–443). Toronto: Elsevier Canada.

TABLE 28-6

CLUES TO RESPIRATORY PROBLEMS

Manifestation	Description
Shortness of breath (dyspnea)	Distressing sensation of uncomfortable breathing. Most common complaint of people with respiratory problems. Person may become accustomed to the sensation and not recognize its presence. Difficult to evaluate because it is a subjective experience.
Wheezing	May or may not be heard by patient. May be described as "chest tightness."
Pleuritic chest pain	Described on a continuum from discomfort during inspiration to intense, sharp pain at the end of inspiration. Pain is usually aggravated by deep breathing and coughing.
Cough	Characteristics and timing of cough are important diagnostic clues.
Sputum production	Material coughed up from lungs. Contains mucus, cellular debris, or microorganisms and may contain blood or pus. Amount, colour, and constituents of sputum constitute important diagnostic information.
Hemoptysis	Coughing up of blood; sputum may be grossly bloody, frankly bloody, or blood-tinged. Precipitating events should be investigated.
Audible changes	Voice changes such as hoarseness and muffling, stridor (whistling sound during inspiration), or a barking cough may indicate abnormalities of upper airway, vocal cord dysfunction, or gastro-esophageal reflux disease.
Fatigue	Sense of overwhelming tiredness, not completely relieved by sleep or rest.

Case Study

Patient Introduction

Source: Monkey Business Images/Shutterstock.com.

Fred Thompson is a 70-year-old man who comes to the emergency department complaining of increased shortness of breath. He states that he started using his salbutamol (Ventolin) inhaler every 4 hours a few days ago, but it does not seem to be helping. He has been having trouble sleeping or doing any activity because of the shortness of breath.

Critical Thinking

As you read through this assessment chapter, think about Mr. Thompson's symptoms with the following questions in mind:

1. What are the possible causes of Mr. Thompson's shortness of breath?
2. What type of assessment would be most appropriate for Mr. Thompson: comprehensive, focused, or emergency?
3. What questions would the nurse ask Mr. Thompson?
4. What should be included in the physical assessment? What would the nurse be looking for?
5. What diagnostic studies might be ordered?

See pp. 567, 570, and 572 for more information on Mr. Thompson.

Subjective Data

Important Health Information

Past Health History.

The nurse should discuss with the patient the types of respiratory illnesses that the patient experienced during childhood (e.g., croup, respiratory syncytial virus, asthma, pneumonia, frequent colds).

The nurse should determine the frequency of upper respiratory problems (e.g., colds, sore throats, sinus problems, allergies) and whether weather changes exacerbate these problems. Patients with allergies should be questioned about possible precipitating factors such as medications or exposure to pollen, smoke, or animal dander. Characteristics of the allergic reaction—such as runny nose, wheezing, scratchy throat, or sensation of tightness in the chest—and the severity of the reaction should be documented. The frequency of asthma exacerbations and cause, if known, should also be determined. Prior use of a peak expiratory flowmeter and personal best values can be helpful information in determining the patient's current asthma status.

A history of lower respiratory tract problems, such as asthma, COPD, pneumonia, and tuberculosis, should also be documented (see the "Determinants of Health: Tuberculosis in Canada" box, Chapter 30). Respiratory symptoms are often manifestations of problems that involve other body systems. Therefore, the patient should be asked whether he or she has a history of other health problems in addition to those involving the respiratory system. For example, patients with cardiac dysfunction may experience **dyspnea** (shortness of breath) as a consequence of heart

failure. Patients with human immunodeficiency virus (HIV) infection may experience frequent respiratory infections because immune function is compromised.

Medications.

Patients should be questioned carefully about prescription and over-the-counter (OTC) drugs used to manage respiratory problems, such as antihistamines, bronchodilators, corticosteroids, cough suppressants, and antibiotics. The nurse should obtain information about the reason for taking the medication, its name, the dose and frequency, length of time taken, its effect, and any adverse effects.

If a patient is using supplemental oxygen to ease a breathing problem, the amount, the method of administration, and effectiveness of the therapy should be documented. Safety practices related to using supplemental oxygen should also be assessed.

Patients should be questioned with regard to OTC and herbal remedies used to treat respiratory illnesses such as the common cold, sore throat, and laryngitis.

Surgery or Other Treatments.

The nurse should determine whether a patient has been hospitalized for a respiratory problem. If so, the dates, therapy (including surgery), and current status of the problem should be recorded. The nurse should ask about the use and results of respiratory treatments such as nebulizer, humidifier, airway clearance modalities, high-frequency chest oscillation, postural drainage, and percussion.

Current Health History.

If a patient has a cough, the nurse should evaluate the quality of the cough. For example, a productive cough indicates the presence of secretions; a dry, hacking cough indicates airway irritation or obstruction; a harsh, barking cough is suggestive of upper airway obstruction from inhibited vocal cord movement related to subglottic edema. The nurse should assess whether the cough is weak or strong and whether it is productive or nonproductive of secretions. Determining the onset and chronicity of a cough is helpful in the differential diagnosis process. The pattern of the cough is determined from answers to questions such as the following: What has been the pattern of coughing? Has it been regular or irregular, and has it been related to a time of day or weather, certain activities, talking, or deep breaths? Has the cough changed over time?

What efforts have been tried to alleviate the coughing? Were any prescription or OTC drugs tried?

If a patient has a productive cough, the following characteristics of sputum should be evaluated: amount, colour, consistency, and odour. The amount should be quantified in teaspoons, tablespoons, or cups per day. The nurse should note any recent increases or decreases in the amount. The normal colour is clear or slightly whitish. If a patient smokes cigarettes, the sputum is usually clear to grey with occasional specks of brown. Patients with COPD may exhibit clear, whitish, or slightly yellow sputum, especially in the morning on rising. If a patient reports any change in sputum from baseline colour to yellow, pink, red, brown, or green, pulmonary complications should be suspected. Changes in consistency of sputum to thick, thin, or frothy should be noted. These changes may indicate dehydration, postnasal drip or sinus drainage, or possible pulmonary edema. Normally sputum should be odourless. A foul odour is suggestive of an infectious process. The patient should be asked whether the sputum was produced along with a position change (e.g., increased with lying down) or a change in activity.

Patients should be questioned about a family history of respiratory problems that may be genetic or familial tendencies, such as asthma, emphysema resulting from α_1-antitrypsin deficiency, or cystic fibrosis. A history of family exposure to tubercle bacilli should be noted.

Risk factors for tuberculosis (TB) include prior residence in Asia, Africa, Latin America, or any developing nation. People who are homeless, those who use injection drugs, Indigenous people, health care workers, residents of long-term care facilities and correctional facilities are also at increased risk of TB infection. People with certain comorbid conditions such as HIV infection and diabetes and those receiving dialysis have an increased risk of TB reactivation (Public Health Agency of Canada, The Lung Association, & Canadian Thoracic Society, 2014). Risk factors for avian influenza A (H7N9) include recent trips to China (Public Health Ontario, 2015a). It is important for the nurse to take droplet or airborne precautions with patients being assessed for new respiratory illness (Public Health Ontario, 2013; 2015b).

The nurse should also ask about current and past smoking habits and quantify exposure in pack-years by multiplying the number of packs smoked per day by the number of years smoked. For example, a person who smoked one pack per day for 15 years has a 15 pack-year history. The risk of lung cancer rises in direct proportion to the number of pack-years smoked. Smoking increases the risk of COPD and exacerbates symptoms

of asthma and chronic bronchitis. In addition to asking about cigarette use, it is important to find out the use of any other tobacco products, including cigars, pipes, chewing tobacco, and smokeless tobacco products. Information about exposure to second-hand smoke is also important. The nurse should also ask whether the patient has made efforts—including the use of prescription, OTC, and herbal remedies—to quit the use of these tobacco products.

The nurse should ask whether the patient received immunization for influenza (flu) and pneumococcal pneumonia (Pneumovax). Influenza vaccine should be administered yearly in the fall (Public Health Agency of Canada, 2015a). Pneumococcal vaccine is recommended for persons 65 years of age or older and for individuals with chronic cardiovascular disease, chronic pulmonary disease, or diabetes mellitus. The current recommendation is one dose of Pneumovax vaccine for adults aged 65 or older. This vaccine is also recommended in immunocompromised persons, such as organ transplant recipients (Public Health Agency of Canada, 2014).

Patients should be asked whether they use equipment to manage respiratory symptoms, such as home oxygen therapy equipment, metered-dose inhaler (MDI) with spacer or nebulizer for medication administration, and positive airway pressure device for relief of sleep apnea. Patients should be questioned about the type of equipment used, frequency of use, its therapeutic effect, and any adverse effects. Patients who use an MDI should be asked to demonstrate its use. Many patients do not know how to use MDI devices correctly (see Chapter 31).

Case Study

Subjective Data

Source: Monkey Business Images/Shutterstock.com.

A focused subjective assessment of Fred Thompson revealed the following information:

History of Current Illness: Has been experiencing increasing difficulty breathing since catching a cold from his granddaughter last week, even with the use of salbutamol (Ventolin). Has had increased shortness of breath on exertion and worsening paroxysmal nocturnal dyspnea. Denies any pain or confusion associated with the shortness of breath.

Past Health: COPD, hypertension, and benign prostatic hyperplasia. No history of environmental allergies. Denies history of coronary artery disease or heart failure.

Medications: Metoprolol, 50 mg/day orally; finasteride (Propecia), 5 mg/day orally; fluticasone and salmeterol (Advair) inhaler, 2 puffs per day; and salbutamol (Ventolin) inhaler, 2 puffs every 4 hours as needed. Does not use O_2 at home.

Functional Assessment: Mr. Thompson states that he usually manages his COPD well with just the fluticasone and salmeterol (Advair) inhaler and occasional use of the salbutamol (Ventolin) inhaler as needed. Has a history of 30 pack-years of smoking, having quit 5 years ago. Had a Pneumovax vaccination 5 years ago and receives the flu vaccine on an annual basis. States that he can typically walk at least 2 blocks and up and down stairs without getting short of breath. However, at this point, he cannot walk 30 metres without feeling short of breath, nor can he walk up one flight of stairs without stopping to catch his breath. Has been having difficulty sleeping with this most recent episode of shortness of breath. Typically uses just one pillow to sleep with but needed three pillows this week, and last night he slept upright in his recliner. Denies any stress or emotional disturbance that could be having an impact on his breathing. Feels slightly irritable because of lack of sleep.

See pp. 565, 570, and 572 for more information on Mr. Thompson.

Objective Data

Physical Examination.

Vital signs, including temperature, pulse, respirations, and blood pressure, are important data to collect before examination of the respiratory system.

Nose.

The nose is inspected for patency, inflammation, deformities, symmetry, and discharge. Each naris (nostril) is checked for air patency with respiration while the other naris is briefly occluded. The nurse tilts the patient's head backward and pushes the tip of the nose upward gently. With a nasal speculum and a good light, the nurse inspects the interior of the nose. The mucous membrane should be pink and moist, with no evidence of edema (bogginess), exudate, or bleeding. The nasal septum should be observed for deviation, perforations, and bleeding. Some nasal deviation is normal in an adult. The turbinates should be observed for polyps, which are abnormal, finger-like projections of swollen nasal mucosa. Polyps may result from long-term irritation of the mucosa, as from allergies. Any discharge should be assessed for colour and consistency. The presence of purulent and malodorous discharge could indicate the presence of a foreign body. Watery discharge could be secondary to allergies or could represent cerebro-spinal fluid. Bloody discharge could be secondary to trauma. Thick mucosal discharge could indicate the presence of infection.

Mouth and Pharynx.

Using a good light source, the nurse inspects the interior of the mouth for colour, lesions, masses, gum retraction, bleeding, and poor dentition. The tongue is inspected for symmetry and presence of lesions. The nurse observes the pharynx by pressing a tongue blade against the middle of the back of the tongue. The pharynx should be smooth and moist, with no evidence of exudate, ulcerations, swelling, or postnasal drip. The colour, symmetry, and any enlargement of the tonsils are noted. The nurse stimulates the gag reflex by placing a tongue blade along the side of the pharynx behind the tonsil. A normal response (gagging) indicates that cranial nerves IX (glossopharyngeal nerve) and X (vagus nerve) are intact and that the airway is protected. Each side of the pharynx should be checked for the gag reflex.

Neck.

The nurse inspects the neck for symmetry and presence of tender or swollen areas. The lymph nodes are palpated while the patient is sitting erect with the neck slightly flexed. Palpation progresses from the nodes around the ears to the nodes at the base of the skull and then to those located under the angles of the mandible to the midline. The nodes may be small, mobile, and nontender (shotty nodes), which is not a sign of a pathological condition. Nodes that are tender, hard, or fixed indicate disease. The location and characteristics of any palpable nodes are described.

Thorax and Lungs.

Imaginary lines can be pictured on the chest to help in identifying abnormalities (see Figure 28-2). The locations of abnormalities can be described in relation to these lines (e.g., 2 cm from the right midclavicular line).

Chest examination is best performed in a well-lit, warm room, with measures taken to ensure the patient's privacy. Either the anterior or the posterior aspect of the chest may be examined first.

Inspection.

The anterior aspect of the chest should be exposed while the patient is sitting upright or with the head of the bed upright. The patient may need to lean forward on the bedside table for support in order to facilitate breathing. First, the nurse observes the patient's appearance and notes any evidence of respiratory distress, such as tachypnea or use of accessory muscles. Next, the nurse determines the shape and symmetry of the chest. Chest movement should be equal on both sides, and the anteroposterior diameter should be less than the transverse diameter. Normal anteroposterior diameter is less than the transverse diameter by a ratio of 1 : 2. An increase in anteroposterior diameter (e.g., in the case of barrel-shaped chest) may be a normal age-related change or a result of lung hyperinflation, as occurs with emphysema. The nurse observes for abnormalities in the sternum, such as *pectus carinatum* (a prominent protrusion of the sternum) and *pectus excavatum* (an indentation of the lower sternum above the xiphoid process).

Next, the nurse should observe the respiratory rate, depth, and rhythm. The normal rate is 12 to 20 breaths per minute; in older persons, it is 16 to 25 breaths per minute. Inspiration should take half as long as expiration (ratio of inspiration to expiration is 1 : 2). The nurse should observe for

abnormal breathing patterns, such as Kussmaul's (rapid, deep breathing), Cheyne–Stokes (abnormal pattern of respiration characterized by alternating periods of apnea and deep, rapid breathing), or Biot's respiration (a sequence with an irregular pattern of three to four respirations varying in depth, followed by a period of apnea) (Jarvis, Browne, MacDonald-Jenkins, et al., 2014). Skin colour provides clues to respiratory status. In dark-skinned patients, cyanosis is best observed in the conjunctivae, lips, palms, and soles of the feet. Causes of cyanosis include hypoxemia and decreased cardiac output. The fingers should be inspected for evidence of *clubbing* (an increase in the angle between the base of the nail and the fingernail to 180 degrees or more, usually accompanied by an increase in depth, bulk, and sponginess of the end of the finger). Nail beds should also be inspected for cyanosis.

When the nurse is inspecting the posterior aspect of the chest, the patient should lean forward with arms folded. This position moves the scapula away from the spine, so there is more exposure of the area to be examined. The observations that were made on the anterior part of the chest are made in the same sequence on the posterior part. In addition, any spinal curvature is noted. Spinal curvatures that affect breathing include kyphosis, scoliosis, and kyphoscoliosis.

Palpation.

The nurse determines tracheal position by gently placing the index fingers on either side of the patient's trachea just above the suprasternal notch and gently pressing backward. Normal tracheal position is midline; deviation to the left or right is abnormal. Tracheal deviation occurs away from the side of a tension pneumothorax or a neck mass but toward the side of a pneumonectomy or lobar atelectasis (Wilson & Giddens, 2013). The nurse determines symmetry of chest expansion and extent of movement at the level of the diaphragm. The nurse places the hands over the lower anterior aspect of the patient's chest wall along the costal margin and moves them inward until the thumbs meet at midline. The patient is asked to breathe deeply, and the nurse observes the movement of the thumbs away from each other. Normal expansion is 2.5 cm. On the posterior side of the chest, the nurse places the hands at the level of the patient's tenth rib and moves the thumbs until they meet over the patient's spine (Figure 28-8).

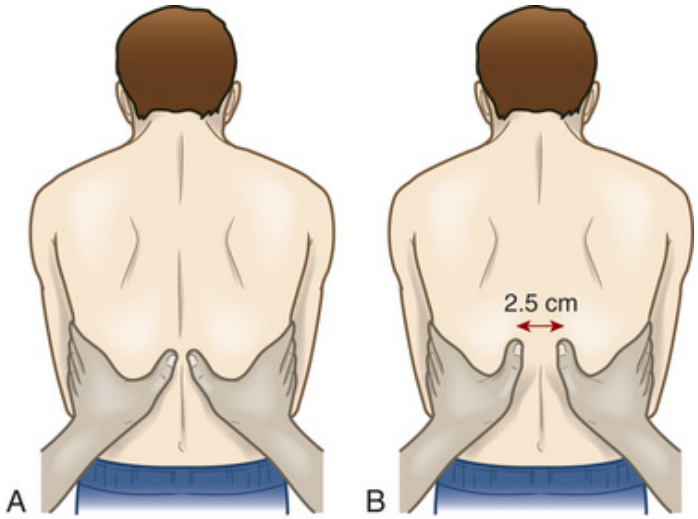

FIGURE 28-8 Estimation of thoracic expansion. **A,** Exhalation. **B,** Maximal inhalation.

Normal chest movement is symmetrical. Expansion is asymmetrical when air entry is limited by conditions involving the lung (e.g., atelectasis, pneumothorax) or the chest wall (e.g., incisional pain). Expansion is symmetrical but diminished in conditions that cause the chest to become hyperinflated or barrel-shaped and in neuro-muscular conditions (e.g., amyotrophic lateral sclerosis, spinal cord lesions). Movement may be absent or asymmetrical over a pleural effusion, an atelectasis, or a pneumothorax.

Fremitus is an abnormal, palpable vibration in the chest wall that is produced during vocalization and caused by the passage of air past thick bronchial mucus. The nurse can feel it with the hand on the chest while the patient takes a deep inspiration, and it may change or clear with coughing. It is produced by vocalization. To elicit tactile fremitus, the nurse places the palms of the hands against the patient's chest and asks the patient to repeat a phrase such as “ninety-nine.” The nurse moves the hands from side to side and from top to bottom on the patient's chest (Figure 28-9). All areas of the chest should be palpated, and vibrations from an area on one side should be compared with those from the corresponding area on the other side. Tactile fremitus is most intense in the first and second interspaces lateral to the sternum and between the scapulae because these areas are closest to the major bronchi. Fremitus is less intense farther away from these areas.

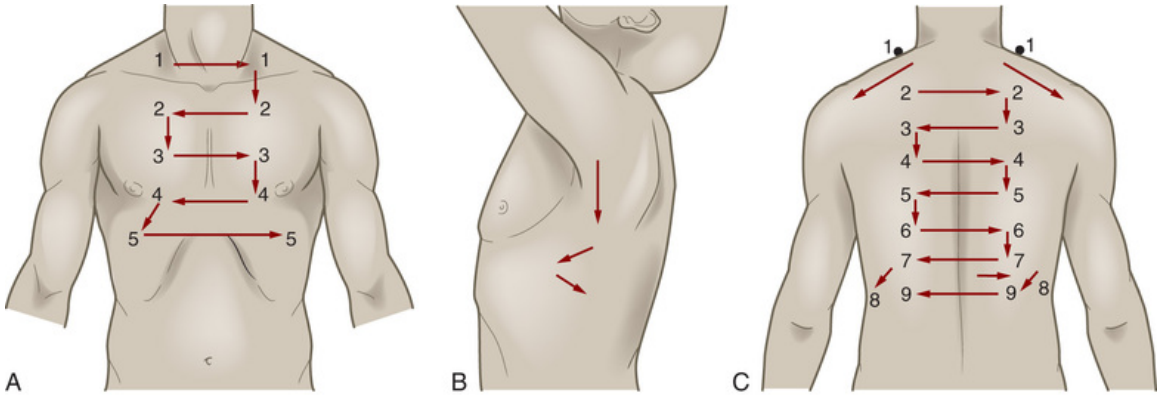

FIGURE 28-9 Sequence for examination of the chest. **A,** Anterior sequence. **B,** Lateral sequence. **C,** Posterior sequence. For palpation, the nurse places the palms of the hands in the position designated as *1* on the right and left sides of the chest. The nurse compares the intensity of vibrations. Then the nurse repeats for all positions in each sequence. For percussion, the nurse taps the chest at each designated position, moving downward from side to side, while comparing percussion notes. For auscultation, the nurse places the stethoscope at each position and listens to at least one complete inspiratory and expiratory cycle.

Increase in, decrease in, or absence of fremitus should be noted. Fremitus is increased when the lung becomes filled with fluid or denser. This is noted with pneumonia, with lung tumours, and above a pleural effusion (the lung is compressed upward). Fremitus is decreased if the hand is farther from the lung (e.g., pleural effusion) or if the lung is hyperinflated (e.g., as in barrel-shaped chest). Absence of fremitus may be noted with pneumothorax or atelectasis. The anterior aspect of the chest is more difficult to palpate for fremitus because of the presence of large muscles and breast tissue.

Percussion.

Percussion is performed to assess density or aeration of the lungs. Percussion sounds are described in Table 28-7. (The technique for percussion is described in Chapter 3.)

TABLE 28-7

PERCUSSION SOUNDS

Sound	Description
Resonance	Low-pitched sound heard over normal lungs
Hyperresonance	Loud, lower-pitched sound than normal resonance heard over hyperinflated lungs, as in chronic obstructive lung disease and acute asthma
Tympany	Drumlike, loud, empty quality heard over gas-filled stomach or intestine or over pneumothorax
Dull	Medium-intensity pitch and duration heard over areas of "mixed" solid and lung tissue, such as over the top area of the liver, partially consolidated lung tissue (pneumonia), or fluid-filled pleural space
Flat	Soft, high-pitched sound of short duration heard over very dense tissue in which air is not present

The anterior aspect of the chest is usually percussed with the patient in a semisitting or supine position. Starting above the clavicles, the nurse percusses downward, interspace by interspace (see Figure 28-9). The area over lung tissue should be resonant, with the exception of the area of cardiac dullness (Figure 28-10). For percussion of the posterior chest, the patient should sit leaning forward with arms folded. The posterior chest should be resonant over lung tissue to the level of the diaphragm (Figure 28-11).

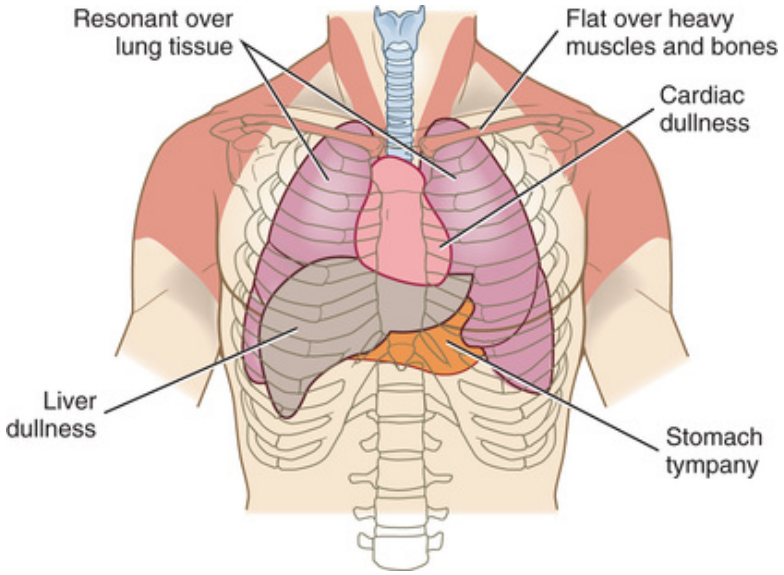

FIGURE 28-10 Diagram of percussion areas and sounds in the anterior aspect of the chest. Source: Redrawn from Thompson, J. M., McFarland, G., & Tucker, S. (2002). *Mosby's clinical nursing* (5th ed.). St. Louis: Mosby.

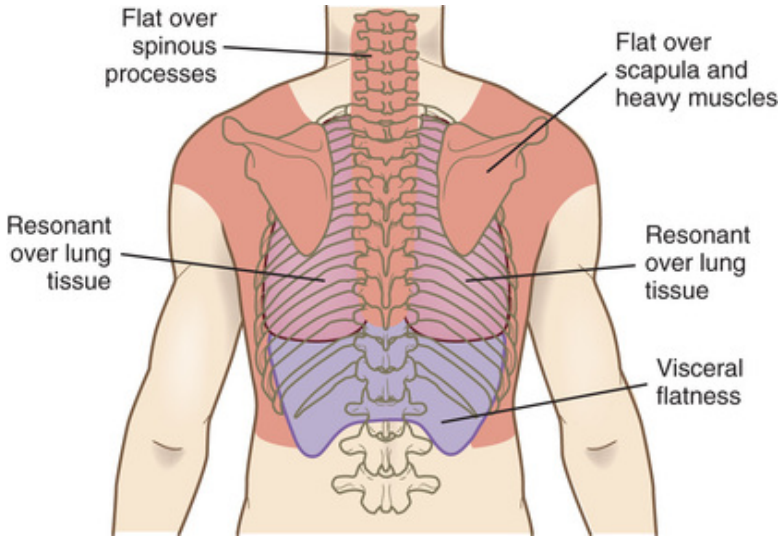

FIGURE 28-11 Diagram of percussion areas and sounds in the posterior aspect of the chest. Percussion proceeds from the lung apices to the lung bases, and sounds from opposite areas of the chest are compared. Source: Redrawn from Thompson, J. M., McFarland, G., & Tucker, S. (2002). *Mosby's clinical nursing* (5th ed.). St. Louis: Mosby.

Auscultation.

During chest auscultation, the patient is instructed to breathe slowly and deeply in through the nose and out through the mouth. The nurse should proceed by comparing opposite areas of the chest, from the lung apices to the bases (see Figure 28-9). The stethoscope should be placed over lung tissue, not over bony prominences. At each placement of the stethoscope, the nurse should listen to at least one cycle of inspiration and expiration. Note the pitch (e.g., high, low), the duration of sound, and presence of any adventitious or abnormal sounds. The location of normal auscultatory sounds is more easily understood through visualization of a lung model (Figure 28-12).

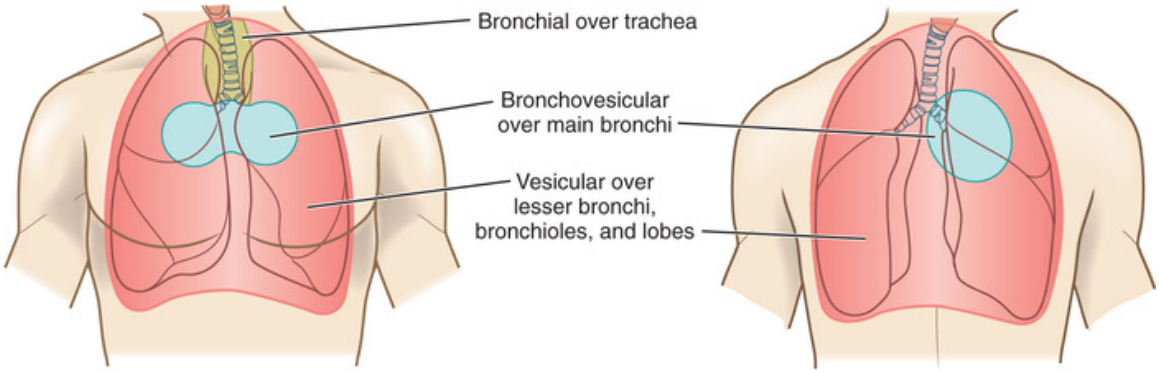

FIGURE 28-12 Normal auscultatory sounds. Source: From Beare, P. G., & Myers, J. L. (1998). *Adult health nursing* (3rd ed.). St. Louis: Mosby.

The lung sounds should be heard down to the sixth rib anteriorly at the midclavicular line, the eighth rib at the midaxillary line, and the tenth rib at the scapular line in the back. In addition, during a deep breath, the lungs expand to the twelfth rib posteriorly. There are three normal breath sounds: vesicular, bronchovesicular, and bronchial. *Vesicular sounds* are relatively soft, low-pitched, gentle, rustling sounds. They are heard over all lung areas except the major bronchi. Vesicular sounds are heard longer on inspiration than on expiration, in a 3 : 1 ratio. *Bronchovesicular sounds* have a medium pitch and intensity and are heard anteriorly over the mainstem bronchi on either side of the sternum and posteriorly between the scapulae. Bronchovesicular sounds are heard for the same length of time on inspiration as on expiration (1 : 1). *Bronchial sounds* last for a shorter time on inspiration than on expiration by a ratio of 2 : 3, with a gap between inspiration and expiration that reflects the short pause between respiratory cycles. Bronchial sounds are louder and higher pitched and resemble air blowing through a hollow pipe. Bronchial sounds can be heard if the stethoscope is placed alongside the trachea in the neck.

The term *abnormal breath sounds* is used to describe bronchial or bronchovesicular sounds heard in the peripheral lung fields. **Adventitious sounds** are extra breath sounds that are abnormal. Adventitious breath sounds, described more fully in Table 28-8, include **crackles** (short, low-pitched sounds caused by the passage of air through an airway intermittently occluded by mucus, unstable bronchial wall, or fold of mucosa), **wheezes** (continuous high-pitched squeaking sound caused by rapid vibration of bronchial walls), and **pleural friction rub** (a creaking or grating sound that occurs when roughened, inflamed surfaces of the pleura rub together; it is evident during inspiration, expiration, or both; and does not change with coughing).

TABLE 28-8
NORMAL PHYSICAL ASSESSMENT OF THE RESPIRATORY SYSTEM

- Nose is symmetrical with no deformities. Nasal mucosa is pink and moist with no edema, exudate, blood, or polyps. Nasal septum is straight, without perforations.
- Oral mucosa is light pink and moist, with no exudate or ulcerations.
- Tonsils are not inflamed or enlarged.
- Pharynx is smooth, moist, and pink.
- Trachea is midline. No nodes are palpable.
- Chest is elliptical in shape, and chest expansion is symmetrical. Respirations are regular and nonlaboured, at the rate of 14/min. Breath sounds noted throughout both lung fields, without crackles or wheezes. No axillary nodes are palpable.

A record of normal findings in the physical assessment of the respiratory system is shown in Table 28-8. Assessment abnormalities of the thorax and lungs are listed in Table 28-9. Chest examination findings in common pulmonary problems are listed in Table 28-10. Age-related changes in the respiratory system and assessment findings are listed in Table 28-4.

TABLE 28-9

ASSESSMENT ABNORMALITIES
Respiratory System

Finding	Description	Possible Etiology and Significance*
Inspection		
Pursed-lip breathing	Exhalation through mouth with lips pursed together to slow exhalation	COPD, asthma; suggests ↑ breathlessness; strategy taught to slow expiration, reduce dyspnea
Tripod position; inability to lie flat	Learning forward with arms and elbows supported on overbed table	COPD, asthma in exacerbation, pulmonary edema; indicates moderate to severe respiratory distress
Accessory muscle use; intercostal retractions	Neck and shoulder muscles used to assist breathing; muscles between ribs pull in during inspiration	COPD, asthma in exacerbation, secretion retention; indicates severe respiratory distress, hypoxemia
Splinting	↓ Inspiratory effort (or ↓ in tidal volume) as a result of sharp pain upon inspiration	Thoracic or abdominal incision; chest trauma, pleurisy
↑ Anteroposterior diameter	Anteroposterior chest diameter equal to transverse diameter; slope of ribs more horizontal (90 degrees) to spine	COPD, asthma, cystic fibrosis; lung hyperinflation; advanced age
Tachypnea	Rate >20 breaths/min; >25 breaths/min in older adults	Fever, anxiety, hypoxemia, restrictive lung disease; ↑ above normal respiratory rate reflects increased work of breathing
Kussmaul's respirations	Regular, rapid, and deep respirations	Metabolic acidosis; ↑ in rate aids body in ↑ CO_2 excretion
Cyanosis	Bluish coloration of skin, best seen in earlobes, under the eyelids, or in nail beds	↓ Oxygen transfer in lungs, ↓ cardiac output; nonspecific, unreliable indicator
Clubbing of fingers	↑ Depth, bulk, sponginess of distal digit of finger	Chronic hypoxemia; cystic fibrosis, lung cancer, bronchiectasis
Abdominal paradox	Inward (rather than normal outward) movement of abdomen during inspiration	Inefficient and ineffective breathing pattern; nonspecific indicator of severe respiratory distress
Palpation		
Tracheal deviation	Leftward or rightward movement of trachea from normal midline position	Nonspecific indicator of change in position of mediastinal structures; medical emergency if caused by tension pneumothorax
Altered tactile fremitus	Increase or decrease in vibrations	↑ In pneumonia, pulmonary edema; ↓ in pleural effusion, lung hyperinflation; absent in pneumothorax, atelectasis
Altered chest movement	Diminished movement (can be asymmetrical or symmetrical) of two sides of chest with inspiration	Asymmetrical movement caused by atelectasis, pneumothorax, pleural effusion, splinting; symmetrical but diminished movement caused by barrel shape of chest, restrictive disease, neuro-muscular disease
Percussion		
Hyper-resonance	Loud, lower-pitched sound over areas that normally produce a resonant sound	Lung hyperinflation (COPD), lung collapse (pneumothorax), air trapping (asthma)
Dullness	Medium-pitched sound over areas that normally produce a resonant sound	↑ Density (pneumonia, widespread atelectasis), ↑ fluid pleural space (pleural effusion)
Auscultation		

Finding	Description	Possible Etiology and Significance*
Fine crackles	Series of short, explosive, high-pitched sounds heard just before the end of inspiration; rapid equalization of gas pressure when collapsed alveoli or terminal bronchioles suddenly snap open; sounds similar to rolling hair between fingers just behind ear	Interstitial fibrosis (asbestosis), interstitial edema (early pulmonary edema), alveolar filling (pneumonia), loss of lung volume (atelectasis), early phase of heart failure
Coarse crackles	Series of short, low-pitched sounds on inspiration and sometimes expiration; air passing through airway intermittently occluded by mucus, unstable bronchial wall, or fold of mucosa; sounds similar to blowing through straw under water (increase in bubbling quality with more fluid)	Heart failure, pulmonary edema, pneumonia with severe congestion, COPD
Wheezes	Continuous high-pitched squeaking sound caused by rapid vibration of bronchial walls; first evident on expiration; possibly evident on inspiration as obstruction of airway increases; possibly audible without stethoscope	Bronchospasm (caused by asthma), airway obstruction (caused by foreign body; tumour; viscous, thick increased secretions), COPD, pneumonia, bronchiectasis
Stridor	Continuous musical sound of constant pitch; result of partial obstruction of larynx or trachea	Croup, epiglottitis, vocal cord edema after extubation, foreign body
Absence of breath sounds	No sound evident over entire lung or area of lung	Pleural effusion, mainstem bronchi obstruction, widespread atelectasis, pneumonectomy, lobectomy, severe acute asthma (i.e., silent chest)
Pleural friction rub	Creaking or grating sound occurs when roughened, inflamed surfaces of pleura rub together; evident on inspiration, expiration, or both; no change with coughing; usually painful, especially on deep inspiration	Pleurisy, pneumonia, pulmonary infarct

*Only common causes are listed. (These conditions are discussed further in Chapters 29 through 31.)

COPD, chronic obstructive pulmonary disease.

TABLE 28-10

CHEST EXAMINATION FINDINGS IN COMMON PULMONARY PROBLEMS

Problem	Inspection	Palpation	Percussion	Auscultation
Chronic bronchitis	Barrel shape of chest; cyanosis; possible clubbing of fingers	—	Resonant	Crackles over deflated areas; wheeze may be present
Emphysema	Barrel shape of chest; tripod position; use of accessory muscles	↓ Chest expansion	Hyper-resonant or dull if consolidation is present	Crackles diminished if no exacerbation is present
Asthma (during an exacerbation)	Prolonged expiration; tripod position; pursed lips	↓ Chest expansion ↓ Fremitus if hyperinflation is present	Hyper-resonance	Wheezes; ↓ breath sounds are ominous sign if no improvement occurs (represent severely diminished air movement)
Pneumonia	Tachypnea; use of accessory muscles; cyanosis	Unequal movement with lobar involvement; ↑ fremitus over affected area	Dull over affected areas	Early: bronchial sounds Later: crackles; wheezes
Atelectasis	No change unless entire segment or lobe is involved	If area affected is small, no change If area affected is large, ↓ movement on affected side; ↑ fremitus	Dull over affected areas	Crackles (may disappear with deep breaths); absence of sounds if large area is affected
Pulmonary edema	Tachypnea; laboured respirations; cyanosis	↓ Chest expansion or normal movement	Dull or normal, depending on amount of fluid	Fine or coarse crackles
Pleural effusion	Tachypnea; use of accessory muscles	↓ Chest expansion ↑ Fremitus above effusion; absence of fremitus over effusion	Dull	Diminished or absent over effusion; egophony over effusion
Pulmonary fibrosis	Tachypnea	↓ Chest expansion	Normal	Crackles

A focused assessment is performed to evaluate the status of previously identified respiratory problems and to monitor for signs of new problems (see Chapter 3, Table 3-6). A focused assessment of the respiratory system is presented in the following "Focused Assessment" box.

Case Study

Objective Data: Physical Examination

Source: Monkey Business Images/Shutterstock.com.

Physical examination findings of Fred Thompson are as follows:

BP 170/90, apical pulse 110, respiratory rate 30, temp 37°C, O_2 saturation 87% on room air. Patient sitting on edge of bed with arms resting on bedside table. Slight use of accessory muscles in neck and shoulders noted. Chest expansion equal. Respirations regular but slightly laboured with prolonged expiration. Skin colour pale with no cyanosis. No clubbing noted. Trachea midline. Bibasilar crackles, scattered rhonchi, and expiratory wheezing heard on auscultation. Moist, productive cough with yellow-tinged sputum.

Throughout this chapter, consider diagnostic studies that may be ordered for Mr. Thompson.

See pp. 565, 567, and 572 for more information on Mr. Thompson.

Focused Assessment

Respiratory System

Use this checklist to make sure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note the responses:

Shortness of breath	Y	N
Wheezing	Y	N
Sputum production (colour, quantity)	Y	N
Pain with breathing	Y	N
Cough	Y	N

Objective: Diagnostic

Check the following laboratory results for critical values:

Arterial blood gas measurements	✓
Chest radiographic examination	✓
Hematocrit, hemoglobin measurements	✓

Objective: Physical Examination

Observe

Respirations for rate, quality, and pattern	✓
Facial expression, level of consciousness, position patient takes to breath	

Inspect

Skin and nails for integrity and colour	✓
Accessory muscle use and position of trachea	✓
Shape, symmetry, and movement of chest wall	✓

Palpate

Chest and back for masses Tactile fremitus	✓

Auscultate

Lung (breath) sounds	✓

Diagnostic Studies of the Respiratory System

Blood Studies

Common blood studies used to assess the respiratory system are the determinations of hemoglobin, hematocrit, and ABGs. Table 28-11 lists nursing responsibilities associated with these tests.

TABLE 28-11
DIAGNOSTIC STUDIES
Respiratory System

Study	Description and Purpose	Nursing Responsibility
Blood Studies		
Hemoglobin (Hb) measurement	Value reflects amount of hemoglobin available for combination with oxygen. Venous blood is sampled. Normal level for men is 140–180 mmol/L; normal level for women is 120–160 mmol/L.	Explain procedure and its purpose.
Hematocrit (Hct) measurement	Value reflects ratio of red blood cells to plasma cells. Hematocrit is increased (polycythemia) in chronic hypoxemia. Venous blood is sampled. Normal value for men is 0.42–0.52; normal value for women is 0.37–0.47.	Explain procedure and its purpose.
ABG measurements	Values reflect acid–base balance, ventilation status, need for oxygen therapy, change in oxygen therapy, or change in ventilator settings.* Arterial blood is obtained through puncture of radial or femoral artery or through arterial catheter. Continuous ABG monitoring is also possible via a sensor or electrode inserted into the arterial catheter.	Indicate whether patient is using supplemental oxygen (percentage, amount per minute). Avoid change in oxygen therapy or interventions (e.g., suctioning, position change) for 20 min before obtaining sample. Assist with positioning (e.g., palm up, wrist slightly hyperextended if radial artery is used). Collect blood into heparinized syringe. To ensure accurate results, expel all air bubbles, and place sample on ice, unless it will be analyzed in <1 min. Apply pressure to artery for 5 min after specimen is obtained to prevent hematoma at the arterial puncture site.
Oximetry	Test monitors arterial or venous oxygen saturation. Oximetry is used for intermittent or continuous monitoring and exercise testing.†‡ Device attaches to finger, forehead, earlobe, or nose for SpO_2 monitoring or is contained in a pulmonary artery catheter for SvO_2 monitoring.	Apply probe to finger, forehead, earlobe, or bridge of nose. Before interpreting SpO_2 and SvO_2 values, first assess patient status and presence of factors that can alter accuracy of pulse oximeter reading. For SpO_2, these include motion, low perfusion, bright lights, use of intravascular dyes, acrylic nails, dark skin colour. For SvO_2, these include change in oxygen delivery or consumption. For SpO_2, notify health care provider of ±4% change from baseline or ↓ to <90%. For SvO_2, notify health care provider of ±10% change from baseline or ↓ to <60%.
Sputum Studies		
Culture and sensitivity	Purpose is to diagnose bacterial infection, select antibiotic, and evaluate treatment. Single sputum specimen is collected in a sterile container.	Instruct patient on how to produce a good specimen (see nursing responsibilities for Gram stain). If patient cannot produce specimen, bronchoscopy may be used (see Figure 28-13).
Gram stain	Staining of sputum enables classification of bacteria into gram-negative and gram-positive types. Results guide therapy until culture and sensitivity results are obtained.	Instruct patient to expectorate sputum into the container after coughing deeply. Obtain sputum (mucoid-like), not saliva. Obtain specimen in early morning because secretions accumulate during night. If sputum production is unsuccessful, try increasing oral fluid intake unless fluids are restricted. Collect sputum in sterile container (sputum trap) during suctioning or by aspirating secretions from the trachea. Send specimen to laboratory promptly.
Sputum Studies—cont'd		

Study	Description and Purpose	Nursing Responsibility
Acid-fast smear and culture	Test is performed to collect sputum for acid-fast bacilli (tuberculosis). A series of three early morning specimens is used.	Instruct patient on how to produce a good specimen (see nursing responsibilities for Gram stain). Cover specimen and send to laboratory for analysis.
Cytology study	Purpose is to determine presence of abnormal cells that may indicate malignant condition. Single sputum specimen is collected in special container with fixative solution.	Send specimen to laboratory promptly. Instruct patient on how to produce a satisfactory specimen (see nursing responsibilities for Gram stain). If patient cannot produce specimen, bronchoscopy may be used (Figure 28-13).
Radiology		
Chest radiograph	Test is used to screen, diagnose, and evaluate change. Most common views are posteroanterior and lateral.	Instruct patient to undress to waist, put on gown, and remove any metal objects (e.g., jewellery, watch) between neck and waist.
Computed tomography (CT)	Test is performed for diagnosis of lesions difficult to assess by conventional radiographic studies, such as those in the hilum, the mediastinum, and the pleura. Images show structures in cross-section.	Same as for chest radiograph.
Magnetic resonance imaging (MRI)	Test is used for diagnosis of lesions difficult to assess by CT (e.g., lung apex near the spine).	Same as for chest radiograph. Instruct the patient to remove all metal objects (e.g., jewellery, watch) before test.
Ventilation–perfusion (VQ) scan	Test is used to identify areas of the lung not receiving airflow (ventilation) or blood flow (perfusion). It involves injection of radioisotope and inhalation of small amount of radioactive gas (xenon). A gamma ray–detecting device records radioactivity. Ventilation without perfusion is suggestive of pulmonary embolus.	Same as for chest radiograph. No precautions needed afterward because the gas and isotope transmit radioactivity for only a brief interval.
Pulmonary angiography	Study is used to visualize pulmonary vasculature and locate obstruction or pathological conditions such as pulmonary embolus. Contrast medium is injected through a catheter into the pulmonary artery or right side of the heart.	Same as for chest radiograph. Know that contrast injection may cause flushing, warm sensation, and coughing. Check pressure dressing site after procedure. Monitor blood pressure, pulse, and circulation distal to injection site. Report and record significant changes.
Positron emission tomography (PET)	Test is used to distinguish benign and malignant lung nodules. It involves IV injection of a radioisotope with short half-life.	Same as for chest radiograph. No precautions needed afterward because isotope transmits radioactivity for only a brief interval.
Endoscopic Examinations		
Bronchoscopy	Flexible fibre optic endoscope is used for diagnosis, biopsy, specimen collection, or assessment of changes. It may also be used to suction mucous plugs or to remove foreign objects. Study is typically performed in outpatient procedure room.	Instruct patient to be on NPO status for 6–12 hr. Obtain informed consent. Give sedative if it is ordered. After procedure, keep patient on NPO status until gag reflex returns, and monitor for laryngeal edema; monitor for recovery from sedatives. If biopsy was performed, monitor for hemorrhage and pneumothorax.
Mediastinoscopy	Test is used for inspection and biopsy of lymph nodes in mediastinal area.	Prepare patient for surgical intervention. Obtain informed consent. Afterward, monitor as for bronchoscopy.
Biopsy		

Study	Description and Purpose	Nursing Responsibility
Lung biopsy	Specimens may be obtained by transbronchial or open lung biopsy. This test is used to obtain specimens for laboratory analysis.	Same as for bronchoscopy if procedure is performed with bronchoscope, and same as for thoracotomy (see Chapter 30) if open-lung biopsy is performed. Obtain informed consent.
Other Studies		
Thoracentesis	Test is used to obtain specimen of pleural fluid for diagnosis, to remove pleural fluid, or to instill medication. The physician inserts a large-bore needle through the chest wall into pleural space. A chest radiograph is always obtained after procedure to check for pneumothorax.	Explain procedure to patient, and obtain informed consent before procedure. Position patient sitting upright with elbows on an overbed table and feet supported. Instruct patient not to talk or cough, and assist during procedure. Observe for signs of hypoxia and verify breath sounds in all fields after procedure. Send labelled specimens to laboratory.
Pulmonary function test	Test is used to evaluate lung function. It involves use of a spirometer to diagram air movement as patient performs prescribed respiratory manoeuvres.†	Avoid scheduling test immediately after mealtime. Avoid administration of inhaled bronchodilator for 6 hr before procedure. Explain procedure to patient. Allow patient to rest after procedure.

*For normal values, see Tables 28-1.

†For normal values, see Table 28-15.

‡For critical values, see Table 28-3.

ABG, arterial blood gas; *IV,* intravenous; *NPO,* nothing by mouth; SpO_2, the oxygen saturation value obtained by pulse oximetry; SvO_2, venous oxygen saturation.

Oximetry

Oximetry is used to noninvasively monitor SpO_2 and SvO_2 (see Tables 28-1 and 28-3). Nursing care associated with oximetry is discussed in Table 28-11.

Sputum Studies

Sputum samples can be obtained by expectoration, tracheal suction, or bronchoscopy, a technique in which a flexible bronchoscope is inserted into the airways. The specimens may be examined for culture and sensitivity to identify an infecting organism (e.g., *Mycobacterium* species, *Pneumocystis jiroveci*) or to confirm a diagnosis (e.g., malignant cells). Nursing responsibilities for specimen collection are described in Table 28-11. Regardless of whether specimen tests are ordered, it is important to observe the sputum for colour, blood, volume, and viscosity.

Skin Tests

Skin tests may be performed to test for allergic reactions or exposure to tubercle bacilli or fungi. Usually, 0.1 mL of purified protein derivative is injected intradermally on the ventral surface of the forearm. Skin tests involve the intradermal injection of an antigen. A positive result indicates that the patient has been exposed to the antigen. It does not indicate that disease is currently present. A negative result indicates that the patient has not been exposed or that cell-mediated immunity is depressed, as occurs in HIV infection.

Nursing responsibilities are similar for all skin tests. First, to prevent a false-negative reaction, the nurse should be certain that the injection is intradermal and not subcutaneous. After the injection, the sites should be circled and the patient instructed not to remove the marks. When charting administration of the antigen, the nurse should draw a diagram of the forearm and hand and label the injection sites. The diagram is especially helpful when more than one test is administered.

Tuberculin Skin Testing.

When reading test results, the nurse should use a good light. The reading should be performed within 48 to 72 hours after the purified protein derivative is administered. It can take up to 48 hours for induration to become maximal. However, it is difficult to interpret a reaction after 72 hours (Public Health Agency of Canada, The Lung Association, & Canadian Thoracic Society, 2014). If an induration is present, a marking pen should be used to indicate the periphery (on all four sides) of the induration. As the pen touches the raised area, a mark should be made. The nurse then determines the diameter of the induration in millimetres. Reddened, flat areas are not measured. Reactions that indicate a positive and potential negative tuberculin skin test (TST) are described in Tables 28-12 and 28-13. Canadian health care settings use tuberculin purified protein (Tubersol) for skin tests. If any patient has had a previous bacille Calmette-Guérin vaccination, it will affect results. This is significant especially for people from Quebec, Newfoundland, and Indigenous populations, who regularly received this vaccine from 1940 through the 1970s (Public Health Agency of Canada, 2015b).

TABLE 28-12

SITUATION IN WHICH TUBERCULIN SKIN TEST REACTION IS CONSIDERED POSITIVE

Test Result	Situation in Which Reaction Is Considered Positive*
0–4 mm†	In a child younger than 5 years of age and at high risk of TB infection
≥5 mm	HIV infection
	Contact with person with infectious TB case within the past 2 years
	Presence of fibronodular disease on chest radiograph (healed TB, and not previously treated)
	Organ transplantation (related to immuno-suppressive therapy)
	Tumour necrosis factor alpha inhibitors
	Other immuno-suppressive drugs, such as corticosteroids (equivalent of ≥15 mg/day of prednisone for 1 month or more; risk of TB disease increases with higher dosage and longer duration)
	End-stage renal disease
≥10 mm	All others, including the following specific situations: • Test result conversion (within 2 years) • Diabetes, malnutrition, alcohol abuse (3 drinks/day) • Silicosis • Hematological malignancies (leukemia, lymphoma) and certain carcinomas (e.g., head and neck)

*The goal of testing for latent tuberculosis is to identify individuals who are at increased risk for the development of tuberculosis and therefore would benefit from treatment of latent tuberculosis. Only those who would benefit from treatment should be tested; thus a decision to test presupposes a decision to treat if the test result is positive.

†In general, this level is considered negative, and no treatment is indicated.

HIV, human immunodeficiency virus; *TB,* tuberculosis.

TABLE 28-13

POTENTIAL CAUSES OF FALSE-NEGATIVE RESULT OF TUBERCULIN TEST

Category	Specific Cause
Technical (Potentially Correctable)	
Tuberculin material:	• Improper storage (exposure to light or heat) • Contamination, improper dilution, or chemical denaturation
Administration:	• Injection of too little tuberculin or injection made too deeply (should be intradermal) • Administration more than 20 minutes after tuberculin material is drawn up into the syringe
Reading:	• Inexperienced or biased reader • Error in recording
Biological (Not Correctable)	
Infections:	• Active TB (especially if advanced) • Other bacterial infection (typhoid fever, brucellosis, typhus, leprosy, pertussis) • HIV infection (especially if CD4 count <200) • Other viral infection (measles, mumps, varicella) • Fungal infection (South American blastomycosis)
Live virus vaccination:	• Measles • Mumps • Polio
Immuno-suppressive drugs:	• Corticosteroids • Tumour necrosis factor inhibitors • Others
Metabolic disease:	• Chronic renal failure • Severe malnutrition • Stress (surgery, burns)
Diseases of lymphoid organs:	• Lymphoma • Chronic lymphocytic leukemia • Sarcoidosis
Age:	• Infants <6 months • Older adults

Case Study

Diagnostic Studies

Source: Monkey Business Images/Shutterstock.com.

The health care provider orders the following diagnostic studies for Fred Thompson:

- Complete blood cell count, basic metabolic panel (electrolytes, blood urea nitrogen, creatinine)
- ABGs
- Chest radiograph
- Sputum for culture and sensitivity

The ABGs demonstrate a compensated respiratory acidosis (pH, 7.37; $PaCO_2$, 58 mm Hg; $HC0_3^-$, 29 mEq/L) with hypoxemia (PaO_2 58 mm Hg; SaO_2, 87%). The white blood cell count is 14.3×10^9/L, and the chest radiograph shows lower lobe pneumonia. Mr. Thompson is admitted to the cardiopulmonary medical-surgical nursing unit.

See pp. 565, 567, and 570 for more information on Mr. Thompson.

Radiological Studies

Chest Radiography.

Chest radiographic examination is the most common method of assessing the respiratory system. It is also used to assess progression of disease and response to treatment. The views most commonly used are posteroanterior and lateral. (See Table 28-11 for nursing responsibilities related to chest radiographic examinations.)

Computed Tomography.

Computed tomography (CT) may be used to examine cross-sections of the entire body. CT is used to evaluate areas that are difficult to assess by conventional radiographic study, such as the mediastinum, the hilum, and the pleura. With enhancement by a contrast medium, with a high-

resolution technique, or with newer spiral CT, even pulmonary arteries can be inspected for emboli.

Magnetic Resonance Imaging.

While in a strong magnetic field, the alignment of spinning nuclei can be changed with a superimposed radiofrequency, and the rate at which they return to alignment with the field can be measured. In magnetic resonance imaging (MRI), this technique is used to produce images of body structures. MRI has limited indications. It is most useful for evaluating images near the lung apex or the spine and for distinguishing vascular from nonvascular structures.

Ventilation–Perfusion Scan.

A ventilation–perfusion scan is used primarily to check for the presence of a pulmonary embolus. There is no specific preparation or aftercare. A radioisotope is administered intravenously for the perfusion portion of the test; it outlines the pulmonary vasculature, which is then photographed. For the ventilation portion, the patient inhales a radioactive gas, which outlines the alveoli, and another photograph is taken. Normal scans show homogeneous radioactivity. Diminished appearance or absence of radioactivity is suggestive of lack of perfusion or airflow.

Pulmonary Angiography.

Pulmonary angiography is used to confirm the diagnosis of an embolus if findings of the lung scan are inconclusive. A series of radiographs is taken after radiopaque dye is injected into the pulmonary artery. This test also detects congenital and acquired lesions of the pulmonary vessels.

Positron Emission Tomography.

Positron emission tomography (PET) scans involve the use of radionuclides with short half-lives. PET scans are used to distinguish benign and malignant solitary pulmonary nodules. Because uptake of glucose is increased in malignant lung cells, the PET scan, in which an intravenous glucose preparation is used, can demonstrate the presence of malignant lung cells.

Endoscopic Examinations

Bronchoscopy.

Bronchoscopy is a procedure in which the bronchi are visualized through a fibre-optic tube. Bronchoscopy may be used to obtain biopsy specimens, assess changes resulting from treatment, and remove mucous plugs or foreign bodies. Small amounts (30 mL) of sterile saline may be injected through the bronchoscope, then withdrawn, and examined for cells. This technique, termed *bronchoalveolar lavage*, is used to diagnose *Pneumocystis jiroveci* pneumonia (PCP; see Figure 28-13).

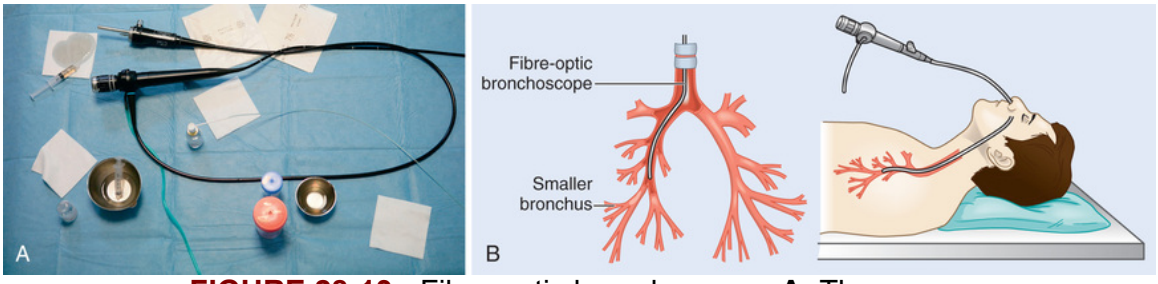

FIGURE 28-13 Fibre-optic bronchoscopy. **A,** The transbronchoscopic balloon-tipped catheter and the flexible fibre-optic bronchoscope. **B,** Procedure. The catheter is introduced into a small airway, and the balloon is inflated with 1.5 to 2 mL of air to occlude the airway. To perform bronchoalveolar lavage, 30 mL aliquots of sterile saline solution are injected and withdrawn, with gentle aspiration after each injection. Specimens are sent to the laboratory for analysis. Source: *A,* BSIP SA/Alamy Stock Photo.

Bronchoscopy can be performed in an outpatient procedure room, in a surgical suite, or at the patient's bedside in the critical care unit or on a medical-surgical floor, with the patient lying down or seated. After local anaesthetic is applied to the nasal pharynx and oral pharynx, the bronchoscope is coated with lidocaine (Xylocaine) and inserted, usually through the nose, and threaded down into the airways. A bronchoscopy can be performed on mechanically ventilated patients through the endotracheal tube. The nursing care for patients undergoing this procedure is described in Table 28-11.

Mediastinoscopy.

For mediastinoscopy, an endoscope is inserted through a small incision in the suprasternal notch and advanced into the mediastinum to inspect lymph nodes and sample them for biopsy. The test is used to diagnose carcinoma, granulomatous infections, and sarcoidosis. The procedure is

performed in the operating room, and the patient is given a general anaesthetic.

Lung Biopsy

Lung biopsy may be performed transbronchially or as an open lung procedure. The purpose is to obtain tissue, cells, or secretions for evaluation. Transbronchial lung biopsy involves passing a forceps or needle through the bronchoscope for a specimen (Figure 28-14). Specimens can be cultured or examined for malignant cells. A combination of transbronchial lung biopsy and bronchoalveolar lavage is used to differentiate infection and rejection in lung transplant recipients. Nursing care is the same as for fibre optic bronchoscopy. Open lung biopsy is used when pulmonary disease cannot be diagnosed by other procedures. The patient receives a general anaesthetic, the chest is opened with a thoracotomy incision, and a biopsy specimen is obtained. Nursing care after the procedure is the same as after thoracotomy (see Chapter 30 and NCP 30-2, available on the Evolve website).

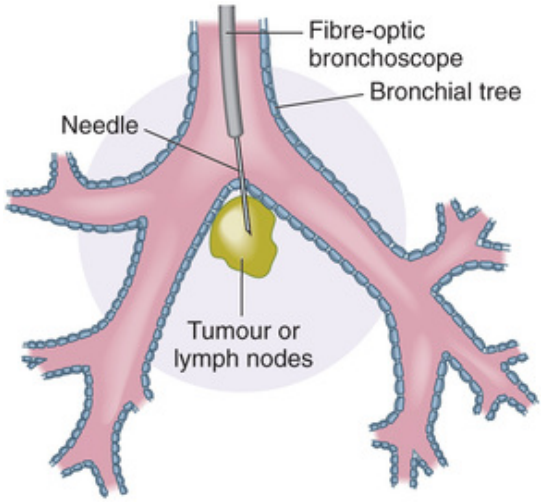

FIGURE 28-14 Transbronchial needle biopsy. In this diagram, a transbronchial biopsy needle penetrates the bronchial wall and enters a mass of subcarinal lymph nodes or tumour. Source: Redrawn from Du Bois, R. M., & Clarke, S. W. (1987). *Fiberoptic bronchoscopy in diagnosis and management.* Orlando, FL: Grune & Stratton.

Thoracentesis

Thoracentesis is the insertion of a needle through the chest wall into the pleural space to obtain specimens for diagnostic evaluation, remove pleural fluid, or instill medication into the pleural space (Figure 28-15). The patient is positioned sitting upright with elbows on an overbed table and feet supported. The skin is cleansed, and a local anaesthetic (lidocaine [Xylocaine]) is instilled subcutaneously. A chest tube may be inserted to enable further drainage of fluid. Nursing care is described in Table 28-11.

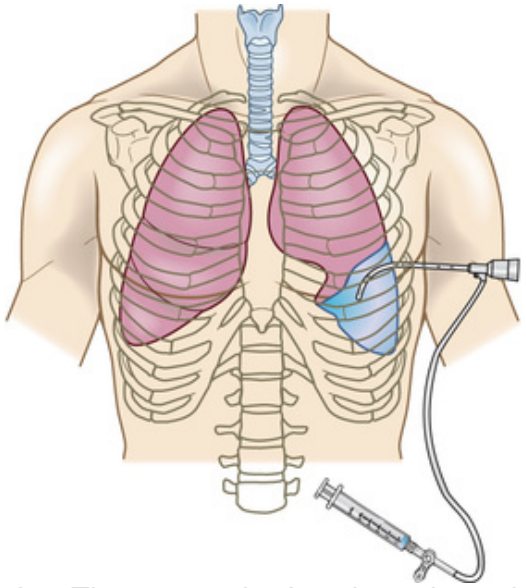

FIGURE 28-15 Thoracentesis. A catheter is positioned in the pleural space to remove accumulated fluid.

Pulmonary Function Tests

Pulmonary function tests (PFTs) are conducted to measure lung volumes and airflow. The results of PFTs are used to diagnose pulmonary disease, monitor disease progression, evaluate disability, and evaluate response to bronchodilators. In PFTs, a spirometer is used. The patient's age, sex, height, and weight are entered into the PFT computer to calculate predicted values. The patient inserts a mouthpiece, takes as deep a breath as possible, and exhales as hard, fast, and long as possible. Verbal coaching is given to ensure that the patient continues blowing out until exhalation is complete. The computer determines the actual value achieved, predicted (normal) value, and percentage of the predicted value for each test. A normal actual value is 80% to 120% of the predicted value. Normal values

for PFTs are shown in Tables 28-14 and 28-15, and the relationships between lung volumes and capacities are described in Figure 28-16.

TABLE 28-14
LUNG VOLUMES AND CAPACITIES

Parameter	Definition	Normal Value
Volumes		
Tidal volume (V_T)	Volume of air inhaled and exhaled with each breath; only a small proportion of total capacity of lungs	0.5 L
Minute volume (MV)	Total amount of air inhaled and exhaled per minute (V_T X respiratory rate).	5–8 L/min
Expiratory reserve volume (ERV)	Additional air that can be forcefully exhaled after normal exhalation is complete	1.0 L
Residual volume (RV)	Amount of air remaining in lungs after forced expiration; air available in lungs for gas exchange between breaths	1.5 L
Inspiratory reserve volume (IRV)	Maximum volume of air that can be inhaled forcefully after normal inhalation	3.0 L
Capacities		
Total lung capacity (TLC)	Maximum volume of air that lungs can contain (TLC = IRV + V_T + ERV + RV)	6.0 L
Functional residual capacity (FRC)	Volume of air remaining in lungs at end of normal exhalation (FRC = ERV + RV); increase or decrease possible with lung disease	2.5 L
Vital capacity (VC)	Maximum volume of air that can be exhaled after maximum inspiration (VC = IRV + V_T + ERV); generally higher in men	4.5 L
Inspiratory capacity (IC)	Maximum volume of air that can be inhaled after normal expiration (IC = V_T + IRV)	3.5 L

TABLE 28-15

COMMON MEASURES OF PULMONARY FUNCTION

Measure	Description	Normal Value*
Forced vital capacity (FVC)	Amount of air that can be quickly and forcefully exhaled after maximum inspiration	>80% of predicted
Forced expiratory volume in first second of expiration (FEV_1)	Amount of air exhaled in first second of FVC; valuable clue to severity of airway obstruction	>80% of predicted
FEV_1/FVC	Ratio of value for FEV_1 to value for FVC; useful in differentiating obstructive and restrictive pulmonary dysfunction	>80% of predicted
Maximal midexpiratory flow rate (MMEF)	Measurement of airflow rate in middle half of forced expiration; early indicator of disease of small airways	>80% of predicted
Maximal voluntary ventilation (MVV)	Deep breathing as rapidly as possible for specified period; test for airflow, muscle strength, coordination, airway resistance; important factor in exercise tolerance	≈170 L/min
Peak expiratory flow rate (PEFR)	Maximum airflow rate during forced expiration; aids in monitoring bronchoconstriction in asthma	≤600 L/min
Maximum inspiratory pressure (MIP) or negative inspiratory force (NIF)	Amount of negative pressure generated on inspiration; indication of ability to breathe deeply and cough	≤80 cm H_2O

*Normal values vary with height, weight, age, and sex of patient.

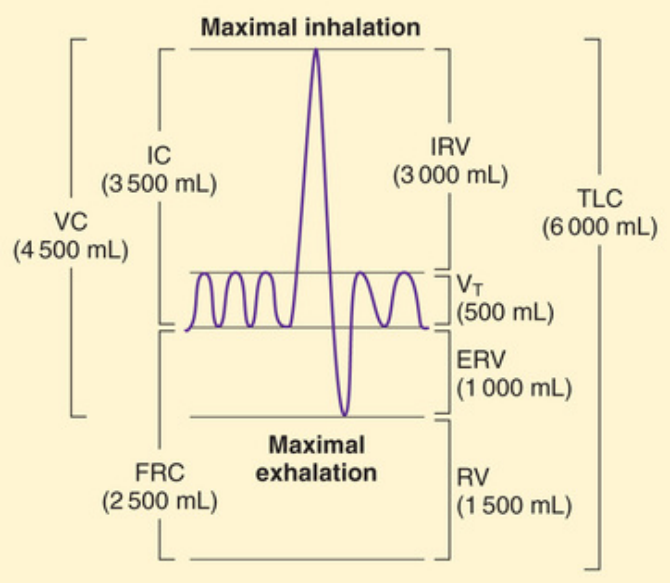

FIGURE 28-16 Relationship of lung volumes and capacities. *ERV,* expiratory reserve volume; *FRC,* functional residual capacity; *IC,* inspiratory capacity; *IRV,* inspiratory reserve volume; *RV*, residual volume; *TLC,* total lung capacity; V_T, tidal volume; *VC,* vital capacity.

Home spirometry may be used to monitor lung function in persons with asthma or cystic fibrosis, as well as before and after lung transplantation. Changes in spirometry values at home can warn of early lung transplant rejection or infection. Feedback from a peak expiratory flowmeter can increase the sense of control achieved when persons with asthma learn to modify activities and medications in response to changes in rates of peak expiratory flow.

Pulmonary function parameters can also be used to determine the need for mechanical ventilation or the readiness to be weaned from ventilatory support. Vital capacity, maximum inspiratory pressure, and minute ventilation are measured to make this determination (see Table 28-14).

Exercise Testing

Exercise testing is used in diagnosis, in determining exercise capacity, and for disability evaluation. A complete exercise test involves walking on a treadmill while expired oxygen and carbon dioxide, respiratory rate, heart rate, and rhythm are monitored. A modified test (desaturation test) may also be used. In that case, only SpO_2 is monitored. A desaturation test can also be used to determine the oxygen flow needed to maintain the SpO_2 at a safe level during activity or exercise in patients who use home oxygen therapy.

A timed walk can also be used to measure exercise capacity. The patient is instructed to walk as far as possible during a timed period (6 or 12 minutes), to stop when short of breath, and to continue when able. The distance walked is measured, and the data are used to monitor progression of disease or improvement after rehabilitation.

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Which of the following is the mechanism that stimulates the release of surfactant?
   a. Fluid accumulation in the alveoli
   b. Alveolar collapse from atelectasis
   c. Alveolar stretch from deep breathing
   d. Air movement through the alveolar pores of Kohn
2. Which of the following causes air to enter the thoracic cavity during inspiration?
   a. Contraction of the accessory abdominal muscles
   b. Increased carbon dioxide and decreased oxygen in the blood
   c. Stimulation of the respiratory muscles by the chemoreceptors
   d. Decreased intrathoracic pressure relative to pressure at the airway
3. Which of the following measures the lungs' ability to adequately oxygenate the arterial blood?
   a. Arterial oxygen tension
   b. Carboxyhemoglobin level
   c. Arterial carbon dioxide tension
   d. Venous carbon dioxide tension
4. Which of the following is the most important respiratory defence mechanism distal to the respiratory bronchioles?
   a. Alveolar macrophage
   b. Impaction of particles
   c. Reflex bronchoconstriction
   d. Mucociliary clearance mechanism
5. Which of the following is caused by a rightward shift of the oxygen–hemoglobin dissociation curve?
   a. Metabolic alkalosis
   b. Postoperative hypothermia
   c. Release of oxygen at the tissue level
   d. Greater affinity of oxygen for hemoglobin

6. Which of the following are very early signs or symptoms of inadequate oxygenation?
   a. Dyspnea and hypotension
   b. Apprehension and restlessness
   c. Cyanosis and cool, clammy skin
   d. Increased urine output and diaphoresis
7. During the respiratory assessment of an older adult, the nurse would expect to find which of the following? *(Select all that apply)*
   a. A vigorous cough
   b. Increased chest expansion
   c. Increased residual volume
   d. Increased breath sounds in the lung apices
   e. Increased anteroposterior (AP) chest diameter
8. Which of the following should the nurse inquire about when assessing activity and exercise related to respiratory health?
   a. Dyspnea during rest or exercise
   b. Recent weight loss or weight gain
   c. Willingness to wear oxygen equipment in public
   d. Ability to sleep through the entire night
9. Which of the following is the best tool to assess for the vibration of tactile fremitus?
   a. Palms
   b. Fingertips
   c. Stethoscope
   d. Index fingers
10. Which of the following is an abnormal finding in the assessment of the respiratory system?
   a. Presence of fremitus
   b. Inspiratory chest expansion of 2.5 cm
   c. Percussion resonance over the lung bases
   d. Symmetrical chest expansion and contraction
11. Which of the following is performed to remove pleural fluid for analysis?

a. Thoracentesis
b. Bronchoscopy
c. Pulmonary angiography
d. Sputum culture and sensitivity

1. c; 2. d; 3. a; 4. a; 5. c; 6. b; 7. c, e; 8. a; 9. a; 10. a; 11. a.

CHAPTER 29

Nursing Management

Upper Respiratory Problems

Written by, Eugene E. Mondor

Adapted by, Micki Puksa, Lesley MacMaster

LEARNING OBJECTIVES

1. Describe the clinical manifestations and nursing management of problems of the nose.
2. Describe the clinical manifestations and nursing management of problems of the paranasal sinuses.
3. Describe the clinical manifestations and nursing management of problems of the pharynx and the larynx.
4. Discuss the nursing management of the patient who requires a tracheostomy.
5. Identify the steps involved in performing tracheostomy care and suctioning an airway.
6. Describe the risk factors and warning symptoms associated with head and neck cancer.
7. Discuss the nursing management of the patient with a laryngectomy.
8. Describe the methods used in voice restoration for the patient with temporary or permanent loss of speech.

KEY TERMS

allergic rhinitis, p. 581
deviated septum, p. 579
epistaxis, p. 580
esophageal speech, p. 597
nasal polyps, p. 587
rhinoplasty, p. 580
tracheostomy, p. 587
tracheotomy, p. 587

Structural and Traumatic Disorders of the Nose

Deviated Septum

Deviated septum is a deflection of the normally straight nasal septum. Most commonly, it is caused by trauma to the nose or arises from a congenital disproportion in which the size of the septum is not proportional to the size of the nose. On inspection, the septum is bent to one side, altering the air passage. Symptoms are variable. The patient may experience obstruction to nasal breathing, nasal edema, or dryness of the nasal mucosa with crusting and bleeding (epistaxis). A severely deviated septum may block drainage of mucus from the sinus cavities, resulting in infection (sinusitis; Patton & Thibodeau, 2016).

Medical management of deviated septum includes nasal allergy control, as in allergic rhinitis (discussed later in this chapter). For patients with severe symptoms, a nasal septoplasty (surgical realignment of the septum) is performed to reconstruct and properly align the deviated septum.

Nasal Fracture

Nasal fracture is most often caused by trauma of substantial force to the middle of the face. Some cases of facial trauma can be prevented by using protective sports equipment and protecting against falls. Complications of a nasal fracture include airway obstruction, epistaxis, meningeal tears, and cosmetic deformity.

Nasal fractures are classified as unilateral, bilateral, or complex. A *unilateral fracture* typically produces little or no displacement. *Bilateral fractures,* the most common type, give the nose a flattened look. Powerful frontal blows cause *complex fractures*, which may also shatter the frontal bones. Diagnosis is based on the health history, direct observation, and radiographic findings.

On inspection, the nurse should assess the patient's ability to breathe through each nostril and note the presence of edema, bleeding, or hematoma (Emergency Nurses Association, 2013). There may be ecchymosis under one or both eyes. Ecchymosis involving both eyes is often termed *raccoon eyes.* The nose is inspected internally for evidence of deviated septum, hemorrhage, or clear drainage. Clear, pink-tinged, or persistent drainage (i.e., rhinorrhea) after control of epistaxis suggests a

cerebro-spinal (CSF) leak. A positive glucose screen can confirm the presence of CSF. Injury of sufficient force to fracture nasal bones results in considerable swelling of soft tissues. With extensive swelling, it may be difficult to verify the extent of deformity or to repair the fracture until several days later, when the edema subsides (Emergency Nurses Association, 2013).

The goals of nursing management are to reduce edema, prevent complications, and provide emotional support. Ice may be applied to the face and nose to reduce edema and bleeding. When a fracture is confirmed, the goal of management is to realign the fracture using closed or open reduction (septoplasty, rhinoplasty). These procedures re-establish cosmetic appearance and proper function of the nose and provide an adequate airway. After the patient undergoes nasal surgery, the patient should be assessed for the ability to mouth-breathe. Nasal intubation or nasogastric tube should be avoided in any patient suspected of a nasal fracture (Rothrock, 2015).

Rhinoplasty

Rhinoplasty, the surgical reconstruction of the nose, is performed for cosmetic reasons or to improve airway function when trauma or congenital deformities result in nasal obstruction. Assessment of the patient's expectations is a critical aspect in preparation for a rhinoplasty. Expected results of surgery should be explained frankly and truthfully to prevent disappointment (Rothrock, 2015).

Collaborative Care

Rhinoplasty is performed as an outpatient procedure, using regional anaesthesia. Nasal tissue may be added or removed, and the nose may be lengthened or shortened. Plastic implants are sometimes used to reshape the nose. After surgery, nasal packing may be inserted to apply pressure and prevent bleeding or septal hematoma formation. Nasal septal splints (small pieces of plastic or Silastic) may be inserted to help prevent scar tissue formation between the surgical site and the lateral nasal wall. Adhesive-strip skin closures are placed to hold the skin against the septal cartilage. Typically, nasal packing is removed the day after surgery, and the splint is removed in 3 to 5 days. A small dressing under the nostrils is changed as often as every 2 hours during the first 24 hours. The patient is instructed to prevent pressure on the surgical site by sneezing through the mouth (Rothrock, 2015).

Nursing Management Nasal Surgery

Examples of nasal surgery include rhinoplasty, septoplasty, and nasal fracture reductions. Before surgery, the patient should be instructed to not take drugs containing acetylsalicylic acid (ASA; Aspirin) or nonsteroidal anti-inflammatory drugs (NSAIDs) for 2 weeks to reduce the risk for bleeding. Nursing interventions during the immediate postoperative period include assessment of respiratory status, pain management, and observation of the surgical site for hemorrhage and edema. Teaching is important because the patient must be able to detect complications at home (Rothrock, 2015). There is an interim period while edema and ecchymosis resolve, before the final cosmetic effect can be achieved.

Epistaxis

Epistaxis (nosebleed) occurs in all age groups, especially in children and older-adult patients. Epistaxis may be caused by trauma, foreign bodies, nasal spray abuse, street drug use, anatomical malformation, allergic rhinitis, or tumours. Any condition that prolongs bleeding time or alters platelet counts will predispose the patient to epistaxis. Bleeding time may also be prolonged if the patient takes ASA (Aspirin) or NSAIDs. Conditions such as hypertension do not increase the risk for epistaxis (Bamimore & Silverberg, 2015; Emergency Nurses Association, 2013). Elevated blood pressure, however, makes bleeding more difficult to control.

Children and young adults have a tendency to develop anterior nasal bleeding, whereas older adults more commonly have posterior nasal bleeding. Anterior bleeding usually stops spontaneously or can be self-treated; posterior bleeding may require medical treatment (Bamimore & Silverberg, 2015).

Nursing and Collaborative Management Epistaxis

Simple first-aid measures should be attempted first to control epistaxis. The nurse should (1) keep the patient quiet; (2) place the patient in a sitting position, leaning forward, or if not possible, in a reclining position with head and shoulders elevated; (3) apply direct pressure by pinching the entire soft lower portion of the nose for 10 to 15 minutes; (4) apply ice compresses to the forehead and have the patient suck on ice; (5) apply digital pressure if bleeding continues; and (6) obtain medical assistance if bleeding does not stop (Emergency Nurses Association, 2013; Nguyen, 2015).

If first aid is not effective, management involves localization of the bleeding site and application of a vasoconstrictive agent, cauterization, or anterior packing by a health care provider. Anterior packing may consist of ribbon gauze impregnated with antibiotic ointment that is wedged firmly in the desired location and remains in place for 48 to 72 hours. If posterior packing is required, the patient should be hospitalized. Inflatable balloons may be used as a nasal pack, or gauze rolls may be inserted (Figure 29-1). Strings attached to the packing are brought to the outside and taped to the cheek for ease of removal. A nasal sling (a folded 2 × 2–inch gauze pad) should be taped over the nares to absorb drainage (Cooper & Gosnell, 2015).

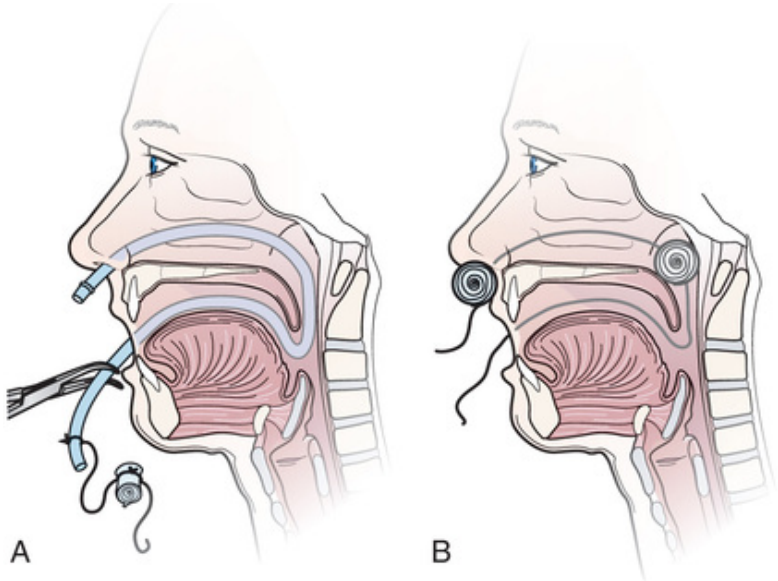

FIGURE 29-1 Method for placing posterior nasal pack. **A,** Catheter is passed through the bleeding side of the nose and pulled out through the mouth with a hemostat. Strings are tied to the catheter, and the pack is pulled up behind the soft palate and into the nasopharynx. **B,** Nasal pack in position in the posterior nasopharynx. Dental roll at the nose helps maintain correct position.

Posterior packing may alter respiratory status, especially in older-adult patients. Some patients experience *hypoventilation* causing *hypercapnia* (increase in the partial pressure of carbon dioxide in arterial blood [$PaCO_2$]) and *hypoxemia* (decrease in the partial pressure of oxygen in arterial blood [PaO_2]) sufficient to lead to cardiac dysrhythmias or respiratory arrest. The nurse should closely monitor respiratory rate, heart rate and rhythm, oxygen saturation using pulse oximetry (SpO_2), and level of consciousness and observe for signs of aspiration (Aghababian, Bird, Braen, et al., 2011).

Packing is painful because sufficient pressure must be applied to stop the bleeding. Nasal packing predisposes to infection from bacteria (e.g., *Staphylococcus aureus*) present in the nasal cavity. The patient should receive a mild opioid analgesic for pain (e.g., acetaminophen with codeine) and an antibiotic effective against staphylococci to protect against infection.

Posterior packs are left in place for no longer than 48 hours because of the incidence of toxic shock syndrome and are usually removed by the surgeon. Before removal, the patient should be medicated for pain because this procedure is very uncomfortable. After removal, the nares may be gently cleaned and then lubricated with petroleum jelly.

Failure of posterior packing to control epistaxis indicates the need for surgery or radiological embolization of the affected artery (Aghababian et al., 2011). The most common surgical procedure of this nature involves ligation of the internal maxillary artery, performed through a Caldwell–Luc incision under the upper lip to gain access to the artery.

The patient can be discharged after being taught about home care. The patient should be instructed to avoid vigorous nose blowing, strenuous activity, lifting, and straining for 4 to 6 weeks. The patient should be taught to sneeze with the mouth open and to avoid the use of ASA (Aspirin)–containing products or NSAIDs (Rothrock, 2015).

Inflammation and Infection of the Nose and Paranasal Sinuses

Allergic Rhinitis

Allergic rhinitis is the reaction of the nasal mucosa to a specific allergen. Attacks of seasonal rhinitis usually occur in the spring and fall and are caused by allergy to pollens from trees, flowers, or grasses. The typical attack lasts for several weeks during times when pollen counts are high, then disappears, and recurs at the same time the following year. Perennial rhinitis is present intermittently or constantly. Symptoms are usually caused by specific environmental triggers such as pet dander, dust mites, moulds, or cockroaches (deSchazo & Kemp, 2016). Because symptoms of perennial rhinitis resemble the common cold, the patient may believe the condition is a continuous or repeated cold.

Clinical Manifestations

Manifestations of allergic rhinitis are nasal congestion; sneezing; watery, itchy eyes and nose; altered sense of smell; and thin, watery nasal discharge. The nasal turbinates appear pale, boggy, and swollen. With chronic exposure to allergens, the patient's responses include headache, congestion, pressure, postnasal drip, and nasal polyps (deSchazo & Kemp, 2016). The patient may complain of cough, hoarseness, snoring, or the recurrent need to clear the throat.

Nursing and Collaborative Management Allergic Rhinitis

Several steps are used in managing allergic rhinitis. The most important step involves identifying and avoiding triggers of allergic reactions (Table 29-1). The patient should be instructed to keep a diary of times when the allergic reaction occurs and the activities that precipitate the reaction. Steps can then be taken to avoid these triggers.

TABLE 29-1

PATIENT & CAREGIVER TEACHING GUIDE
How to Reduce Symptoms of Allergic Rhinitis

Include the following information when teaching the patient and caregiver how to reduce symptoms of allergic rhinitis.
1. Avoidance of allergens is the best treatment. 2. Avoid house dust. Use the approach, "less is best." Focus on the bedroom. Remove carpeting. Limit furniture. Enclose pillows, mattress, and springs in airtight, vinyl encasements. Limit clothing in the bedroom to items used frequently. Place clothing in airtight, zipper-sealed, vinyl clothes bags. Install an air filter. Close the air-conditioning vent into the room. 3. Avoid house dust mites. Wash bedding in hot water (55°C), weekly. Wear a mask when vacuuming. Double-bag the vacuum cleaner. Install a filter on the outlet port of the vacuum cleaner. Avoid sleeping or lying on upholstered furniture. Remove carpets that are laid on concrete. If possible, have someone else clean the house. 4. Avoid mould spores. The three *D*s that promote growth of mould spores are **d**arkness, **d**ampness, and **d**rafts. Avoid places where humidity is high (e.g., basements, camps on the lake, clothes hampers, greenhouses, stables, barns). Dehumidifiers may be helpful in humid weather and in damp spaces. Ventilate closed rooms, open doors, and install fans. HEPA (high-efficiency particulate air) filters may be beneficial. Consider adding windows to dark rooms. Consider keeping a small light on in closets. A basement light with a timer that provides light several hours a day may decrease mould growth. 5. Avoid pollens. Stay inside, with doors and windows closed, during high-pollen season. Avoid the use of fans. Install an air conditioner with a good air filter. Wash filters weekly during high pollen season. Put the car air conditioner on "recirculate" when driving. Get someone else to tend to your yard. 6. Avoid pet allergens. Remove pets from the interior of the home. Clean the living area thoroughly. Do not expect instant relief. Symptoms usually do not improve significantly for 2 months following pet removal. 7. Avoid smoke. The presence of a smoker will sabotage the best of all possible symptom-reduction programs.

Drug therapy involves using nasal sprays, leukotriene receptor antagonists (LTRAs; deSchazo & Kemp, 2016), antihistamines, and decongestants to manage symptoms (Table 29-2). Intranasal corticosteroid and cromolyn sprays are effective for seasonal and perennial rhinitis. Nasal corticosteroid sprays are used to decrease inflammation locally; there is little absorption in the systemic circulation, and therefore, systemic adverse drug events are rare. Relief may require combining a nasal corticosteroid spray and an antihistamine. The patient using nasal inhalers needs careful instructions about proper use. Nasal decongestant sprays

can be used only for up to 5 days because they can cause a rebound effect from prolonged use (deSchazo & Kemp, 2016).

TABLE 29-2

DRUG THERAPY
Allergic Rhinitis and Sinusitis

Preparation	Mechanism of Action	Adverse Effects	Nursing Actions
Corticosteroids			
Nasal Spray			
Beclomethasone (Apo-Beclomethasone) Budesonide (Rhinocort) Flunisolide (Apo-Flunisolide) Fluticasone (Flonase) Triamcinolone (Nasacort) Ciclesonide (Omnaris)	Inhibits inflammatory response At recommended dosage, systemic adverse effects are unlikely because of low systemic absorption Systemic effects may occur with greater-than-recommended dosages	Mild transient nasal burning and stinging; in rare instances, localized fungal infection with *Candida albicans*	• Teach patient correct use • Instruct patient to use on regular basis and not PRN • Explain to patient that the spray acts to decrease inflammation over time and does not have an immediate effect • Discontinue use if nasal infection develops
Mast Cell Stabilizer			
Nasal Spray			
Cromolyn spray (Apo-Cromolyn)	Inhibits degranulation of sensitized mast cells that occurs after exposure to specific antigens	Minimal adverse effects; occasional burning or nasal irritation	• Teach patient correct use • Reinforce that spray prevents symptoms • Begin 2 wk before pollen season starts and use throughout pollen season • If isolated allergy, such as to cats, use prophylactically (i.e., 10–15 min before exposure to allergen)
Leukotriene Receptor Antagonists (LTRAs)			
Antagonists			
Zafirlukast (Accolate) Montelukast (Singulair)	Antagonize or inhibit leukotriene activity, thereby inhibiting airway edema and bronchoconstriction through decreasing inflammatory process	Headaches, dizziness, rash, altered liver function tests, abdominal pain *Zafirlukast:* Monitor PT levels and theophylline levels if patient is taking coumadin or theophylline	• Monitor liver function tests periodically while on therapy; discontinue if values elevate • Administer on empty stomach • Do not discontinue therapy without consulting health care provider • Not to be used for acute attacks
Anticholinergic			
Nasal Spray			

Preparation	Mechanism of Action	Adverse Effects	Nursing Actions
Ipratropium bromide (Atrovent)	Blocks hypersecretory effects by competing for binding sites on the cell. Reduces rhinorrhea in the common cold and allergic and nonallergic rhinitis	Dryness of the mouth and nose may occur Does not cause systemic adverse effects	• Teach patient correct use • Reinforce that spray prevents symptoms, with onset of action within 1 hr of use • May reduce need for other rhinitis medications
Antihistamines			
First-Generation Agents			
Ethanolamines Diphenhydramine (Benadryl) Ethylenediamines Tripelennamine (Vagin-X) Alkylamines Brompheniramine (Dimetane) Chlorpheniramine (Chlor-Tripolon)	Bind with H_1 receptors on target cells, blocking histamine binding Relieve acute symptoms of allergic response itching, sneezing, excessive secretions, mild congestion)	First-generation agents cross blood–brain barrier, bind to H_1 receptors in brain, cause sedation (diminished alertness, slow reaction time, somnolence) and stimulation (restless, nervous, insomnia) Some drugs (e.g., ethanolamines) are more likely to cause sedation Patients vary in their sensitivity to these adverse effects. The next most common adverse effects involve the GI system and include loss of appetite, epigastric distress, constipation, or diarrhea May cause palpitations, tachycardia, urinary retention or frequency	• Warn patient that operating machinery and driving may be dangerous because of sedative effect Drowsiness usually passes after 2 wk of treatment • Teach patient to report palpitations, change in heart rate, change in bowel, bladder habits • Instruct patient not to use alcohol with antihistamines because of additive depressant effect • Rapid onset of action, no drug tolerance with prolonged use • Limited use with sinusitis
Second-Generation Agents			

Loratadine (Claritin)
Cetirizine (Reactine)
Fexofenadine (Allegra)
Desloratadine (Aerius)
	—	Second-generation agents have limited affinity for brain H_1 receptors; cause minimal sedation; few effects on psychomotor activities, bladder function	• Teach patient to expect few, if any, adverse effects
			• More expensive than classical antihistamines
			• Rapid onset of action, no drug tolerance with prolonged use
			• General interactions:
			  • Do not take with alcohol or any form of tranquilizer or sedative
			  • Do not take with any monoamine oxidase inhibitor

Decongestants			
Oral			

Preparation	Mechanism of Action	Adverse Effects	Nursing Actions
Pseudoephedrine (Sudafed)	Stimulate adrenergic receptors on blood vessels, promote vasoconstriction and reduce nasal edema and rhinorrhea	CNS stimulation, causing insomnia, excitation, headache, irritability, increased blood and ocular pressure, dysuria, palpitations, tachycardia	• Advise patient of adverse reactions • Advise that use of some preparations is contraindicated for patients with cardiovascular disease, hypertension, diabetes, glaucoma, prostate hyperplasia, hepatic and renal disease • Teach patient that these drugs should not be used for more than 3 days or more than three or four times a day; longer use increases risk for rebound vasodilation, which can increase congestion
Topical (Nasal Spray)			
Oxymetazoline (Dristan) Phenylephrine (Dimetapp)	Same as above Blocks action of histamine	Same as above, plus rhinitis medicamentosa (rebound nasal congestion), headache, bitter taste, somnolence, nasal irritation	—

CNS, central nervous system; *GI*, gastro-intestinal; H_1, histamine 1; *PRN*, as needed; *PT*, prothrombin time.

Immunotherapy ("allergy injections") may be used if drugs are not tolerated, or ineffective, when a specific, unavoidable allergen is identified. Immunotherapy involves controlled exposure to small amounts of a known allergen through frequent (at least weekly) injections, with the goal to decrease sensitivity. (The mechanisms involved in the allergic response and immunotherapy are discussed in Chapter 16.)

Drug Alert

Antihistamines

- First-generation antihistamines (e.g., chlorpheniramine) can cause drowsiness and sedation.
- Warn patients that operating machinery and driving may be dangerous because of the sedative effect.

Drug Alert

Pseudoephedrine

- Large doses may produce tachycardia and palpitations, especially in patients with cardiac disease.
- Overdose in people over 60 years of age may result in central nervous system depression, seizures, and hallucinations.

Acute Viral Rhinitis

Acute viral rhinitis (common cold or acute coryza) is caused by viruses that invade the upper respiratory tract. It is the most prevalent infectious disease and is spread by airborne droplet sprays emitted by the infected person while breathing, talking, sneezing, or coughing or by direct hand contact. Frequency increases in the winter months, when people stay indoors and overcrowding is more common. Other factors, such as chilling, fatigue, physical and emotional stress, and compromised immune status, may increase susceptibility. The patient with acute viral rhinitis typically first experiences tickling, irritation, sneezing, or dryness of the nose or nasopharynx, followed by copious nasal secretions, some nasal obstruction, watery eyes, elevated temperature, general malaise, and headache. After the early profuse secretions, the nose becomes more obstructed, and the discharge is thicker. Within a few days, the general symptoms improve, nasal passages reopen, and normal breathing is re-established (Goldman & Schafer, 2012; National Institute of Allergy and Infectious Diseases [NIAID], 2016).

Nursing and Collaborative Management Acute Viral Rhinitis

Supportive therapy such as rest, fluids, proper diet, antipyretics, and analgesics is the recommended treatment. Complications of acute viral rhinitis include pharyngitis, sinusitis, otitis media, tonsillitis, and lung infections. Antibiotics do not have a role in the treatment of viral rhinitis during the cold season; the patient with a chronic illness or a compromised immune status should be advised to avoid crowded, close situations and other persons who have obvious cold symptoms. Frequent hand hygiene and avoiding hand-to-face contact may help prevent direct spread.

Interventions are directed toward relieving annoying and uncomfortable symptoms. The patient should be encouraged to drink increased amounts of fluids to liquefy secretions. Antihistamine or decongestant therapy reduces postnasal drip and significantly decreases severity of cough, nasal obstruction, and nasal discharge. The patient should also be taught to recognize the symptoms of secondary bacterial infection, such as a temperature higher than 38°C (100.4°F); purulent nasal exudate; tender, swollen glands; and a sore, red throat. In the patient with pulmonary disease, signs of infection include a change in consistency, colour, or volume of the sputum. Because infection can progress rapidly, the patient with chronic respiratory disease may be taught to begin antibiotics in response to sputum changes (Goldman & Schafer, 2012; NIAID, 2016).

Complementary & Alternative Therapies

Echinacea

Clinical Uses

Common cold, upper respiratory tract infection, wound healing, urinary tract infections.

Effects

Stimulates immune system; has antibacterial and anti-inflammatory activity.

Nursing Implications

Because Echinacea has immuno-modulating actions, individuals with systemic lupus erythematosus, tuberculosis, multiple sclerosis, leukemia, or acquired immune deficiency syndrome (AIDS) should not use it. Long-term use may suppress the immune system. Should not be used in conjunction with corticosteroids or immuno-suppression therapy. May be used in conjunction with antibiotics. Is considered safe when used in recommended dosages. Therapy for 10 to 14 days is usually long enough. Should not be taken for more than 8 weeks.

Evidence-Informed Practice

Research Highlight

Do Probiotics Prevent Upper Respiratory Tract Infections?

Clinical Question

In healthy patients (P), what is the effect of probiotics (I) versus placebo (C) in preventing acute upper respiratory tract infections (URIs) (O)?

Best Available Evidence

Systematic review of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence

- Ten RCTs (n = 3 451) including healthy children and adults up to age 40.
- Intervention was ingestion of any probiotic (single or mixture of strains, any dosage regimen or route of administration) for more than 7 days, compared with placebo or no treatment.
- Most common probiotics were lactic acid bacteria and bifidobacteria, often consumed in fermented foods (e.g., yogourt) or as dietary supplements.
- Probiotics were better than placebo in reducing the occurrence of acute URIs.

- The number of URIs requiring antibiotics was lower in patients using probiotics compared with those using placebo.

Conclusion

- Probiotics are effective in reducing the incidence of URIs.

Implications for Nursing Practice

- Encourage continued probiotic use to prevent acute URIs.
- Yogourt is an excellent food source for probiotics.
- Probiotics are also available as a dietary supplement.
- Advise patients with frequent URIs of potential benefit from probiotic ingestion.
- Probiotics are typically well tolerated but can cause gastro-intestinal (GI) adverse effects
- Counsel patients of minor probiotic adverse effects, including flatulence and increased GI irritability.

P, Patient population of interest; *I,* intervention or area of interest; *C,* comparison of interest or comparison group; *O,* outcomes of interest (see Chapter 1).

Influenza

Approximately 10% to 20% of Canadians become infected with seasonal influenza each year, which runs from November to April. Although the majority recover completely, an estimated 4 000 to 8 000, mostly older adults, die every year from flu-related pneumonia. Many others die from other complications of flu (Immunize Canada, 2015). Much of the influenza-related morbidity and mortality could be prevented by vaccination of high-risk groups (Table 29-3). There are three groups of influenza viruses—A, B, and C; note that influenza C has little pathogenic potential. Influenza viruses have a remarkable ability to change over time. This ability accounts for widespread disease and the need for annual vaccination against new strains. Fewer cases of influenza result when a minor change in the virus occurs because most persons have partial immunity (Public Health Agency of Canada [PHAC], 2015a). Birds are natural carriers of influenza A viruses. Avian influenza H5N1 is circulating in some countries, especially in Asia and northeast Africa, and infecting many poultry populations and some humans (PHAC, 2013). This strain is highly pathogenic to birds and has infected a limited number of people. There is no evidence that this virus is transmitted from person to person. Although seasonal influenza immunization will not prevent avian influenza infection, immunization is recommended for those in direct contact with poultry infected with avian influenza during the culling operation. The rationale is that preventing infection with human influenza strains may reduce the theoretical potential for human–avian reassortment of genes should workers become co-infected with both influenza viruses (PHAC, 2015b).

TABLE 29-3
TARGET GROUPS FOR INFLUENZA IMMUNIZATION

Groups at High Risk
• Adults and children with cardiac or pulmonary disease • Adults ≥65 yr old • Healthy children between 6 and 23 mo • Pregnant females, in the third trimester, if their delivery date is in influenza season • Residents of nursing homes or long-term care facilities • People with chronic conditions such as diabetes, anemia, cancer, immunodeficiency, immuno-suppression, neurological conditions, renal disease, or conditions that compromise management of respiratory secretions • Children or adolescents on long-term acetylsalicylic acid therapy • Health care workers, and those who provide essential community services, and other caregivers and household contacts capable of transmitting influenza to the above at-risk groups • People at high risk for influenza complications • People who are also travelling to areas where the flu virus is likely to be circulating

Public Health Agency of Canada. (2015). Canadian communicable disease report: Summary of the National Advisory Committee on Immunization (NACI). Retrieved from http://www.phac-aspc.gc.ca/publicat/ccdr-rmtc/15vol41/dr-rm41-10/ar-02-eng.php.

The Canadian Pandemic Influenza Preparedness: Planning Guidance for the Health Sector document, updated in 2015, provides strategic guidance and a framework for pan-Canadian preparedness and response. It is not a response plan (PHAC, 2015a).

Clinical Manifestations

The onset of flu is typically abrupt, with systemic symptoms of cough, fever, and myalgia often accompanied by a headache and sore throat. Milder symptoms, similar to those of the common cold, may also occur. Physical findings are usually minimal, with normal assessment on chest auscultation. Dyspnea and diffuse crackles are signs of pulmonary complications. In uncomplicated cases, symptoms subside within 7 days. Some patients, particularly older adults, experience weakness or lassitude that persists for weeks. The convalescent phase may be marked by hyperactive airways and a chronic cough. Important diagnostic factors include the patient's health history and clinical findings and the presence of other cases of influenza in the community.

The most common complication of influenza is pneumonia. The patient who develops secondary bacterial pneumonia experiences gradual improvement of influenza symptoms and then worsening cough and purulent sputum. Treatment with antibiotics is usually effective if started early.

Nursing and Collaborative Management Influenza

The nurse should advocate regular handwashing as an effective strategy to reduce the risk for influenza. The nurse should also advocate influenza vaccination for patients at high risk, during routine office visits or, if hospitalized, at the time of discharge (see Table 29-3). The vaccine is 70% to 90% effective in preventing influenza in adults. To be effective, the vaccine must be given in the fall (mid-October), before exposure occurs. Although all healthy people between 2 and 65 years old should be encouraged to receive the vaccination, high priority should also be given to groups that can transmit influenza to high-risk persons, such as health care workers. By being vaccinated, the nurse can decrease the risk of transmitting influenza to those who have less ability to cope with the effects of this illness. Despite obvious benefits, many persons are reluctant to be vaccinated. Current vaccines are highly purified, and reactions are extremely uncommon. Soreness at the injection site is usually the only adverse effect. The only contraindications are for children younger than 6 months, people who have a hypersensitivity to eggs, or those who had a reaction to a previous immunization. People with a previous history of Guillain-Barré syndrome following a vaccination should avoid future vaccinations.

The primary goals in nursing management are supportive measures directed toward relief of symptoms and prevention of secondary infection. The patient should drink plenty of fluids and get plenty of rest. Older adults and those with a chronic illness may require hospitalization. Drug therapy with oral oseltamivir (Tamiflu) and inhaled zanamivir (Relenza) may be given to prevent or decrease symptoms of influenza in high-risk patients. Amantadine is effective only against influenza A. These drugs prevent the virus from budding and spreading to other cells. For maximum benefit, they should be initiated as soon as possible and ideally within 2 days of the onset of symptoms. They shorten the duration and severity of influenza and can be used prophylactically for control of outbreaks.

Complementary & Alternative Therapies

Goldenseal

Clinical Uses

Common cold, respiratory and gastro-intestinal infections, wound healing, cirrhosis of the liver, gallbladder inflammation, peptic ulcers.

Effects

Has a wide variety of effects such as anti-inflammatory properties, antimicrobial, and immuno-stimulating actions. Goldenseal can stimulate the flow of bile.

Nursing Implications

Because of the anticoagulant effects, goldenseal should not be used for longer than 2 weeks. Large doses may cause gastro-intestinal distress (e.g., diarrhea, vomiting) and possible nervous system effects. Commonly combined with Echinacea in preparations. May be used in conjunction with antibiotics. Should not be used concurrently with anticoagulants, antihypertensives, β-adrenergic blockers, or calcium channel blockers. Should not be used if person has heart or vascular disease, especially hypertension, heart failure, or dysrhythmias.

Source: Rothrock, J. (2015). *Alexander's care of the patient in surgery* (15th ed.). St. Louis: Mosby.

Complementary & Alternative Therapies

Zinc

Clinical Uses

Common cold, upper respiratory tract infections, wound healing, dermatitis, acne, herpes simplex.

Effects

Prevents replication of viruses and stimulates the immune system. Severe zinc deficiency results in severely depressed immune function and frequent infections.

Nursing Implications

Zinc supplements are available as oral tablets and lozenges. Oral zinc should not be taken with foods that will reduce its absorption, such as coffee, bran, protein, or calcium. Long-term use of zinc supplements over 15 mg/day is not recommended without medical supervision.

Sinusitis

Sinusitis develops when the ostia (exit) from the sinuses is narrowed or blocked by inflammation or hypertrophy (swelling) of the mucosa (Figure 29-2). The secretions that accumulate behind the obstruction provide a rich medium for growth of bacteria, viruses, and fungi, all of which may cause infection (Tung, Landers, Li, et al., 2016). Bacterial sinusitis is most commonly caused by *Streptococcus pneumoniae, Haemophilus influenzae,* or *Moraxella catarrhalis* (Kaplan, 2014). Viral sinusitis follows an upper respiratory infection in which the virus penetrates the mucous membrane and decreases ciliary transport. Fungal sinusitis is uncommon and is usually found in patients who are debilitated or immuno-compromised.

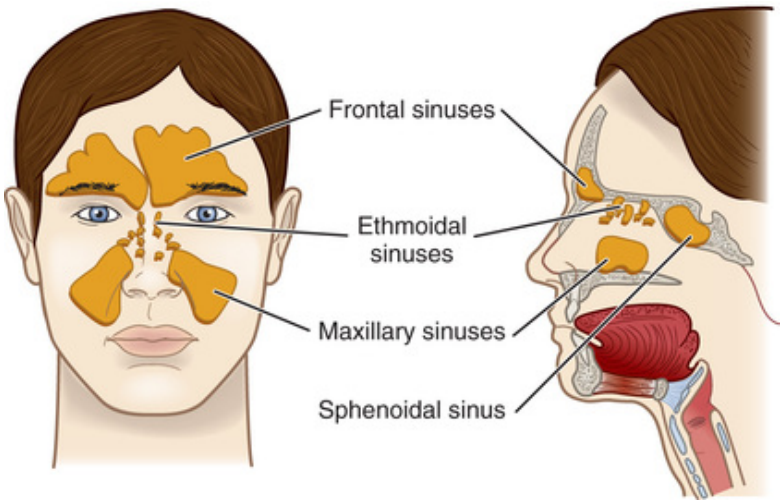

FIGURE 29-2 Location of the sinuses.

Acute sinusitis usually results from an upper respiratory infection, allergic rhinitis, swimming, or dental manipulation, all of which can cause inflammatory changes and retention of secretions. When acute sinusitis follows viral rhinitis, symptoms worsen after 5 to 7 days and are worse than the original rhinitis. *Chronic sinusitis* is a persistent infection usually associated with allergies and nasal polyps. Chronic sinusitis generally

results from repeated episodes of acute sinusitis that result in irreversible loss of the normal ciliated epithelium lining the sinus cavity.

Clinical Manifestations

Acute sinusitis causes significant pain over the affected sinus(es), purulent nasal drainage, nasal obstruction, congestion, fever, and malaise. The patient looks and feels sick. Assessment involves inspection of the nasal mucosa and palpation of the sinus points for pain. Findings that indicate acute sinusitis include a hyperemic and edematous mucosa, enlarged turbinates, and tenderness over the involved sinus(es). The patient may have recurrent headaches that change in intensity with position changes or when secretions drain (Kaplan, 2014).

Chronic sinusitis is difficult to diagnose because symptoms may be nonspecific. The patient is rarely febrile. Although there may be facial pain, nasal congestion, and increased drainage, often, severe pain and purulent drainage are absent. Symptoms may mimic those seen with allergies. Radiographic studies of the sinuses or a sinus computed tomographic (CT) scan may be performed to confirm the diagnosis. CT scans may show the sinuses to be filled with fluid or the mucous membrane to be thickened. Nasal endoscopy with a flexible scope may be used to examine the sinuses, obtain drainage for culture, and restore normal drainage.

Many patients with asthma have sinusitis. The link between these conditions is unclear. Sinusitis may trigger asthma by stimulating reflex bronchospasm. Appropriate treatment of sinusitis often causes a reduction in asthma symptoms (Calhoun, Omachi, Reddy, et al., 2016).

Nursing and Collaborative Management Sinusitis

If allergies are the precipitating cause of sinusitis, the patient needs to be instructed in ways to reduce sinus inflammation and infection, including environmental control of allergies and appropriate drug therapy (see section on allergic rhinitis earlier in this chapter). Treatment of acute sinusitis includes antibiotics to treat the infection, decongestants to promote drainage, nasal corticosteroids to decrease inflammation, and mucolytics to promote mucus flow (Table 29-4). Classical (first-generation) antihistamines increase the viscosity of mucus and promote continued symptoms, so they should be avoided. Nonsedating (second-generation) antihistamines do not cause this problem. For acute sinusitis, antibiotic therapy is usually continued for 10 to 14 days.

TABLE 29-4

PATIENT & CAREGIVER TEACHING GUIDE
Acute or Chronic Sinusitis

The following information should be included when teaching the patient and caregiver about sinusitis.
1. Keep well hydrated by drinking six to eight glasses of water daily to liquefy secretions. 2. Take hot showers twice daily; use a steam inhaler (15-min vaporization of boiled water), bedside humidifier, or nasal saline spray to promote secretion drainage. 3. Report temperature of ≥38°C, which may indicate infection. 4. Follow prescribed medication regimen: • Take analgesics to relieve pain. • Take decongestants or expectorants, or both, to relieve swelling and to thin mucus. • Take antibiotics, as prescribed, for infection. Be sure to take entire prescription and report continued symptoms or a change in symptoms. • Administer nasal sprays correctly. 5. Do not smoke, and avoid exposure to smoke—smoke is an irritant and may worsen symptoms. 6. If allergies predispose to sinusitis, follow instructions regarding environmental control, drug therapy, and immunotherapy to reduce the inflammation and prevent sinus infection. 7. Avoid use of nasogastric tube inserted via the nares.

If symptoms do not resolve, the antibiotic should be changed to a broader-spectrum agent. With chronic sinusitis, mixed bacterial florae are often present, and infections are difficult to eliminate. Broad-spectrum antibiotics may be used for 4 to 6 weeks.

The patient should be encouraged to increase fluid intake (six to eight glasses daily) and use nasal cleaning techniques. This may include taking a hot shower in the morning and the evening, followed by blowing the nose thoroughly each time. Other interventions to cleanse the nasal passages

and promote drainage include irrigating the nose with salt water (Cooper & Gosnell, 2015).

The patient with persistent or recurrent sinus complaints that are not alleviated by medical therapy may require nasal endoscopic surgery to relieve blockage caused by hypertrophy or deviated septum. This is an outpatient procedure usually performed under local anaesthesia (Cooper & Gosnell, 2015).

Obstruction of the Nose and Paranasal Sinuses

Polyps

Nasal polyps are benign mucous membrane masses that form slowly in response to repeated inflammation of the sinus or the nasal mucosa. Polyps, which appear as bluish, glossy projections in the naris (nostril), can exceed the size of a grape. The patient may be anxious, fearing the polyps are malignant. Clinical manifestations include nasal obstruction, nasal discharge (usually clear mucus), and speech distortion. Nasal polyps can be removed with endoscopic or laser surgery, but recurrence is common. Topical or systemic corticosteroids may slow polyp growth (Cooper & Gosnell, 2015).

Foreign Bodies

A variety of foreign bodies may lodge in the upper respiratory tract. Inorganic foreign bodies such as buttons and beads may cause no symptoms, lie undetected, and be accidentally discovered on routine examination. Organic foreign bodies such as wood, cotton, beans, peas, and paper produce a local inflammatory reaction and nasal discharge, which may become purulent and foul smelling. Foreign bodies should be removed from the nose through the route of entry. Sneezing with the opposite nostril closed may be effective in assisting the removal of foreign bodies. Irrigation of the nose or pushing the object backward should not be done because either could cause aspiration and airway obstruction. If sneezing or blowing the nose does not remove the object, the patient should see a health care provider.

Problems Related to the Pharynx

Acute Pharyngitis

Acute pharyngitis is an acute inflammation of the pharyngeal walls. It may include the tonsils, palate, and uvula. It can be caused by a viral, bacterial, or fungal infection. Viral pharyngitis accounts for approximately 70% of cases. Acute follicular pharyngitis ("strep throat") results from β-hemolytic streptococcal invasion and accounts for an additional 5% to 15% of episodes (Chow & Doron, 2016; Cooper & Gosnell, 2015). Fungal pharyngitis, especially candidiasis, can develop with prolonged use of antibiotics or inhaled corticosteroids or in immuno-suppressed patients, especially those with human immunodeficiency virus (HIV).

Clinical Manifestations

Symptoms of acute pharyngitis range in severity from complaints of a "scratchy throat" to pain so severe that swallowing is difficult. Both viral and strep infections appear as a red and edematous pharynx, with or without patchy yellow exudates. Appearance is not always diagnostic. Cultures or a rapid strep antigen test is done to establish the cause and direct appropriate management. Inadequate treatment of acute streptococcal pharyngitis can result in rheumatic heart disease or glomerulonephritis.

White, irregular patches suggest fungal infection with *Candida albicans*. In diphtheria, a grey-white false membrane, termed a *pseudomembrane*, is seen covering the oropharynx, nasopharynx, and laryngopharynx and sometimes extending to the trachea.

Nursing and Collaborative Management Acute Pharyngitis

The goals of nursing management are infection control, symptomatic relief, and prevention of secondary complications. The patient with documented strep throat is treated with antibiotics. Antibiotics do not alter the course of viral infections and should not be used to treat this type of infection (Nathan & Cars, 2014). *Candida* infections are treated with nystatin, an antifungal antibiotic. The preparation should be swished in the mouth for as long as possible before it is swallowed, and treatment should continue until symptoms are gone. The patient should be encouraged to increase fluid intake. Cool, bland liquids and gelatin will not irritate the pharynx; the patient should avoid citrus juices, which can be irritating to the throat.

Peritonsillar Abscess

Peritonsillar abscess is a complication of acute pharyngitis or acute tonsillitis, when bacterial infection invades one or both tonsils. The tonsils may enlarge sufficiently to threaten airway patency. The patient experiences a high fever, leukocytosis, and chills. Intravenous antibiotic therapy is given along with needle aspiration or incision and drainage of the abscess. An emergency tonsillectomy may be performed, or an elective tonsillectomy may be scheduled after the infection has subsided.

Problems Related to the Trachea and Larynx

Airway Obstruction

Airway obstruction may be complete or partial. *Complete airway obstruction* is a medical emergency. *Partial airway obstruction* may occur as a result of aspiration of food or a foreign body. In addition, partial airway obstruction may result from laryngeal edema following extubation, laryngeal or tracheal stenosis, central nervous system (CNS) depression, and allergic reactions. Symptoms include stridor, use of accessory muscles, suprasternal and intercostal retractions, wheezing, restlessness, tachycardia, and cyanosis. Prompt assessment and treatment are essential because partial obstruction may quickly progress to complete obstruction. Interventions to re-establish a patent airway include the obstructed airway (Heimlich) manoeuvre, cricothyroidotomy, endotracheal intubation, and tracheostomy. Unexplained or recurrent symptoms indicate the need for additional tests, such as a chest radiography, pulmonary function tests, and bronchoscopy.

Tracheostomy

A **tracheotomy** is a surgical incision into the trachea for the purpose of establishing an airway. A **tracheostomy** is the stoma (opening) that results from the tracheotomy. A tracheostomy tube is an artificial airway that is inserted into the trachea during a tracheotomy. Indications for a tracheostomy are to (1) bypass an upper airway obstruction, (2) facilitate removal of secretions, (3) permit long-term mechanical ventilation, and (4) permit oral intake and speech in the patient who requires long-term mechanical ventilation. Most patients who require mechanical ventilation are initially managed with an endotracheal tube (ETT), which can be quickly inserted in an emergency (see Chapter 68). A tracheotomy may be performed for patients requiring intubation longer than 7 to 10 days or when an airway is obstructed due to trauma, tumours, or swelling. A tracheostomy may also be required to facilitate airway clearance when spinal cord injury, neuro-muscular disease, or severe debilitation is present (Stacy, 2014). A tracheostomy tube is usually inserted by an open procedure in the operating room but can also be inserted emergently in a percutaneous procedure at the bedside (Stacy, 2014).

Several advantages make a tracheostomy a better option than an ETT for long-term nursing management and weaning from the ventilator. Without a tube in the mouth, patient comfort and mobility can be increased, and risk for long-term damage to the vocal cords is decreased. The patient is able to eat and talk with a tracheostomy because the tube enters lower in the airway (Stacy, 2014; Figure 29-3).

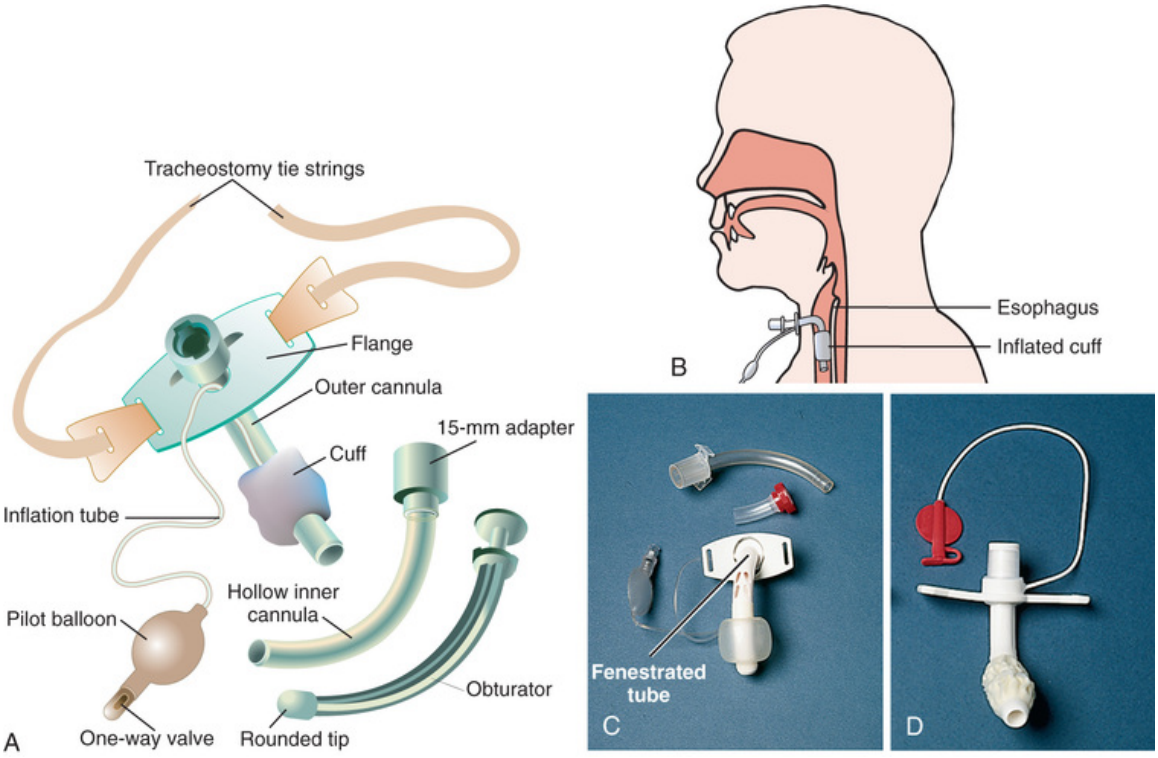

FIGURE 29-3 Types of tracheostomy tubes. **A,** Parts of a tracheostomy tube. **B,** Tracheostomy tube inserted in the airway with an inflated cuff. **C,** Fenestrated tracheostomy tube with cuff, inner cannula, decannulation plug, and pilot balloon. **D,** Tracheostomy tube with a foam cuff and obturator (one cuff is deflated on tracheostomy tube). (See Table 29-6 and NCP 29-1 for related nursing management.)

Nursing Management Tracheostomy

Providing Tracheostomy Care

Before the tracheotomy procedure, the nurse should explain to the patient and caregivers the purpose of the procedure and inform them that the patient will not be able to speak while an inflated cuff is used. A number of complications can occur with tracheostomies (see Table 29-5).

TABLE 29-5
COMPLICATIONS OF TRACHEOSTOMIES

Complication	Causes	Nursing Management
Abnormal bleeding	Surgical intervention Erosion or rupture of blood vessel, or both	• Monitor bleeding • Notify physician if it continues or is excessive
Tube dislodgement	Excessive manipulation or suctioning	• Ensure ties are secure • Keep obturator, hemostat, and new tracheostomy tube at bedside
Obstructed tube	Dried or excessive secretions	• Assess patient's respiratory status • Suction as necessary • Maintain humidification • Perform tracheostomy care • Ensure adequate hydration
Subcutaneous emphysema	Air escapes from the incision to the subcutaneous tissue	• Monitor subcutaneous emphysema • Reassure patient and family
Tracheo-esophageal fistula	Tracheal wall necrosis, leading to fistula formation	• Monitor cuff pressure • Monitor patient for coughing and choking while eating or drinking
Tracheal stenosis	Narrowing of tracheal lumen owing to scarring caused by tracheal irritation	• Monitor cuff pressure • Ensure prompt treatment of infections • Ensure ties are secure

A variety of tubes are available to meet individual patient needs (Table 29-6). All tracheostomy tubes contain a faceplate or flange, which rests on the neck between the clavicle and an outer cannula. In addition, all tubes have an obturator, which is used when inserting the tube (see Figure 29-3, *A*). In the event of accidental decannulation, a spare tracheostomy set, obturator and tracheal dilator, should be kept at the bedside, preferably taped at the head of the bed (Stacy, 2014).

TABLE 29-6

CHARACTERISTICS AND NURSING MANAGEMENT OF TRACHEOSTOMIES

Tube	Characteristics	Nursing Management
Tracheostomy tube with cuff and pilot balloon (see Figure 29-3, *A* and *B*)	When properly inflated, low-pressure, high-volume cuff distributes cuff pressure over large area, minimizing pressure on tracheal wall	**Procedure for Cuff Inflation** • *Spontaneously breathing patient:* Inflate cuff to minimal occlusion pressure by slowly injecting air into the cuff until no sound is heard after deep breath or during inhalation with manual resuscitation bag. If using MLT, remove 0.1 mL of air while maintaining seal. MLT should not be used if there is risk for aspiration. • *Immediately after cuff inflation:* Verify that pressure is within accepted range (≤20 mm Hg or ≤25 cm H_2O) with a manometer. Record cuff pressure and volume of air used for cuff inflation in chart.
		Care of Patients With an Inflated Cuff • Monitor and record cuff pressure q8h. Cuff pressure should be ≤20 mm Hg or ≤25 cm H_2O to allow adequate tracheal capillary perfusion. If necessary, remove or add air to the pilot tubing using a syringe and stopcock. Afterward, verify that cuff pressure is within accepted range with manometer. • Report inability to keep the cuff inflated or need to use progressively larger volumes of air to keep cuff inflated. Potential causes of these problems include tracheal dilation at the cuff site or a crack or slow leak in the housing of the one-way inflation valve. If the leak is caused by tracheal dilation, the physician may intubate the patient with a larger tube. Cracks in the inflation valve may be temporarily managed by clamping the small-bore tubing with a hemostat. The tube should be changed within 24 hr.
Fenestrated tracheostomy tube (Shiley, Portex) with cuff, inner cannula, and decannulation plug (see Figures 29-3, *B* and 29-6, *A*)	When inner cannula is removed, cuff deflated, and decannulation plug inserted, air flows around tube, through fenestration in outer cannula, and up over vocal cords. Patient can then use voice.	• Signs or symptoms of aspiration need further evaluation by a speech pathologist or radiologist. • *Never* insert decannulation plug in tracheostomy tube until cuff is deflated and inner cannula removed. Prior insertion will prevent patient from breathing (no air inflow). This may precipitate a respiratory arrest. • Assess for signs of respiratory distress when a fenestrated cannula is first used. If this occurs, the cap should be removed, the inner cannula replaced, and the cuff reinflated. • Cuff management as described above.
Speaking tracheostomy tube (Portex, National) with cuff, two external tubings (see Figure 29-6, *B*)	Has two tubings, one leading to cuff and one to opening above the cuff. When port is connected to air source, air flows out of opening and up over the vocal cords, allowing voicing with cuff inflated.	• Once tube is inserted, wait 2 days before use so that the stoma can close around the tube and prevent leaks. • When patient desires to speak, connect port to compressed air (or oxygen). Be certain to identify correct tubing. If gas enters the cuff, it will overinflate and rupture, necessitating an emergency tube change. Use lowest flow (typically 4–6 L/min) that permits use of the voice. High flows dehydrate mucosa. • Cover port adaptor. This will cause the air to flow upward. Instruct patient to speak in short sentences because voice becomes a whisper with long sentences. • Disconnect flow when patient does not want to speak to prevent mucosal dehydration. • Cuff management as described above.

Tube	Characteristics	Nursing Management
Tracheostomy tube (Bivona Fome-Cuf) foam-filled cuff (see Figure 29-3, D)	Cuff is filled with plastic foam. Before insertion, cuff is deflated. After insertion, cuff is allowed to fill passively with air. Pilot tubing is not capped, and no cuff pressure monitoring is required.	• Before insertion, withdraw all air from the cuff, using a 20-mL syringe. Cap pilot balloon tubing to prevent re-entry of air. After tracheostomy is inserted, remove cap from pilot tubing, allowing cuff to passively reinflate. • Do not inject air into tubing or cap pilot balloon tubing while in patient. Air will flow in and out in response to pressure changes (e.g., with head turning). Place tag on tubing, alerting staff not to cap or inflate cuff. • Deflate cuff daily via pilot balloon to evaluate integrity of cuff. Also assess ability to easily deflate cuff. Difficulty deflating cuff indicates a need for tube change. If aspirate returns with air, the cuff is no longer intact. • Tube can be used for up to 1 mo in patients on home mechanical ventilation. Good choice for patients who require inflated cuff at home because teaching about cuff pressure is simplified.

MLT, minimal leak technique.

Some tracheostomy tubes also have an inner cannula, which can be removed for cleaning (see Figure 29-3, *C*). The cleaning procedure removes mucus from the inside of the tube. If humidification is adequate, mucus may not accumulate and a tube without an inner cannula can be used. Care of the patient with a tracheostomy involves suctioning the airway to remove secretions (Figure 29-4 and Table 29-7) and cleaning around the stoma. In addition, tracheostomy care includes changing tracheostomy ties (Figure 29-5 and Table 29-8). If an inner cannula is used, whether disposable or nondisposable, tracheostomy care also involves inner cannula care (Stacey, 2014; see Table 29-8).

FIGURE 29-4 Suctioning tracheostomy with closed system suction catheter. Source: Potter, P. A., Perry, A. G., Stockert, P. A., et al. (2011). *Basic nursing: Essentials for practice* (7th ed., p. 826). St. Louis: Mosby.

TABLE 29-7
PROCEDURE FOR SUCTIONING A TRACHEOSTOMY TUBE

1. The nurse should assess the need for suctioning q2h. Indications include coarse crackles or wheezes over large airways, moist cough, and restlessness or agitation if accompanied by decrease in SpO_2 or PaO_2. The patient should not be suctioned routinely or if able to clear secretions with cough.
2. If suctioning is indicated, the nurse should explain procedure to patient.
3. The necessary sterile equipment should be collected: suction catheter (no larger than half the lumen of the tracheostomy tube), gloves, water, cup, and drape. If a closed tracheal suction system is used, the catheter is enclosed in a plastic sleeve and reused. No additional equipment is needed.
4. The next step is to adjust suction pressure until the dial reads between 100 and 150 mm Hg pressure (for adults) with tubing occluded. For infants and children, the pressure should read between 50 and 100 mm Hg, depending upon the size of the child. (NOTE: The nurse should check the institution or agency's policy and procedure manuals for specific guidelines.)
5. The nurse should wash hands and put on goggles and gloves.
6. Sterile technique should be used to open package, fill cup with water, put on gloves, and connect catheter to suction. One hand should be designated as contaminated for disconnecting, bagging, and operating the suction control, and water should be suctioned through the catheter to test the system.
7. The nurse must assess SpO_2 and heart rate and rhythm to provide baseline for detecting change during suctioning.
8. Preoxygenation should be provided by using a reservoir-equipped MRB connected to 100% oxygen or by asking the patient to take three to four deep breaths while administering oxygen. The method chosen will depend on the patient's underlying disease and acuity of illness. The patient who has had a tracheostomy for an extended period and is not acutely ill may be able to tolerate suctioning without use of an MRB.
9. The nurse should gently insert catheter *without suction* to minimize the amount of oxygen removed from the lungs and then insert the catheter approximately 13 to 15 cm. Suctioning should be stopped if an obstruction is met.
10. Then the catheter should be withdrawn 1 to 2 cm and suction applied intermittently while withdrawing catheter in a rotating manner. If secretion volume is large, suctioning should be applied continuously.
11. *Suctioning time should be limited to 10 seconds.* Suctioning should be discontinued if heart rate decreases from baseline by 20 beats per minute, increases from baseline by 40 beats per minute, a dysrhythmia occurs, or SpO_2 decreases to less than 90%.
12. After each suction pass, the nurse should oxygenate with three to four breaths by MRB or deep breaths with oxygen.
13. Single-use catheters should not be reintroduced into the tracheostomy tube. (The nurse should check the institution's policy and procedure manuals.)
14. The procedure should be repeated until airway is clear, and insertions of suction catheter should be limited to as few as needed.
15. Oxygen concentration should be returned to prior setting.
16. The nurse should suction the oropharynx or use mouth suction.
17. The catheter should be disposed of by wrapping it around fingers of gloved hand and pulling glove over catheter. Then equipment should be discarded in proper waste container.
18. The nurse should auscultate to assess changes in lung sounds and then record time, amount, and character of secretions and response to suctioning.

MRB, manual resuscitation bag.

The slit end is put into the opening of the faceplate. **B,** A loop is made with the other end of the tape. **C,** The tapes are tied together with a double knot on the side of the neck, avoiding any blood vessels. **D,** A tracheostomy tube holder can be used in place of twill ties to make tracheostomy tube stabilization more secure. Source: **D,** Dale Medical Products, Inc.

TABLE 29-8
TRACHEOSTOMY CARE

1. The nurse should explain procedure to patient.
2. A tracheostomy care kit should be used or necessary sterile equipment should be collected (e.g., suction catheter, gloves, water, basin, drape, tracheostomy ties, tube brush or pipe cleaners, 4 × 4–inch gauze pads, normal saline or sterile water, and tracheostomy dressing [optional]). NOTE: Clean rather than sterile technique is used at home.
3. The patient should be positioned in a semi-Fowler's position.
4. The needed materials should be assembled on bedside table next to patient.
5. The nurse should wash hands and put on goggles and clean gloves.
6. The next step is to auscultate chest sounds. If wheezes or coarse crackles are present, the patient should be suctioned if unable to cough up secretions (see Table 29-7) and then the nurse should remove soiled dressing and clean gloves.
7. The nurse should open sterile equipment, pour sterile normal saline into basins, and put on sterile gloves.
8. The inner cannula, if present, should be unlocked and removed. Many tracheostomy tubes do not have inner cannulas. Care for these tubes includes all steps except for inner cannula care.
9. If disposable inner cannula is used, it should be replaced with new cannula. If a nondisposable cannula is used, the following applies:
    a. Inner cannula should be immersed in sterile normal saline and the inside and outside of cannula cleaned using tube brush or pipe cleaners.
    b. Inner cannula should be rinsed in normal saline and shaken to dry.
    c. Inner cannula should be inserted into outer cannula with the curved part downward and then locked in place.
10. Dried secretions should be removed from stoma, outer cannula, and neck plate, using 4 × 4–inch gauze pad soaked in normal saline. Then the area around the stoma should be gently pat dry.
11. The nurse should maintain position of tracheal retention sutures, if present, by taping above and below the stoma.
12. Tracheostomy ties should be changed as follows: secure new ties to flanges before removing the old ones. Tie tracheostomy ties securely with room for one finger between ties and skin (see Figure 29-5). To prevent accidental tube removal, secure the tracheostomy tube by gently applying pressure to the flange of the tube during the tie changes. *Tracheostomy ties should not be changed for first 72 hours after the tracheotomy procedure.*
13. As an alternative, some patients prefer tracheostomy ties made of Velcro, which are easier to adjust.
14. If drainage is excessive, dressings should be placed around tube (see Figure 29-5). A tracheostomy dressing or unlined gauze should be used. The gauze should not be cut because threads may be inhaled or wrap around the tracheostomy tube. Dressing should be changed frequently—wet dressings promote infection and stoma irritation.
15. The nurse should repeat care three times a day and as needed.

Both cuffed and uncuffed tracheostomy tubes are available. A tracheostomy tube with an inflated cuff is used if the patient is at risk for aspiration or needs mechanical ventilation. Because an inflated cuff exerts pressure on tracheal mucosa, it is important to inflate the cuff with the minimum volume of air required to obtain an airway seal. Cuff inflation pressure should not exceed 20 mm Hg or 25 cm H_2O because higher pressures may compress tracheal capillaries, limit blood flow, and predispose to tracheal necrosis. An alternative approach, termed the *minimal leak technique (MLT)*, involves inflating the cuff with the minimum amount of air to obtain a seal and then withdrawing 0.1 mL of air. Disadvantages of MLT are the risk for aspiration from secretions leaking around the cuff and difficulty maintaining positive end-expiratory pressure (Stacy, 2014).

In some patients, cuff deflation is performed to remove secretions that accumulate above the cuff. Before deflation, the patient should cough up secretions, if possible, and the tracheostomy tube and mouth should be suctioned (see Figure 29-4 and Table 29-7). This step is important to prevent secretions from being aspirated during deflation. The cuff is deflated during exhalation because the exhaled gas helps propel secretions into the mouth. The patient should also cough or be suctioned after cuff deflation. The cuff should be reinflated during inspiration. The volume of air required to inflate the cuff should be monitored daily because this volume may increase if there is tracheal dilation from cuff pressure. The nurse should assess the patient's ability to protect the airway from aspiration and remain with the patient when the cuff is initially deflated, unless the patient can protect the airway from aspiration and breathe without respiratory distress.

When the patient can protect the airway from aspiration and does not require mechanical ventilation, a cuffless tracheostomy tube should be used.

Retention sutures are often placed in the tracheal cartilage when the tracheotomy is performed. The free ends should be taped to the skin in a place and manner that leaves them accessible if the tube becomes dislodged. Care should be taken not to dislodge the tracheostomy tube during the first few days when the stoma is not mature (healed). Because tube replacement can be difficult, several precautions are required: (1) a replacement tube of equal or smaller size is kept at the bedside, readily available for emergency reinsertion; (2) tracheostomy tapes are not changed for at least 24 hours after the insertion procedure; and (3) the first tube change is performed by a physician, usually no sooner than 7 days after the tracheotomy.

If accidental decannulation occurs, the retention sutures (if present) are grasped and the opening is spread with a tracheal dilator or hemostat, and the replacement tube is guided in, using the obturator. To permit airflow, the obturator is immediately removed once the tube is inserted. Another method is to insert a suction catheter to allow passage of air. The new tube is threaded over the catheter, followed by removal of the suction catheter. If the tube cannot be replaced, the level of respiratory distress is assessed. Minor dyspnea may be alleviated by use of semi-Fowler's position until assistance arrives. Severe dyspnea may progress to respiratory arrest; if this situation occurs, the stoma should be covered with a sterile dressing, and the patient should be ventilated with bag–mask ventilation until help arrives.

After the first tube change, the tube should be changed approximately once a month. When a tracheostomy has been in place for several months, the healed tract will be well formed. The patient can then be taught to change the tube using clean technique at home. Teaching will vary depending on how ill the patient is and what device has been selected.

Swallowing Dysfunction

The patient who cannot protect the airway from aspiration requires an inflated cuff. However, an inflated cuff may promote swallowing dysfunction (dysphagia) because the cuff interferes with the normal function of the muscles used to swallow. For this reason, it is important to evaluate the risk for aspiration with the cuff deflated. The patient may be able to swallow without aspirating when the cuff is deflated but not when it is inflated. The cuff may then be left deflated or a cuffless tube substituted (Figure 29-6).

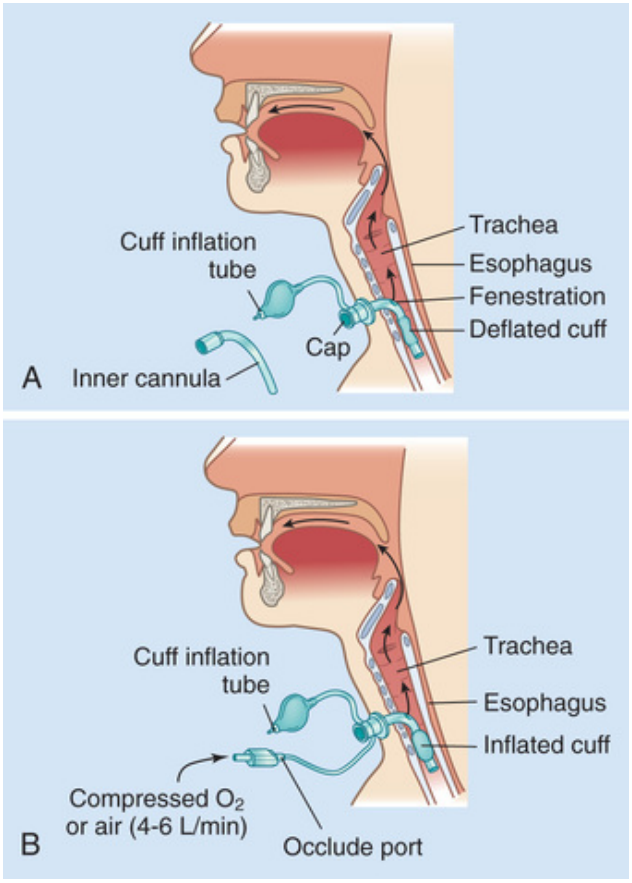

FIGURE 29-6 Speaking tracheostomy tubes. **A,** Fenestrated tracheostomy tube with cuff deflated, inner cannula removed, and tracheostomy tube capped to allow air to pass over the vocal cords. **B,** Speaking tracheostomy tube. One tube is used for cuff inflation. The second tube is connected to a source of compressed air or oxygen. When the port on the second tube is occluded, air flows up over the vocal cords, allowing use of the voice with an inflated cuff. (See Table 29-6 and NCP 29-1 for related nursing management.)

Use of the Voice With a Tracheostomy Tube

A number of techniques promote use of the voice in the patient with a tracheostomy. The patient who can breathe spontaneously may be able to talk by deflating the cuff, which allows exhaled air to flow upward over the vocal cords. This can be enhanced by the patient occluding the tube with a finger or plug. Frequently, a small cuffless tube is inserted so exhaled air can pass freely around the tube. These tracheostomy tubes and valves have been designed to facilitate use of the voice. The nurse can be an advocate in promoting use of these specialized devices. Their use can

provide great psychological benefit and facilitate self-care for the patient with a tracheostomy.

A fenestrated tube has openings on the surface of the outer cannula that permit air from the lungs to flow over the vocal cords (see Figures 29-3, *C* and 29-6, *A*). A fenestrated tube allows the patient to breathe spontaneously through the larynx, speak, and cough up secretions with the tracheostomy tube in place. It can be used by the patient who can swallow without risk for aspiration but requires suctioning for secretion removal. It may also be used by the patient who requires mechanical ventilation for less than 24 hours a day (e.g., during sleep).

Before the fenestrated tube is used, the patient's ability to swallow without aspiration is determined (see Table 29-5 and Nursing Care Plan [NCP] 29-1, available on the Evolve website). If there is no aspiration, (1) the inner cannula is removed, (2) the cuff is deflated, and (3) the decannulation cap is placed in the tube (see Figure 29-6, *A*). It is important to perform the steps in order because severe respiratory distress may result if the tube is capped before the inner cannula is removed and the cuff deflated. When a fenestrated cannula is first used, the nurse should frequently assess the patient for signs of respiratory distress.

If the patient is not able to tolerate the procedure, the cap should be removed, the inner cannula replaced, and the cuff reinflated. A disadvantage of fenestrated tubes is the potential for development of tracheal polyps from tracheal tissue granulating into the fenestrated openings.

A speaking tracheostomy tube has two pigtail tubings. One tubing connects to the cuff and is used for cuff inflation, and the second connects to an opening just above the cuff (see Figure 29-6, *B*). When the second tubing is connected to a low-flow (4–6 L/min) air source, sufficient air moves up over the vocal cords to produce the voice. The patient can then use the voice, even though the cuff is inflated.

When a speaking tracheostomy valve is used, a cuffless tube must be in place, or the cuff must be deflated, to allow exhalation (Figure 29-7). Ability to tolerate cuff deflation without aspiration or respiratory distress must also be evaluated in patients using this device. If there is no aspiration, the cuff is deflated and the valve is placed over the tracheostomy tube opening. The speaking valve contains a thin plastic diaphragm that opens on inspiration and closes on expiration. During inspiration, air flows in through the valve. During expiration, the diaphragm prevents exhalation and air flows upward over the vocal cords and into the mouth.

FIGURE 29-7 Passy–Muir speaking tracheostomy valve. The valve is placed over the hub of the tracheostomy tube after the cuff is deflated. Multiple options are available and can be used for ventilated and nonventilated patients. The valve contains a one-way valve that allows air to enter the lungs during inspiration and redirects air upward over the vocal cords into the mouth during expiration. Source: Image courtesy of Passy Muir, Inc. Irvine, CA.

If speaking devices are not used, the patient should be provided with a paper and pencil, a whiteboard with marker, or a computer tablet (e.g., iPad). A word (communication) board can usually be obtained from speech therapy, or one can be devised with pictures of common needs and an alphabet for spelling words.

Informatics in Practice

Communication Devices for Patient With Laryngectomy

- Assisting with communication will improve a patient's quality of life after a laryngectomy.
- A tablet (e.g., iPad) or smartphone can be used with a downloaded text-to-speech application. These applications allow the patient to type in text, and then a computer voice says the text aloud.
- The nurse can also teach the patient how to use a keyboard-based communication program. The patient types on a traditional keyboard and generates speech that is transmitted through hand-held speakers.

Decannulation

When the patient can adequately exchange air and expectorate secretions, the tracheostomy tube can be removed. The stoma is closed with tape strips and covered with an occlusive dressing. The dressing must be changed if it gets soiled or wet. The patient should be instructed to splint the stoma with the fingers when coughing, swallowing, or speaking. Epithelial tissue begins to form in 24 to 48 hours, and the opening will close in several days. Surgical intervention to close the tracheostomy is not required.

Laryngeal Polyps

Laryngeal polyps may develop on the vocal cords from vocal abuse (e.g., excessive talking, singing) or irritation (e.g., intubation, cigarette smoking). The most common symptom is hoarseness. Polyps may be treated conservatively with voice rest. Surgical removal may be indicated for large polyps, which may cause dyspnea and stridor. Polyps are usually benign but may be removed because they may later become malignant.

Head and Neck Cancer

Head and neck cancer arises from mucosal surfaces and is typically squamous cell in origin. This category of tumours includes those of the paranasal sinuses, the oral cavity, and the nasopharynx, oropharynx, and larynx. (Cancer of the oral cavity is discussed in Chapter 44.) Although this type of cancer is not common, disability is great because of the potential loss of voice, disfigurement, and social consequences.

Clinical Manifestations

Early signs and symptoms of head and neck cancer vary with the tumour location (Carr, 2016). Cancer of the oral cavity may first be signalled by a painless growth in the mouth, an ulcer that does not heal, or a change in fit of dentures. Pain is a late symptom that may be aggravated by acidic food. Cancers of the oropharynx, hypopharynx, and supraglottic larynx rarely produce early symptoms and are usually diagnosed in late stages. The patient may complain of persistent unilateral sore throat or otalgia (ear pain). Hoarseness may be a symptom of early laryngeal cancer. If a lump in the neck or hoarseness lasts longer than 2 weeks, a medical evaluation is

indicated. Some patients experience what feels like a lump in the throat or a change in voice quality.

Late stages of head and neck cancers have easily detectable signs and symptoms, including pain, dysphagia, decreased tongue mobility, airway obstruction, and cranial nerve neuropathies. The nurse should thoroughly examine the oral cavity, including the areas under the tongue and the dentures. The floor of the mouth, the tongue, and the lymph nodes in the neck should be bimanually palpated. There may be thickening of the normally soft and pliable oral mucosa. *Leukoplakia* (white patch) or *erythroplakia* (red patch) may be seen and should be noted for later biopsy. Both leukoplakia and carcinoma in situ (localized to a defined area) may precede invasive carcinoma by many years.

Diagnostic Studies

If lesions are suspected, the upper airways may be examined using indirect laryngoscopy—using a laryngeal mirror to visualize the laryngeal area—or a flexible nasopharyngoscope. The larynx and vocal cords are visually inspected for lesions and tissue mobility. A CT scan, magnetic resonance imaging (MRI), or positron emission tomography (PET) scan may be performed to detect local and regional spread. Neoplastic tissue is identifiable because it contains tissue of greater density or because it distorts, displaces, or destroys normal anatomical structures. Typically, multiple biopsy specimens are obtained to determine the extent of the disease (Goldman & Schafer, 2012).

Collaborative Care

The stage of the disease will be determined based on tumour size (T), number and location of involved nodes (N), and extent of metastasis (M). TNM staging classifies disease over the range between stage I through stage IV and guides treatment. Choice of treatment is based on medical history, extent of disease, cosmetic considerations, urgency of treatment, and patient choice. Approximately one-third of patients with head and neck cancers have highly confined lesions that are stage I or II at diagnosis. Such patients can undergo radiation therapy or surgery with the goal of cure.

Radiation therapy may be effective in curing early vocal cord lesions. This therapy is usually successful in eliminating the tumour while preserving the quality of the voice. If radiation therapy is not successful or the lesion is too advanced for this therapy, surgery may be performed. A

cordectomy (partial removal of one vocal cord) is used when there is a superficial tumour involving one cord (Figure 29-8). A *hemilaryngectomy* involves removal of thyroid cartilage, a portion of the larynx and one vocal cord or part of a cord and necessitates a temporary tracheostomy. A *supraglottic laryngectomy* involves removing structures above the true cords —the false vocal cords and epiglottis. The patient is left at high risk for aspiration following surgery and requires a temporary tracheostomy. Both a hemilaryngectomy and a supraglottic laryngectomy allow the voice to be preserved, but quality is breathy and hoarse.

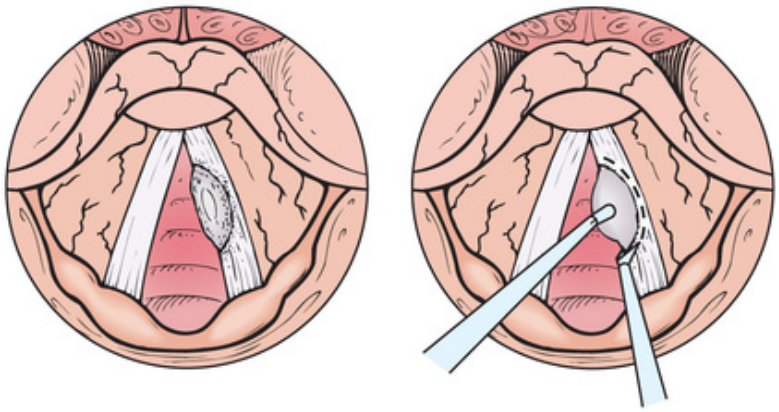

FIGURE 29-8 Excision of laryngeal cancer. This cancer of the right vocal cord meets criteria for resection by transoral cordectomy. The cord is fully mobile and the lesion can be fully exposed. It does not approach or cross the anterior commissure.

Advanced lesions are treated by a total laryngectomy in which the entire larynx and pre-epiglottic region is removed and a permanent tracheostomy performed. Airflow patterns before and after total laryngectomy are shown in Figure 29-9. *Radical neck dissection* frequently accompanies total laryngectomy to decrease the risk for lymphatic spread. Depending on the extent of involvement, extensive dissection and reconstruction may be performed. This procedure involves wide excision of the lymph nodes and their lymphatic channels (Figure 29-10). The following structures may also be removed or transected: sternocleidomastoid muscle and other closely associated muscles, internal jugular vein, mandible, submaxillary gland, part of the thyroid and parathyroid glands, and the spinal accessory nerve.

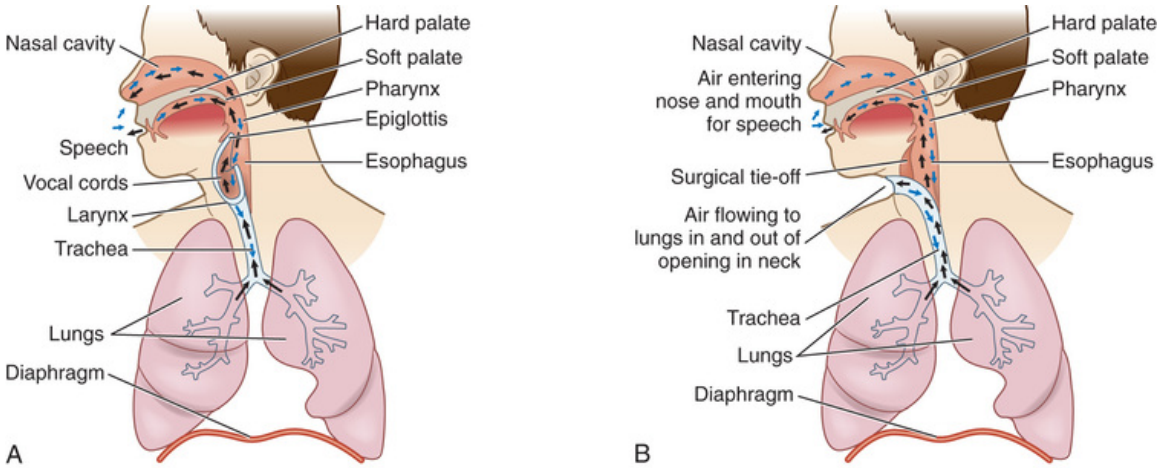

FIGURE 29-9 **A,** Normal airflow in and out of the lungs. **B,** Airflow in and out of the lungs after total laryngectomy. Patients using esophageal speech by trapping air in the esophagus and releasing it to create sound. Source: The American Cancer Society.

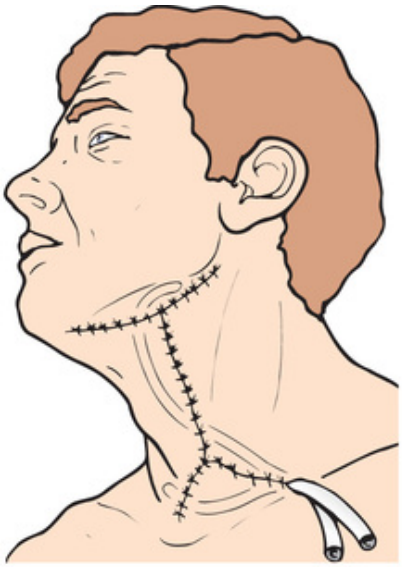

FIGURE 29-10 Radical neck incision with drains in place.

A *modified neck dissection* is performed whenever possible as an alternative to a radical neck dissection. The dissection is modified by sparing as many structures as possible to limit disfigurement and functional loss. A modified neck dissection usually involves dissection of the major cervical lymphatic vessels and lateral cervical space, with preservation of nerves and vessels, including the sympathetic and vagus nerves, spinal accessory nerves, and internal jugular vein. Neck dissection

with vocal cord cancer usually involves one side of the neck. However, if the lesion is midline, a bilateral neck dissection may be performed. In this case, it is always modified on at least one side to minimize structural and functional deficits (Rothrock, 2015).

The patient may refuse surgical intervention for advanced lesions because of the extent of the procedure, or the patient may be judged to be at too great a medical risk to undergo the procedure. In these situations, external radiation therapy may be used as the sole treatment or in combination with chemotherapy (Rothrock, 2015).

In addition, brachytherapy, a concentrated and localized method of delivering radiation that involves placing a radioactive source into or near the tumour, may be used to treat head and neck cancer. The goal of brachytherapy is to deliver high doses of radiation to the target area while limiting exposure of surrounding tissues. Thin, hollow, plastic needles are inserted into the tumour area, and radioactive iridium seeds are placed in the needles. The seeds emit continuous radiation. Brachytherapy can be used alone or combined with external radiation or surgical intervention. (Radiation therapy and brachytherapy are discussed in Chapter 18.)

Nutritional Therapy.

The patient's nutritional status should be assessed before surgery as 60% of patients with head and neck cancer initially present with malnutrition (Carr, 2016). After radical neck surgery, the patient may be unable to take in nutrients through the normal route of ingestion because of swelling, the location of sutures, or difficulty swallowing. Parenteral fluids will be given for the first 24 to 48 hours. Tube feedings are usually given via a nasogastric, nasointestinal, or gastrostomy tube that was placed during surgery. (Nasogastric and gastrostomy feedings are described in Chapter 42.) The nurse must observe for tolerance of the feedings and adjust amount, time, and formula if nausea, vomiting, diarrhea, or distension occurs. The patient is instructed about the tube feedings. When the patient can swallow, small amounts of water are given. Close observation for difficulty swallowing is essential. Suctioning may be necessary to prevent aspiration.

Swallowing problems should be anticipated when the patient resumes eating. All patients should be referred to a speech pathologist for a dysphagia/swallowing assessment and recommendations during treatment. The type and degree of difficulty vary, depending on the surgical procedure. When a supraglottic laryngectomy is performed, the surgeon excises the upper portion of the larynx, including the epiglottis

and the false vocal cords. The patient can speak because the true vocal cords remain intact. However, a new technique, the supraglottic swallow, must be learned to compensate for removal of the epiglottis and minimize risk for aspiration (Table 29-9). When the patient is learning this technique, it may be helpful to start with carbonated beverages because the effervescence provides cues about the liquid's position. With this exception, thin, watery fluids should be avoided because they are difficult to swallow and increase the risk for aspiration. A better choice is nonpourable puréed foods, which are thicker and allow more control during swallowing. Swallowing can be enhanced by thickening liquids using a commercially available thickening agent. Consultation with a dietitian will assist with appropriate diet texture, while ensuring nutritional and caloric needs are maintained.

TABLE 29-9

PATIENT & CAREGIVER TEACHING GUIDE
Steps for Performing the Supraglottic Swallow

The following information should be included when teaching the patient and caregiver how to perform the supraglottic swallow.
1. Take a deep breath to aerate lungs. 2. Perform the Valsalva manoeuvre to approximate the vocal cords. 3. Place food in the mouth and swallow. Some food will enter airway and remain on top of the closed vocal cords. 4. Cough to remove food from top of vocal cords. 5. Swallow so food is moved from top of vocal cords. 6. Breathe after cough–swallow sequence to prevent aspiration of food collected on top of vocal cords.

Good nutrition is important during radiation therapy because calories and protein are needed for tissue repair. Antiemetics or analgesics may be given before meals to reduce nausea and mouth pain. Bland foods may be better tolerated than more highly flavoured foods. Caloric intake may be increased by adding dry milk to foods during preparation, selecting foods high in calories, and using oral supplements. It is helpful to add sauces and gravies to food, which adds calories and moistens food so it is more easily swallowed. If an adequate intake cannot be maintained, enteral feedings may be used. When eating, the patient should always be positioned with the head elevated.

Nursing Management Head and Neck Cancer

Nursing Assessment

Subjective and objective data that should be obtained from a person with head and neck cancer are presented in Table 29-10.

TABLE 29-10

NURSING ASSESSMENT
Head and Neck Cancer

Subjective Data
Important Health Information
Past health history: Positive family history; prolonged tobacco use (cigarettes, pipes, cigars, chewing tobacco, smokeless tobacco); prolonged, heavy alcohol use *Medications:* Prolonged use of over-the-counter medication for sore throat, decongestants
Symptoms
Mouth ulcer that does not heal, change in fit of dentures, change in appetite, weight loss, swallowing difficulty (e.g., sensation of lump in throat, pain with swallowing, aspiration when swallowing) Fatigue with minimal exertion Sore throat, hoarseness, change in voice quality, referred ear pain
Objective Data
Respiratory
Hoarseness, chronic laryngitis, nasal voice, palpable neck mass and lymph nodes (tender, hard, fixed), tracheal deviation; dyspnea, stridor (late sign)
Gastro-Intestinal
White (leukoplakia) or red (erythroplakia) patches inside mouth, ulceration of mucosa, asymmetrical tongue, exudate in mouth or pharynx, mass or thickening of mucosa
Possible Findings
Mass on direct or indirect laryngoscopy; tumour on soft tissue radiographic study, computed tomographic scan, magnetic resonance imaging, or positron emission tomography; positive biopsy

Nursing Diagnoses

Nursing diagnoses for the patient with head and neck cancer include, but are not limited to, the following:

- *Ineffective airway clearance* related to *presence of artificial airway and excessive mucus*
- *Risk for aspiration* related to *presence of oral/nasal tube and impaired ability to swallow*

- *Anxiety* related to *unmet needs* (lack of knowledge about surgical procedure and pain management)
- *Acute pain* related to *physical injury agent* (surgery)
- *Impaired verbal communication* related to *physiological condition* (removal of vocal chords)

Additional information on nursing diagnoses for the patient with head and neck cancer is presented in NCP 29-2, available on the Evolve website.

Planning

The overall goals are that the patient will have (1) a patent airway, (2) no spread of cancer, (3) no complications related to therapy, (4) adequate nutritional intake, (5) minimal to no pain, (6) the ability to communicate, and (7) an acceptable body image.

Nursing Implementation

Health Promotion.

Development of head and neck cancer is closely related to personal habits, primarily tobacco use, including the use of cigarettes, cigars, chewing tobacco, and snuff. Prolonged alcohol use has been implicated as a potentiating factor in head and neck cancer. Excessive sun exposure to the lips also increases the risk for oral cancer.

The nurse should include information about risk factors in health teaching (Carr, 2016). If cancer has been diagnosed, tobacco cessation is still important. The patient with head and neck cancer who continues to smoke during radiation therapy has a lower rate of response and survival than the patient who does not smoke during radiation therapy. In addition, risk for a second primary cancer is significantly increased in patients who continue to smoke.

Acute Intervention.

The patient and the family must be taught about the type of therapy to be performed and care required. Assessment of concerns is integral to the plan of care. The patient and family must deal with the psychological impact of the diagnosis of cancer, alteration of physical appearance, and possible need for alternative methods of communication (Carr, 2016). The

care plan should include assessment of the patient's support system. The patient may not have someone to provide assistance after discharge, may not be employed, or may be employed in a job that cannot be continued.

Radiation Therapy.

The nurse can suggest interventions to reduce adverse effects of radiation therapy. (Radiation is discussed in Chapter 18.) Fatigue is common. Patients should be encouraged to take frequent rest periods. Light, regular exercise, such as walking, may be helpful.

Dry mouth (xerostomia), the most frequent and annoying problem, typically begins within a few weeks of treatment. The patient's saliva decreases in volume and becomes thick. The change may be temporary or permanent. Pilocarpine hydrochloride (Salagen) can be effective in increasing saliva production and should be started before the initiation of radiation therapy and continued for 90 days. Symptom relief can also be obtained by increasing fluid intake, chewing sugarless gum or eating sugarless candy, using nonalcoholic mouth rinses (baking soda or glycerin solutions), and using artificial saliva.

The patient may also complain of stomatitis, especially if the oral cavity is in the field of therapy. Irritation, ulceration, and pain are common complaints. Normal saline mouth rinses after meals and at bedtime can be used to clean and soothe irritated tissues. Commercial mouthwashes and hot or spicy foods should be avoided because they are irritating. If the problem is severe, a mouthwash mixture of equal parts of antacid, diphenhydramine (Benadryl), and topical lidocaine can be used.

Skin over the irradiated area often becomes reddened and sensitive to touch. It is common for patients to require a break from their scheduled radiation program because of altered skin integrity. Only prescribed lotions and products should be used during radiation therapy. All exposure to the sun should be avoided to reduce discomfort.

Surgical Therapy.

Preoperative care for the patient who is to have a radical neck dissection involves consideration of the patient's physical and psychosocial needs. Physical preparation is the same as for any major surgery, with special emphasis on oral hygiene. Explanations and emotional support are of special significance and should include postoperative measures relating to communication and feeding. The surgical procedure should be explained to the patient and family or caregivers, and the nurse should make sure that the information is understood.

Teaching must be tailored to the planned surgical procedure. For surgeries that involve a laryngectomy, teaching should include information about expected changes in speech. The nurse or speech pathologist should demonstrate means of communicating other than speaking that can be used temporarily or permanently. This may include some type of communication board.

After surgery, maintenance of a patent airway is essential. The inflammation in the surgical area may compress the trachea. A tracheostomy tube will be in place. The patient will be placed in a semi-Fowler's position to decrease edema and limit tension on the suture lines. Vital signs should be monitored frequently because of the risk for hemorrhage and respiratory compromise. Pressure dressings, packing, or drainage tubes (Hemovac, Jackson Pratt) may be used for wound management, depending on the type of surgical procedure. When a radical neck dissection is performed, wound suction using a portable system, such as a Hemovac, is generally used. If skin flaps are employed, dressings are typically not used. This allows better visualization of the incision and helps prevent excessive pressure on tissue (see Figure 29-10). The drainage should be serosanguineous and gradually decrease in volume over 24 hours. Patency of drainage tubes should be monitored every 4 hours to ensure that they are properly removing serous drainage and for the amount and character of drainage. If the tubing becomes obstructed, fluid will accumulate under the skin flap and predispose to impaired wound healing and infection. After drainage tubes are removed, the area should be closely monitored for any swelling. If fluid continues to accumulate, aspiration may be necessary.

Immediately after surgery, the patient with a laryngectomy requires frequent suctioning via the laryngectomy tube. Secretions typically change in amount and consistency over time. The patient may initially have copious blood-tinged secretions that diminish and thicken. Standard administration of saline boluses via the tracheostomy tube to loosen secretions is no longer recommended as it may increase risk for infection (Astobelli, 2013).

The patient will benefit from the use of a humidifier while hospitalized and at home.

Following a neck dissection, an exercise program should be instituted to maintain strength and movement in the affected shoulder and the neck. This is especially important when the spinal accessory nerve and the sternocleidomastoid muscles are removed or damaged. Without exercise, the patient will be left with a “frozen” shoulder and limited range of

motion in the neck. This exercise program should be continued following discharge to prevent future functional disabilities. The patient may need the neck supported to be able to move the head after surgery.

Voice Rehabilitation.

A speech pathologist should meet with the patient preoperatively and following a total laryngectomy to discuss voice restoration options. The International Association of Laryngectomees, an association of patients who have had laryngectomies, focuses on assisting patients to re-establish speech. Local groups, called Lost Cord Clubs, often provide member volunteers to visit the patient, preferably before surgery. Several options are available to restore speech. These include use of a voice prosthesis, esophageal speech, and an electrolarynx.

The most commonly used voice prosthesis is the Blom–Singer (Figure 29-11). This soft plastic device is inserted into a fistula made between the esophagus and the trachea. The puncture may be created at the time of surgery or afterward, depending on the preference of the surgeon. A red rubber catheter is placed in the tracheo-esophageal puncture and must remain in place until a tract is formed. Once the tract is formed, the voice prosthesis is inserted. This prosthesis allows air from the lungs to enter the esophagus by way of the tracheal stoma. A one-way valve prevents aspiration of food or saliva from the esophagus into the tracheostomy. To produce the voice, the patient manually blocks the stoma with the finger. Air moves from the lungs, through the prosthesis, into the esophagus, and out the mouth. The voice is produced by the air vibrating against the esophagus, and speech sounds are formed into words by moving the tongue, jaw, and lips. A valve may also be used with this device. When the valve is in place, the stoma does not need to be closed with the finger to speak. The prosthesis must be cleaned regularly and replaced when it becomes blocked with mucus.

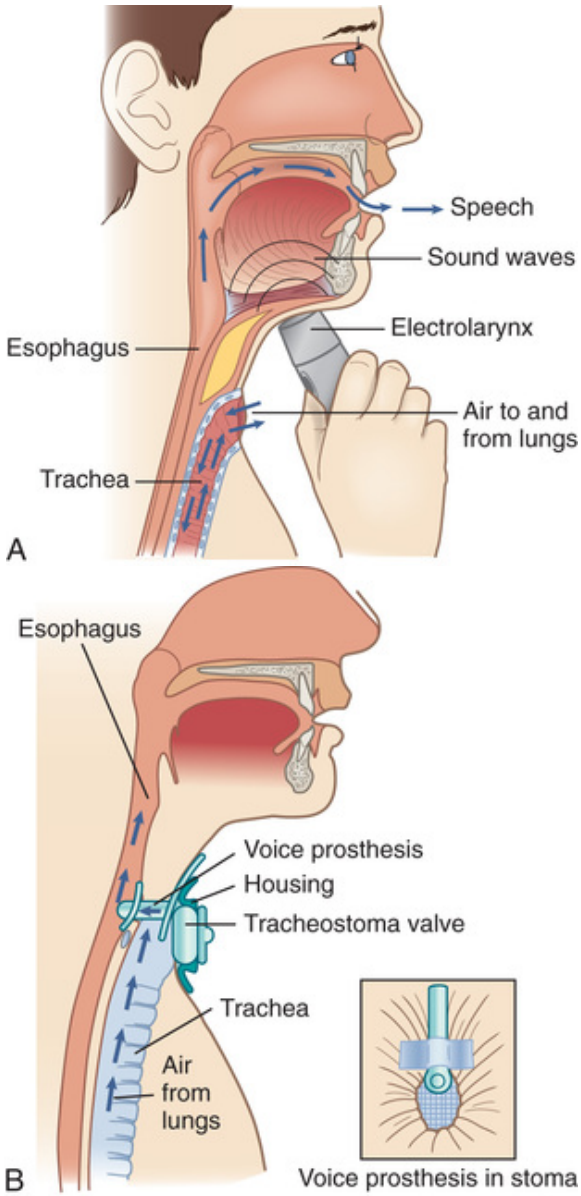

FIGURE 29-11 **A,** The sound waves created by the electrolarynx allow the person to speak. **B,** The Blom–Singer voice prosthesis and valve.

An electrolarynx is a handheld, battery-powered device that creates speech with the use of sound waves. There are two main types: the intra-oral type and the neck type. One intra-oral device, the Cooper-Rand, uses a plastic tube placed in the corner of the roof of the mouth to create vibrations. To create the most normal sound when using this device, the patient should (1) avoid trying to use the tongue to hold the tube in place; (2) compress the tone generator for short intervals and speak in phrases, rather than full sentences; (3) speak using large movements of the lips,

tongue, and jaw, rather than keeping the mouth partially closed; (4) talk face-to-face with the listener; and (5) practise because it takes time to develop this skill.

With the neck type of artificial larynx, the device is placed against the neck rather than in the mouth. This device is used after surgical healing is complete and no edema remains (Figure 29-12). With experience, the patient can learn to move the lips in ways that create somewhat normal-sounding speech. With both devices, voice pitch is low, and the sound is mechanical.

FIGURE 29-12 Artificial larynx. Battery-powered electronic artificial larynx for a patient who has had a total laryngectomy. Source: Courtesy CLG Photographics, Inc. St. Louis.

Esophageal speech is a method of swallowing air, trapping it in the esophagus, and releasing it to create sound. The air causes vibration of the pharyngoesophageal segment to create sound (which initially is similar to a belch). With practice, 50% of patients develop some speech skills, but only 10% develop fluent speech.

Stoma Care.

Before discharge, the patient should be instructed in the care of the laryngectomy stoma. The area around the stoma should be washed daily with a moist cloth. If a laryngectomy tube is in place, the entire tube must be removed at least daily and cleaned in the same manner as a tracheostomy tube. The inner cannula may have to be removed and cleaned more frequently. A scarf, a loose shirt, or a crocheted shield can be used to shield the stoma.

The patient should cover the stoma when coughing (because mucus may be expectorated) and during any activity (e.g., shaving, applying

makeup) that might lead to inhalation of foreign materials. Because water can easily enter the stoma, the patient should wear a plastic collar when taking a shower. Swimming is contraindicated. Initially, humidification will be administered via a tracheostomy mask. After discharge, a bedside humidifier can be used. A high oral fluid intake must be maintained, especially in dry weather.

The patient should be told the importance of wearing a medical alert bracelet or other identification that alerts others in an emergency situation of the need for neck breathing. Because the patient no longer breathes through the nose, the ability to smell smoke and food may be lost. Advise the patient to install smoke and carbon monoxide detectors in the home. It is important for food to be colourful, attractively prepared, and nutritious because taste may also be diminished secondary to the loss of smell as well as to radiation therapy.

Depression.

Depression is common in the patient who has had a radical neck dissection. The patient may not be able to speak because of the laryngectomy and cannot control saliva. The neck and shoulders may be numb because of the transected nerves. The facial appearance may be significantly altered, with swelling, edema, and deformities. The patient must understand that many of the physical changes are reversible as the edema subsides and the tracheostomy tube is removed. Depression may also be related to concern about the prognosis. The nurse can help the patient through the depression by allowing verbalization of feelings, conveying acceptance, and helping the patient regain an acceptable self-concept. The nurse should obtain a psychiatric referral for the patient who is experiencing prolonged or severe depression.

Sexuality.

Surgery and the presence of foreign attachments such as tracheostomy and gastrostomy tubes may affect body image dramatically. The patient may feel less desirable sexually. The nurse can assist the patient by allowing discussions regarding sexuality and encouraging the patient to discuss this problem with the sexual partner. It may be difficult for the patient to discuss sexual problems verbally because of the alteration in communication. The nurse can help the patient to plan how to communicate with the sexual partner and offer support and guidance to the sexual partner. Helping the patient see that sexuality involves much more than appearance may relieve some anxiety.

Ambulatory and Home Care.

The patient is often discharged with a tracheostomy and a nasogastric or gastrostomy feeding tube. Home health care may be needed initially as the family's or the patient's ability to perform self-care activities is evaluated. The patient and the family must be taught how to manage tubes and who to call if there are problems.

The patient can resume exercise, recreation, and sexual activity when able. Most patients can return to work 1 to 2 months after surgery. However, many never return to full-time employment. The changes that follow a total laryngectomy can be upsetting. Loss of speech, loss of the ability to taste and smell, inability to produce audible sounds (including laughing and weeping), and the presence of a permanent tracheal stoma that produces undesirable mucus are often overwhelming to the patient. Although changes are discussed before surgery, the patient may not be prepared for the extent of these changes. If the patient has a significant other, the reaction of this person to the patient's altered appearance is important. Acceptance by another person can promote an improved self-image. Encouraging the patient to participate in self-care is another important part of rehabilitation.

Reconstructive surgery may be performed at the time of the initial surgery or soon after the tumour is removed. Various types of flaps and grafts are used. It may be necessary to rebuild the nose or the mandible or to close oral cutaneous openings. Prosthetic materials, such as Silastic and Plastigel (which is soft), are often used to reconstruct various deformities.

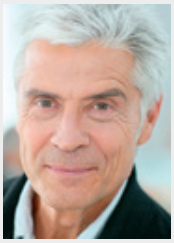
Despite the use of surgical interventions and radiation therapy, the cure rate is disappointingly low for advanced head and neck cancer. Metastatic cancer is often painful, leaving the affected person in a severely debilitated state. If pain is a problem, a pain control regimen should be instituted to provide comfort, and referral should be made to a hospice if indicated.

Evaluation

Expected outcomes for the patient with head and neck cancer who is treated surgically are addressed in NCP 29-2, available on the Evolve website.

Case Study

Laryngeal Cancer



Source: goodluz/Shutterstock.com.

Patient Profile

Tomas Pereira, a 60-year-old man, was admitted for evaluation of mild pain on swallowing and a persistent sore throat over the past year. He has a history of type 2 diabetes mellitus.

Subjective Data

- States that his symptoms worsened in the past 2 mo
- Has used various cold remedies to relieve symptoms, without relief
- Has lost weight because of decrease in appetite and difficulty swallowing
- Has smoked three packs of cigarettes a day for 40 yr
- Consumes four to six cans of beer a day

Objective Data

Laryngoscopy

- Subglottic mass

Physical Examination

- Enlarged cervical nodes

Computed Tomographic Scan

- Subglottic lesion with lymph node involvement

Collaborative Care

- Percutaneous gastrostomy tube inserted preoperatively for enteral tube feeding
- Total laryngectomy with tracheostomy with inflated cuff
- Nasogastric tube postoperatively

Discussion Questions

1. What information in the assessment suggests that Mr. Pereira is at risk for cancer of the larynx?
2. What diagnostic tests are typically performed to evaluate the extent of this problem?
3. ***Priority decision:*** What are the priority teaching strategies for Mr. Pereira before and after laryngectomy?
4. Discuss methods used to restore speech after laryngectomy.
5. Is there anything in his history that may affect wound healing after surgery?
6. ***Priority decision:*** While in the recovery room, Mr. Pereira develops shortness of breath. What are the priority nursing interventions?
7. What teaching is required to help this patient assume self-care after his surgery? What precautions should the patient take because of his stoma?
8. While on the medical-surgical unit, Mr. Pereira is tearful and is staring at the wall. What should the nurse do?
9. ***Priority decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
10. ***Evidence-informed practice:*** How could the nurse best meet Mr. Pereira's communication needs during the first few postoperative days?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. A client is seen in the clinic for an episode of epistaxis, which is controlled by placement of anterior nasal packing. During discharge teaching, what should the nurse instruct the client to do?
   a. Use ASA (Aspirin) for pain relief.
   b. Remove the packing later that day.
   c. Skip the next dose of antihypertensive medication.
   d. Avoid vigorous nose blowing and strenuous activity.
2. A client with allergic rhinitis reports severe nasal congestion, sneezing, and watery, itchy eyes and nose, at various times of the year. What should the nurse advise the client to do?
   a. Avoid all intranasal sprays and oral antihistamines.
   b. Limit the duration of use of nasal decongestant spray to 10 days.
   c. Use oral decongestants at bedtime to prevent symptoms during the night.
   d. Keep a diary of when the allergic reaction occurs and what precipitates it.
3. A client is seen at the clinic with fever, muscle aches, sore throat with yellowish exudate, and headache. Which of the following does the nurse anticipate that the collaborative management will include? *(Select all that apply)*
   a. Antiviral agents to treat influenza
   b. Treatment with antibiotics starting ASAP
   c. A throat culture or rapid strep antigen test
   d. Supportive care, including cool, bland liquids
   e. Comprehensive history to determine possible etiology
4. What type of tracheostomy tube prevents the use of the voice?
   a. Cuffless tracheostomy tube
   b. Fenestrated tracheostomy tube
   c. Tube with an inflated foam cuff
   d. Cuffed tube with the cuff deflated

5. Which nursing action related to the tracheostomy tube cuff pressure would prevent excessive pressure on tracheal capillaries?
   a. Monitor pressure every 2 to 3 days.
   b. Ensure pressure is less than 20 mm Hg or 25 cm H_2O.
   c. Ensure pressure is less than 30 mm Hg or 35 cm H_2O.
   d. Ensure pressure is sufficient to fill the pilot balloon until it is tense.
6. Which of the following is not an early symptom of head and neck cancer?
   a. Hoarseness
   b. Change in fit of dentures
   c. Mouth ulcers that do not heal
   d. Decreased mobility of the tongue
7. While in the recovery room, a client with a total laryngectomy is suctioned and has bloody mucus with some clots. Which of the following nursing interventions would apply?
   a. Notify the physician immediately.
   b. Place the client in the prone position to facilitate drainage.
   c. Instill 3 mL of normal saline into the tracheostomy tube to loosen secretions.
   d. Continue the assessment of the client, including oxygen saturation, respiratory rate, and breath sounds.
8. How should the client use a voice prosthesis?
   a. Place a vibrating device in the mouth.
   b. Place a speaking valve over the stoma.
   c. Block the stoma entrance with a finger.
   d. Swallow air using the Valsalva manoeuvre.

1. d; 2. d; 3. c, d, e; 4. c; 5. b; 6. d; 7. d; 8. c.

CHAPTER 30

Nursing Management

Lower Respiratory Problems

Written by, Eugene E. Mondor

Adapted by, Cydnee Seneviratne

LEARNING OBJECTIVES

1. Describe the pathophysiology, types, clinical manifestations, and collaborative care of pneumonia.
2. Explain the nursing management of the patient with pneumonia.
3. Describe the pathogenesis, classification, clinical manifestations, complications, diagnostic abnormalities, and nursing and collaborative management of tuberculosis.
4. Identify the causes, clinical manifestations, and nursing and collaborative management of pulmonary fungal infections.
5. Explain the pathophysiology, clinical manifestations, and nursing and collaborative management of bronchiectasis and lung abscess.
6. Identify the causative factors, clinical features, and management of environmental lung diseases.
7. Describe the causes, risk factors, pathogenesis, clinical manifestations, and nursing and collaborative management of lung cancer.
8. Identify the mechanisms involved and the clinical manifestations of pneumothorax, fractured ribs, and flail chest.

9. Describe the purpose, methods, and nursing responsibilities related to chest tubes.
10. Explain the types of chest surgery and appropriate preoperative and postoperative care.
11. Compare and contrast extrapulmonary and intrapulmonary restrictive lung disorders in terms of causes, clinical manifestations, and collaborative management.
12. Describe the pathophysiology, clinical manifestations, and management of pulmonary hypertension and cor pulmonale.
13. Discuss the use of lung transplantation as a treatment for pulmonary disorders.

pulmonary hypertension, p. 636

tension pneumothorax, p. 624

thoracentesis, p. 631

thoracotomy, p. 630

tuberculosis (TB), p. 607

A wide variety of problems affect the lower respiratory system. Lung diseases that are characterized primarily by an obstructive disorder, such as asthma, emphysema, chronic bronchitis, and cystic fibrosis, are discussed in Chapter 31. All other lower respiratory problems are discussed in this chapter.

Respiratory tract infections are a common cause of morbidity and mortality worldwide. Respiratory diseases account for some of the most common reasons for hospitalization in Canada (Canadian Institute for Health Information, 2015). During the 2014/2015 influenza ("flu") season, there were 43 510 cases of influenza leading to 7 719 hospitalizations and 591 deaths in Canada (Public Health Agency of Canada [PHAC], 2016). Tuberculosis (TB), although potentially curable and preventable, is a worldwide public health threat of epidemic proportion.

Acute Bronchitis

Acute bronchitis is an inflammation of the bronchi in the lower respiratory tract that is usually caused by infection. It is one of the most common conditions seen in primary care. It usually occurs as a sequel to an upper respiratory tract infection. A type of acute bronchitis is acute exacerbation of chronic bronchitis (AECB). AECB represents acute infection superimposed on chronic bronchitis. AECB is a potentially serious condition that may lead to respiratory failure. (Chronic bronchitis is discussed in Chapter 31.)

The cause of most cases of acute bronchitis is viral (rhinovirus, influenza). However, bacterial causes are also common both in smokers (e.g., *Streptococcus pneumoniae, Haemophilus influenzae*) and nonsmokers (e.g., *Mycoplasma pneumoniae, Chlamydia pneumoniae*).

In acute bronchitis, persistent cough following an acute upper airway infection (e.g., rhinitis, pharyngitis) is the most common symptom. Cough is often accompanied by production of clear, mucoid sputum, although some patients produce purulent sputum. Associated symptoms include fever, headache, malaise, and shortness of breath on exertion. Physical examination may reveal mildly elevated temperature, pulse, and respiratory rate with either normal breath sounds or expiratory wheezing. Chest radiographic studies can differentiate acute bronchitis from pneumonia because there is no radiographic evidence of consolidation or infiltrates with bronchitis.

Acute bronchitis is usually self-limiting, and the treatment is generally supportive, including fluids, rest, and anti-inflammatory agents. Cough suppressants or bronchodilators may be prescribed for symptomatic treatment of nocturnal cough or wheezing. Antibiotics are generally not prescribed unless the person has a prolonged infection associated with constitutional symptoms (which indicate systemic disease effects) including mild to moderate pain, the person is a smoker, or the person has chronic obstructive pulmonary disease (COPD).

The patient with AECB is usually treated empirically with broad-spectrum antibiotics. Often, the patient with COPD is taught to recognize symptoms of acute bronchitis and to begin a course of

antibiotics when symptoms occur. Many health care providers believe that a more severe infection often results if the patient delays taking antibiotics until after a clinical examination. Early initiation of antibiotic treatment in patients with COPD has resulted in a decrease in relapses and a decrease in hospital admissions.

Pneumonia

Pneumonia is an acute inflammation of the lung parenchyma caused by a microbial agent. The discovery of sulpha drugs and penicillin was pivotal in the treatment of pneumonia. Since that time, there has been remarkable progress in the development of antibiotics to treat pneumonia. However, despite the new antimicrobial agents, pneumonia is still common and is associated with significant morbidity and mortality rates.

Etiology

Normally, the airway distal to the larynx is sterile because of protective defence mechanisms. These mechanisms include the following: filtration of air, warming and humidification of inspired air, epiglottis closure over the trachea, cough reflex, mucociliary escalator mechanism, secretion of immunoglobulin A, and alveolar macrophages (see Chapter 28).

Factors Predisposing to Pneumonia.

Pneumonia is more likely to result when defence mechanisms become incompetent or are overwhelmed by the virulence or quantity of infectious agents. Decreased consciousness depresses the cough and epiglottal reflexes, which may allow aspiration of oropharyngeal contents into the lungs. Tracheal intubation interferes with the normal cough reflex and the mucociliary escalator mechanism. It also bypasses the upper airways, in which filtration and humidification of air normally take place. The mucociliary escalator mechanism is impaired by air pollution, cigarette smoking, viral upper respiratory infections (URIs), and normal changes of aging. In the presence of malnutrition, the functions of lymphocytes and polymorphonuclear leukocytes are altered. Certain diseases, such as leukemia, alcoholism, and diabetes mellitus, are associated with an increased frequency of Gram-negative bacilli in the oropharynx. (Gram-negative bacilli are not normal flora in the respiratory tract.) Altered oropharyngeal flora can also occur

secondary to antibiotic therapy given for an infection elsewhere in the body. The factors predisposing to pneumonia are listed in Table 30-1.

TABLE 30-1

FACTORS PREDISPOSING TO PNEUMONIA

- Aging
- Air pollution
- Altered consciousness: alcohol use disorder, head injury, seizures, anaesthesia, drug overdose, stroke
- Altered oropharyngeal flora
- Bed rest and prolonged immobility
- Chronic diseases: chronic lung disease, diabetes mellitus, heart disease, cancer, end-stage renal disease
- Debilitating illness
- Human immunodeficiency virus infection
- Immuno-suppressive drugs (corticosteroids, cancer chemotherapy, immuno-suppressive therapy after organ transplant)
- Inhalation or aspiration of noxious substances
- Intestinal and gastric feedings
- Malnutrition
- Smoking
- Tracheal intubation (endotracheal intubation, tracheostomy)
- Upper respiratory tract infection

Acquisition of Organisms.

Organisms that cause pneumonia reach the lung by three methods:

1. *Aspiration* from the nasopharynx or oropharynx. Many of the organisms that cause pneumonia are normal inhabitants of the pharynx in healthy adults.
2. *Inhalation* of microbes present in the air (e.g., *M. pneumoniae,* fungal pneumonias).
3. *Hematogenous spread* from a primary infection elsewhere in the body. An example is *Staphylococcus aureus.*

Types of Pneumonia

Pneumonia can be caused by bacteria, viruses, *Mycoplasma,* fungi, parasites, and chemicals. Although pneumonia can be classified according to the causative organism, a clinically effective way to classify pneumonia is as *community-acquired* or *hospital-acquired.* Classifying pneumonia is important because of differences in the

likely causative organisms and the selection of appropriate antibiotics.

Community-Acquired Pneumonia.

Community-acquired pneumonia (CAP) is defined as a lower respiratory tract infection of the lung parenchyma with onset in the community or during the first 2 days of hospitalization. The incidence of CAP is highest in the winter months. Smoking is an important risk factor. The causative organism in CAP is identified only 50% of the time. Organisms that are commonly implicated in CAP include *S. pneumoniae* and atypical organisms (e.g., *Legionella, Mycoplasma, Chlamydia,* viral). Modifying risk factors include the presence of COPD, recent use of antibiotics, and conditions incurring risk of aspiration.

In 2000, the Canadian Infectious Disease Society and the Canadian Thoracic Society conducted an evidence-informed update of the Canadian guidelines for initial management of CAP (Mandell, Marrie, Grossman, et al., 2000). Considering that there are over 100 microorganisms that cause pneumonia, Mandel, Marrie, Grossman, and colleagues stressed that, in addition to chest radiography and clinical evaluation, assessment and diagnosis be based on serology results as well as sputum culture, pleural fluid culture, or both, and blood cultures. Pharmacological intervention should include specific antimicrobial selection based on type of pneumonia, including where acquired, and modifying factors such as pathogens (Table 30-2).

TABLE 30-2

EMPIRICAL ANTIMICROBIAL SELECTION FOR ADULT PATIENTS WITH COMMUNITY-ACQUIRED PNEUMONIA

Type of Pneumonia	Modifying Factors and/or Pathogens	First Choice	Second Choice
Outpatient without modifying factors		Macrolide*	Doxycycline
Outpatient with modifying factors	COPD (no recent antibiotics or oral steroids within past 3 months)	Newer macrolides†	Doxycycline
	COPD (antibiotics or oral steroids within past 3 months)—*Haemophilus influenzae* and enteric Gram-negative rods	"Respiratory" fluoroquinolone‡	Amoxicillin–clavulanate + macrolide or second-generation cephalosporin + macrolide
	Suspected macroaspiration—oral anaerobes	Amoxicillin–clavulanate ± macrolide, or fourth-generation fluoroquinolone‡ (e.g., moxifloxacin)	Third-generation fluoroquinolones‡ (e.g., levofloxacin) + clindamycin or metronidazole
Nursing home resident in nursing home	*Streptococcus pneumoniae*, enteric Gram-negative rods, *H. influenzae*	"Respiratory" fluoroquinolone‡ alone or amoxicillin–clavulanate + macrolide	Second-generation cephalosporin + macrolide
Nursing home resident in hospital		Identical to treatment for other hospitalized patients (see below)	
Hospitalized patient on medical ward	*S. pneumoniae*, *Legionella pneumophila*, *Chlamydia pneumoniae*	"Respiratory" fluoroquinolone‡	Second-, third-, or fourth-generation cephalosporin + macrolide
Hospitalized patient in intensive care unit	*Pseudomonas aeruginosa* not suspected (*S. pneumoniae*, *L. pneumophila*, *C. pneumoniae*, enteric Gram-negative rods implicated)	IV "respiratory" fluoroquinolone + cefotaxime, ceftriaxone, or β-lactam–β-lactamase inhibitor	IV macrolide + cefotaxime, ceftriaxone, or β-lactam–β-lactamase inhibitor
	P. aeruginosa suspected	Antipseudomonal fluoroquinolone (e.g., ciprofloxacin) + antipseudomonal β-lactam (e.g., ceftazidime, carbapenem, piperacillin–tazobactam) or aminoglycoside (e.g., gentamicin, tobramycin, amikacin)	Triple therapy with antipseudomonal β-lactam + aminoglycoside + macrolide

*Macrolide—erythromycin, azithromycin, clarithromycin.

†Newer macrolide—azithromycin, clarithromycin.

‡Respiratory fluoroquinolone—levofloxacin (third generation), gatifloxacin, and moxifloxacin (fourth generation); trovafloxacin (fourth generation) is restricted because of potential severe hepatoxicity.

COPD, chronic obstructive pulmonary disease; *IV,* intravenous.

Source: Mandell, Lionel A., Marrie, Thomas J., "Canadian Guidelines for the Initial Management of Community-Acquired Pneumonia: An Evidence-Based Update by the Canadian Infectious Diseases Society and the Canadian Thoracic Society," *Clinical Infectious Diseases,* 2000, Volume 31, Issue 2, Pages 383–421, by permission of Oxford University Press.

Hospital-Acquired Pneumonia.

Hospital-acquired pneumonia (HAP) is pneumonia occurring 48 hours or longer after hospital admission and not incubating at the time of hospitalization. HAP accounts for 25% of all intensive care unit infections. It is the second most common hospital-associated infection in Canada and has high mortality and morbidity rates (Rotstein, Evans, Born, et al., 2008). The microorganisms responsible for HAP are different from those organisms implicated in CAP. Bacteria are responsible for the majority of HAP infections, including *Pseudomonas, Enterobacter, S. aureus,* methicillin-resistant *Staphylococcus aureus* (MRSA), and *S. pneumoniae.* Many of the organisms causing HAP enter the lungs after aspiration of particles from the patient's own pharynx. Immuno-suppressive therapy, general debility, and endotracheal intubation may be predisposing factors. Contaminated respiratory therapy equipment is another source of infection.

Fungal Pneumonia.

Fungi may also be a cause of pneumonia (see "Pulmonary Fungal Infections" later in this chapter).

Aspiration Pneumonia.

Aspiration pneumonia refers to the sequelae of abnormal entry of secretions or substances into the lower airway. It usually follows aspiration of material from the mouth or the stomach into the trachea and subsequently the lungs. The person who has aspiration

pneumonia usually has a history of loss of consciousness (e.g., as a result of seizure, anaesthesia, head injury, stroke, alcohol intake). With loss of consciousness, the gag and cough reflexes are depressed, and aspiration is more likely to occur. Another risk factor is tube feedings. The dependent portions of the lung are most often affected, primarily the superior segments of the lower lobes and the posterior segments of the upper lobes, which are dependent in the supine position.

The aspirated material—food, water, vomitus, or toxic fluids—is the pathological triggering mechanism for the development of this type of pneumonia. There are three distinct forms of aspiration pneumonia. If the aspirated material is an inert substance (e.g., barium), the initial manifestation is usually caused by mechanical obstruction of airways. When the aspirated materials contain toxic fluids, such as gastric juices, there is chemical injury to the lung with infection as a secondary event, usually 48 to 72 hours later; this is identified as *chemical (noninfectious) pneumonitis.* The most important form of aspiration pneumonia is bacterial infection. The infecting organism is usually one of the normal oropharyngeal flora, and multiple organisms, including both aerobes and anaerobes, are isolated from the sputum of the patient with aspiration pneumonia. Antibiotic therapy is based on an assessment of the severity of illness, where the infection was acquired (community or hospital), and the type of organisms present.

Opportunistic Pneumonia.

Patients with altered immune response are highly susceptible to respiratory infections. Specific individuals considered at risk include those who have severe protein–calorie malnutrition; those who have immune deficiencies; those who have received transplants and been treated with immuno-suppressive drugs; and patients who are being treated with radiation therapy, chemotherapeutic drugs, or corticosteroids (especially for a prolonged period). These individuals have a variety of altered conditions, including altered B- and T-lymphocyte function, depressed bone marrow function, and decreased levels or function of neutrophils and macrophages. In addition to the risk for bacterial and viral pneumonia, immuno-

compromised patients may develop an infection from microorganisms that do not normally cause disease, such as *Pneumocystis jiroveci* (formerly *P. carinii*) and cytomegalovirus (CMV).

P. jiroveci is an opportunistic pathogen whose natural habitat is the lung. This organism rarely causes pneumonia in healthy individuals. *P. jiroveci* pneumonia (PJP) affects 70% of human immunodeficiency virus (HIV)–infected individuals and is the most common opportunistic infection in patients with acquired immune deficiency syndrome (AIDS). In this type of pneumonia, the chest radiograph usually shows a diffuse bilateral alveolar pattern of infiltration. In widespread disease, the lungs are massively consolidated.

Clinical manifestations are insidious and include fever, tachypnea, tachycardia, dyspnea, nonproductive cough, and hypoxemia. Pulmonary physical findings are minimal in proportion to the serious nature of the disease. Treatment consists of antibiotics. In populations at risk for development of *P. jiroveci* pneumonitis (e.g., patients with hematological malignancies or AIDS), antibiotic prophylaxis may be advocated. (PJP is discussed in Chapter 17.)

Cytomegalovirus (CMV) is a cause of viral pneumonia in the immuno-compromised patient, particularly in transplant recipients. CMV, a type of herpesvirus, gives rise to latent infections and reactivation with shedding of infectious virus. This type of interstitial pneumonia can be a mild disease, or it can be fulminant and produce pulmonary insufficiency and death. Often, CMV coexists with other opportunistic bacterial or fungal agents in causing pneumonia. Ganciclovir (Cytovene) is recommended for treatment of CMV pneumonia.

Pathophysiology

Pneumococcal pneumonia is the most common cause of bacterial pneumonia. However, regardless of causative factors, pneumonia is characterized by four stages of the disease process:

1. *Congestion.* After the pneumococcus organisms reach the alveoli via droplets or saliva, there is an outpouring of fluid into the alveoli. The organisms multiply in the serous fluid, and the infection is spread. The pneumococci damage the host

by their overwhelming growth and interference with lung function.

2. *Red hepatization.* There is massive dilation of the capillaries, and alveoli are filled with organisms, neutrophils, red blood cells, and fibrin (Figure 30-1). The lung appears red and granular, similar to the liver, which is why the process is called *hepatization.*

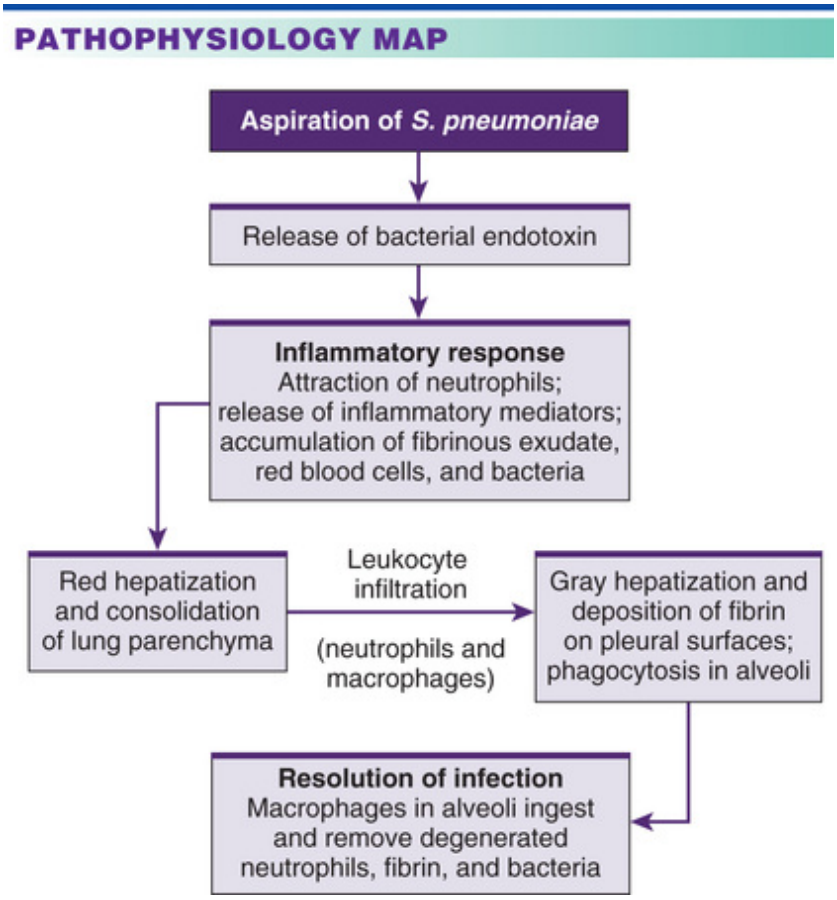

FIGURE 30-1 Pathophysiological course of pneumococcal pneumonia.

3. *Grey hepatization.* Blood flow decreases, and leukocytes and fibrin consolidate in the affected part of the lung.
4. *Resolution.* Complete resolution and healing occur if there are no complications.

The exudate becomes lysed and is processed by the macrophages. The normal lung tissue is restored, and the person's gas-exchange ability returns to normal.

Clinical Manifestations

Patients with pneumonia usually have a constellation of symptoms including sudden onset of fever, chills, a cough producing purulent sputum, and pleuritic chest pain (in some cases). In the older adult or debilitated patient, confusion or stupor (possibly related to hypoxia) may be the predominant finding. On physical examination, signs of pulmonary consolidation, such as dullness to percussion, increased fremitus, bronchial breath sounds, and crackles, may be found. The typical pneumonia syndrome is usually caused by the most common pathogen in CAP, which is *S. pneumoniae,* but can also be caused by other bacterial pathogens, such as *H. influenzae.*

Pneumonia may also manifest atypically with a more gradual onset, a dry cough, and extrapulmonary manifestations such as headache, myalgias, fatigue, sore throat, nausea, vomiting, and diarrhea. On physical examination, crackles are often heard. This presentation of symptoms is classically produced by *M. pneumoniae* but can also be caused by *Legionella* and *C. pneumoniae.* Patients with hematogenous *S. aureus* pneumonia may have only dyspnea and fever. This necrotizing infection causes destruction of lung tissue, and these patients are usually very sick.

Manifestations of viral pneumonia are highly variable but may be characterized by chills, fever, dry, nonproductive cough, and extrapulmonary symptoms. Viral pneumonia may be found in association with systemic viral diseases such as measles, varicella-zoster, herpes simplex, or influenza virus infection.

Complications

Most cases of pneumonia run an uncomplicated course. Complications generally develop more frequently in individuals with underlying chronic diseases and may include the following:

1. *Pleurisy* (inflammation of the pleura) is a relatively common accompanying problem of pneumonia.
2. *Pleural effusion* can occur. Usually, the effusion is sterile and is reabsorbed in 1 to 2 weeks. Occasionally, it necessitates aspiration by means of thoracentesis.
3. *Atelectasis* (collapsed, airless alveoli) of one or part of one lobe may occur. These areas usually clear with effective coughing and deep breathing.
4. *Delayed resolution* results from persistent infection and is seen on radiograph as residual consolidation. Usually, the physical findings return to normal within 2 to 4 weeks. Delayed resolution occurs most frequently in patients who are older or malnourished or have alcohol use disorder or COPD.
5. *Lung abscess* is not a common complication of pneumonia. It may be seen with pneumonia caused by *S. aureus* and Gram-negative pneumonias (see Lung Abscess later in this chapter).
6. *Empyema* (accumulation of purulent exudate in the pleural cavity) is relatively infrequent but necessitates antibiotic therapy and drainage of the exudate by a chest tube or by open surgery.
7. *Pericarditis* results from spread of the infecting organism from an infected pleura or via a hematogenous route to the pericardium (the fibroserous sac around the heart).
8. Bacteremia can occur with pneumococcal pneumonia, more so in older-adult patients.
9. *Meningitis* can be caused by *S. pneumoniae.* The patient with pneumonia who is disoriented, confused, or somnolent should have a lumbar puncture to evaluate the possibility of meningitis.
10. *Endocarditis* can develop when the organisms attack the endocardium and the valves of the heart. The clinical manifestations are similar to those of acute infective endocarditis (see Chapter 39).

Diagnostic Studies.

The common diagnostic measures for pneumonia are presented in Table 30-3. History, physical examination, and chest radiographic

study often provide enough information to make management decisions without costly laboratory tests.

TABLE 30-3
COLLABORATIVE CARE
Pneumonia

Diagnostic	Collaborative Therapy
• History and physical examination • Chest radiograph • Gram stain examination of sputum • Sputum culture and sensitivity test (if drug-resistant pathogen or organism not covered by empirical therapy) • Pulse oximetry or ABGs (if indicated) • Complete blood cell count, differential, and routine blood chemistries (if indicated) • Blood cultures (if indicated)	• Appropriate antibiotic therapy • Increased fluid intake (at least 3 L/day) • Limited activity and rest • Antipyretics • Analgesics • Oxygen therapy (if indicated)

ABGs, arterial blood gases.

The chest radiograph often shows a typical pattern characteristic of the infecting organism and is an invaluable adjunct in the diagnosis of pneumonia. Lobar or segmental consolidation suggests a bacterial cause, usually *S. pneumoniae* or *Klebsiella.* Diffuse pulmonary infiltrates are most commonly caused by infection with viruses, *Legionella,* or pathogenic fungi. Cavitary shadows suggest the presence of a necrotizing infection with destruction of lung tissue commonly caused by *S. aureus,* Gram-negative bacteria, or *Mycobacterium tuberculosis.* Pleural effusions, which can occur in up to 30% of patients with CAP, can also be seen on radiographic study.

Sputum cultures are recommended in the case of the suspected presence of a drug-resistant pathogen or an organism that is not covered by the usual **empirical therapy** (therapy based on observation and experience, implemented when the condition's exact cause is not known). A Gram stain examination of the sputum provides information on the predominant causative organism. A sputum culture should be collected before initiating antibiotic therapy as a means to intervene with patients with community- or hospital-acquired pneumonia (Health Quality Ontario and Ministry of Health and Long-Term Care, 2013; Mandell, Marrie, Grossman, et al., 2000). Because of the poor sensitivity and specificity of sputum cultures, any sputum culture results should be correlated with the

predominant organisms found on Gram stain examination results. Before treatment, two blood cultures may be done for patients who are seriously ill. Although microbial studies are expected before treatment, initiation of antibiotics should not be delayed.

Arterial blood gases (ABGs), if obtained, usually reveal hypoxemia. Leukocytosis is found in the majority of patients with bacterial pneumonia, usually with a white blood cell (WBC) count greater than 15×10^9/L with the presence of bands (immature neutrophils).

Collaborative Care

Prompt treatment with the appropriate antibiotic almost always cures bacterial and mycoplasma pneumonia. In uncomplicated cases, the patient responds to drug therapy within 48 to 72 hours. Indications of improvement include decreased temperature, improved breathing, and reduced chest pain. Abnormal physical findings can last for more than 7 days.

In addition to antibiotic therapy, supportive measures may be used, including oxygen therapy to treat hypoxemia, analgesics to relieve the chest pain for patient comfort, and antipyretics such as acetylsalicylic acid (ASA; Aspirin) or acetaminophen (Tylenol) for significantly elevated temperature. During the acute febrile phase, the patient's activity should be restricted, and rest should be encouraged and planned. The Health Quality Ontario and Ministry of Health and Long-Term Care CAP guidelines (2013) recommend airway clearance, supportive therapy, antiviral therapy during flu season, smoking cessation, and vaccinations for CAP in addition to antibiotic therapy.

Most individuals with mild to moderate illness who have no other underlying disease process can be treated on an outpatient basis. If there is a serious underlying disease or if the pneumonia is accompanied by severe dyspnea, hypoxemia, or other complications, the patient should be hospitalized.

Currently, there is no definitive treatment for viral pneumonia. An antiviral drug, amantadine, is approved for oral use in the treatment of influenza A virus. The neuraminidase inhibitors zanamivir (Relenza) and oseltamivir (Tamiflu) are active against both influenza A and B (see Chapter 29). An influenza vaccine is available. It is modified annually to reflect the anticipated strains in the upcoming

season. The flu vaccine is considered a mainstay of prevention and is recommended annually for individuals considered to be at risk for influenza, including older adults, long-term care residents, patients with COPD or diabetes mellitus, and health care workers. For older adults with signs and symptoms of influenza, including those who have received the influenza vaccine, treatment with amantadine or a neuraminidase inhibitor is recommended. During epidemics of influenza A, especially in long-term care facilities, chemoprophylaxis with these agents is recommended for unvaccinated patients, immunodeficient patients, or those who have received the vaccine within the past 2 weeks.

Pneumococcal Vaccine.

Pneumococcal vaccine is indicated primarily for the individual considered at risk who (1) has a chronic illness such as lung or heart disease or diabetes mellitus, (2) is recovering from a severe illness, (3) is 65 years of age or older, or (4) resides in a long-term care facility. Vaccination is particularly important because the rate of drug-resistant *S. pneumoniae* infections is increasing. Pneumococcal vaccine can be given simultaneously with other vaccines such as the flu vaccine, but each should be administered in a separate site (PHAC, 2015).

The current recommendation is that pneumococcal vaccine is good for a person's lifetime (PHAC, 2015). However, in the immuno-suppressed individual at risk for development of fatal pneumococcal infection (e.g., asplenic patient; patient with nephrotic syndrome, renal failure, or AIDS; or transplant recipient), revaccination is recommended every 5 years.

Drug Therapy.

The main problems with the use of antibiotics to treat pneumonia are the development of resistant strains of organisms and the patient's hypersensitivity or allergic reaction to certain antibiotics.

Most cases of CAP in otherwise healthy adults do not necessitate hospitalization. The Canadian Infectious Diseases Society and

Canadian Thoracic Society have guidelines aimed at classifying patients to determine therapy options (see Table 30-2).

The oral antibiotic therapy administered is frequently empirical treatment with broad-spectrum antibiotics. Once the patient is assigned a treatment classification, therapy can be based on the likely infecting organism.

For HAP, empirical antibiotic therapy should be based on the likely pathogens in the various patient groups. Even with extensive diagnostic testing, an etiological organism is often not identified. It is important to recognize when a patient is not responding to treatment. Therapy may require modification based on the patient's culture results or clinical response. Clinical response is evaluated by factors such as a change in fever, sputum purulence, leukocytosis, oxygenation, or radiographic study patterns. Improvement is often not apparent for the first 48 to 72 hours, and therapy need not be altered during this period unless deterioration is noted or culture results dictate that a different antibiotic should be used. Common antibiotics for HAP include cephalosporins (third-generation antipseudomonal [ceftazidime]), β-lactam or β-lactamase inhibitor, vancomycin (for MRSA), aminoglycosides (gentamicin), and antipseudomonal quinolones (ciprofloxacin) (Rotstein, Evans, Born, et al., 2008).

Patients with ventilator-associated pneumonia may experience rapid deterioration. Patients who deteriorate or fail to respond to therapy will require aggressive evaluation to assess noninfectious etiologies, complications, other coexisting infectious processes, or pneumonia caused by a resistant pathogen (Rotstein, Evans, Born, et al., 2008). It may be necessary to broaden antimicrobial coverage while awaiting results of cultures and other studies, such as computed tomographic (CT) scan, ultrasound, or lung scans.

Nutritional Therapy.

Fluid intake of at least 3 L/day is important in the supportive treatment of pneumonia. If the patient has heart failure, fluid intake must be individualized. If oral intake cannot be maintained, intravenous (IV) administration of fluids and electrolytes may be necessary for the acutely ill patient. An intake of at least 1 500 calories

per day should be maintained to provide energy for the increased metabolic processes in the patient. Small, frequent meals are better tolerated by the patient with dyspnea.

Nursing Management Pneumonia

Nursing Assessment

Subjective and objective data that should be obtained from a patient with pneumonia are presented in Table 30-4.

TABLE 30-4

NURSING ASSESSMENT
Pneumonia

Subjective Data
Important Health Information
Past health history: Lung cancer, COPD, diabetes mellitus; cigarette smoking; alcohol use disorder; recent upper respiratory tract infection; chronic debilitating disease; malnutrition; altered consciousness; AIDS; exposure to chemical toxins, dust, or allergens; immobility or prolonged bed rest *Medications:* Use of antibiotics, corticosteroids, chemotherapy, or any other immuno-suppressants *Surgery or other treatments:* Recent abdominal or thoracic surgery, splenectomy, endotracheal intubation, general anaesthesia; tube feedings
Symptoms
• Fatigue, weakness, malaise • Anorexia, nausea, vomiting • Fever, chills • Dyspnea, cough (productive or nonproductive), nasal congestion, pain with breathing • Chest pain, sore throat, headache, abdominal pain, muscle aches
Objective Data
General
Fever, restlessness, or lethargy; splinting of affected area
Respiratory
Tachypnea; dyspnea, nasal congestion, pharyngitis; asymmetrical chest movements or retraction; decreased excursion; nasal flaring; use of accessory muscles (neck, abdomen); grunting; crackles, friction rub on auscultation; dullness on percussion over consolidated areas, increased tactile fremitus on palpation; pink, rusty, purulent, green, yellow, or white sputum (amount may be scant to copious)
Cardiovascular
Tachycardia
Neurological
Changes in mental status, ranging from confusion to delirium
Possible Findings
Leukocytosis; abnormal ABGs with ↓ or normal PaO_2, ↓ $PaCO_2$, and ↑ pH initially, and later ↓ PaO_2, ↑ $PaCO_2$, and ↓ pH; positive sputum Gram stain examination and culture; patchy or diffuse infiltrates, abscesses, pleural effusion, or pneumothorax on chest radiographic study

ABGs, arterial blood gases; *AIDS,* acquired immune deficiency syndrome; *COPD,* chronic obstructive pulmonary disease; *PaO_2,* partial pressure of oxygen in arterial blood; *$PaCO_2$,* partial pressure of carbon dioxide in arterial blood.

Nursing Diagnoses

Nursing diagnoses for the patient with pneumonia may include but are not limited to the following:

- *Impaired gas exchange* (related to fluid and exudate accumulation with the alveoli and surrounding lung tissue)
- *Ineffective breathing pattern* related to *pain*
- *Acute pain* related to *biological injury agent* (infection)
- *Activity intolerance* related to *respiratory condition, physical deconditioning*

Additional information on nursing diagnoses for the patient with pneumonia is presented in Nursing Care Plan (NCP) 30-1, available on the Evolve website.

Planning

The overall goals are that the patient with pneumonia will have (a) clear breath sounds, (b) normal breathing patterns, (c) no signs of hypoxia, (d) a normal chest radiograph, and (e) no complications related to pneumonia.

Nursing Implementation

Health Promotion.

Many nursing interventions are available to help prevent the occurrence of pneumonia as well as the morbidity associated with it. Teaching a patient to practise good health habits, such as proper diet and hygiene, adequate rest, and regular exercise, can help the patient maintain the natural resistance to infecting organisms. If possible, exposure to people with URIs should be avoided. If a URI occurs, it should be treated promptly with supportive measures (e.g., rest,

fluids). If symptoms persist for more than 7 days, the person should obtain medical care. Individuals at risk for pneumonia (e.g., people who are chronically ill, older adults) should be encouraged to obtain both influenza and pneumococcal vaccines.

In the hospital, the nursing role involves identifying the patient at risk (see Table 30-1) and taking measures to prevent the development of pneumonia. The patient with altered consciousness should be placed in positions (e.g., side-lying, upright) that will prevent or minimize the risk for aspiration. The patient should be turned and repositioned at least every 2 hours to facilitate adequate lung expansion and to discourage pooling of secretions.

The patient who has a feeding tube generally requires that measures be taken to prevent aspiration (see Chapter 42). Although feeding tubes are small, an interruption in the integrity of the lower esophageal sphincter still exists and can allow reflux of gastric and intestinal contents. The patient who has difficulty swallowing (e.g., a patient who has had a stroke) needs assistance in eating, drinking, and taking medication to prevent aspiration. The patient who has recently had surgery and others who are immobile need assistance with turning and measures to facilitate deep breathing at frequent intervals (see Chapter 22). The nurse must be careful to avoid overmedication with opioids or sedatives, which can cause a depressed cough reflex and accumulation of fluid in the lungs. Presence of the gag reflex should be ascertained before the administration of fluids or food to the individual who has had local anaesthesia to the throat.

To reduce the incidence of hospital-associated infections, the nurse should practise strict medical asepsis and adherence to infection-control guidelines. Poor handwashing practices allow spread of pathogens via the hands of the health care worker. Staff members should wash their hands or, if hands are not visibly soiled, use hand rubs with 60% alcohol (Infection Prevention and Control Canada, n.d.) before providing care to a patient. Respiratory devices can harbour microorganisms and have been associated with outbreaks of pneumonia. Strict sterile aseptic technique should be used when suctioning the trachea of a patient.

Acute Intervention.

Although many patients with pneumonia are treated on an outpatient basis, the NCP for a patient with pneumonia (see NCP 30-1, available on the Evolve website) is applicable to outpatients and inpatients. It is important for the nurse to remember that pneumonia is an acute, infectious disease. Although most cases of pneumonia are potentially completely curable, complications can result. The nurse must be aware of these complications and their manifestations. The infection-control nurse can be a valuable resource in assisting with the care of patients with pneumonia.

Therapeutic positioning for patients with pneumonia ensures stable oxygenation status. The "good lung down" position is used for patients with unilateral lung disease, in whom better oxygenation is achieved when the unaffected lung (good lung) is placed in the down (lateral) position to achieve maximum lung expansion. Incentive spirometry, turning, coughing, and deep breathing all increase lung volume, mobilize secretions, and prevent atelectasis. Exercise and early ambulation augment bronchial hygiene and are encouraged as tolerated.

Ambulatory and Home Care.

The patient needs to be reassured that complete recovery from pneumonia is possible. It is extremely important to emphasize the need to take all of any drugs prescribed and to return for follow-up medical care and evaluation. The patient needs to be taught about the drug–drug and the food–drug interactions for the prescribed antibiotic. Adequate rest is needed to maintain progress toward recovery and to prevent a relapse. The patient should be told that it may take weeks to feel the usual vigour and sense of well-being. A prolonged period of convalescence may be necessary for the older-adult or chronically ill patient.

The patient considered to be at risk for pneumonia should be told about available vaccines and should discuss them with the health care provider. Deep-breathing exercises should be practised for 6 to 8 weeks after the patient is discharged from the hospital.

Evaluation.

The expected outcomes for the patient with pneumonia are presented in NCP 30-1, available on the Evolve website.

Tuberculosis

Tuberculosis (TB) is an infectious disease caused by *M. tuberculosis*. It usually involves the lungs, but it also occurs in the larynx, the kidneys, the bones, the adrenal glands, the lymph nodes, and the meninges and can be disseminated throughout the body. TB is a reportable communicable disease; it kills more people worldwide than any other infectious disease, with an estimated 8.8 million of the world's population having been infected. In Canada, the number of reported cases of active TB has remained relatively stable, averaging 1 623 cases per year and showing some indication of decline. In 2010, the Public Health Agency of Canada (PHAC) determined that since 1970, Canadian-born people diagnosed with TB significantly declined from 67.8% to 11.8%. However, during the same period, immigrants with TB increased from 17.7% to 67.0%, and reported cases of TB in Canadian-born Indigenous peoples increased from 14.7% to 21.1% (PHAC & Canadian Lung Association, 2014). The pulmonary system continues to be the main diagnostic site of disease, representing 68% of all reported TB cases (PHAC, 2014).

The populations most at risk in Canada are the Indigenous and immigrant populations. TB among Canadian-born Indigenous peoples is 31 times higher than the national average (Assembly of First Nations, 2011). Factors or challenges the Canadian-born Indigenous peoples face that influence the transmission of TB are poor nutrition, overcrowding, poorly ventilated homes, comorbidities (diabetes, HIV) as well as limited or remote access to health care facilities (PHAC, 2014). Immigrant populations are challenged with poverty and stress related to living in a new country and are more susceptible to latent TB infection with subsequent progression to active TB (PHAC, 2014).

Determinants of Health

Tuberculosis

Income and Social Status

- Low socioeconomic groups have higher rates of TB.*

Physical Environments

- Residing in overcrowded institutions (e.g., long-term care facilities, correctional facilities), and urban homelessness increase the risk for acquiring TB.*

Personal Health Practices and Coping Skills

- Smoking and air pollution increase the risk for TB.

Culture

- TB is most prevalent in immigrants and Indigenous peoples.†

Gender

- TB is more prevalent in males than in females.‡

TB, tuberculosis.

Etiology and Pathophysiology

M. tuberculosis, a Gram-positive, acid-fast bacillus, is usually spread from person to person via airborne droplets, which are produced when the infected individual with pulmonary or laryngeal TB coughs, sneezes, speaks, or sings. Once released into a room, the organisms are dispersed and can be inhaled. TB is not highly infectious, and transmission usually requires close, frequent, or prolonged exposure. Brief exposure to a few tubercle bacilli rarely causes an infection. The disease cannot be spread by hands, books, glasses, dishes, or other fomites.

The very small droplets, 1 to 5 mcm in size, contain *M. tuberculosis.* Because they are so small, the particles remain airborne indoors for minutes to hours. Once inhaled, these small particles lodge in the bronchiole and alveolus. Factors that influence the likelihood of transmission include the (a) number of organisms expelled into the air, (b) concentration of organisms (small spaces with limited ventilation would mean higher concentration), (c) length of time of exposure, and (d) immune system of the exposed person. *M. tuberculosis* replicates slowly and spreads via the lymphatic system. The organisms find favourable environments for growth primarily in the upper lobes of the lungs, kidneys, epiphyses of the bone, cerebral cortex, and adrenal glands.

Healing of the primary lesion usually takes place by resolution, fibrosis, and calcification. The granulation tissue surrounding the lesion may become more fibrous and form a collagenous scar around the tubercle. A *Ghon complex* is formed, consisting of the Ghon tubercle and regional lymph nodes. Calcified Ghon complexes may be seen on chest radiographic studies.

When a TB lesion regresses and heals, the infection enters a latent period in which it may persist without producing clinical symptoms of illness. The infection may develop into clinical disease if the persisting organisms begin to multiply rapidly, or it may remain dormant.

People who are infected with *M. tuberculosis* but do not have TB disease cannot spread the infection to other people. TB infection occurs when the bacteria are inhaled but there is an ineffective immune response and the bacteria become inactive. The majority of people mount effective immune responses to encapsulate these organisms for the rest of their lives, preventing primary infection from progressing to disease. TB infection in a person who does not have the active TB disease is not considered a case of TB and is often referred to as *latent tuberculosis infection* (LTBI). If the initial immune response is not adequate, control of the organisms is not maintained, and clinical disease results. Dormant but viable organisms persist for years. Reactivation of TB can occur if the host's defence mechanisms become impaired. The reasons for reactivation are not well understood, but they are related to decreased resistance found in older adults, individuals with concomitant diseases, and those who receive immuno-suppressive therapy.

Clinical Manifestations

In the early stages of TB, the person is usually free of symptoms. Many cases are found incidentally when routine chest radiographic studies are done, especially in older adults.

Systemic manifestations may initially consist of fatigue, malaise, anorexia, weight loss, low-grade fevers, and night sweats. The weight loss may not be excessive until late in the disease and is often attributed to overwork or other factors.

A characteristic pulmonary manifestation is a cough that becomes frequent and produces mucoid or mucopurulent sputum. Dyspnea is unusual. Chest pain characterized as dull or tight may be present. Hemoptysis is not a common finding and is usually associated with more advanced cases. Sometimes TB has more acute, sudden manifestations: the patient has high fever, chills, generalized flulike symptoms, pleuritic pain, and a productive cough.

The HIV-infected patient with TB often has atypical physical examination and chest radiographic examination findings. Classical signs such as fever, cough, and weight loss may be attributed to PCP or other HIV-associated opportunistic diseases. Clinical manifestations of respiratory problems in patients with HIV must be carefully investigated to determine the cause.

Complications

Miliary Tuberculosis.

If a necrotic Ghon complex erodes through a blood vessel, large numbers of organisms invade the bloodstream and spread to all body organs. This is called *miliary* or *hematogenous* TB. The patient may be either acutely ill with fever, dyspnea, and cyanosis or chronically ill with systemic manifestations of weight loss, fever, and gastro-intestinal (GI) disturbance. Hepatomegaly, splenomegaly, and generalized lymphadenopathy may be present.

Pleural Effusion and Empyema.

A pleural effusion is caused by the release of caseous material into the pleural space. The bacteria-containing material triggers an inflammatory reaction and a pleural exudate of protein-rich fluid. A form of pleurisy called *dry pleurisy* may result from a superficial tubercular lesion involving the pleura. It appears as localized pleuritic pain on deep inspiration. Empyema is less common than effusion but may occur from large numbers of organisms spilling into the pleural space, usually from rupture of a cavity.

Tuberculosis Pneumonia.

Acute pneumonia may result when large amounts of tubercle bacilli are discharged from the liquefied necrotic lesion into the lung or lymph nodes. The clinical manifestations are similar to those of bacterial pneumonia, including chills, fever, productive cough, pleuritic pain, and leukocytosis.

Other Organ Involvement.

Although the lungs are the primary site of TB, other body organs may also be involved. The meninges may become infected. Bone and joint tissue may be involved in the infectious disease process. The kidneys, the adrenal glands, the lymph nodes, and the genital tract (in both females and males) may also be infected.

Diagnostic Studies

Tuberculin Skin Testing.

The body's immune response can be demonstrated by hypersensitivity to a tuberculin skin test. A positive reaction occurs 2 to 12 weeks after the initial infection, corresponding to the time needed to mount an immune response.

Purified protein derivative (PPD) of tuberculin is used primarily to detect the delayed hypersensitivity response. (The procedure for performing the tuberculin skin test is described in Chapter 28.) Once acquired, sensitivity to tuberculin tends to persist throughout life. A positive reaction indicates the presence of a TB infection, but it does not show whether the infection is latent or active, that is, causing a clinical illness. Because the response to TB skin testing may be decreased in the immuno-compromised patient, induration reactions equal to or greater than 5 mm are considered positive. Sometimes, a repeat PPD can cause an accelerated response (the "booster" effect). Thus, two-step testing is recommended for initial screening of health care workers who will be getting regularly retested in the future and for those who have a decreased response to allergens. This procedure helps identify individuals with past disease and prevent a later positive PPD test from being misinterpreted as a new, infection-related PPD conversion. See Chapter 28, Tables 28-12 and 28-13, for guidelines in interpreting TB skin tests. Recent guidelines for targeted

tuberculin testing emphasize targeting only high-risk groups and discourage testing low-risk individuals (PHAC & Canadian Lung Association, 2014).

Chest Radiographic Study.

Although the findings on chest radiographic examination are important, it is not possible to make a diagnosis of TB solely on the basis of this examination. This is because other diseases can mimic the radiographic appearance of TB. The abnormality most commonly found in TB is multinodular lymph node involvement with cavitation in the upper lobes of the lungs. Calcification of the lung lesions generally occurs within several years of the infection.

Bacteriological Studies.

The demonstration of tubercle bacilli bacteriologically is essential for establishing a diagnosis. Microscopic examination of stained sputum smears for acid-fast bacilli (AFB) is usually the first bacteriological evidence of the presence of tubercle bacilli. Three consecutive sputum specimens are collected on different days and sent for smear and culture. In addition to sputum, material for examination can be obtained from gastric washings, cerebro-spinal fluid (CSF), or pus from an abscess.

The most accurate means of diagnosis is the culture technique. The major disadvantage of this method is that it may take 6 to 8 weeks for the mycobacteria to grow. The advantage is that it can detect small quantities (as few as 10 bacteria/mL of specimen).

Nucleic acid amplification (NAA) is a rapid diagnostic test for TB. Test results are available in a few hours. They are more sensitive than AFB smears but less sensitive than TB cultures. NAA does not replace routine sputum smears and cultures, but it offers a health care provider increased confidence in the diagnosis (PHAC & Canadian Lung Association, 2014).

Since 2007, Canada has been testing using QuantiFERON-TB Gold In-Tube. The patient's blood is mixed with mycobacterial antigens and is then measured using an enzyme-linked immunosorbent assay (ELISA). If the patient is infected with TB organisms, the lymphocytes in the blood will recognize the antigens. Guidelines for when to use

this rapid diagnostic tool are outlined in the Canadian Tuberculosis Standards (PHAC & Canadian Lung Association, 2014).

Collaborative Care

Hospitalization for initial treatment of TB is not necessary in most patients. Most patients are treated on an outpatient basis (Table 30-5), and many can continue to work and maintain their lifestyles with few changes. Hospitalization may be used for diagnostic evaluation, for the severely ill or debilitated, and for those who experience adverse drug reactions or treatment failures.

TABLE 30-5
COLLABORATIVE CARE
Tuberculosis

Diagnostic	Collaborative Therapy

• History and physical examination
• Tuberculin skin test

• Bacteriological studies
  • Sputum smear
  • Sputum culture
	• Long-term treatment with antimicrobial drugs (see Tables 30-6 and 30-7)
	• Follow-up bacteriological studies and chest radiographic examinations

The mainstay of TB treatment is drug therapy. Drug therapy is used to treat an individual with clinical disease and to prevent disease in an infected person.

Drug Therapy

Active Disease.

Standard therapy for active TB has been revised because of the global increase in prevalence of multidrug-resistant TB (MDR TB) (World Health Organization [WHO], 2014). MDR TB occurs when resistance develops to two or more anti-TB drugs. In Canada, MDR TB risk factors include previous TB treatment, birth outside of Canada, and exposure to an individual or individuals diagnosed with infectious drug-resistant TB. The PHAC and Canadian Lung Association (2014) guidelines recommend prevention over management of MDR TB in

order to prevent resistance. It is important to ensure proper drug and dosage regimens and management as well as not to prescribe a new single drug when a regimen is failing. It is also important that prescribed regimens are adhered to through direct observed therapy (DOT) and that nonadherent individuals are identified. As such, treatment is individualized, and an initial phase of treatment for a minimum of 8 months is recommended (PHAC & Canadian Lung Association, 2014).

The patient with active TB should be managed aggressively; treatment usually consists of a combination of at least four drugs. The reason for combination therapy is to increase the therapeutic effectiveness and decrease the development of resistant strains of *M. tuberculosis*. It has been shown that single-drug therapy can result in rapid development of resistant strains.

Drugs are divided into first-line and second-line drugs. The four first-line drugs used in Canada are isoniazid (INH), rifampin (RMP), pyrazinamide (PZA), and ethambutol (EMB) (Table 30-6). The most commonly used second-line drugs include fluoroquinolones (e.g., moxifloxacin, levofloxacin) and injectables (e.g., streptomycin, amikacin). Second-line drugs are used in special situations such as drug-resistant tuberculosis (PHAC & Canadian Lung Association, 2014).

TABLE 30-6

DRUG THERAPY
First-Line Drug Therapy for Tuberculosis

Drug	Mechanisms of Action	Adverse Effects	Comments
First-Line Drugs			
Isoniazid (INH)	Bacteriocidal; interferes with DNA metabolism of tubercle bacillus	Peripheral neuritis, hepatotoxicity, hypersensitivity (skin rash, arthralgia, fever), optic neuritis	Metabolism primarily by liver and excretion by kidneys; pyridoxine (vitamin B_6) administration during high-dose therapy as prophylactic measure; use as single prophylactic agent for active TB in individuals whose PPD converts to positive; ability to cross blood–brain barrier; safe in pregnancy*
Rifampin (RMP)	Bacteriocidal; has broad-spectrum effects, inhibits RNA polymerase of tubercle bacillus	Drug interactions, rash, hepatitis, febrile reaction, GI disturbance, peripheral neuropathy, hypersensitivity	Most commonly used with INH; low incidence of adverse effects; suppression of effect of birth control pills; possibility of orange urine and bodily fluids; safe in pregnancy
Pyrazinamide (PZA)	Bacteriocidal; exact mechanism unknown	Hepatitis, arthralgia, fever, skin rash, hyperuricemia, GI symptoms, jaundice (rare)	High rate of effectiveness when used with streptomycin or capreomycin
Ethambutol (EMB)	Bacteriostatic; inhibits RNA synthesis	Skin rash, GI disturbance, malaise, peripheral neuritis, optic neuritis	Adverse effects uncommon and reversible with discontinuation of drug; most commonly used as substitute drug when adverse effects occur with INH or RMP; safe in pregnancy*

*Pyridoxine (vitamin B_6) supplements should be prescribed for patients who may be or are pregnant or who are breastfeeding or are diagnosed with renal failure, diabetes, seizures, malnutrition, or substance use disorder, as these patients are at risk for symptoms of pyridoxine deficiency. Canadian tuberculosis standards suggest pyridoxine dose of 25 mg.

DNA, deoxyribonucleic acid; *GI,* gastro-intestinal; *PPD,* purified protein derivative; *RNA,* ribonucleic acid.

Various drug and dosing regimens are available (Table 30-7). Fixed-dose combination anti-TB drugs may enhance adherence to treatment

recommendations. Patients on antiretroviral drugs for HIV cannot take RMP because it can impair the effectiveness of the antiretroviral drugs. Other drugs are primarily used for treatment of resistant strains or in the case of the patient's developing adverse effects to the primary drugs. Many second-line drugs carry a greater risk for adverse effects and necessitate closer monitoring.

TABLE 30-7

DRUG THERAPY
Drug Regimen Options for Treatment of Tuberculosis

Standard	Initial Phase (First 2 Months)	Continuation Phase
Regimen 1	INH + RMP + PZA +/− EMB* daily or 5 days/week	INH + RMP for 4 months daily or 3 times/week
Regimen 2	INH + RMP +/− EMB daily or 5 days/week	INH + RMP for 7 months daily or 3 times/week

*EMB can be stopped as soon as drug susceptibility testing results are available and the strain is pan-sensitive. PZA is continued for the full 2 months.

EMB, ethambutol; *INH,* isoniazid; *PZA,* pyrazinamide; *RMP,* rifampin.

In follow-up care for patients on long-term therapy, it is important to monitor the effectiveness of drugs and the development of adverse effects. Usually, sputum specimens are initially obtained weekly and then monthly to assess the effectiveness of the medication. The regimen is considered to be effective if the patient converts to a negative TB sputum status.

Although TB tends to have a rapidly progressive course in the patient co-infected with HIV, it responds well to standard medication. The co-infected patient should receive treatment for TB for at least 6 months beyond the conversion of sputum cultures to negative status.

An important reason for follow-up care in the patient with TB is to ensure adherence to the treatment regimen. Nonadherence is a major factor in the emergence of multidrug resistance and treatment

failures. Many individuals do not adhere to the treatment program in spite of understanding the disease process and the value of treatment. DOT is recommended for patients known to be at risk for nonadherence with therapy. DOT is an expensive but essential public health issue. DOT involves observing the ingestion of every dose of medication for the TB patient's entire course of treatment. Completing therapy is important because of the danger of reactivation of TB and the development of MDR TB seen in patients who do not complete the full course of therapy. In many regions, the public health nurse administers DOT at a clinic site. The patient needs to have follow-up visits for 12 months after completion of therapy to check for the presence of resistant strains. DOT protocols and options in remote or rural areas and in Indigenous communities remain problematic.

Teaching patients about the adverse effects of these drugs and when to seek medical attention is critical. The major adverse effect of INH, RMP, and PZA is hepatitis. Liver function tests should be monitored. Baseline liver function tests are done at the start of treatment, and routine monitoring of liver function is done if baseline tests are abnormal.

Latent Tuberculosis Infection.

Latent TB infection (LTBI) occurs when an individual becomes infected with *M. tuberculosis* but does not become acutely ill. Drug therapy can be used to prevent a TB infection from developing into a clinical disease. Previously used terms such as *preventive therapy* and *chemoprophylaxis* were confusing. Therefore, LTBI is the preferred term. The indications for treatment of LTBI are presented in Table 30-8.

TABLE 30-8

INDICATIONS FOR TREATMENT OF LATENT TUBERCULOSIS INFECTION

Treatment is indicated with positive tuberculin skin tests in people with the following:
• Known or suspected HIV infection
• Recent contact with infectious TB
• Presence of lung scar
Treatment is indicated with significant tuberculin skin test reaction in the following situations:
• Special clinical situations (immuno-suppression therapy, use of corticosteroids, diabetes mellitus, silicosis, chronic renal failure, organ transplant, hematological malignancies)
• If the person was born in a high-prevalence country, is a resident of a communal setting, is a health care worker, or is Indigenous

HIV, human immunodeficiency virus; *TB,* tuberculosis.

Source: Adapted from Public Health Agency of Canada & Canadian Lung Association. (2014). *Canadian tuberculosis standards* (7th ed.). Retrieved from *https://cts.lung.ca/sites/default/files/documents/cts/Canadian%20Tuberculosis%20Standards_7th%20edition_Complete.pdf.*

The drug generally used in treatment of LTBI is INH. It is effective and inexpensive and can be administered orally.

Vaccine.

Immunization with bacille Calmette–Guérin (BCG) vaccine to prevent TB is currently in use in many parts of the world. Although millions of people have been vaccinated with BCG, the efficacy of the vaccine is not clear. BCG vaccination can result in a positive PPD reaction. The BCG vaccine reaction will wane over time, and the mean PPD reaction size among people who received BCG is less than 10 mm. Because it may be difficult to determine the relevance of increases in individuals who have undergone BCG vaccination, the PHAC and Canadian Lung Association (2014) recommend that a conversion to "positive" be defined as a reaction of 10 mm or greater. People who receive BCG are from high-prevalence areas of the world, and it is important that a positive skin reaction be evaluated for TB.

Nursing Management Tuberculosis

Nursing Assessment

It is important to determine whether the patient was ever exposed to a person with TB. The patient should be assessed for productive cough, night sweats, afternoon temperature elevation, weight loss, pleuritic chest pain, and crackles over the apices of the lungs. If the patient has a productive cough, an early-morning sputum specimen will be required for an AFB smear to detect the presence of mycobacteria.

Nursing Diagnoses

Nursing diagnoses for the patient with TB may include but are not limited to the following:

- *Ineffective airway clearance* related to *excessive mucus, retained secretions*
- *Risk for infection* (of others) as evidenced by *insufficient knowledge to avoid exposure to pathogens*
- *Ineffective health management* related to *insufficient knowledge of therapeutic regimen, insufficient social support*

Planning

The overall goals are that the patient with TB will (a) comply with the therapeutic regimen, (b) have no recurrence of disease, (c) have normal pulmonary function, and (d) take appropriate measures to prevent the spread of the disease.

Nursing Implementation

Health Promotion.

The ultimate goal related to TB in Canada is eradication. Selective screening programs in known risk groups are of value in detecting individuals with TB. The person with a positive tuberculin skin test should have a chest radiographic examination to assess for the presence of TB. Another important measure is to identify the contacts of the individual who has TB. These contacts should be assessed for the possibility of infection and the need for prophylactic drug therapy.

When an individual has respiratory symptoms such as cough, dyspnea, or sputum production, especially if accompanied by a history of night sweats or unexplained weight loss, the nurse should assess for exposure to people with TB. Even if the suspected respiratory problem is something else, such as emphysema, pneumonia, or lung cancer, it is possible that the patient may have TB as well.

Acute Intervention.

Acute in-hospital care is seldom required for the patient with TB. If hospitalization is needed, it is usually for a brief period. Patients strongly suspected of having TB should (a) be placed in respiratory isolation; (b) receive four-drug therapy; and (c) receive an immediate medical workup, including chest radiographic examination, sputum smear, and culture. Respiratory isolation is indicated for the patient with pulmonary or laryngeal TB until the patient is considered to be noninfectious (effective drug therapy, clinical improvement, three negative AFB smears). A negative-pressure isolation room that offers six or more exchanges per hour may be used. Ultraviolet radiation of the air in the upper part of the room is another approach for reducing airborne TB organisms. Therefore, ultraviolet lights are commonly seen in clinics and homeless shelters. Masks are needed to filter out droplet nuclei. Use of institution-approved high-efficiency particulate air (HEPA) masks is indicated. The mask must be moulded to fit tightly around the nose and mouth.

The patient should be taught to cover the nose and mouth with paper tissue every time he or she coughs, sneezes, or produces sputum. The tissues should be thrown into a paper bag and disposed of with the trash, burned, or flushed down the toilet. The patient

should also be taught careful handwashing techniques to be used after handling sputum and soiled tissues. Special precautions should be taken during high-risk procedures such as sputum induction, aerosolized pentamidine treatments, intubation, bronchoscopy, or endoscopy.

Ambulatory and Home Care.

Patients who have responded clinically are discharged home despite positive smears if their household contacts have already been exposed and the patient is not posing a risk to susceptible people. Determination of absolute noninfectiousness requires negative cultures. Most treatment failures occur because the patient neglects to take the drug, discontinues it prematurely, or takes it irregularly. On discharge, the physician may order a combination of drugs to increase the likelihood of adherence, ensure that all drugs are taken, and reduce the risk of developing drug resistance.

It is important for the nurse to develop a therapeutic, consistent relationship with each patient. The nurse must understand the patient's lifestyle and be flexible in planning a program that facilitates the patient's participation in and completion of therapy. The nurse should teach the patient so that the patient fully understands the need for dedication to the prescribed regimen. Ongoing reassurance helps the patient understand that adherence can mean cure. If the patient cannot or will not adhere to a self-administered medication regimen, medication may have to be given by a responsible person on a daily or intermittent basis (see the “Ethical Dilemmas” box). The public health department must be notified if patient adherence to the drug regimen is questionable so that follow-up of close contacts can be accomplished. In some cases, the public health nurse will be responsible for DOT. In other situations, a spouse, grown child, other relative living with the patient, or co-worker may be asked to supervise drug taking.

Ethical Dilemmas

Patient Adherence

Situation

The health clinic for the homeless discovers that a man with tuberculosis has not been adhering to instructions for taking his medication. He tells the nurse that it is hard for him to get to the clinic to obtain the medication, much less to keep on a schedule. The nurse is concerned not only about this patient but also about the risks for the other people at the shelter, in the park, and at the meal sites.

Important Points for Consideration

- Adherence is a complex issue involving a person's culture and values, perceived risk for disease, availability of resources, access to treatment, and perceived consequences of available choices.
- Nurses in the community are concerned not only with providing benefits and supporting decision making for individual patients but also with the health and well-being of the entire community.
- Greater harm may result for the community when more virulent drug-resistant strains of microorganisms develop as a consequence of partial treatment or inability of the patient to complete a course of therapy.
- Advocacy for the patient and the community obliges the nurse to involve other members of the health care team, such as those in social services, to assist in obtaining the necessary resources or support to facilitate the patient's completion of the course of treatment.
- If the patient is unable to comply with the treatment program, even with necessary supports in place, concern for the public's health would take priority and necessitate placing him in a supervised living situation until his treatment is completed.

Clinical Decision-Making Questions

1. Under what circumstances are health care providers justified in overriding a patient's autonomy or decision making?
2. How would the nurse determine whether there were cultural beliefs interfering with this man's ability to understand the importance of completing the treatment? What would the nurse do about it?

Some patients may feel that there is a social stigma attached to TB. Many people still remember when TB patients were sent away to TB sanatoriums and isolated from society. These feelings should be discussed, and the patient should be reassured that an individual with TB can be cured if the prescribed regimen is followed. The Canadian Lung Association provides excellent literature for teaching about the disease as well as providing emotional support to the patient and family (Canadian Lung Association, 2015).

When the chemotherapy regimen has been completed, there is evidence of negative cultures, the patient is improving clinically, and there is radiological evidence of improvement, most individuals can be considered adequately treated. Follow-up care may be indicated during the subsequent 12 months, including bacteriological studies and chest radiographic examinations. Because approximately 5% of individuals experience relapses, the patient should be taught to recognize the symptoms that indicate recurrence of TB. If these symptoms occur, immediate medical attention should be sought.

The patient needs to be instructed about certain factors that could reactivate TB, such as immuno-suppressive therapy, malignancy, and prolonged debilitating illness. If the patient experiences any of these events, the health care provider must be told so that reactivation of TB can be closely monitored. In some situations, it may be necessary to put the patient on anti-TB therapy.

Evaluation

The following are the expected outcomes for the patient with TB:

- Patient will have complete resolution of the disease.

- Patient will have normal pulmonary function.
- Patient will have absence of any complications.
- Patient will have no transmission of TB.

Atypical Mycobacteria

Pulmonary disease that closely resembles TB may be caused by atypical acid-fast mycobacteria. This type of pulmonary disease is indistinguishable from TB clinically and radiologically but can be differentiated by bacteriological culture. These organisms are not believed to be airborne and, thus, are not transmitted by droplet nuclei.

Atypical mycobacteria may also invade the cervical lymph nodes, causing lymphadenitis. This type of pulmonary disease typically occurs in White men with a history of COPD, cystic fibrosis, or silicosis. *Mycobacterium avium-intracellulare (MAI)* is a common cause of opportunistic infections in the patient with HIV infection (see Chapter 17).

Treatment depends on identification of the causative agent and determination of drug sensitivity. Many of the drugs used in treating TB are used in combating infections from atypical mycobacteria.

Pulmonary Fungal Infections

Pulmonary fungal infections are increasing in incidence. They appear most frequently in seriously ill patients being treated with corticosteroids, antineoplastic immuno-suppressive drugs, or multiple antibiotics. They are also more common in patients with AIDS or cystic fibrosis. Types of fungal infections are presented in Table 30-9. These infections are not transmitted from person to person, and the patient does not have to be placed in isolation. The clinical manifestations are similar to those of bacterial pneumonia. Skin and serology tests are available to assist in identifying the infecting organism. However, identification of the organism in a sputum specimen or in other body fluids is the best diagnostic indicator.

TABLE 30-9
FUNGAL INFECTIONS OF THE LUNG

Organism	Characteristics
Histoplasmosis	
Histoplasma capsulatum	Indigenous to soil of the St. Lawrence River valleys; inhalation of mycelia into lungs; infected individual often free of symptoms; generally self-limiting, chronic disease similar to TB
Coccidioidomycosis	
Coccidioides immitis	Indigenous to semi-arid regions of southwestern United States (not normally found in Canada); inhalation of arthrospores into lungs; suppurative (pus-forming) and granulomatous reaction in lungs; symptomatic infection in one-third of individuals
Blastomycosis	
Blastomyces dermatitidis	Indigenous to southern Canada; inhalation of fungus into lungs; progression of disease often insidious; possible involvement of skin
Cryptococcosis	
Cryptococcus neoformans	True yeast; indigenous worldwide in soil and pigeon excreta; inhalation of fungus into lungs; possible meningitis
Aspergillosis	
Aspergillus niger or *A. fumigatus*	True mould inhabiting mouth; widely distributed; invasion of lung tissue resulting in possible necrotizing pneumonia; in individual with asthma, allergic bronchopulmonary aspergillosis may necessitate corticosteroid therapy
Candidiasis	
Candida albicans	Leading cause of mycotic infections in hospitalized and immuno-compromised hosts; ubiquitous and frequent colonization of upper respiratory and gastro-intestinal tracts; infections often following broad-spectrum antibiotic therapy (systemic or inhaled); possible development of localized pulmonary infiltrate to widespread bilateral consolidation with hypoxemia
Actinomycosis	
Actinomyces israelii	Not a true fungus; anaerobic; Gram-positive bacteria with branching hyphae; presence of necrotizing pneumonia after aspiration; pneumonitis; commonly in lower lobes with abscess or empyema formation
Nocardiosis	
Nocardia asteroides	Not a true fungus; aerobic; soil saprophyte widely distributed in nature; acquisition of infection from nature; rarely present in sputum without accompanying disease
Pneumocystis Pneumonia (PCP)	
Pneumocystis jiroveci	Rarely causes pneumonia in healthy individuals; fungus present in the environment; common opportunistic pneumonia in people with impaired immune systems, HIV infection, or both

HIV, human immunodeficiency virus; *TB,* tuberculosis.

Collaborative Care

Amphotericin B (Fungizone) is the drug most widely used in treating serious systemic fungal infections. It must be given intravenously to achieve adequate blood and tissue levels because it is poorly absorbed from the GI tract. Amphotericin B is considered a toxic drug with many possible adverse effects, including hypersensitivity

reactions, fever, chills, malaise, nausea and vomiting, thrombophlebitis at the injection site, and abnormal renal function. Many of the adverse effects during infusion can be avoided by premedicating with an anti-inflammatory or with diphenhydramine (Benadryl) 1 hour before the infusion. Monitoring renal function and ensuring adequate hydration are essential while a person is receiving this drug. Renal changes are at least partially reversible. Amphotericin infusions are incompatible with most other drugs. Amphotericin is frequently administered every other day after daily therapy for an initial period of several weeks. Total treatment with the drug may range from 4 to 12 weeks.

Oral antifungal drugs such as ketoconazole (Nizoral), fluconazole (Diflucan), and itraconazole (Sporanox) have also been successful in the treatment of fungal infections. Their effectiveness in treatment allows an alternative to the use of amphotericin B in many cases. Effectiveness of therapy can be monitored with fungal serology titres.

Bronchiectasis

Etiology and Pathophysiology

Bronchiectasis is characterized by permanent, abnormal dilation of one or more large bronchi. The pathophysiological change that results in dilation is destruction of the elastic and muscular structures of the bronchial wall. There are two pathological types of bronchiectasis: saccular and cylindrical (Figure 30-2). *Saccular bronchiectasis* occurs mainly in large bronchi and is characterized by cavity-like dilations. The affected bronchi end in large sacs. *Cylindrical bronchiectasis* involves medium-sized bronchi that are mildly to moderately dilated.

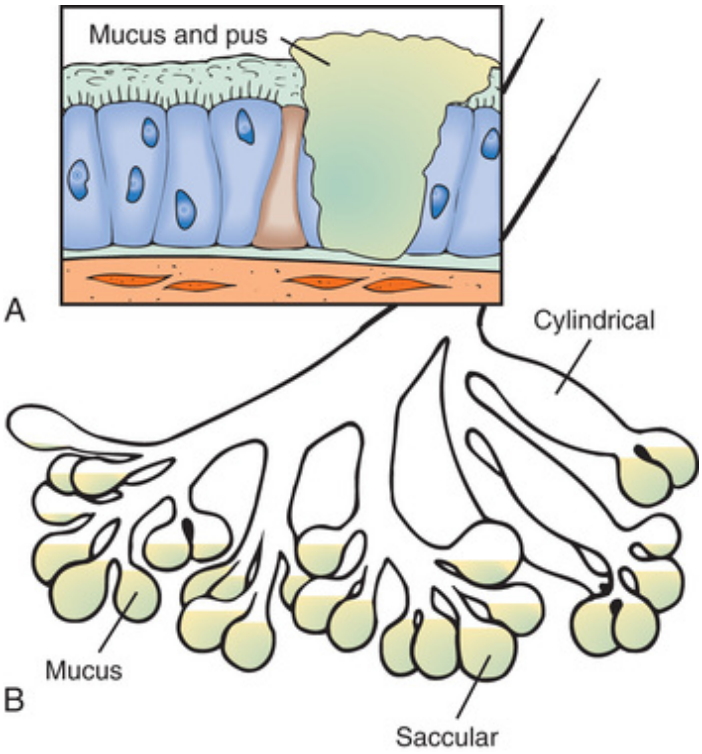

FIGURE 30-2 Pathological changes in bronchiectasis. **A,** Longitudinal section of bronchial wall where chronic infection has caused damage. **B,** Collection of purulent material in dilated bronchioles, leading to persistent infection.

Almost all forms of bronchiectasis are associated with bacterial infections. A wide variety of infectious agents can initiate bronchiectasis, including adenovirus, influenza virus, *S. aureus, Klebsiella,* and anaerobes. Infections cause the bronchial walls to weaken, and pockets of infection begin to form. When the walls of the bronchial system are injured, the mucociliary mechanism is damaged, allowing bacteria and mucus to accumulate within the pockets. The infection becomes worse and results in bronchiectasis.

The incidence of bronchiectasis has shown a decline in recent years. The emergence of atypical mycobacteria, especially MAI, presents a new threat because MAI can progress to bronchiectasis. MAI is an opportunistic infection found in patients with HIV.

Clinical Manifestations

The hallmark of bronchiectasis is persistent or recurrent cough with production of greater than 20 mL of purulent sputum per day. The

cough is paroxysmal and is often stimulated by position changes. Other manifestations include exertional dyspnea, fatigue, weight loss, anorexia, and fetid breath. On auscultation of the lungs, crackle and wheezing may be heard. Sinusitis frequently accompanies diffuse bronchiectasis. The manifestations of advanced, widespread bronchiectasis are generalized wheezing, digital clubbing, and cor pulmonale.

Diagnostic Studies

An individual with a chronic productive cough with copious purulent sputum (which may be blood streaked) should be suspected of having bronchiectasis. Chest radiographic studies are usually done and may show streaky infiltrates or may be normal. The availability of high-resolution CT scans of the chest, which have excellent sensitivity for detecting bronchiectasis, has made diagnosis easier. Bronchoscopy can also be useful in identifying the source of secretions, in identifying sites of hemoptysis, or for collecting microbiological samples.

Sputum may provide additional information regarding the severity of impairment and the presence of active infection. Pulmonary function studies may be abnormal in advanced bronchiectasis, showing a decrease in vital capacity, expiratory flow, and maximum voluntary ventilation. Complete blood cell count may be normal or show evidence of leukocytosis or anemia from chronic infection.

Collaborative Care

Bronchiectasis is difficult to treat. Therapy is aimed at treating acute flare-ups and preventing decline in lung function. Antibiotics are the mainstay of treatment and are given on the basis of sputum culture results. Long-term suppressive therapy with antibiotics is occasionally used but is fraught with risks for antibiotic resistance. A form of treatment gaining popularity is the use of nebulized antibiotics. Studies indicate that they are safe and may reduce the number of flare-ups and hospitalizations in bronchiectatic patients (Rubin & Williams, 2014). Antipseudomonal antibiotics, such as tobramycin, are commonly used. Concurrent bronchodilator therapy

is given to prevent bronchospasm. Other forms of drug therapy may include mucolytic agents and expectorants. Maintaining good hydration is important to liquefy secretions. Chest physiotherapy and other airway clearance techniques are important to facilitate expectoration of sputum. (These techniques are discussed in Chapter 31.) The individual should reduce exposure to excessive air pollutants and irritants, avoid cigarette smoking, and obtain pneumococcal and influenza vaccinations.

Surgical resection of parts of the lungs, although not used as often as in the past, may be done if more conservative treatment is not effective. Surgical resection of an affected lobe or segment may be indicated for the patient with repeated bouts of pneumonia, hemoptysis, and disabling complications. Surgery is not advisable when there is diffuse or widespread involvement. For select patients who are disabled in spite of maximal therapy, lung transplantation is an option. (Lung transplantation is discussed later in this chapter.)

Nursing Management Bronchiectasis

The early detection and treatment of lower respiratory tract infections will help prevent complications such as bronchiectasis. Any obstructing lesion or foreign body should be removed promptly. Other measures to decrease the occurrence or progression of bronchiectasis include avoiding cigarette smoking and decreasing exposure to pollution and irritants.

An important nursing goal is to promote drainage and removal of bronchial mucus. Various airway clearance techniques can be effectively used to facilitate secretion removal. The patient should be taught effective deep-breathing exercises and effective ways to cough (see Chapter 31, Table 31-18). Chest physiotherapy with postural drainage should be done on affected parts of the lung (see Chapter 31, Figure 31-17). Some individuals require elevation of the foot of the bed by 10 to 15 cm to facilitate drainage. Pillows may be used in the hospital and at home to help the patient assume postural drainage positions. A Flutter mucus clearance device is a hand-held device that provides airway vibration during the expiratory phase of breathing (see Chapter 31, Figure 31-18). Two to four 15-minute sessions daily by a patient who has been properly trained can provide satisfactory mucus clearance. Positive expiratory pressure therapy is a breathing manoeuvre against an expiratory resistance often used in conjunction with nebulized medications. (Respiratory therapy procedures are explained in Chapter 31.)

Administration of the prescribed antibiotics, bronchodilators, or expectorants is important. The patient needs to understand the importance of taking the prescribed regimen of drugs to obtain maximum effectiveness. The patient should be aware of possible adverse effects and of adverse effects that must be reported to the physician.

Health teaching must include information regarding the importance of getting adequate rest, avoiding overexertion, consuming adequate nutrients, ensuring hydration, and performing oral care. Unless there are contraindications such as concomitant heart failure or renal disease, the patient should be instructed to

drink at least 3 L of fluid daily. Generally, the patient should be counselled to use low-sodium fluids to avoid systemic fluid retention.

Direct hydration of the respiratory system may also prove beneficial in the expectoration of secretions. Usually, a bland aerosol with normal saline solution delivered by a jet-type nebulizer is used. The patient with bronchiectasis should avoid ultrasonic nebulizers because they often induce bronchospasm. At home, a steamy shower can prove effective; expensive equipment that requires frequent cleaning is usually unnecessary. It is important that the patient medicate with an inhaled bronchodilator 10 to 15 minutes before using a bland aerosol to prevent bronchoconstriction.

The patient and caregivers should be taught to recognize significant clinical manifestations to be reported to the health care provider. These manifestations include increased sputum production, grossly bloody sputum, increasing dyspnea, fever, chills, and chest pain.

Lung Abscess

Etiology and Pathophysiology

A **lung abscess** is a pus-containing lesion of the lung parenchyma that gives rise to a cavity. The cavity is formed by necrosis of the lung tissue. In many cases, the causes and pathogenesis of lung abscesses are similar to those of pneumonia. Most lung abscesses are caused by aspiration of material from the oral cavity (the gingival crevices) into the lungs. In general, infectious agents including enteric Gram-negative organisms (e.g., *Klebsiella*), *S. aureus,* and anaerobic bacilli (e.g., *Bacteroides*) are responsible for lung abscesses and the associated infection and necrosis of the lung tissue. A lung abscess can also result from a lung infarct secondary to pulmonary embolus, malignant growth, TB, and various parasitic and fungal diseases of the lung.

The areas of the lung most commonly affected are the superior segments of the lower lobes and the posterior segments of the upper lobes. Fibrous tissue usually forms around the abscess in an attempt to wall it off. The abscess may erode into the bronchial system, causing the production of foul-smelling sputum. It may grow toward

the pleura and cause pleuritic pain. Multiple small abscesses can occur within the lung.

Clinical Manifestations and Complications

The onset of a lung abscess is usually insidious, especially if anaerobic organisms are the primary cause. A more acute onset occurs with aerobic organisms. The most common manifestation is a cough that produces purulent sputum (often dark brown) that is foul smelling and foul tasting. Hemoptysis is common, especially at the time that an abscess ruptures into a bronchus. Other common manifestations are fever, chills, prostration, pleuritic pain, dyspnea, cough, and weight loss.

Physical examination of the lungs indicates dullness to percussion and decreased breath sounds on auscultation over the segment of lung involved. There may be transmission of bronchial breath sounds to the periphery if the communicating bronchus becomes patent and drainage of the segment begins. Crackles may also be present in the later stages as the abscess drains. Oral examination often reveals dental caries, gingivitis, and periodontal infection.

Complications that can occur include chronic pulmonary abscess, bronchiectasis, and brain abscess as a result of the hematogenous spread of infection, and bronchopleural fistula and empyema as a result of abscess perforation into the pleural cavity.

Diagnostic Studies

A chest radiographic examination will reveal a solitary cavitary lesion with fluid. CT scanning is used if there is suspicion of cavitation not clearly seen. A lung abscess, in contrast to other types of abscesses, does not require assisted drainage, as long as there is drainage via the bronchus. Routine sputum cultures can be collected, but contaminants can confuse the results and it is difficult to isolate anaerobic bacteria. Pleural fluid and blood cultures may be obtained. Bronchoscopy may be used in cases of abscess in which drainage is delayed or in which there are factors that suggest an underlying malignancy.

Nursing and Collaborative Management Lung Abscess

Antibiotics given for a prolonged period (up to 2 to 4 months) are usually the primary method of treatment. Penicillin has historically been the drug of choice because of the frequent presence of anaerobic organisms. However, recent studies suggest that the anaerobic bacteria involved in abscesses of the lung produce β-lactamase, which is resistant to penicillin. Clindamycin has been shown to be superior to penicillin and is the standard treatment for an anaerobic lung infection. Patients with putrid lung abscesses usually show clinical improvement with decreased fever within 3 to 4 days of beginning antibiotics.

Because of the need for prolonged antibiotic therapy, the patient must be aware of the importance of continuing the medication for the prescribed period. As well, the patient needs to know about adverse effects to be reported to the health care provider. Sometimes, the patient is asked to return periodically during the course of antibiotic therapy for repeat cultures and sensitivity tests to ensure that the infecting organism is not becoming resistant to the antibiotic. When antibiotic therapy is completed, the patient is re-evaluated.

The patient should be taught how to cough effectively (see Chapter 31, Table 31-18). Chest physiotherapy and postural drainage are sometimes used to drain abscesses located in the lower or posterior portions of the lung. Postural drainage according to the lung area involved will aid the removal of secretions (see Chapter 31, Figure 31-17). Frequent (every 2 to 3 hours) mouth care is needed to relieve the foul-smelling odour and taste from the sputum. Diluted hydrogen peroxide and mouthwash are often effective.

Rest, good nutrition, and adequate fluid intake are all supportive measures to facilitate recovery. If dentition is poor and dental hygiene is not adequate, the patient should be encouraged to obtain dental care.

Surgery is rarely indicated but occasionally may be necessary when reinfection of a large cavitary lesion occurs or to establish a diagnosis

when there is evidence of an underlying neoplasm or chronic associated disease. The usual procedure in such cases is a lobectomy or pneumonectomy. An alternative to surgery is percutaneous drainage, but this has a high risk for contamination of the pleural space.

Environmental Lung Diseases

Environmental or occupational lung diseases result from inhaled dust or chemicals. The duration of exposure and the amount of inhalant have a major influence on whether the exposed individual will have lung damage, as does the susceptibility of the host.

Pneumoconiosis is a general term for lung diseases caused by the inhalation and retention of dust particles. The literal meaning of *pneumoconiosis* is "dust in the lungs." Examples of this condition are silicosis, asbestosis, berylliosis, and hantavirus, a potentially fatal disease transmitted by inhalation of aerosolized rodent excreta particles, which has had outbreaks reported in Canada and the United States. The classical response to the inhaled substance is diffuse parenchymal infiltration with phagocytic cells. This eventually results in diffuse pulmonary fibrosis (excess connective tissue). Fibrosis is the result of tissue repair after inflammation. Pneumoconiosis and other environmental lung diseases are presented in Table 30-10.

TABLE 30-10
ENVIRONMENTAL LUNG DISEASES

Agents and Industries	Description	Complications
Asbestosis		
Asbestos fibres present in insulation, construction material (roof tiling, cement products), shipyards, textiles (for fireproofing), automobile clutch and brake linings	Disease appears 15–35 yrs after first exposure. Interstitial fibrosis develops. Pleural plaques, which are calcified lesions, develop on pleura. Dyspnea, basal crackles, and decreased vital capacity are early manifestations.	Diffuse interstitial pulmonary fibrosis; lung cancer, especially in cigarette smokers; mesothelioma (rare type of cancer affecting pleura and peritoneal membrane)
Berylliosis		
Beryllium dust present in aircraft manufacturing, metallurgy, rocket fuels	Formation of noncaseating granulomas is seen. Acute pneumonitis occurs after heavy exposure. Interstitial fibrosis can also occur.	Progress of disease possible even after removal of stimulating inhalant
Bird Fancier's, Breeder's, or Handler's Lung		
Bird droppings or feathers	Hypersensitivity pneumonitis is present.	Progressive fibrosis of lung
Byssinosis		
Cotton, flax, and hemp dust (textile industry)	Airway obstruction is caused by contraction of smooth muscles. Chronic disease results from severe airway obstruction and decreased elastic recoil.	Progression of chronic disease after cessation of dust exposure
Coal Worker's Pneumoconiosis (Black Lung)		
Coal dust	Incidence is high (20%–30%) in coal workers. Deposits of carbon dust cause lesions to develop along respiratory bronchioles. Bronchioles dilate because of loss of wall structure. Chronic airway obstruction and bronchitis develop. Dyspnea and cough are common early symptoms.	Progressive, massive lung fibrosis; increased risk for chronic bronchitis and emphysema in smokers
Farmer's Lung		
Inhalation of airborne material from mouldy hay or similar matter	Hypersensitivity pneumonitis occurs. Acute form is similar to pneumonia, with manifestations of chills, fever, and malaise. Chronic, insidious form is type of pulmonary fibrosis.	Progressive fibrosis of lung
Hantavirus Pulmonary Syndrome (HPS)		
Rodent droppings inhaled while in rodent-infested areas	Acute hemorrhagic fever associated with severe pulmonary and cardiovascular collapse and death. Incubation period is 1–4 wks with prodrome (3–5 days) of flulike symptoms. No cure or specific treatment exists.	Intensive care unit with careful monitoring of fluid and electrolyte balance and blood pressure; supportive therapy and early intervention vital; research on this virus is done in high-level biocontainment facilities
Siderosis		

Agents and Industries	Description	Complications
Iron oxide present in welding materials, foundries, iron ore mining	Dust deposits are found in lung.	—
Silicosis		
Silica dust present in quartz rock in mining of gold, copper, tin, coal, lead; also present in sandblasting, foundries, quarries, pottery making, masonry	In chronic disease, dust is engulfed by macrophages and may be destroyed, resulting in fibrotic nodules. Acute disease results from intense exposure in short period. Within 5 yrs, it progresses to severe disability from lung fibrosis.	Increased susceptibility to tuberculosis; progressive, massive fibrosis; high incidence of chronic bronchitis
Silo Filler's Disease		
Nitrogen oxides from fermentation of vegetation in freshly filled silo	Chemical pneumonitis occurs.	Progressive bronchiolitis obliterans

Chemical pneumonitis results from exposure to toxic chemical fumes. Acutely, there is diffuse lung injury characterized as pulmonary edema. Chronically, the clinical picture is that of bronchiolitis obliterans, which is usually associated with a normal chest radiograph or one that shows hyperinflation. An example is silo filler's disease. *Hypersensitivity pneumonitis* or extrinsic allergic alveolitis is the response seen when antigens to which an individual is allergic are inhaled. Examples include bird fancier's lung and farmer's lung.

Although many occupational respiratory diseases have declined, occupational asthma is the most common occupational lung disease (Canadian Centre for Occupational Health and Safety, 2013). *Occupational asthma* refers to the development of symptoms of shortness of breath, wheezing, cough, and chest tightness as a result of exposure to dust or fumes that trigger an allergic response. The obstruction may initially be reversible or intermittent, but continued exposure results in permanent obstructive changes. The best-known causative agent in occupational asthma is toluene di-isocyanate (TDI), which is used in the production of rigid polyurethane foam.

Lung cancer, either squamous cell carcinoma or adenocarcinoma, is the most frequent cancer associated with asbestos exposure. People who have experienced more exposure are at a greater risk for disease. There is a minimum lapse of 15 to 19 years between first exposure

and development of lung cancer. Mesotheliomas, both pleural and peritoneal, are also associated with asbestos exposure.

Clinical Manifestations

Acute symptoms of pulmonary edema may be seen following early exposure to chemical fumes. However, symptoms of many environmental lung diseases may not occur until at least 10 to 15 years after the initial exposure to the inhaled irritant. Dyspnea and cough are often the earliest manifestations. Chest pain and cough with sputum production usually occur later. Complications that often result are pneumonia, chronic bronchitis, emphysema, and lung cancer. Manifestations of these complications can be the reason the patient seeks health care. Cor pulmonale is a late complication, especially in conditions characterized by diffuse pulmonary fibrosis.

Pulmonary function studies often show reduced vital capacity. A chest radiograph will often reveal lung involvement specific to the primary problem. CT scans have been shown to be useful in detecting early lung involvement.

Collaborative Care

The best approach to management is to try to prevent or decrease environmental and occupational risks. Well-designed, effective ventilation systems can reduce exposure to irritants. Wearing a mask is appropriate in some occupations. Periodic inspections and monitoring of workplaces by agencies such as the Canadian Centre for Occupational Health and Safety (CCOHS) reinforce the obligations of employers to provide a safe work environment (CCOHS, 2013). In addition, the Canada Labour Code requires that an occupational health and safety committee be established in all workplaces with 20 or more regular employees (Human Resources and Skills Development Canada, 2012).

Cigarette smoking adds increased insult to the lungs, so the person at risk for occupational lung disease should not smoke. In addition, second-hand smoke is an important source of exposure that increases risk for development of lung cancer. This risk has led to regulations requiring a smoke-free workspace for all employees.

Early diagnosis is essential if the disease process is to be halted. Places of employment in which there is a known risk for lung disease may require periodic chest radiographic examinations and pulmonary function studies for exposed employees. This measure can detect pulmonary changes before symptoms develop.

There is no specific treatment for most environmental lung diseases. The best treatment is to decrease or stop exposure to the harmful agent. Strategies are directed toward providing symptomatic relief. If there are coexisting problems, such as pneumonia, chronic bronchitis, emphysema, or asthma, they are treated.

Lung Cancer

Lung cancer, the most preventable cancer, is the leading cause of cancer-related deaths in men and women in Canada. In 2012, lung cancer accounted for 1.59 million deaths worldwide, making it the most deadly of all cancers (WHO, 2017). It was estimated that in 2017 there would be 28 600 new cases of lung cancer in Canada and 20 100 deaths (Canadian Cancer Society's Advisory Committee on Cancer Statistics, 2017).

Lung cancer most commonly occurs in people who have a long history of cigarette smoking and who are 40 to 75 years of age, with peak incidence between 55 and 65.

Etiology

Cigarette smoking is the most important risk factor in the development of lung cancer. Smoking is responsible for approximately 85% of all lung cancers in Canada (Canadian Cancer Society, 2017a). Tobacco smoke contains 60 carcinogens in addition to substances (e.g., carbon monoxide, nicotine) that interfere with normal cell development. Cigarette smoking, a lower airway irritant, causes a change in the bronchial epithelium, which usually returns to normal when smoking is discontinued. The risk for lung cancer is gradually lowered when smoking ceases, and it continues to decline with time. After 10 years following cessation of smoking, the risk for lung cancer is cut in half (Canadian Lung Association, 2016a). In 2013, 11% of Canadian youth between the ages of 15 and 19 were

smokers. This number has been gradually decreasing (Canadian Tobacco, Alcohol and Drugs Survey [CTADS], 2013).

The risk of developing lung cancer is directly related to total exposure to cigarette smoke measured by total number of cigarettes smoked in a lifetime; age of smoking onset; depth of inhalation; tar and nicotine content; and the use of unfiltered cigarettes. Sidestream smoke (smoke from burning cigarettes and cigars) contains the same carcinogens found in mainstream smoke (smoke inhaled by smoker). This environmental tobacco smoke (ETS) inhaled by nonsmokers poses a 35% increased risk for the development of lung cancer in nonsmokers (Registered Nurses' Association of Ontario [RNAO], 2007). In 2013, 3.9% of Canadian children between the ages of 0 and 17 years were exposed to second-hand smoke at home every day or almost every day (CTADS, 2013). Children are more vulnerable to ETS than adults because their respiratory and immune systems are not fully developed.

Compared with nonsmokers, those who smoke pipes and cigars have also been shown to have an increased risk of developing lung cancer. Cigar smokers are at higher risk for lung cancer than pipe smokers. In fact, rates of lung cancer caused by heavy smoking of cigars and inhalation of smoke from small cigars have been shown to correlate with the rates of lung cancer caused by cigarette smoking.

Another major risk factor for lung cancer is inhaled carcinogens. These include asbestos, radon, nickel, iron and iron oxides, uranium, polycyclic aromatic hydrocarbons, chromates, arsenic, and air pollution. Exposure to these substances is common for employees of industries such as mining, smelting, or chemical or petroleum manufacturing. The cigarette smoker who is also exposed to one or more of these chemicals or to high amounts of air pollution is at significantly higher risk for lung cancer.

There are marked variations in a person's propensity to develop lung cancer. To date, no genetic abnormality has conclusively been defined for lung cancer. It is known that the carcinogens in cigarette smoke directly damage deoxyribonucleic acid (DNA). One theory is that people have different genetic carcinogen-metabolizing pathways.

Pathophysiology

The pathogenesis of primary lung cancer is not well understood. More than 90% of cancers originate from the epithelium of the bronchus (bronchogenic). They grow slowly, and it takes 8 to 10 years for a tumour to reach 1 cm in size, which is the smallest detectable lesion on a radiographic study. Lung cancers occur primarily in the segmental bronchi or beyond and have a preference for the upper lobes of the lungs (Figures 30-3 and 30-4). Pathological changes in the bronchial system show nonspecific inflammatory changes with hypersecretion of mucus, desquamation of cells, reactive hyperplasia of the basal cells, and metaplasia of normal respiratory epithelium into stratified squamous cells.

FIGURE 30-3 Lung cancer. Peripheral adenocarcinoma. The tumour shows prominent black pigmentation, suggestive of having evolved in an anthracotic scar. Source: Damjanov, I., & Linder, J. (1996). *Anderson's pathology* (10th ed.). St. Louis: Mosby.

FIGURE 30-4 Lung carcinoma. The grey-white tumour tissue is infiltrating the lung. Histologically, this tumour is identified as a squamous cell carcinoma. Source: Kumar, V., Abbas, A. K., Aster, J. C., et al. (2010). *Robbins and Cotran pathologic basis of disease* (8th ed.). Philadelphia: Saunders.

Primary lung cancers are often categorized into two broad subtypes (Table 30-11): non–small cell lung cancer (NSCLC; 85% to 90%) and small cell lung cancer (SCLC; 10% to 15%) (Canadian Cancer Society, 2017b). Lung cancers metastasize primarily by direct extension and via the blood circulation and the lymph system. The common sites for metastatic growth are liver, brain, bones, scalene lymph nodes, and adrenal glands.

TABLE 30-11
COMPARISON OF THE TYPES OF PRIMARY LUNG CANCER

Cell Type	Risk Factors	Characteristics	Response to Therapy
Non–Small Cell Lung Cancer (NSCLC)			
Squamous cell (epidermoid) carcinoma	Almost always associated with cigarette smoking; is associated with exposure to environmental carcinogens (e.g., uranium, asbestos)	Accounts for 30% of lung cancers; is more common in men; arises from the bronchial epithelium; produces earlier symptoms because of bronchial obstructive characteristics; does not have a strong tendency to metastasize; metastasizes locally by direct extension; causes cavitating pulmonary lesions	Surgical resection is often attempted; life expectancy is better than for small cell lung cancer.
Adenocarcinoma	Has been associated with lung scarring and chronic interstitial fibrosis; is not related to cigarette smoking	Accounts for approximately 40% of lung cancers; is more common in women; often has no clinical manifestations until widespread metastasis is present; metastasizes via bloodstream; is most commonly located in peripheral portions of lungs*	Surgical resection is often attempted; cancer does not respond well to chemotherapy.
Large cell undifferentiated carcinoma	High correlation with cigarette smoking and exposure to environmental carcinogens	Accounts for 10% of lung cancers; commonly causes cavitation; is highly metastatic via lymphatics and blood; commonly peripheral rather than central	Surgery is not usually attempted because of high rate of metastases; tumour may be radiosensitive but often recurs.
Small Cell Lung Cancer (SCLC)			
Small cell anaplastic undifferentiated (includes oat cell)	Associated with cigarette smoking, exposure to environmental carcinogens	Accounts for 20%–25% of lung cancers; is most malignant form; tends to spread early via lymphatics and bloodstream; is frequently associated with endocrine disturbances; predominantly central and can cause bronchial obstruction and pneumonia	This cancer has the poorest prognosis; however, chemotherapy advances have been substantial; radiation is used as adjuvant therapy as well as palliative measure. Average median survival is 12–18 months.

*See Figure 30-3.

Paraneoplastic Syndrome.

Certain lung cancers cause *paraneoplastic syndrome,* which is characterized by various systemic manifestations caused by factors (e.g., hormones, enzymes, antigens) produced by the tumour cells. SCLCs are most commonly associated with paraneoplastic syndrome. The systemic manifestations seen are hormonal, dermatological,

neuro-muscular, vascular, hematological, and connective tissue syndromes. Examples of paraneoplastic syndromes include hypercalcemia, syndrome of inappropriate antidiuretic hormone (SIADH) secretion, anemia, leukocytosis, hypercoagulable disorders, and neurological syndromes. These syndromes can respond temporarily to symptomatic treatment, but they are impossible to control without successful treatment of the underlying lung cancer.

Clinical Manifestations

Lung cancer is clinically silent for most individuals for the majority of its course. The clinical manifestations of lung cancer are usually nonspecific and appear late in the disease process. Manifestations depend on the type of primary lung cancer, its location, and metastatic spread. Often, there is extensive metastasis before symptoms become apparent. Persistent pneumonitis that is a result of obstructed bronchi may be one of the earliest manifestations, causing fever, chills, and cough.

One of the most significant symptoms, and often the one reported first, is a persistent cough that may produce sputum. Sputum may be blood-tinged because of bleeding caused by malignancy, but hemoptysis is not a common early symptom. Chest pain may be present and localized or unilateral, ranging from mild to severe. Dyspnea and an auscultatory wheeze may be present if there is bronchial obstruction.

Later manifestations may include nonspecific systemic symptoms such as anorexia, fatigue, weight loss, and nausea and vomiting. Hoarseness may be present as a result of involvement of the recurrent laryngeal nerve. Unilateral paralysis of the diaphragm, dysphagia, and superior vena cava obstruction may occur because of intrathoracic spread of the malignancy. There may be palpable lymph nodes in the neck or the axilla. Mediastinal involvement may lead to pericardial effusion, cardiac tamponade, and dysrhythmias.

Diagnostic Studies

Chest radiographic studies are widely used in the diagnosis of lung cancer. The findings may show the presence of the tumour or

abnormalities related to the obstructive features of the tumour such as atelectasis and pneumonitis. The radiograph can also show evidence of metastasis to the ribs or vertebrae and the presence of pleural effusion.

CT scanning is the single most effective noninvasive technique for evaluating lung cancer. CT scans of the brain and bone scans complete the evaluation for metastatic disease. With CT scans, the location and extent of masses in the chest can be identified, as well as any mediastinal involvement or lymph node enlargement. Magnetic resonance imaging (MRI) may be used in combination with or instead of CT scans. Positron emission tomography (PET) can be a useful diagnostic tool in early clinical staging. PET allows measurement of differential metabolic activity in normal and diseased tissues.

A definitive diagnosis of lung cancer is made by identifying malignant cells. Sputum specimens are usually obtained for cytological studies. An early-morning specimen that has been obtained by having the patient cough deeply provides the most accurate results. However, malignant cells may not be obtained even in the presence of a lung cancer.

The use of the fibre-optic bronchoscope is important in the diagnosis of lung cancer, particularly when the lesions are endobronchial or close to an airway. It provides direct visualization and allows biopsy specimens to be obtained. A biopsy is usually the best method for establishing the presence of a malignant tumour.

Mediastinoscopy—the insertion of a scope via a small anterior chest incision into the mediastinum—is done to examine for metastasis in the anterior mediastinum or in the hilum or in the chest extrapleurally. It is also used to determine the stage of the lung cancer, an important step toward preparing a treatment plan. Video-assisted thoracoscopy (VAT), which involves the insertion of a scope into a small thoracic incision, may be used to explore areas inaccessible by mediastinoscopy.

Pulmonary angiography and lung scans may be performed to assess overall pulmonary status. Fine-needle aspiration (FNA) may be used to obtain a tissue sample to determine tumour histology. FNA is most useful in cases involving a peripheral lesion near the chest wall, and it is usually attempted in an effort to avoid a thoracotomy. If a

thoracentesis is performed to relieve a pleural effusion, the fluid should be analyzed for malignant cells. (Table 30-12 summarizes the diagnostic management of lung cancer.)

TABLE 30-12

COLLABORATIVE CARE
Lung Cancer

Diagnostic	Collaborative Therapy
• History and physical examination • Chest radiographic examination • Sputum for cytological study • Bronchoscopy • CT scan • MRI • PET • Spirometry (preoperative) • Mediastinoscopy • VAT • Pulmonary angiography • Lung scan • Fine-needle aspiration	• Surgery • Radiation therapy • Chemotherapy • Biological therapy • Bronchoscopic laser therapy • Phototherapy • Airway stenting • Cryotherapy • Respiratory therapy • Nutritional therapy

Staging.

Staging of NSCLC is performed according to the tumour–node–metastasis (TNM) staging system in a manner similar to that for other tumours (Tables 30-13 and 30-14). Assessment criteria are *T*, which denotes tumour size, location, and degree of invasion; *N*, which indicates regional lymph node involvement; and *M*, which represents the presence or absence of distant metastases. Depending on the TNM designation, the tumour is then staged, which assists in estimating prognosis and determining the appropriate therapy.

Springer Science and Business Media LLC

Staging of SCLC has not been useful because the cancer has usually metastasized by the time a diagnosis is made. Instead, SCLC is determined to be *limited* (confined to one hemothorax and to regional lymph nodes) or *extensive* (any disease exceeding those boundaries).

Screening for Lung Cancer.

In 2016, new guidelines were published recommending the screening of asymptomatic adults aged 55 to 74 with at least a 30 pack-year smoking history (who currently smoke or quit smoking less than 15 years ago). Screening is done using a low-dose CT scan every year for 3 consecutive years (Canadian Task Force on Preventive Health Care, 2016).

Collaborative Care

Cancer Care Ontario has published evidence-informed clinical guidelines for treating lung cancer. The guidelines can be accessed at its website in the Cancer Care Ontario Toolbox, under Evidence-Based Guidelines. (See the Resources at the end of the chapter.)

Surgical Therapy.

Surgical resection is considered the treatment of choice in NSCLC Stages I and II because the disease is potentially curable with resection. For other NSCLC stages, surgery may be indicated in conjunction with radiation therapy, chemotherapy, or both. In limited-stage SCLC, which is rare, surgical resection, chemotherapy, and radiation therapy may be recommended.

When the tumour is considered operable with a potential for cure, the patient's cardiopulmonary status must be evaluated to determine the ability to withstand surgery. This is done by clinical studies of pulmonary function, ABGs, and others, as indicated by the individual's status. Contraindications for thoracotomy include hypercapnia, pulmonary hypertension, cor pulmonale, and markedly reduced lung function. Coexisting conditions such as cardiac, renal, and liver disease may also be contraindications for surgery.

A tumour may be considered inoperable. If operable, the type of surgery performed is usually a lobectomy (removal of one or more lobes of the lung) and, less often, a *pneumonectomy* (removal of one entire lung).

Radiation Therapy.

Radiation therapy is used as a curative approach in the individual who has a resectable tumour but who is considered a poor surgical risk. There has been improved survival when radiation therapy is used in combination with surgery and chemotherapy. Adenocarcinomas are the most radioresistant type of cancer cell. Although SCLCs are radiosensitive, radiation (even when used in combination with chemotherapy) does not significantly improve the mortality rate because of the early metastases of this type of cancer.

Radiation therapy is also done as a palliative procedure to reduce distressing symptoms such as cough, hemoptysis, bronchial

obstruction, and superior vena cava syndrome. It can be used to treat pain that is caused by metastatic bone lesions or cerebral metastasis. Radiation used as a preoperative or postoperative adjuvant measure has not been found to significantly increase survival in the patient with lung cancer.

Stereotactic Radiotherapy.

Stereotactic radiotherapy (SRT), also called *stereotactic surgery* or *radiosurgery,* is a new lung cancer treatment. It is a type of radiation therapy that uses high doses of radiation delivered very accurately to the tumour. SRT provides an option to older-adult patients, patients with severe lung or heart disease, and other patients in poor health who are not good candidates for surgery. SRT is an outpatient procedure that uses special positioning procedures and radiology techniques so that a higher dose of radiation can be delivered to the tumour and a smaller part of the healthy lung is exposed.

Chemotherapy.

Chemotherapy may be used in the treatment of nonresectable tumours or as adjuvant therapy to surgery in NSCLC with distant metastases. A variety of chemotherapy drugs and multidrug regimens (i.e., protocols) including combination chemotherapy have been used. These drugs include etoposide (VePesid), carboplatin, cisplatin, paclitaxel, vinorelbine, cyclophosphamide (Procytox), ifosfamide (Ifex), docetaxel (Taxotere), gemcitabine, topotecan (Hycamtin), and irinotecan (Camptosar). Chemotherapy has improved survival in patients with advanced NSCLC and is now considered standard treatment.

Biological Therapy.

Biological (targeted) therapy as adjuvant therapy has been used in individuals with cancer, including malignant lung tumours. (Biological therapy is discussed in Chapter 18.)

Other Therapies

Prophylactic Cranial Radiation.

Brain metastasis is a common complication of SCLC. Most chemotherapy drugs do not adequately penetrate the blood–brain barrier. Prophylactic cranial radiation may be used as a potential way to improve the prognosis of patients, especially those who have a complete response to chemotherapy. Toxicity of this therapy may include scalp erythema, fatigue, and alopecia.

Bronchoscopic Laser Therapy.

Bronchoscopic laser therapy makes it possible to remove obstructing bronchial lesions. The thermal energy of the laser is transmitted to the target tissue. It is a complicated procedure that often requires general anaesthesia to control the patient's cough reflex. Relief of the symptoms from airway obstruction as a result of thermal necrosis and shrinkage of the tumour can be dramatic. However, it is not a curative therapy for cancer.

Phototherapy.

Photodynamic therapy is a safe, nonsurgical therapy for lung cancer. Porfimer (Photofrin) is injected intravenously and selectively concentrates in tumour cells. After a set time (usually 48 hours), the tumour is exposed to laser light, producing a toxic form of oxygen that destroys tumour cells. Necrotic tissue is removed through a bronchoscope.

Airway Stenting.

Stents can be used alone or in combination with other techniques for palliation of dyspnea, cough, or respiratory insufficiency. The advantage of an airway stent is that it supports the airway wall against collapse or external compression and can impede extension of the tumour into the airway lumen.

Cryotherapy.

Cryotherapy is a technique in which tissue is destroyed as a result of freezing. Bronchoscopic cryotherapy is used to ablate (destroy) bronchogenic carcinomas, especially polypoid lesions. A repeat bronchoscopy is performed 8 to 10 days after the first session. The second examination enables assessment of cryodestruction, removal

of any slough, and repeat cryotherapy if required for the treatment of large lesions.

Nursing Management Lung Cancer

Nursing Assessment

It is important to determine the understanding of the patient and the family concerning the diagnostic tests (those completed as well as those planned), the diagnosis or potential diagnosis, the treatment options, and the prognosis. At the same time, the nurse can assess the level of anxiety experienced by the patient and the support provided and needed by the patient's significant others. Subjective and objective data that should be obtained from a patient with lung cancer are presented in Table 30-15.

TABLE 30-15

NURSING ASSESSMENT
Lung Cancer

Subjective Data
Important Health Information
Past health history: Exposure to second-hand smoke; airborne carcinogens (e.g., asbestos, uranium, chromates, hydrocarbons, arsenic) or other pollutants; urban living environment; chronic lung disease, including TB, COPD, bronchiectasis; smoking history; frequent respiratory infections; family history of lung cancer *Medications:* Use of cough medicines or other respiratory medications
Symptoms
• Anorexia, nausea, vomiting, dysphagia (late symptom), weight loss • Persistent cough (productive or nonproductive), dyspnea, hemoptysis (late symptom) • Fatigue, fever, chills • Chest pain or tightness, shoulder and arm pain; headache; bone pain (late symptom)
Objective Data
General
Fever, neck and axillary lymphadenopathy, paraneoplastic syndromes (e.g., SIADH secretion)
Integumentary
Jaundice (liver metastasis); edema of neck and face (superior vena cava syndrome), digital clubbing
Respiratory
Wheezing, hoarseness, stridor, unilateral diaphragm paralysis, pleural effusions (late signs)
Cardiovascular
Pericardial effusion, cardiac tamponade, dysrhythmias (late signs)
Neurological
Unsteady gait (brain metastasis)
Musculo-skeletal
Pathological fractures, muscle wasting (late sign)
Possible Findings
Observance of lesion on chest radiographic examination, CT scan, lung scan, or PET scan; MRI findings of mediastinal invasion, positive sputum or bronchial washings for cytological studies; positive fibre-optic bronchoscopy and biopsy findings; low serum sodium and hypercalcemia (paraneoplastic syndrome)

COPD, chronic obstructive pulmonary disease; *CT,* computed tomography; *MRI*, magnetic resonance imaging; *PET*, positron emission tomography; *SIADH,* syndrome of inappropriate antidiuretic hormone; *TB,* tuberculosis.

Nursing Diagnoses

Nursing diagnoses for the patient with lung cancer may include but are not limited to the following:

- *Ineffective airway clearance* related to *excessive mucus, retained secretions, foreign body in airway*

(tumour)
- *Ineffective breathing pattern* related to *body position that inhibits lung expansion* (space occupying lesion)
- *Impaired gas exchange* (related to tumour obstructing airflow)
- *Anxiety* related to *unmet needs* (lack of knowledge of the disease process)
- *Grieving* (related to new cancer diagnosis and therapeutic regimen)

Planning

The overall goals are that the patient with lung cancer will have (a) effective breathing patterns, (b) adequate airway clearance, (c) adequate oxygenation of tissues, (d) minimal to no pain, and (e) a realistic attitude toward treatment and prognosis.

Nursing Implementation

Health Promotion.

The best way to halt the epidemic of lung cancer is for people to stop smoking. Important nursing activities to assist in the progress toward this goal include promoting smoking cessation programs and actively supporting education and policy changes related to smoking. Important changes have occurred as a result of the recognition that sidestream smoke is a health hazard. There are now laws that (a) require designation of nonsmoking areas in most public places, (b) prohibit smoking, and (c) ban smoking on airline flights. Other actions aimed at controlling tobacco use include restrictions on tobacco advertising on television and warning label requirements for cigarette packaging. These are examples of beginning steps toward the goal of a smokeless society. Despite the small advances

being made, tobacco-producer organizations such as marketing boards and tobacco companies still have strong political influences.

The nurse should make an effort to assist patients who smoke to stop smoking. There are many resources available to help. The Registered Nurses' Association of Ontario's Best Practice Guideline *Integrating Smoking Cessation Into Daily Nursing Practice* recommends nurses use the "ask, advise, assist, arrange" protocol to motivate smokers and other tobacco users to quit (RNAO, 2007). The six stages of change identified in smokers attempting to quit include precontemplation, contemplation, preparation, action, maintenance, and termination. (The stages of change in relationship to patient teaching [Transtheoretical Model] are discussed in Chapter 4, Table 4-3.) Each stage requires specific actions to progress to the next stage. Nurses working with patients at their individual stage of change will help them progress to the next stage. For patients unwilling to quit, motivational interviewing is recommended (discussed in Chapter 11). The Canadian Lung Association (2016b) provides information on access to counselling, medications, and supports to help Canadians quit smoking. The Canadian Cancer Society (2012) launched the "Break It Off" campaign, funded by Health Canada (2014a/b), which developed smoking cessation guides for both adults and young adults. Tobacco use and dependence and strategies to assist patients to stop smoking are discussed in Chapter 11.

The evidence-informed guideline also offers the five *R*s strategy for motivating smokers to quit: **r**elevance, **r**isk, **r**eward, **r**oadblocks, and **r**epetition. Because some patients relapse months or years after having stopped smoking, nurses must continually provide interactions to prevent relapse.

Nicotine's addictive properties make quitting a difficult task that requires much support. Nicotine replacement significantly lessens the urge to smoke and increases the percentage of smokers who successfully quit smoking. There is no evidence that one product has better results than another, so the choice of agent is dependent on the health care provider and patient preferences.

The advice and motivation of health care providers can be a powerful force in smoking cessation. Nurses are in a unique position to promote smoking cessation because they see large numbers of

smokers who may be reluctant to seek help. Support for the smoker includes education that smoking a few cigarettes during a cessation attempt (a slip) is much different from resuming the full smoking habit (a relapse). Despite the slip, smokers should be encouraged to continue the attempt at cessation without viewing the effort as a failure. Measures to assist an individual in quitting should be directed toward the meaning that smoking has to that individual. The nurse must be aware of resources in the community to assist the individual who is interested in quitting.

Acute Intervention.

Care of the patient with lung cancer will initially involve support and reassurance during the diagnostic evaluation. (Specific nursing measures related to the diagnostic studies are outlined in Chapter 28.)

Another major responsibility of the nurse is to help the patient and the family deal with the diagnosis of lung cancer. The patient may feel guilty about cigarette smoking having caused the cancer and need to discuss this feeling with someone who has a nonjudgemental attitude. Questions regarding the patient's condition should be answered honestly. Additional counselling from a social worker, psychologist, or member of the clergy may be needed. Specific care of the patient will depend on the treatment plan. Postoperative care for the patient having surgery is discussed later in this chapter. Care of the patient undergoing radiation therapy and chemotherapy is discussed in Chapter 18 and in NCPs 18-1 and 18-2, on the Evolve website. The nurse has a major role in providing patient comfort, teaching methods to reduce pain, assessing for signs and symptoms of progressive or recurrent disease, and assessing indications for hospitalization.

Ambulatory and Home Care.

Patient teaching needs to include signs and symptoms to report, such as hemoptysis, dysphagia, chest pain, and hoarseness. The patient and caregivers should be encouraged to provide a smoke-

free environment, which may include smoking cessation for multiple family members.

If the treatment plan includes the use of home oxygen, teaching must include the safe use of oxygen. The patient who has had a surgical resection with intent to cure should be followed up with carefully to watch for manifestations of metastasis. The patient and family should be told to contact the physician if symptoms such as hemoptysis, dysphagia, chest pain, and hoarseness develop. For many individuals who have lung cancer, little can be done to significantly prolong their lives. Radiation therapy and chemotherapy can be used to provide palliative relief from distressing symptoms. Constant pain becomes a major problem. (Measures used to relieve pain are discussed in Chapter 10. Care of the patient with cancer is discussed in Chapter 18.) The patient and family or caregivers may need information about palliative care options in the community.

Evaluation

The following are the expected outcomes for the patient with lung cancer:

- Patient will have adequate breathing patterns.
- Patient will have adequate airway clearance.
- Patient will have adequate tissue oxygenation.
- Patient will have minimal to no pain.
- Patient will have realistic attitude about prognosis.

Evidence-Informed Practice

Research Highlight

Do Noninvasive Interventions Improve Quality of Life in Patients With Lung Cancer?

Clinical Question

In lung cancer patients (P), does receiving noninvasive interventions (I) compared with receiving no additional treatment (C) improve symptoms, psychological functioning, and quality of life (O)?

Best Available Evidence

Systematic review of RCTs or quasi-RCTs

Critical Appraisal and Synthesis of Evidence

- Meta-analysis of 15 clinical trials.
- Interventions studied included nursing interventions to manage breathlessness, nursing care programs, nutritional interventions, psychotherapeutic interventions, exercise, and reflexology.

Conclusions

- Nursing interventions to manage breathlessness showed improved symptom control, performance status, and emotional functioning.
- Nursing programs were effective in delaying clinical deterioration, dependency, and symptom distress as well as improving emotional functioning and satisfaction with care.
- Exercise and nutritional interventions had no significant or lasting effects on quality of life.
- Psychological interventions and reflexology had some short-lasting positive effects on quality of life.

Implications for Nursing Practice

- It is important to develop and maintain a supportive and empathic relationship with the patient with lung cancer.
- Nurses should offer patients supportive multidisciplinary interventions that may benefit their emotional, psychological, and physical well-being.
- These interventions may also help patients with other types of cancers.
- Further research is needed to accurately assess the effectiveness of noninvasive nursing interventions on the well-being and quality of life of patients with cancer.

P, Patient population of interest; *I,* intervention or area of interest; *C,* comparison of interest or comparison group; *O,* outcome(s) of interest (see Chapter 1).

RCTs, randomized controlled trials.

Other Types of Lung Tumours

Other types of primary lung tumours include sarcomas, lymphomas, and bronchial adenomas. Bronchial adenomas are small tumours that arise from the lower trachea or major bronchi and are considered malignant because they are locally invasive and frequently metastasize. Clinical manifestations of bronchial adenomas include hemoptysis, persistent cough, localized obstructive wheezing, and pneumonia. Bronchial adenomas can usually be treated successfully with surgical resection.

The lungs are a common site for secondary metastases and are more often affected by metastatic growth than by primary lung tumours. The pulmonary capillaries, with their extensive network, are ideal sites for tumour emboli. In addition, the lungs have an extensive lymphatic network. The primary malignancies that spread to the lungs often originate in the GI or genito-urinary tracts and in the breast. General symptoms of lung metastases are chest pain and nonproductive cough.

Benign tumours of the lung are generally classified as *mesenchymal.* Their occurrence is rare, and they have the potential to become malignant. The most common mesenchymal tumours are *chondromas,* which arise in the bronchial cartilage, and *leiomyomas,* which are myomas of smooth, nonstriated muscle fibres. Mesotheliomas may be malignant or benign and originate from the visceral pleura. Benign mesotheliomas are localized lesions.

Hamartomas of the lung are the most common benign tumour. These tumours, composed of fibrous tissue, fat, and blood vessels, are congenital malformations of the connective tissue of the bronchiolar walls. Hamartomas are slow-growing tumours.

Chest Trauma and Thoracic Injuries

Traumatic injuries fall into two major categories: (1) blunt trauma and (2) penetrating trauma. *Blunt trauma* occurs when the body is struck by a blunt object, such as a steering wheel. The external injury may appear minor, but the impact may cause severe, life-threatening internal injuries, such as a ruptured spleen. *Contrecoup trauma,* a type of blunt trauma, is caused by the impact of parts of the body against other objects. This type of injury differs from blunt trauma primarily in the velocity of the impact. Internal organs are rapidly forced back and forth within the bony structures that surround them so that internal injury is sustained not only on the side of the impact but also on the opposite side, where the organ or organs hit bony structures. If the velocity of impact is great enough, organs and blood vessels can literally be torn from their points of origin. This is the shearing injury that can cause transection of the aorta, hemothorax, and diaphragmatic rupture injuries. Compression injury occurs when the body cannot handle the degree of external pressure during blunt trauma, resulting in contusions, crush injuries, and organ rupture.

Penetrating trauma occurs when a foreign body impales or passes through the body tissues (e.g., gunshot wounds, stabbings). Table 30-16 describes selective traumatic injuries as they relate to the categories of trauma and the mechanism of injury. Emergency care of the patient with a chest injury is presented in Table 30-17.

TABLE 30-16

COMMON TRAUMATIC CHEST INJURIES AND MECHANISMS OF INJURY

Mechanism of Injury	Common Related Injury
Blunt Trauma	
Blunt steering-wheel injury to chest	Rib fractures, flail chest, pneumothorax, hemo-pneumothorax, cardiac contusion, pulmonary contusion, cardiac tamponade, great vessel tears
Shoulder-harness seat belt injury	Fractured clavicle, dislocated shoulder, rib fractures, pulmonary contusion, pericardial contusion, cardiac tamponade
Crush injury (e.g., heavy equipment, crushing thorax)	Pneumothorax and hemo-pneumothorax, flail chest, great vessel tears and rupture, decreased blood return to heart with decreased cardiac output
Penetrating Trauma	
Gunshot or stab wound to chest	Open pneumothorax, tension pneumothorax, hemo-pneumothorax, cardiac tamponade, esophageal damage, tracheal tear, great vessel tears

TABLE 30-17

EMERGENCY MANAGEMENT
Chest Trauma

Etiology	Assessment Findings	Interventions
Blunt • Motor vehicle collision • Pedestrian accident • Fall • Assault with blunt object • Crush injury • Explosion **Penetrating** • Knife • Gunshot • Stick • Arrow • Other missiles	**Respiratory** • Dyspnea, respiratory distress • Cough with or without hemoptysis • Cyanosis of mouth, face, nail beds, mucous membranes • Tracheal deviation • Audible air escaping from chest wound • Decreased breath sounds on side of injury • Decreased O_2 saturation • Frothy secretions **Cardiovascular** • Rapid, thready pulse • Decreased blood pressure • Narrowed pulse pressure • Asymmetrical blood pressure values in arms • Distended neck veins • Muffled heart sounds • Chest pain • Crunching sound synchronous with heart sounds • Dysrhythmias **Surface Findings** • Bruising • Abrasions • Open chest wound • Asymmetrical chest movement • Subcutaneous emphysema	**Initial** • Ensure patent airway. • Administer high-flow O_2 with nonrebreather mask. • Establish IV access with two large-bore catheters. Begin fluid resuscitation as appropriate. • Remove clothing to assess injury. • Cover sucking chest wound with nonporous dressing taped on three sides. • Stabilize impaling objects with bulky dressings. Do not remove. • Assess for other significant injuries and treat appropriately. • Stabilize flail rib segment first with hand and then by application of large pieces of tape horizontal across the flail segment. • After cervical spine injury has been ruled out, place patient in a semi-Fowler's position or position patient on the injured side if breathing is easier. **Ongoing Monitoring** • Monitor vital signs, level of consciousness, O_2 saturation, cardiac rhythm, respiratory status, and urinary output. • Anticipate intubation for respiratory distress. • Release dressing if tension pneumothorax develops after sucking chest wound is covered.

IV, intravenous; O_2, oxygen.

Thoracic injuries range from simple rib fractures to life-threatening tears of the aorta, vena cava, and other major vessels.

The most common thoracic emergencies and their management are described in Table 30-18.

TABLE 30-18

EMERGENCY MANAGEMENT
Thoracic Injuries

Definition	Clinical Manifestations	Emergency Management
Pneumothorax		
Air in pleural space (see Figure 30-5)	Dyspnea, decreased movement of involved chest wall, diminished or absent breath sounds on the affected side, hyper-resonance to percussion	Chest tube insertion with chest drainage system; Heimlich (flutter) valve
Hemothorax		
Blood in the pleural space, usually occurs in conjunction with pneumothorax	Dyspnea, diminished or absent breath sounds, dullness to percussion, shock	Chest tube insertion with chest drainage system; autotransfusion of collected blood, treatment of hypovolemia as necessary
Tension Pneumothorax		
Air in pleural space that does not escape Continued increase in amount of air shifts intrathoracic organs and increases intrathoracic pressure (see Figure 30-6)	Cyanosis, air hunger, violent agitation, tracheal deviation away from affected side, subcutaneous emphysema, neck vein distension, hyper-resonance to percussion	Medical emergency: needle decompression followed by chest tube insertion with chest drainage system
Flail Chest		
Fracture of two or more adjacent ribs in two or more places with loss of chest-wall stability (see Figure 30-7)	Paradoxical movement of chest wall, respiratory distress, associated hemothorax, pneumothorax, pulmonary contusion	Stabilization of flail segment with intubation in some patients and taping in others; oxygen therapy; treatment of associated injuries; analgesia
Cardiac Tamponade		
Blood rapidly collects in pericardial sac, compresses myocardium because the pericardium does not stretch, and prevents heart from pumping effectively	Muffled, distant heart sounds, hypotension, neck vein distension, increased central venous pressure	Medical emergency: pericardiocentesis with surgical repair as appropriate

Pneumothorax

A **pneumothorax** is the presence of air in the pleural space. A complete or partial collapse of a lung results from this accumulation of air. This condition should be suspected after any blunt trauma to the chest wall. Pneumothorax may be closed or open. Pneumothorax

associated with trauma may be accompanied by hemothorax, a condition called *hemo-pneumothorax.*

Types of Pneumothorax

Closed Pneumothorax.

Closed pneumothorax has no associated external wound. The most common form is a spontaneous pneumothorax, which is accumulation of air in the pleural space without an apparent antecedent event. It is caused by the rupture of small **blebs** (air-filled alveolar dilations <1 cm in diameter on the edge of the lung at the apex of the upper lobe or superior segment of the lower lobe) on the visceral pleural space. The cause of the blebs is unknown. This condition occurs most commonly in underweight male cigarette smokers between 20 and 40 years of age. There is a tendency for this condition to recur.

Other causes of closed pneumothorax include the following:

- Injury to the lungs from mechanical ventilation
- Injury to the lungs from insertion of a subclavian catheter
- Perforation of the esophagus
- Injury to the lungs from broken ribs
- Ruptured blebs or bullae in a patient with COPD

Open Pneumothorax.

Open pneumothorax occurs when air enters the pleural space through an opening in the chest wall (Figure 30-5, *B*). Examples include stab or gunshot wounds and surgical thoracotomies. A penetrating chest wound is often referred to as a *sucking chest wound.*

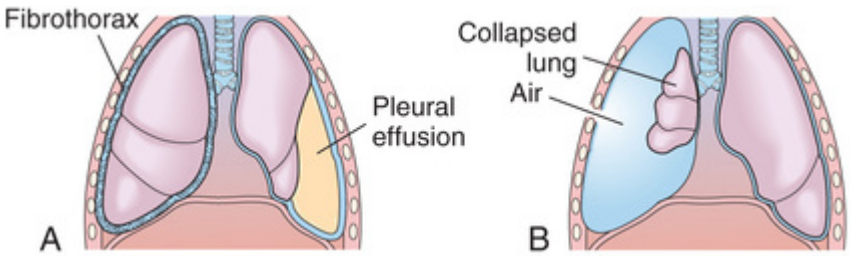

FIGURE 30-5 Disorders of the pleura. **A,** Fibrothorax resulting from an organization of inflammatory exudate and pleural effusion. **B,** Open pneumothorax resulting from collapse of the lung caused by disruption of the chest wall and outside air entering.

An open pneumothorax should be covered with a vented dressing. (A vented dressing is one secured on three sides with the fourth side left untaped.) This allows air to escape from the vent and decreases the likelihood of tension pneumothorax developing. If the object that caused the open chest wound is still in place, it should not be removed until a physician is present. The impaling object should be stabilized with a bulky dressing.

Tension Pneumothorax.

Tension pneumothorax is a pneumothorax with rapid accumulation of air in the pleural space, causing severely high intrapleural pressures with resultant tension on the heart and great vessels. It may result from either an open or a closed pneumothorax (Figure 30-6). In an open chest wound, a flap may act as a one-way valve; thus, air can enter on inspiration but cannot escape. The intrathoracic pressure increases, the lung collapses, and the mediastinum shifts toward the unaffected side, which is subsequently compressed. As the pressure increases, cardiac output is altered because of decreased venous return and compression of the vena cava and aorta. Tension pneumothorax can occur with mechanical ventilation and resuscitative efforts. It can also occur if chest tubes are clamped or become blocked in a patient with a pneumothorax. Unclamping the tube or relieving the obstruction will remedy this situation.

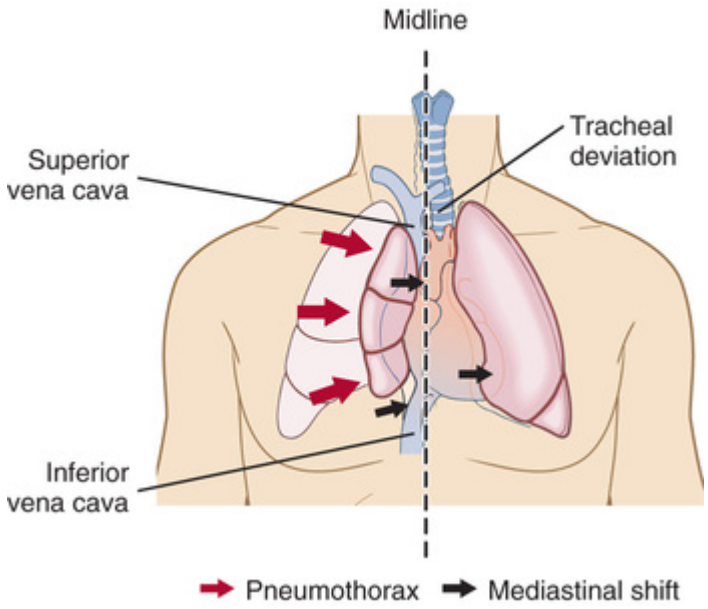

FIGURE 30-6 Tension pneumothorax. As pleural pressure on the affected side increases, mediastinal displacement ensues with resultant respiratory and cardiovascular compromise.

Tension pneumothorax is a medical emergency with both the respiratory and the circulatory systems affected. If the tension in the pleural space is not relieved, the patient is likely to die from inadequate cardiac output or marked hypoxemia. Nurses and paramedics are now being trained to insert large-bore needles and chest tubes into the chest wall to release the trapped air.

Hemothorax.

Hemothorax is an accumulation of blood in the intrapleural space. It is frequently found in association with open pneumothorax and is then called a *hemo-pneumothorax.* Causes of hemothorax include chest trauma, lung malignancy, complications of anticoagulant therapy, pulmonary embolus, and tearing of pleural adhesions.

Chylothorax.

Chylothorax is the presence of lymphatic fluid in the pleural space because of a leak in the thoracic duct. Causes include trauma, surgical procedures, and malignancy. The thoracic duct is disrupted, and the chylous fluid, milky white with high lipid content, fills the

pleural space. Total lymphatic flow through the thoracic duct is 1 500 to 2 400 mL/day. Fifty percent of those affected will heal with conservative treatment (chest drainage, bowel rest, and total parenteral nutrition). Surgery and pleurodesis are options if conservative therapy fails. *Pleurodesis* is the artificial production of adhesions between the parietal and the visceral pleurae, usually done with a chemical sclerosing agent.

Clinical Manifestations

If the pneumothorax is small, mild tachycardia and dyspnea may be the only manifestations. If the pneumothorax is large, respiratory distress may be present, including shallow, rapid respirations; dyspnea; air hunger; and decreased oxygen saturation. Chest pain and a cough with or without hemoptysis may be present. On auscultation, there are no breath sounds over the affected area, and hyper-resonance may be present. A chest radiograph shows the presence of air or fluid in the pleural space. If a tension pneumothorax develops, the patient experiences severe respiratory distress, tachycardia, and hypotension. Mediastinal displacement occurs, and the trachea shifts to the unaffected side. The patient is hemodynamically unstable.

Collaborative Care

Treatment depends on the severity of the pneumothorax and the nature of the underlying disease. If the patient is stable and the amount of air and fluid accumulated in the intrapleural space is minimal, no treatment may be needed as the pneumothorax resolves spontaneously. If the amount of air or fluid is minimal, the pleural space can be aspirated with a large-bore needle. As a life-saving measure, needle venting (using a large-bore needle) of the pleural space may be used. A Heimlich valve may also be used to evacuate air from the pleural space. The most definitive and common form of treatment of pneumothorax and hemothorax is the insertion of a chest tube that is connected to water-seal drainage. Repeated spontaneous pneumothorax may have to be treated surgically by a

partial pleurectomy, stapling, or pleurodesis to promote adherence of the pleurae to one another.

Fractured Ribs

Rib fractures are the most common type of chest injury resulting from trauma. Ribs 5 through 10 are most commonly fractured because they are least protected by chest muscles. If the fractured rib is splintered or displaced, it may damage the pleura and the lungs.

Clinical manifestations of fractured ribs include pain (especially on inspiration) at the site of injury. The individual splints the affected area and takes shallow breaths to try to decrease the pain. The individual is reluctant to take deep breaths, and the decreased ventilation may cause atelectasis to develop.

The main goal of treatment is to decrease pain so that the patient can breathe adequately to promote good chest expansion. Intercostal nerve blocks with local anaesthesia may be used to provide pain relief. The effect of the anaesthesia lasts for a period of hours to days. It must be repeated as necessary to provide pain relief. Opioid drug therapy must be individualized and used with caution because these drugs can depress respirations. Nonsteroidal anti-inflammatory drugs are used to reduce pain and aid with deep breathing and coughing. Patient teaching should emphasize deep breathing, coughing, use of incentive spirometry, and use of pain medications. Strapping the chest with tape or using a binder is not common practice. Most physicians believe that these measures should be avoided because they reduce lung expansion and predispose the individual to atelectasis.

Flail Chest

Flail chest results from multiple rib fractures, causing instability of the chest wall (Figure 30-7). The chest wall cannot provide the bony structure necessary to maintain bellows action and ventilation. The affected (flail) area will move paradoxically to the intact portion of the chest during respiration. During inspiration, the affected portion is sucked in, and during expiration, it bulges out. This paradoxical chest movement prevents adequate ventilation of the lung in the

injured area. The underlying lung may or may not have a serious injury. Associated pain and any lung injury giving rise to loss of compliance will contribute to an alteration in breathing patterns and lead to hypoxemia.

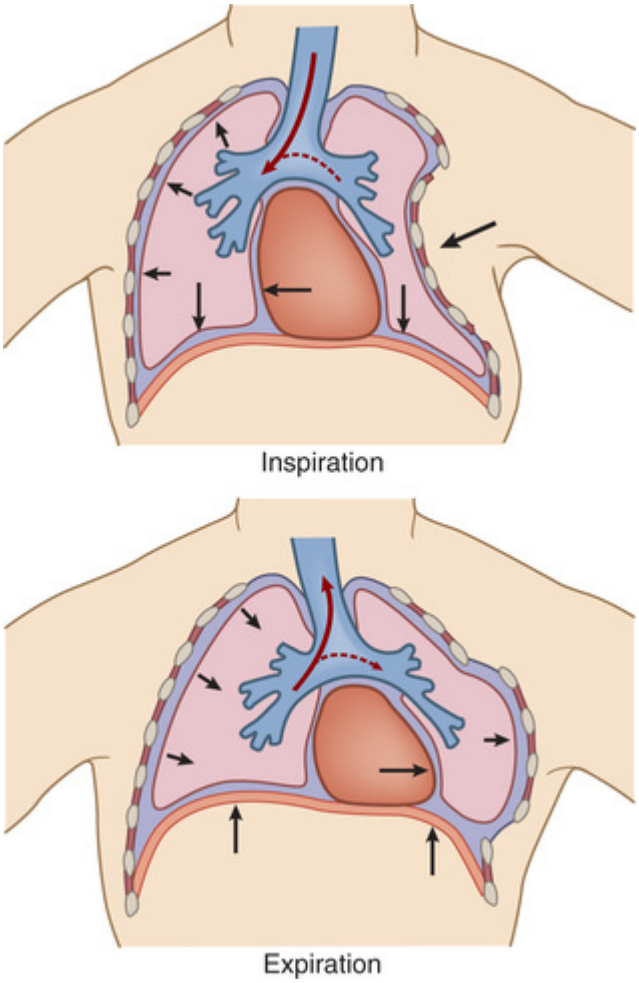

FIGURE 30-7 Flail chest produces paradoxical respiration. On inspiration, the flail section sinks in with the mediastinal shift to the uninjured side. On expiration, the flail section bulges outward with the mediastinal shift to the injured side.

A flail chest is usually apparent on visual examination of the unconscious patient. The patient manifests rapid, shallow respirations and tachycardia. A flail chest may not be initially apparent in the conscious patient as a result of splinting of the chest wall. The patient moves air poorly, and movement of the thorax is

asymmetrical and uncoordinated. Palpation of abnormal respiratory movements, crepitus of the rib, chest radiography, and ABG assessment assist in diagnosis.

Initial therapy consists of adequate ventilation, administration of humidified oxygen (O_2), careful administration of crystalloid IV solutions, and pain control. The definitive therapy is to re-expand the lung and ensure adequate oxygenation. Although many patients can be managed without the use of mechanical ventilation, a short period of intubation and ventilation may be necessary until the diagnosis of the lung injury is complete. The lung parenchyma and fractured ribs will heal with time. Some patients continue to experience intercostal pain after the flail chest has resolved.

Chest Tubes and Pleural Drainage

The purpose of chest tubes and pleural drainage is to remove the air and fluid from the pleural space and to restore normal intrapleural pressure so that the lungs can re-expand. (Intrapleural pressure, also known as intrathoracic pressure, and the intrapleural space are described in Chapter 28.) Small accumulations of air or fluid in the pleural space may not require removal by thoracentesis or chest tube insertion. Instead, the air and fluid may be reabsorbed over time.

Chest Tube Insertion

Chest tubes can be inserted in the emergency department, at the patient's bedside, or in the operating room, depending on the situation. In the operating room, the chest tube is inserted via the thoracotomy incision. In the emergency department or at the bedside, the patient is placed in a sitting position or is lying down with the affected side elevated. The area is prepared with antiseptic solution, and the site is infiltrated with a local anaesthetic agent. After a small incision is made, one or two chest tubes are inserted into the pleural space. One catheter is placed anteriorly through the second intercostal space to remove air (Figure 30-8). The other is placed posteriorly through the eighth or ninth intercostal space to drain fluid and blood. The tubes are sutured to the chest wall, and

the puncture wound is covered with an airtight dressing. During insertion, the tubes are kept clamped. After the tubes are in place in the pleural space, they are connected to drainage tubing and pleural drainage, and the clamp is removed. Each tube may be connected to a separate drainage system and suction. More commonly, a Y-connector is used to attach both chest tubes to the same drainage system.

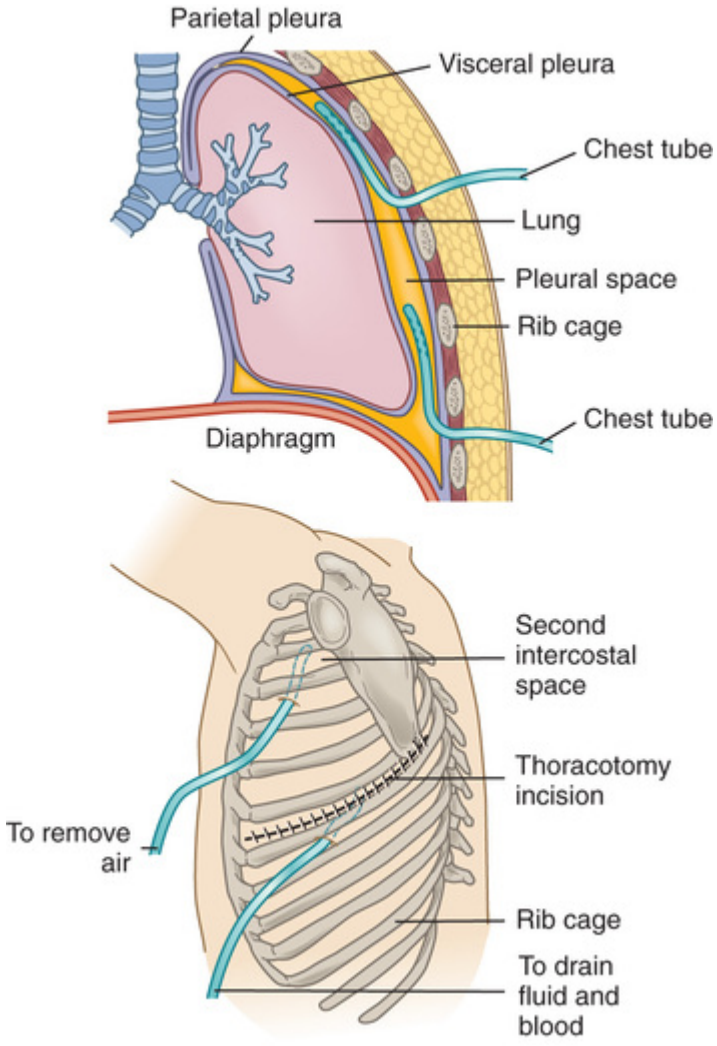

FIGURE 30-8 Placement of chest tubes.

Pleural Drainage

Most pleural drainage systems have three basic compartments, each with its own separate function.

The first compartment, the *collection chamber,* receives fluid and air from the chest cavity. The fluid stays in this chamber while the air vents to the second compartment (Figure 30-9). The second compartment, called the *water-seal chamber,* contains 2 cm of water, which acts as a one-way valve. The incoming air enters from the collection chamber and bubbles up through the water. (The water acts as a one-way valve to prevent backflow of air into the patient from the system.) Initial bubbling of air is seen in this chamber when a pneumothorax is evacuated. Intermittent bubbling can also be seen during exhalation, coughing, or sneezing because of an increase in the patient's intrathoracic pressure. In this chamber, fluctuations, or "tidalling," will be seen and reflect the pressures in the pleural space. If tidalling is not seen, either the lungs have re-expanded or there is a kink or obstruction in the tubing. The air then exits the water seal and enters the suction chamber.

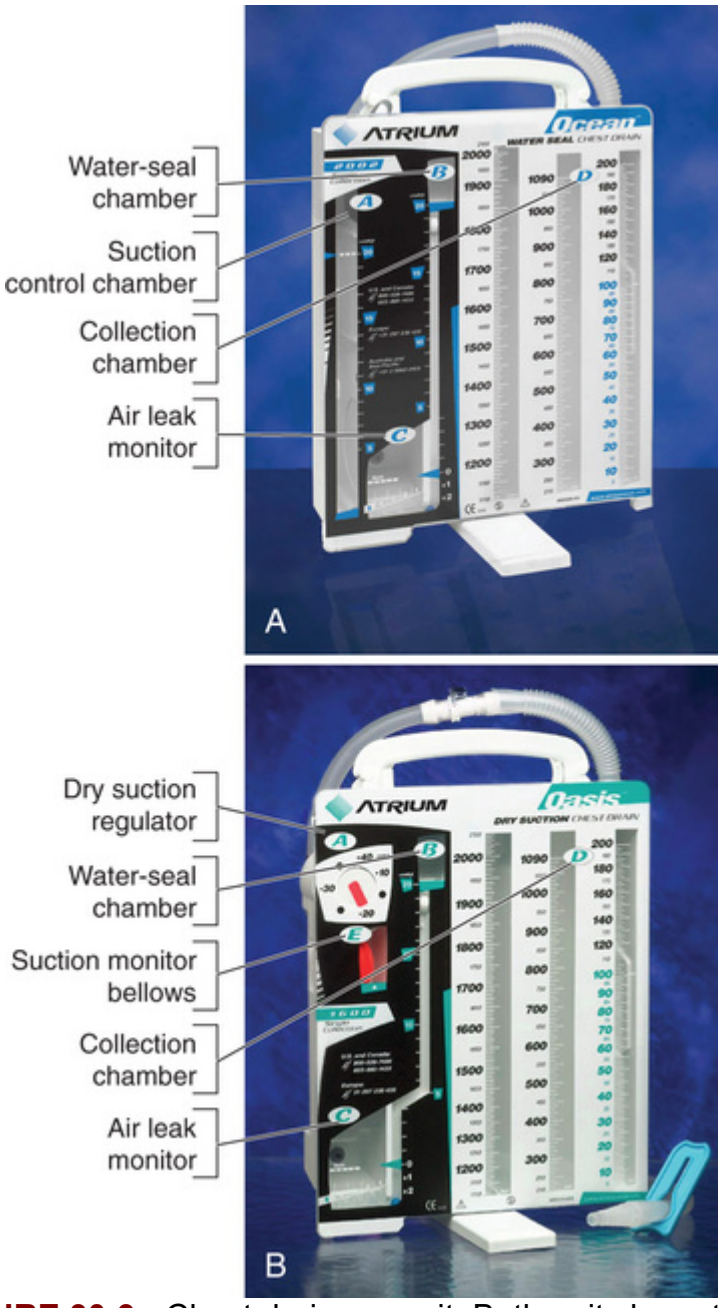

FIGURE 30-9 Chest drainage unit. Both units have three chambers: (1) collection chamber; (2) water-seal chamber; and (3) suction control chamber. The suction control chamber requires a connection to a wall suction source that is dialed up higher than prescribed so that the suction will work. **A,** Water suction. This unit uses water in the suction control chamber to control the wall suction pressure. **B,** Dry suction. This unit controls wall suction by using a regulator control dial. Source: Getinge Group, Merrimack, NH.

A third compartment, the *suction control chamber,* applies controlled suction to the chest drainage system. The classic suction control chamber uses tubing with one end submerged in a column of water and the other end vented to the atmosphere. It is typically filled with 20 cm of water. When the negative pressure generated by the suction source exceeds 20 cm, the air from the atmosphere enters the chamber through a vent and begins bubbling up through the water. As a result, excess pressure is relieved. The amount of suction applied is regulated by the depth of the suction control tube in the water and not by the amount of suction applied to the system. An increase in suction does not result in an increase in negative pressure to the system because any excess suction merely draws in air through the vented tubing. The suction pressure is usually ordered to be −20 cm H_2O.

Two types of suction control chambers are available on the market: wet and dry. The wet suction control chamber system is the classic system outlined previously. Bubbling is one way to tell that suction is functioning. Suction is started by turning up the vacuum source until gentle bubbling appears. Turning the vacuum source higher just makes the bubbling more vigorous and makes the water evaporate faster. Even with gentle bubbling, water evaporates in this chamber, and water must be added periodically. The dry suction control chamber system, on the other hand, contains no water. It uses either a restrictive device or a regulator, internal to the chest drainage system, to dial the desired negative pressure. The dry system has a visual alert that indicates if the suction is working, so bubbling is not seen in a third chamber. The suction pressures are increased by turning the dial on the drainage system. Increasing the vacuum suction source will not increase the pressure (see Figure 30-9).

A variety of commercial disposable plastic chest drainage systems are available. The manufacturer's suggestions for use are included with the equipment. The plastic units allow the patient mobility and decrease the risk of breaking or spilling the drainage system.

Informatics in Practice

Chest Drainage System

- A nurse needs to set up a chest drainage system but has not done so since simulation lab in nursing school.
- On the Internet, find a procedure manual, watch a video, or listen to a podcast of the procedure that would aid the nurse in this situation.

Heimlich Valves.

Another device that may be used to evacuate air from the pleural space is the Heimlich valve (Figure 30-10). This device consists of a rubber flutter one-way valve within a rigid plastic tube. It is attached to the external end of the chest tube. The valve opens whenever the pressure is greater than the atmospheric pressure and closes when the reverse occurs. The Heimlich valve functions like a water seal and is usually used for emergency transport or in special home care situations.

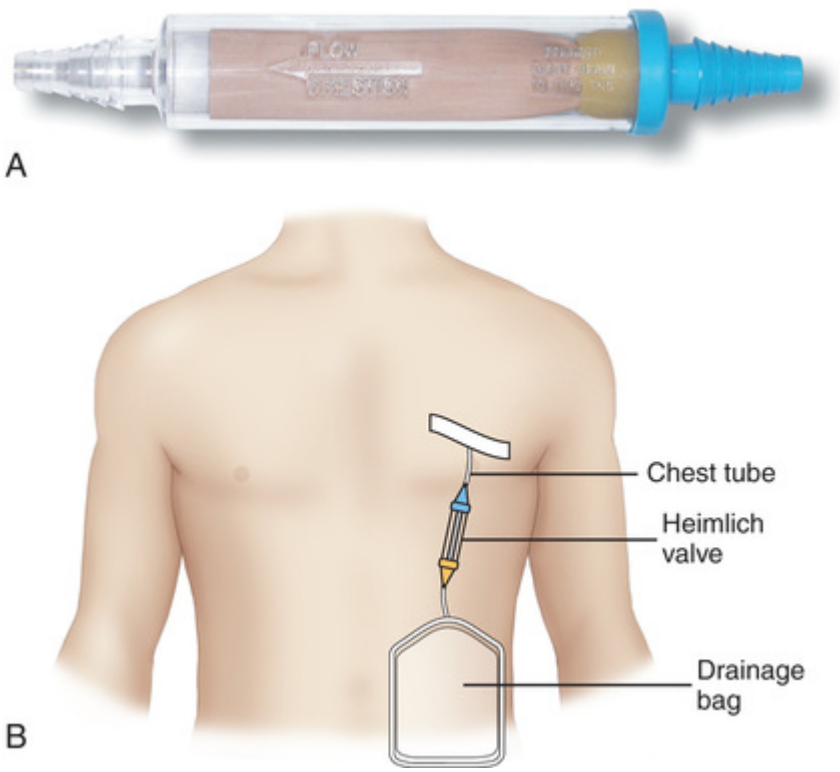

FIGURE 30-10 **A,** The Heimlich chest drain valve is a specially designed flutter valve that is used in place of a chest drainage unit for small, uncomplicated pneumothorax with little or no drainage and no need for suction. The valve allows for escape of air but prevents the re-entry of air into the pleural space. **B,** The valve is placed between the chest tube and the drainage bag, which can be worn under a person's clothes.

Small Chest Tubes.

Small chest tubes ("pigtail catheters") are used in selected patients because they are less traumatic. The drains may be straight catheters or "pigtail" catheters (curled at the distal end, resembling a pig's tail). Curled catheters are considered to be less traumatic than straight catheters. These catheters, if occluded, can be irrigated by the physician using sterile water. Chemical pleurodesis can also be performed through this catheter. This system is not suitable for trauma or for drainage of blood. Owing to the smaller size, the tube can become kinked, occluded, or dislodged more easily. Small-bore chest tubes and Heimlich valves should be used with caution in

patients on mechanical ventilators because there is a potential for rapid accumulation of air and a tension pneumothorax (Light, 2011).

Nursing Management Chest Drainage

Some general guidelines for nursing care of the patient with chest tubes and water-seal drainage systems are presented in Table 30-19. The traditional practice of routine milking or stripping of chest tubes to maintain patency is no longer recommended because it can cause dangerously high intrapleural pressure and damage to pleural tissue. Drainage and blood are not likely to clot inside chest tubes because the newer chest tubes are made with a coating that makes them nonthrombogenic. The nurse should remember that insertion of the chest tube, as well as its continued presence, can be painful to the patient. Dislodgement of the tube may occur if the tube is not stabilized.

TABLE 30-19

CLINICAL GUIDELINES FOR CARE OF PATIENT WITH CHEST TUBES AND WATER-SEAL DRAINAGE SYSTEM

1. Keep all tubing loosely coiled below chest level. Tubing should drop straight from bed or chair to drainage unit. Do not let it be compressed.
2. Keep all connections between chest tubes, drainage tubing, and drainage collector tight, and tape at connections.
3. Observe for air fluctuations (tidalling) and bubbling in the water-seal chamber.
    - If no tidalling is observed (rising with inspiration and falling with expiration in the spontaneously breathing patient), the drainage system is blocked, the lungs are re-expanded, or the system is attached to suction.
    - If bubbling increases, there may be an air leak in the drainage system or a leak from the patient (bronchopleural leak).
4. If the chest tube is connected to suction, disconnect from wall suction to check for tidalling.
5. Suspect a system leak when bubbling is continuous.
    - To determine the source of the air leak, momentarily clamp the tubing successively from the chest tube insertion site to the drainage set, observing for the bubbling to cease. When bubbling ceases, the leak is above the clamp.
    - Retape tubing connections.
    - If leak continues, notify physician. It may be necessary to replace the drainage apparatus or to secure the chest tube with an air-occlusive dressing.
6. High fluid levels in the water seal indicate residual negative pressure.
    - The chest system may need to be vented by using the high negativity release valve available on the drainage system to release residual pressure from the system.
    - Do not lower water-seal column when wall suction is not operating or when patient is on gravity drainage.

Patient's Clinical Status

1. Monitor the patient's clinical status. Assess vital signs, lung sounds, pain.
2. Assess for manifestations of reaccumulation of air and fluid in the chest (↓ or absent breath sounds), significant bleeding (>100 mL/hr), chest drainage site infection (drainage, erythema, fever, ↑ white blood cell count), or poor wound healing. Notify physician for management plan. Evaluate for subcutaneous emphysema at chest tube site.
3. Encourage the patient to breathe deeply periodically to facilitate lung expansion, and encourage range-of-motion exercises to the shoulder on the affected side. Incentive spirometry every hour while awake may be necessary to prevent atelectasis or pneumonia.
4. Chest tubes are *not routinely clamped.* A physician order is required. A physician may order clamping for 24 hours to evaluate for reaccumulation of fluid or air before discontinuing the chest tube.

Chest Drainage

1. Never elevate the drainage system to the level of the patient's chest because doing so will cause fluid to drain back into the lungs. Secure the unit to the drainage stand. If the drainage chambers are full, notify the physician and anticipate changing the system. Do not try to empty it.
2. Mark the time of measurement and the fluid level on the drainage unit according to the unit standards. Report any change in the quantity or characteristics of drainage (e.g., clear yellow to bloody) to the physician and record the change. Notify physician if >100 mL/hr drainage.
3. Check the position of the chest drainage container. If the drainage system is overturned and the water seal is disrupted, return it to an upright position and encourage the patient to take a few deep breaths, followed by forced exhalations and cough manoeuvres.
4. If the drainage system breaks, place the distal end of the chest tubing connection in a sterile water container at a 2-cm level as an emergency water seal.
5. Do not strip chest tubes. Doing so dangerously increases intrapleural pressures. Drainage tubes may be milked (alternately folded or squeezed and then released) on physician order. Milk only if drainage has evidence of clots or obstruction. Take 15-cm strips of the chest tube and squeeze and release starting close to the chest and repeating down the tube distally.

Monitoring Wet Versus Dry Suction Chest Drainage Systems
Suction Control Chamber in Wet Suction System
1. Keep the suction control chamber at the appropriate water level by adding sterile water as needed to replace water lost to evaporation. 2. Keep the muffler covering the suction control chamber in place to prevent more rapid evaporation of water and to decrease the noise of the bubbling. 3. After filling the suction control chamber to the ordered suction amount (generally −20 cm water suction), connect the suction tubing to the wall suction. 4. Dial the wall suction regulator until continuous gentle bubbling is seen in the suction control chamber (generally 80–120 mm Hg). Vigorous bubbling is not necessary and will increase the rate of evaporation. 5. If no bubbling is seen in the suction control chamber, (a) there is no suction, (b) the suction is not set high enough, or (c) the pleural air leak is so large that suction is not high enough to evacuate it.
Suction Control Chamber in Dry Suction System (See Manufacturer's Directions)
• After connecting patient to system, turn the dial on the chest drainage system to amount ordered (generally −20 cm pressure), connect suction tubing to wall suction source, and increase the suction until the correct amount of negative pressure is indicated. There will be a high negative-pressure release valve in the system.
Chest Tube Dressings
1. Dressings are not routinely changed. If there is visible drainage, notify physician for instructions. 2. If ordered to change dressings, remove old dressing carefully to avoid removing unsecured chest tube. Assess the site, and culture site as indicated. 3. Cleanse the site with sterile normal saline. Apply sterile gauze and tape to secure the dressing. Some physicians may prefer use of petroleum gauze dressing around the tube to prevent air leak. Date the dressing and document dressing change.
Obtaining a Sample From the Chest Tube
1. Form a loop in the tubing in an area to get the most recently drained fluid. 2. Swab the sampling site of the tubing with antiseptic and allow to air-dry. 3. Aspirate from the sampling site with syringe; cap syringe; label with patient name, date, time, and source of specimen. 4. Send to laboratory.

Clamping of chest tubes during transport or when the tube is accidentally disconnected is no longer advocated. The danger of rapid accumulation of air in the pleural space causing tension pneumothorax is far greater than that of a small amount of atmospheric air entering the pleural space. Chest tubes may be momentarily clamped to change the drainage apparatus or to check for air leaks. Clamping for more than a few moments is indicated only for assessing how the patient will tolerate chest tube removal. It is done to simulate chest tube removal and identify if there will be negative clinical repercussions with tube removal. Generally, this is done 4 to 6 hours before the tube is removed, and the patient is monitored closely. If a chest tube becomes disconnected, the most important intervention is immediate re-establishment of the water-seal system and attachment of a new drainage system as soon as possible. In some hospitals, when disconnection occurs, the chest tube is immersed in sterile water (≈2 cm) until the system can be re-

established. It is important for the nurse to know the unit protocol, individual clinical situation (e.g., whether an air leak exists), and physician preference before resorting to prolonged chest tube clamping.

As with many procedures, the hospital may have policies and procedures referring to the care of chest tubes. Ensure that these are reviewed and followed.

Complications

Chest tube malposition is the most common complication. The nurse does routine monitoring to evaluate whether the chest drainage is successful by observing for tidalling in the water-seal chamber, listening for breath sounds over the lung fields, and measuring the amount of fluid drainage. Re-expansion pulmonary edema can occur after rapid expansion of a collapsed lung in patients with a pneumothorax or with evacuation of large volumes of pleural fluid (>1 to 1.5 L). A vasovagal response with symptomatic hypotension can occur from too rapid removal of fluid.

Infection at the skin site is also a concern. Meticulous sterile technique during dressing changes can reduce the incidence of infected sites. Other complications include (a) pneumonia from not taking deep breaths, from not using an incentive spirometer, and from splinting on the affected side and (b) shoulder disuse ("frozen shoulder") from lack of range-of-motion exercises. Poor patient adherence or lack of patient teaching can contribute to these complications. Nurses can make a tremendous impact on preventing these complications.

Chest Tube Removal

The patient with chest tubes may have chest radiographic studies to follow the course of lung expansion. The chest tubes are removed when the lungs are re-expanded and fluid drainage has ceased. Generally, suction is discontinued, and the patient is placed on gravity drainage for a period of time before the tubes are removed. The tube is removed by cutting the sutures; applying a sterile petroleum jelly gauze dressing; having the patient take a deep

breath, exhale, and bear down (Valsalva manoeuvre); and then removing the tube. Pain medication is generally given before chest tube removal. The site is covered with an airtight dressing, the pleura seals itself off, and the wound heals in several days. A chest radiograph is obtained after chest tube removal to evaluate for pneumothorax, reaccumulation of fluid, or both. The wound should be observed for drainage and should be reinforced if necessary. The patient should be observed for respiratory distress, which may signify a recurrent or new pneumothorax.

Chest Surgery

Chest surgery is performed for a variety of reasons, some of which are unrelated to primary lung problems. For example, a thoracotomy may be performed for heart and esophageal surgery. The types of chest surgery are compared in Table 30-20.

TABLE 30-20
CHEST SURGERIES

Type and Description	Indication	Comments
Lobectomy		
Removal of one lobe of lung	Lung cancer, bronchiectasis, TB, emphysematous bullae, benign lung tumours, fungal infections	Most common lung surgery; postoperative insertion of chest tubes; expansion of remaining lung tissue to fill up space
Pneumonectomy		
Removal of entire lung	Lung cancer (most common), extensive TB, bronchiectasis, lung abscess	Done only when lobectomy or segmental resection will not remove all diseased lung; no drainage tubes (generally), fluid gradually fills space where lung was; patient positioned on operative side to facilitate expansion of remaining lung
Segmental Resection		
Removal of one or more lung segments	Lung cancer, bronchiectasis, TB	Technically difficult; done to remove lung segment; insertion of chest tubes; expansion of remaining lung tissue to fill space
Wedge Resection		
Removal of small, localized lesion that occupies only part of a segment	Lung biopsy, excision of small nodules	Need for chest tubes after surgery
Decortication		
Removal of thick, fibrous membrane from visceral pleura	Empyema	Use of chest tubes and drainage after surgery
Exploratory Thoracotomy		
Incision into thorax to look for injured or bleeding tissues	Chest trauma	Use of chest tubes and drainage after surgery
Thoracotomy Not Involving Lungs*		
Incision into thorax for surgery on other organs	Hiatal hernia repair, open-heart surgery, esophageal surgery, tracheal resection, aortic aneurysm repair	
Video-Assisted Thoracoscopic Surgery (VATS)		
VATS under general anaesthesia in OR	Procedures performed using VATS include lung biopsy, lobectomy, resection of nodules, repair of fistulas	Video-assisted technique involving insertion of a rigid scope with a distal lens into the pleura with image shown on a monitor screen, allowing surgeon to manipulate instruments passed into the pleural space through separate small intercostal incisions
Lung Volume Reduction Surgery (LVRS)		
	Advanced bullous emphysema, α_1-antitrypsin emphysema	Involves reducing lung volume by multiple wedge excisions or VATS (see Video-Assisted Thoracoscopic Surgery)

*For comments on thoracotomy not involving the lungs, see discussion of individual diseases in text.

OR, operating room; *TB,* tuberculosis.

Preoperative Care

Before chest surgery, baseline data are obtained on the respiratory and cardiovascular systems. Diagnostic studies performed are pulmonary function, chest radiography, electrocardiogram (ECG), ABGs, blood urea nitrogen (serum urea [nitrogen]), serum creatinine, blood glucose, serum electrolytes, and complete blood cell count. Additional studies of cardiac function such as cardiac catheterization may be done for the patient who is to undergo a pneumonectomy. A careful physical assessment of the lungs, including percussion and auscultation, should be done. This will allow the nurse to compare preoperative and postoperative findings.

The patient should be encouraged to stop smoking before surgery to decrease secretions and increase O_2 saturation. In the anxious period before surgery, refraining from smoking is not easy for the habitual smoker to do. Chest physiotherapy may be indicated to help drain the lungs of accumulated secretions. This is especially indicated for the patient with a lung abscess or bronchiectasis.

Preoperative teaching should include exercises for effective deep breathing and incentive spirometry. If the patient practices these techniques before surgery, the techniques will be easier to perform after surgery. The patient should be told that adequate medication will be given to reduce the pain and should be helped to splint the incision with a pillow to facilitate deep breathing.

For most types of chest surgery, chest tubes are inserted and connected to water-sealed drainage systems. The purpose of these tubes should be explained to the patient. In addition, O_2 is frequently given the first 24 hours after surgery. Range-of-motion exercises on the surgical side, similar to those for the mastectomy patient, should be taught (see Chapter 54).

The thought of losing part of a vital organ is frequently frightening. The patient should be reassured that the lungs have a

large degree of functional reserve. Even after the removal of one lung, there is enough lung tissue to maintain adequate oxygenation.

The nurse should be available to deal with the questions asked by the patient and the family, and questions should be answered honestly. The nurse should try to facilitate the expression of concerns, feelings, and questions. (General preoperative care and teaching are discussed in Chapter 20.)

Surgical Therapy

Thoracotomy (surgical opening into the thoracic cavity) surgery is considered major surgery because the incision is large and cuts into bone, muscle, and cartilage. The two types of thoracic incisions are median sternotomy, performed by splitting the sternum, and lateral thoracotomy. The median sternotomy is primarily used for surgery involving the heart. The two types of lateral thoracotomy are posterolateral and anterolateral. The posterolateral thoracotomy is used for most surgeries involving the lung. The incision is made from the anterior axillary line below the nipple level posteriorly at the fourth, fifth, or sixth intercostal space. It is rarely necessary to remove the ribs. Strong mechanical retractors are used to gain access to the lung. The anterolateral incision is made in the fourth or fifth intercostal space from the sternal border to the midaxillary line. This procedure is commonly used for surgery or trauma victims, mediastinal operations, and wedge resections of the upper and middle lobes of the lung.

The extensiveness of the thoracotomy incision often results in severe pain for the patient after surgery. Because muscles have been severed, the patient is reluctant to move the shoulder and arm on the surgical side. Chest tubes are placed in the pleural space except in pneumonectomy surgery. In a pneumonectomy, the space from which the lung was removed gradually fills with serosanguinous fluid.

Video-Assisted Thorascopic Surgery.

Video-assisted thorascopic surgery (VATS) is a thorascopic surgical procedure that, in many cases, can enable the avoidance of a full

thoracotomy. The procedure involves three or four 2.5-cm incisions made on the chest that allow the thorascope (a special fibre-optic camera) and instruments to be inserted and manipulated. Video-assisted thorascopes improve visualization because the surgeon can view the thoracic cavity from the video monitor. The thorascope is equipped with a camera that magnifies the image on the monitor. Thorascopy can be used to diagnose and treat a variety of conditions of the lung, the pleura, and the mediastinum.

The candidate for this type of procedure should not have a prior history of conventional thoracic surgery because of the probability of adhesion formation, which would make access more difficult. The patient whose lesions are in the lung periphery or the mediastinum is a better candidate because of better accessibility. The patient considered for thorascopic surgery should have sufficient pulmonary function before surgery to allow the surgeon to perform conventional thoracotomy if complications occur. Complications that may occur are bleeding, diaphragmatic perforation, air emboli, persistent pleural air leaks, and tension pneumothorax.

There are many benefits of thorascopic surgery when compared with a conventional thoracotomy procedure. These include less adhesion formation, minimal blood loss, less time under anaesthesia, shorter hospitalization, faster recovery, less pain, and no need for postoperative rehabilitation therapy because of minimal disruption of thoracic structures.

Chest tubes are placed at the end of the procedure through one of the incisions. The incisions are closed with sutures or a wound-approximating adhesive bandage. Nursing assessment and care after surgery include monitoring respiratory status and lung re-expansion with the chest tubes and checking the incisions for drainage or dehiscence. The most common complication is prolonged air leak. A return to prior activities should be encouraged as quickly as possible. The hospital stay averages from 1 to 5 days, depending on the type of surgery.

Postoperative Care

Specific measures related to the care after a thoracotomy are presented in NCP 30-2, available on the Evolve website. The specific follow-up care depends on the type of surgical procedure. General postoperative care is discussed in Chapter 22.

Restrictive Respiratory Disorders

Restrictive respiratory disorders are characterized by a restriction in lung volume (caused by decreased compliance of the lungs or chest wall). This is in contrast to obstructive disorders, which are characterized by increased resistance to airflow (see Chapter 31). Pulmonary function tests are the best means of differentiating between restrictive and obstructive respiratory disorders (Table 30-21). Mixed obstructive and restrictive disorders are often manifested. For example, a patient may have both chronic bronchitis (an obstructive problem) and pulmonary fibrosis (a restrictive problem).

TABLE 30-21

RELATIONSHIP OF LUNG VOLUMES TO TYPE OF VENTILATORY DISORDER

Lung Volumes	Restrictive	Obstructive	Restrictive and Obstructive
Vital capacity (VC)	↓	Normal or ↓	↓
Total lung capacity (TLC)	↓	↑	Variable
Residual volume (RV)	Normal or ↓	↑	Variable
Forced expiratory volume in 1 sec (FEV_1)	Normal or ↓	↓	↓
FEV_1/Functional vital capacity (FVC)	Normal or ↑	↓	↓

Restrictive problems are generally categorized into extrapulmonary and intrapulmonary disorders. Extrapulmonary causes of restrictive lung disease include disorders involving the central nervous system, neuro-muscular system, and chest wall (Table 30-22). In these disorders, the lung tissue is normal. Intrapulmonary causes of restrictive lung disease involve the pleura or the lung tissue (Table 30-23).

TABLE 30-22
EXTRAPULMONARY CAUSES OF RESTRICTIVE LUNG DISEASE

Disease or Alteration	Description	Comments
Central Nervous System		
Head injury, CNS lesion (e.g., tumour, stroke)	Injury to or impingement on respiratory centre, causing hypoventilation or hyperventilation; relationship of manifestations to increased intracranial pressure (see Chapters 59 and 60)	Management is directed toward treating the underlying cause, maintaining the airway, using mechanical ventilation for supportive care, and assessing for manifestations of increased intracranial pressure.
Opioid and barbiturate use	Depression of respiratory centre, respiratory rate of <12 breaths/min	Respiratory depression is caused by drug overdose or inadvertent administration of drugs to a person with respiratory difficulty. These drugs should not be administered to a person with a respiratory rate of <12 breaths/min.
Neuro-Muscular System		
Spinal cord injury	Complete cervical- and complete upper thoracic–level injuries have restrictive ventilation. The lung volumes are reduced owing to inspiratory muscle weakness	Patient with a cervical injury may need mechanical ventilator support initially.
Guillain-Barré syndrome	Acute inflammation of peripheral nerves and ganglia; paralysis of intercostal nerves leading to diaphragmatic breathing; paralysis of vagal preganglionic and postganglionic fibres leading to reduced ability of bronchioles to constrict, dilate, and respond to irritants	Patient often has to be put on mechanical ventilation for supportive care (see Chapter 63).
Amyotrophic lateral sclerosis	Progressive degenerative disorder of the motor neurons in the spinal cord, brain stem, and motor cortex; respiratory system involvement as a result of interruption of nerve transmission to respiratory muscles, especially diaphragm	See Chapter 61 for clinical manifestations and management.
Myasthenia gravis	Defect in neuro-muscular junction; respiratory system involvement as a result of interruption of nerve transmission to respiratory muscles	See Chapter 61 for clinical manifestations and management.
Muscular dystrophy	Hereditary disease; eventual involvement of all skeletal muscles; paralysis of respiratory muscles, including intercostals, diaphragm, and accessory muscles	Pulmonary problems develop late in disease process.
Chest Wall		
Chest-wall trauma (e.g., flail chest, fractured rib)	Rib fracture causing inspiratory pain; voluntary splinting of chest, resulting in shallow, rapid breathing; impaired ventilatory ability caused by paradoxical breathing	Strapping the chest wall to stabilize the fractures is not recommended because this increases the restrictive defect.

Disease or Alteration	Description	Comments
Pickwickian syndrome (extreme obesity)	Excess adipose tissue interfering with chest-wall and diaphragmatic excursion, somnolence from hypoxemia and CO_2 retention, polycythemia from chronic hypoxia	Weight loss generally causes reversal of symptoms. Prevention and prompt treatment of respiratory infections is important. Condition is worsened in supine position.
Kyphoscoliosis	Posterior and lateral angulation of the spine; restriction of ventilation as a result of alteration in thoracic excursion; increase in work of breathing; pattern of rapid, shallow breathing; reduction of lung volume; compression of alveoli and blood vessels	Only a small number of people with condition develop severe respiratory problems. Atelectasis and pneumonia are common complications.

CNS, central nervous system; *CO_2*, carbon dioxide.

TABLE 30-23

INTRAPULMONARY CAUSES OF RESTRICTIVE LUNG DISEASE

Disease or Alteration	Description
Pleural disorders	Inflammation, scarring, or fluid in the pleural space causing restriction
Pleural effusion	Accumulation of fluid in pleural space secondary to altered hydrostatic or oncotic pressure; fluid collection >250 mL, showing up on chest radiograph
Pleurisy (pleuritis)	Inflammation of pleura; classification as fibrinous (dry) or serofibrinous (wet); wet pleurisy accompanied by an increase in pleural fluid and possibly resulting in pleural effusion
Pneumothorax	Accumulation of air in pleural space with accompanying lung collapse
Parenchymal disorders	Inflammation, collapse, or scarring of the lung tissue
Atelectasis	Condition of lung characterized by collapsed, airless alveoli; possibly acute (e.g., in postoperative patient) or chronic (e.g., in patient with malignant tumour)
Pneumonia	Acute inflammation of lung tissue caused by bacteria, viruses, fungi, chemicals, dusts, and other factors
Interstitial lung diseases (ILDs)	General term that includes a variety of chronic lung disorders characterized by some type of injury, inflammation, and scarring (or fibrosis); this process occurs in the interstitium (tissue between the alveoli), and the lung becomes stiff (fibrotic); can be caused by occupational and environmental exposures (see Table 30-10), infections (e.g., TB), and connective tissue disorders (e.g., rheumatoid arthritis); when all known causes of ILDs are ruled out, the condition is termed *idiopathic pulmonary fibrosis* (IPF)
Acute respiratory distress syndrome (ARDS)*	Atelectasis, pulmonary edema, congestion, and hyaline membrane lining the alveolar wall; result of variety of conditions, including shock lung, O_2 toxicity, Gram-negative sepsis, cardiopulmonary bypass, and aspiration pneumonia

*See Chapter 70 for clinical manifestations and management.

O_2, oxygen; *TB*, tuberculosis.

Pleural Effusion

Types

The pleural space lies between the lung and the chest wall and normally contains a very thin layer of fluid. **Pleural effusion** is a collection of fluid in the pleural space (see Figure 30-5, *A*). It is not a disease but rather a sign of a serious disease. Pleural effusion is frequently classified as *transudative* or *exudative* according to whether the protein content of the effusion is low or high, respectively. A transudate occurs primarily in noninflammatory conditions and is an accumulation of protein- and cell-poor fluid. Transudative pleural effusions (also called *hydrothorax*) are caused by (1) increased hydrostatic pressure found in heart failure, which is the most common cause of pleural effusion, or (2) decreased oncotic pressure (from hypoalbuminemia) found in chronic liver or renal disease. In these situations, fluid movement is facilitated out of the capillaries and into the pleural space.

An exudative effusion is an accumulation of fluid and cells in an area of inflammation. An exudative pleural effusion results from the increased capillary permeability characteristic of the inflammatory reaction. This type of effusion occurs secondary to conditions such as pulmonary malignancies, pulmonary infections, pulmonary embolization, and GI disease (e.g., pancreatic disease, esophageal perforation).

The type of pleural effusion can be determined from a sample of pleural fluid obtained via **thoracentesis** (a procedure to remove fluid from the pleural space). Exudates have a high protein content, and the fluid is generally dark yellow or amber. Transudates have a low protein content or contain no protein, and the fluid is clear or pale yellow. The fluid can also be analyzed for red and white blood cells, malignant cells, bacteria, and glucose.

An **empyema** is a pleural effusion that contains pus. It is caused by conditions such as pneumonia, TB, lung abscess, and infection of surgical wounds of the chest. Treatment of empyema is generally chest tube drainage. Appropriate antibiotic therapy is also needed to eradicate the causative organism. A complication of empyema is fibrothorax, in which there is fibrous fusion of the visceral and

parietal pleurae (see Figure 30-5, *A*). A condition called *trapped lung* can occur with effusions and empyema. It occurs when the visceral pleura becomes encased with a fibrous peel or rind. The fibrous peel causes severe pulmonary restriction. The pathological process affecting the visceral pleura prevents the lung from expanding and from filling the thoracic cavity. A decortication surgical procedure to remove the pleural peel may be needed.

Clinical Manifestations

Common clinical manifestations of pleural effusion are progressive dyspnea and decreased movement of the chest wall on the affected side. There may be pleuritic pain from the underlying disease. Physical examination of the chest will indicate dullness to percussion and absent or decreased breath sounds over the affected area. The chest radiograph will indicate an abnormality if the effusion is greater than 250 mL. Manifestations of empyema include the manifestations of pleural effusion as well as fever, night sweats, cough, and weight loss. A thoracentesis reveals an exudate containing thick, purulent material.

Thoracentesis

If the cause of the pleural effusion is not known, a diagnostic thoracentesis is needed to obtain pleural fluid for analysis (see Chapter 28, Figure 28-15). If the degree of pleural effusion is severe enough to impair breathing, a therapeutic thoracentesis is done to remove fluid as well as to obtain fluid for analysis.

A thoracentesis is performed by having the patient sit on the edge of a bed and lean forward over a bedside table. The puncture site is determined by chest radiograph, and percussion of the chest is used to assess the maximum degree of dullness. The skin is cleaned with an antiseptic solution and anaesthetized locally. The thoracentesis needle is inserted into the intercostal space. Fluid can be aspirated with a syringe, or tubing can be connected to allow fluid to drain into a sterile collection bag. After the fluid is removed, the needle is withdrawn, and a bandage is applied over the insertion site.

Usually, only 1 000 to 1 200 mL of pleural fluid is removed at one time. Because high volumes are removed, rapid removal can result in hypotension, hypoxemia, or pulmonary edema. A follow-up chest radiograph should be obtained to detect a possible pneumothorax that could have been induced by perforation of the visceral pleura. During and after the procedure, the patient should be observed for any manifestations of respiratory distress.

Collaborative Care

The main goal of management of pleural effusions is to treat the underlying cause. For example, adequate treatment of heart failure with diuretics and sodium restriction will result in decreased pleural effusions. The treatment of pleural effusions secondary to malignant disease represents a more difficult problem. These types of pleural effusions are frequently recurrent and accumulate quickly after thoracentesis. Chemical pleurodesis may be used to sclerose the pleural space and prevent reaccumulation of effusion fluid. Although doxycycline and bleomycin have been used for sclerosing with good results, talc appears to be the most effective agent for pleurodesis. Thoracoscopy can be used to perform talc pleurodesis after inspection of the pleural space. After instillation of the sclerosing agent, patients are usually instructed to rotate their positions to spread the agent uniformly throughout the pleural space. Chest tubes are left in place after pleurodesis until fluid drainage is less than 150 mL/day and no air leaks are noted.

Pleurisy

Pleurisy (pleuritis) is an inflammation of the pleura. The most common causes are pneumonia, TB, chest trauma, pulmonary infarctions, and neoplasms. The inflammation usually subsides with adequate treatment of the primary disease. Pleurisy can be classified as fibrinous (dry), with fibrinous deposits on the pleural surface, or serofibrinous (wet), with increased production of pleural fluid that may result in pleural effusion.

The pain of pleurisy is typically abrupt and sharp in onset and is aggravated by inspiration. The patient's breathing is shallow and

rapid to avoid unnecessary movement of the pleura and chest wall. A pleural friction rub may occur, which is the sound over areas where inflamed visceral and parietal pleurae rub over one another during inspiration. This sound is usually loudest at peak inspiration but can be heard during exhalation as well.

Treatment of pleurisy is aimed at treating the underlying disease and providing pain relief. Taking analgesics and lying on or splinting the affected side may provide some relief. The patient should be taught to splint the rib cage when coughing. Intercostal nerve blocks may be done if the pain is severe.

Atelectasis

Atelectasis is a complete or partial collapse of a lung or segment of a lung that occurs when the alveoli become deflated. The most common cause of atelectasis is airway obstruction that results from retained exudates and secretions, which is frequently observed in the postoperative patient. Normally, the pores of Kohn (see Chapter 28, Figure 28-1) provide for collateral passage of air from one alveolus to another. Deep inspiration is necessary to open the pores effectively. For this reason, deep-breathing exercises are important in preventing atelectasis in the high-risk patient (e.g., postoperative, immobilized patient). (The prevention and treatment of atelectasis are discussed in Chapter 22.)

Interstitial Lung Disease

Many acute and chronic lung disorders with variable degrees of pulmonary inflammation and fibrosis are collectively referred to as *interstitial lung diseases* (ILDs) or *diffuse parenchymal lung diseases*. ILDs have been difficult to classify because more than 200 known diseases have diffuse lung involvement, either as the primary condition or as a significant part of a multiorgan process, as may occur in connective tissue disorders (e.g., systemic lupus erythematosus, rheumatoid arthritis).

Among the ILDs of known cause, the largest group comprises occupational and environmental exposures, especially the inhalation of dusts and various fumes or gases. The most common ILDs of unknown etiology are idiopathic pulmonary fibrosis and sarcoidosis.

Idiopathic Pulmonary Fibrosis

Idiopathic pulmonary fibrosis (IPF) is characterized by scar tissue in the connective tissue of the lungs as a sequel to inflammation or irritation. A common risk factor for IPF is environmental or occupational inhalation of organic and inorganic substances (see discussion earlier in this chapter). Other risk factors include cigarette smoking and history of chronic aspiration. There also may be genetic risk factors.

Clinical manifestations of IPF include exertional dyspnea, nonproductive cough, and inspirational crackles with or without clubbing. High-resolution CT scan is the most definitive diagnostic study. Chest radiographic studies show changes characteristic of IPF. Pulmonary function tests show a typical pattern characteristic of restrictive lung disease (see Table 30-21). Open lung biopsy using VATS may help to differentiate the specific pathology.

The clinical course is variable, with a 5-year survival rate of 30% to 50% after diagnosis. Treatment includes corticosteroids, cytotoxic agents (azathioprine [Imuran], cyclophosphamide [Procytox]), and antifibrotic agents (colchicine). However, there is no good evidence that any of these treatments improves survival or quality of life.

Lung transplantation is an option that should be considered for those who meet the criteria. (Lung transplantation is discussed later in this chapter.)

Sarcoidosis

Sarcoidosis is a chronic, multisystem granulomatous disease of unknown cause that primarily affects the lungs. The disease may also involve skin, eyes, liver, kidney, heart, and lymph nodes. The disease is often acute or subacute and self-limiting, but in many individuals, it is chronic with remissions and exacerbations. Marked pulmonary fibrosis can be present with severe restrictive lung disease. Cor pulmonale and bronchiectasis can develop in the advanced stages.

Corticosteroids are the most commonly used drugs for the treatment of pulmonary sarcoidosis. A trial of methotrexate may be considered if the patient does not respond to or cannot tolerate corticosteroid therapy. If methotrexate is ineffective or not tolerated, cyclophosphamide (Procytox) or azathioprine (Imuran) may be initiated (King, 2017). Nonsteroidal anti-inflammatory agents, such as ibuprofen (Motrin), may help decrease acute inflammation or relieve symptoms but are not a treatment of sarcoidosis. Disease progression is monitored by pulmonary function tests, chest radiographic studies, and CT scan.

Vascular Lung Disorders

Pulmonary Edema

Pulmonary edema is an abnormal, life-threatening accumulation of fluid in the alveoli and the interstitial spaces of the lungs. It is a complication of various heart and lung diseases (Table 30-24) and is considered a medical emergency.

TABLE 30-24
CAUSES OF PULMONARY EDEMA

- Heart failure
- Overhydration with intravenous fluids
- Hypoalbuminemia: nephrotic syndrome, hepatic disease, nutritional disorders
- Altered capillary permeability of lungs: inhaled toxins, inflammation (e.g., pneumonia), severe hypoxia, near-drowning
- Malignancies of the lymph system
- Respiratory distress syndrome (e.g., oxygen toxicity)
- Unknown causes: neurogenic condition, opioid overdose, high altitude

Normally, there is a balance between the hydrostatic and the oncotic pressures in the pulmonary capillaries. If the hydrostatic pressure increases or the colloid oncotic pressure decreases, the net effect will be fluid leaving the pulmonary capillaries and entering the interstitial space, an event referred to as *interstitial edema.* At this stage, the lymphatic system can usually drain away the excess fluid. If fluid continues to leak from the pulmonary capillaries, it will enter the alveoli, an event referred to as *alveolar edema.* Pulmonary edema interferes with gas exchange by causing an alteration in the diffusing pathway between the alveoli and the pulmonary capillaries. The most common cause of pulmonary edema is left-sided heart failure. (The clinical manifestations and management of pulmonary edema are described in Chapter 37.)

Pulmonary Embolism

Etiology and Pathophysiology

Pulmonary embolism (PE) is the blockage of pulmonary arteries by a thrombus, fat or air embolus, or tumour tissue. The word *embolus* derives from a Greek word meaning "plug" or "stopper." Emboli are mobile clots that generally do not stop moving until they lodge at a narrowed part of the circulatory system. A PE consists of material that gains access to the venous system and then to the pulmonary circulation. The embolus travels with the blood flow through ever-smaller blood vessels until it lodges and obstructs perfusion of the alveoli (Figure 30-11). Because of higher blood flow, the lower lobes of the lung are commonly affected. PE is associated with a mortality rate of up to 30% in patients who are not treated. With diagnosis and anticoagulant therapy, the mortality rate is reduced to 6% to 8% (Hogg, Thomas, Mackway-Jones, et al., 2011). Most PEs arise from deep-vein thromboses (DVT) in the deep veins of the legs. *Venous thrombo-embolism* (VTE) is the preferred term to describe the spectrum of pathology from DVT to PE (see Table 40-7). Lethal PEs most commonly originate in the femoral or iliac veins. Generally, the VTEs that are below the knee have not been considered a risk factor for PE because they rarely migrate to the pulmonary circulation without first extending above the knee.

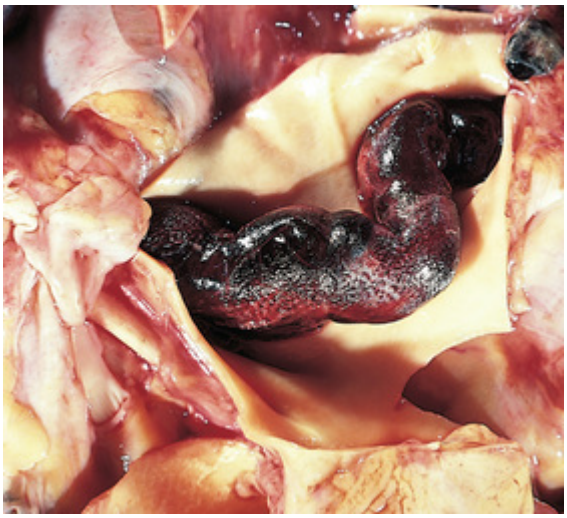

FIGURE 30-11 Large embolus from the femoral vein lying in the main left and right pulmonary arteries. Source: From the teaching collection of the Department of Pathology, University of Texas Southwestern Medical School, Dallas.

Other sites of origin of PE include the right side of the heart (especially with atrial fibrillation), the upper extremities (rare), and the pelvic veins (especially after surgery or childbirth). Upper-extremity VTE occasionally occurs in the presence of a central venous catheters or cardiac pacing wires. These cases may resolve with removal of the catheter. Thrombi in the deep veins can dislodge spontaneously. However, it is more common for mechanical forces (e.g., sudden standing) or changes in the rate of blood flow (e.g., those that occur with Valsalva manoeuvre) to dislodge the thrombus. The majority of patients with PE caused by VTE have no leg symptoms at the time of diagnosis (Thrombosis Canada, 2015). Less common causes of PE include fat emboli (from fractured long bones), air emboli (from improperly administered IV therapy), bacterial vegetations, amniotic fluid, and tumours. Tumour emboli may originate from primary or metastatic malignancies. Risk factors for PE include immobility or reduced mobility, surgery within the past 3 months (especially pelvic and lower-extremity surgery, including hip and knee joint replacement), history of DVT, malignancy, obesity, oral contraceptives, hormone therapy, cigarette smoking, prolonged air travel, heart failure, pregnancy, and clotting disorders.

Clinical Manifestations

The signs and symptoms in PE are varied and nonspecific, making diagnosis difficult. The classic triad—dyspnea, chest pain, and hemoptysis—occurs in only about 20% of patients. Symptoms may begin slowly or suddenly. A mild to moderate hypoxemia with a low partial pressure of carbon dioxide in arterial blood ($PaCO_2$) is a common finding. Other manifestations are cough, pleuritic chest pain, hemoptysis, crackles, fever, accentuation of the pulmonic heart sound, and sudden change in mental status as a result of hypoxemia. Massive emboli may produce abrupt hypotension, pallor, severe dyspnea, and hypoxemia. Chest pain may or may not be present. ECG may indicate tachycardia and right ventricular strain. The mortality rate of people with symptomatic PEs is approximately 10% (Thrombosis Canada, 2015). Medium-sized emboli often cause pleuritic chest pain, dyspnea, slight fever, and a productive cough with blood-streaked sputum. A physical examination may reveal tachycardia and a pleural friction rub. Small emboli frequently are undetected or produce vague, transient symptoms. The exception to this is the patient with underlying cardiopulmonary disease. In these patients, even small or medium-sized emboli may result in severe cardiopulmonary compromise. However, repeated small emboli gradually cause a reduction in the capillary bed and eventual pulmonary hypertension. An ECG and chest radiograph may indicate right ventricular hypertrophy secondary to pulmonary hypertension.

Complications

Pulmonary infarction (death of lung tissue) is most likely when the following factors are present: (a) occlusion of a large or medium-sized pulmonary vessel (>2 mm in diameter), (b) insufficient collateral blood flow from the bronchial circulation, or (c) pre-existing lung disease. Infarction results in alveolar necrosis and hemorrhage. Occasionally, the necrotic tissue becomes infected, and an abscess may develop. Concomitant pleural effusion is frequent. *Pulmonary hypertension* results from hypoxemia or from involvement of more than 50% of the area of the normal pulmonary bed. As a

single event, an embolus does not cause pulmonary hypertension unless it is massive. Recurrent emboli may result in chronic pulmonary hypertension.

Diagnostic Studies

A spiral (helical) CT scan is the most frequently used test to diagnose PE (see Table 30-25). An IV injection of contrast media is required to view the blood vessels. The scanner continuously rotates while obtaining slices and does not start and stop between each slice. This allows visualization of all anatomical regions of the lungs. The computer reconstructs the data to provide a three-dimensional picture and assist in emboli visualization. If a patient cannot have contrast media, a ventilation–perfusion (VQ) scan is done.

TABLE 30-25

COLLABORATIVE CARE
Acute Pulmonary Embolism

Diagnostic	Collaborative Therapy
• History and physical examination • Chest radiographic study • Continuous ECG monitoring • ABGs • Venous ultrasound • CBC count with WBC differential • Spiral (helical) CT scan • Ventilation–perfusion (VQ) scan • Lung scan • D-dimer level • Troponin level, BNP level • Pulmonary angiography	• Supplemental oxygen, intubation may be necessary • Fibrinolytic agent • Unfractionated heparin IV infusion • Low-molecular-weight heparin (e.g., enoxaparin [Lovenox]) • Warfarin (Coumadin) for long-term therapy • Monitoring of aPTT and INR levels • Limited activity • Opioids for pain relief • Inferior vena cava filter • Pulmonary embolectomy in life-threatening situation

ABGs, arterial blood gases; *aPTT,* activated partial thromboplastin time; *BNP,* B-type natriuretic peptide; *CBC,* complete blood cell; *CT,* computed tomography; *ECG,* electrocardiogram; *INR,* international normalized ratio; *IV,* intravenous; *WBC,* white blood cell.

The VQ scan has two components and is most accurate when both are performed:

1. Perfusion scanning involves IV injection of a radioisotope. A scanning device images the pulmonary circulation.

2. Ventilation scanning involves inhalation of a radioactive gas such as xenon. Scanning reflects the distribution of gas through the lung. The ventilation component requires the cooperation of the patient and may be impossible to perform in a critically ill patient, particularly if the patient is intubated.

D-dimer is a laboratory test that measures the amount of cross-linked fibrin fragments. These fragments are found in the circulation after clotting events such as VTE, acute myocardial infarction, unstable angina, and acute stroke. This degradation product is rarely found in healthy individuals. The disadvantage of D-dimer is that it is neither specific (other conditions cause elevation) nor sensitive because up to 50% of patients with small PEs have normal results. Patients with suspected PE and an elevated D-dimer level but normal venous ultrasound may need a lung scan or spiral CT.

Pulmonary angiography is a sensitive and specific test for PE. However, it is an invasive procedure that involves the insertion of a catheter through the antecubital or femoral vein, advancement to the pulmonary artery, and injection of contrast medium. It allows visualization of the pulmonary vascular system and location of the embolus. However, with spiral CT, pulmonary angiography is now used less frequently.

ABG analysis is important, but not diagnostic. The partial pressure of oxygen in arterial blood (PaO_2) is low because of inadequate oxygenation secondary to an occluded pulmonary vasculature preventing matching of perfusion to ventilation. The pH remains normal unless respiratory alkalosis develops as a result of prolonged hyperventilation or to compensate for lactic acidosis caused by shock. Abnormal findings are usually reported on the chest radiograph (atelectasis, pleural effusion) and on the ECG (ST-segment and T-wave changes), but they are not diagnostic for PE. Serum troponin levels are elevated in 30% to 50% of patients with PE, and, although not diagnostic, they are predictive of an adverse prognosis. Serum B-type natriuretic peptide levels, although not diagnostic, may be helpful in identifying the severity of the clinical course.

Collaborative Care

Prevention of PE begins with prevention of VTE. VTE prophylaxis includes the use of sequential compression devices, early ambulation, and prophylactic use of anticoagulant medications. To reduce mortality risk, treatment is begun as soon as PE is suspected (see Table 30-25). The objectives are to (a) prevent further growth or multiplication of thrombi in the lower extremities, (b) prevent embolization from the upper or lower extremities to the pulmonary vascular system, and (c) provide cardiopulmonary support if indicated.

Supportive therapy for the patient's cardiopulmonary status varies according to the severity of the PE. The administration of supplemental O_2 by mask or cannula is adequate for some patients. Oxygen is given in a concentration determined by ABG analysis. In some situations, endotracheal intubation and mechanical ventilation are necessary to maintain adequate oxygenation. Respiratory measures such as turning, coughing, deep breathing, and incentive spirometry are important to help prevent or treat atelectasis. If symptoms of shock are present, IV fluids are administered followed by vasopressor agents as needed to support perfusion (see Chapter 69). If heart failure is present, diuretics are used. (Heart failure is discussed in Chapter 37.) Pain resulting from pleural irritation or reduced coronary blood flow is treated with opioids, usually morphine.

Drug Therapy.

Fibrinolytic drugs, such as tissue plasminogen activator (tPA) or alteplase (Activase), dissolve the PE and the source of the thrombus in the pelvis or deep leg veins, thereby decreasing the likelihood of recurrent emboli. Indications for thrombolytic therapy in PE include hemodynamic instability and right ventricular dysfunction. (Thrombolytic therapy is discussed in Chapter 40; see Table 40-10.) Because most deaths are caused by recurrent PEs, treatment should begin immediately. Properly managed anticoagulant therapy is effective in the prevention of further emboli. Heparin works to prevent future clots but does not dissolve existing clots. Although

unfractionated heparin IV has traditionally been used, low-molecular-weight heparin (e.g., enoxaparin [Lovenox]) is becoming more common. Warfarin (Coumadin) should be initiated within the first 24 hours and is typically administered for 3 to 6 months. Some health care providers use Factor Xa inhibitors and direct thrombin inhibitors in the treatment of PEs. The dosage of heparin is adjusted according to the activated partial thromboplastin time (aPTT), and the dosage of warfarin is determined by the international normalized ratio (INR).

Frequent changes and titrations of heparin doses are needed initially in order to obtain a therapeutic aPTT level. Anticoagulant therapy may be contraindicated if the patient has complicating factors such as blood dyscrasias, hepatic dysfunction causing alteration in the clotting mechanism, injury to the intestine, overt bleeding, a history of hemorrhagic stroke, or neurological conditions.

Surgical Therapy.

If the degree of pulmonary arterial obstruction is severe and the patient does not respond to conservative therapy, an immediate embolectomy may be indicated. Pulmonary embolectomy, a rare procedure, has a 50% mortality rate. Preoperative pulmonary angiography is necessary to identify and locate the site of the embolus. When a pulmonary embolectomy is performed, the patient also has placement of a vena cava filter. To prevent further emboli, an inferior vena cava filter may be the treatment of choice in patients who remain at high risk and for patients for whom anticoagulation is contraindicated. This device is placed at the level of the diaphragm in the inferior vena cava via the femoral vein. It prevents migration of large clots into the pulmonary system. Research has shown complications associated with this device include recurrent VTEs and post-thrombotic syndrome, in addition to misplacement, migration, and perforation (Sheares, 2011).

Nursing Management Pulmonary Embolism

Nursing Implementation

Health Promotion.

Nursing measures aimed at prevention of PEs are similar to those for prophylaxis of VTEs (Association of Perioperative Registered Nurses, 2007; see the discussion of venous thrombosis in Chapter 40).

Acute Intervention.

The prognosis of a patient with PE is good if therapy is promptly instituted. The patient should be kept on bed rest in a semi-Fowler's position to facilitate breathing. An IV line should be maintained for medications and fluid therapy. The nurse should know the adverse effects of medications and observe for them. Oxygen therapy should be administered as ordered. Careful monitoring of vital signs, cardiac dysrhythmia, pulse oximetry, ABGs, and lung sounds is critical to assess the patient's status. Laboratory results should be monitored to ensure normal ranges of aPTT and INR. Nursing care includes assessing for the complications of anticoagulant therapy (e.g., bleeding, hematomas, bruising) and for PEs (e.g., hypoxia, hypotension). The nurse should perform appropriate interventions related to immobility and fall precautions. Patients are usually anxious because of pain, a sense of doom, inability to breathe, and fear of death. Explaining the situation and providing emotional support and reassurance can help relieve this anxiety.

Ambulatory and Home Care.

The patient affected by thrombo-embolic processes may require emotional support. In addition, some patients may have an underlying chronic illness requiring long-term treatment. To provide

supportive therapy, the nurse must understand and differentiate between the various problems caused by the underlying disease and those related to thrombo-embolic disease. Patient teaching regarding long-term anticoagulant therapy is critical.

Anticoagulant therapy continues for at least 3 to 6 months; patients with recurrent emboli are treated indefinitely. INR levels are drawn at intervals and warfarin dosage is adjusted. Some patients are monitored by nurses in an anticoagulation clinic. Long-term management is similar to that for the patient with VTE (see the discussion of VTE in Chapter 40). Discharge planning is aimed at limiting progression of the condition and preventing complications and recurrence. The need for the patient to return to the health care provider for regular follow-up examinations should be reinforced.

Evaluation

The expected outcomes are that the patient who has a PE will have:

- Adequate tissue perfusion and respiratory function
- Adequate cardiac output
- Increased level of comfort
- No recurrence of PE

Pulmonary Hypertension

Pulmonary hypertension comprises a variety of disorders occurring as a primary disease (primary pulmonary hypertension) or as a complication of a large number of respiratory and cardiac disorders (secondary pulmonary hypertension). Pulmonary hypertension is elevated pulmonary pressure resulting from an increase in pulmonary vascular resistance to blood flow through small arteries and arterioles.

Primary Pulmonary Hypertension

Primary pulmonary hypertension (PPH) is a rare, severe, and progressive disease. PPH is characterized by mean pulmonary arterial pressure greater than 25 mm Hg at rest or greater than 30 mm Hg with exercise, in the absence of a demonstrable cause. PPH is associated with a poor prognosis because there is no definitive therapy.

Etiology and Pathophysiology

The exact etiology of PPH is unknown. PPH has been linked to the use of fenfluramine in the drug Fen-Phen, which was used as an appetite suppressant to treat obesity. The drug was withdrawn from the market in 1996. PPH affects more women than men. It may have a genetic component because the incidence is higher in families. It is a rare and potentially fatal disease; the mean age at diagnosis is 36 years.

Normally, the pulmonary circulation is characterized by low resistance and low pressure. In pulmonary hypertension, the pulmonary pressures are elevated. Until recently, the pathophysiology of PPH was poorly understood. Recently, it was discovered that a key mechanism involved in PPH is a deficient release of vasodilator mediators from the pulmonary epithelium with a resultant cascade of injury (Figure 30-12).

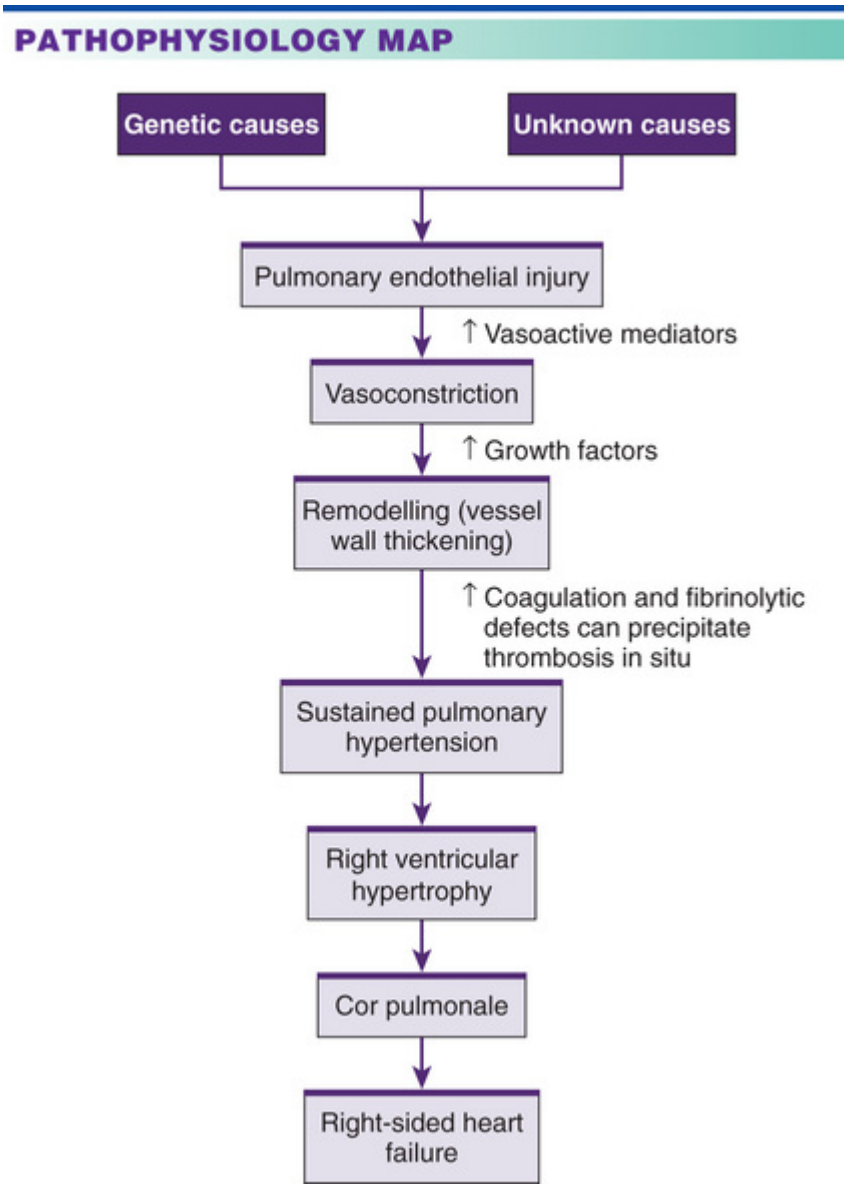

FIGURE 30-12 Pathogenesis of pulmonary hypertension and cor pulmonale.

Clinical Manifestations

Classic symptoms of pulmonary hypertension are dyspnea on exertion and fatigue. Exertional chest pain, dizziness, and exertional syncope are other symptoms. These symptoms are related to the inability of cardiac output to increase in response to increased oxygen demand. Eventually, as the disease progresses, dyspnea occurs at rest. Pulmonary hypertension increases the workload of

the right ventricle and causes right ventricular hypertrophy (a condition called *cor pulmonale*) and eventually heart failure. A chest radiograph generally shows enlarged central pulmonary arteries and clear lung fields. A heart enlarged on the right may be seen. Echocardiogram usually reveals right ventricular hypertrophy.

Collaborative Care

Diagnostic evaluation includes ECG, chest radiographic study, and echocardiogram. CT and cardiac catheterization to measure pulmonary artery pressures can be used. Additional tests may be done to exclude secondary factors. Early recognition of pulmonary hypertension is essential to interrupt the self-perpetuation cycle responsible for the progression of this problem (see Figure 30-12). The mean time between onset of symptoms and diagnosis is 2 years. By the time patients become symptomatic, the disease is already in the advanced stages and the size of pulmonary artery pressure is two to three times normal.

Although there is no cure for PPH, treatment can relieve symptoms, improve quality of life, and prolong life. Diuretic therapy relieves dyspnea and peripheral edema and may be useful in reducing right ventricular volume overload. Anticoagulation therapy is recommended for patients with severe pulmonary hypertension to prevent in situ thrombus formation and venous thrombosis.

Vasodilator therapy is used to reduce right ventricular overload by dilating pulmonary vessels and reversing remodelling. Many patients with pulmonary hypertension can be effectively managed with calcium channel blocker therapy, such as nifedipine (Adalat) and diltiazem (Cardizem).

Synthetic prostacyclins promote pulmonary vasodilation and reduce pulmonary vascular resistance and have revolutionized the management of PPH. They are now the treatment of choice for select patients unresponsive to calcium channel blockers. They can be administered orally (e.g., bosentan), subcutaneously (e.g., treprostinil), or intravenously (e.g., epoprostenol). Aerosolized forms are not yet available in Canada.

Bosentan (Tracleer) is an oral form of prostacyclin used to treat PPH. It is an active endothelin receptor antagonist. This medication works by blocking the hormone endothelin, which causes blood vessels to constrict. Treprostinil (Remodulin), a prostacyclin, is used as a continuous subcutaneous injection. It causes vasodilation of the pulmonary arterial system and inhibits platelet aggregation.

Surgical interventions include atrial septostomy, pulmonary thromboendarterectomy, and lung transplantation (Stamm, Risbano, & Mathier, 2011). Lung transplantation is the mainstay of treatment for those patients who do not respond to prostacyclins and progress to severe right-sided heart failure. Recurrence of the disease has not been reported in individuals who have undergone transplantation. A patient education and support site for pulmonary hypertension is located on the Pulmonary Hypertension Association's website (see the Resources at the end of this chapter).

Secondary Pulmonary Hypertension

Secondary pulmonary hypertension (SPH) occurs when a primary disease causes a chronic increase in pulmonary artery pressures. It can develop as a result of parenchymal lung disease, left ventricular dysfunction, intracardiac shunts, chronic pulmonary thrombo-embolism, or systemic connective tissue disease. The specific primary disease pathology may result in anatomical or vascular changes causing the pulmonary hypertension. Anatomical changes causing increased vascular resistance include (1) loss of capillaries as a result of alveolar wall damage (e.g., COPD), (2) stiffening of the pulmonary vasculature (e.g., pulmonary fibrosis connective tissue disorders), and (3) obstruction of blood flow (chronic emboli).

Vasomotor increases in pulmonary vascular resistance are found in conditions characterized by alveolar hypoxia. Hypoxia causes localized vasoconstriction and shunting of blood away from poorly ventilated alveoli. Alveolar hypoxia can be caused by a wide variety of conditions. It is possible to have a combination of anatomical restriction and vasomotor constriction. This combination is found in the patient with longstanding chronic bronchitis who has chronic hypoxia in addition to loss of lung tissue.

Symptoms can reflect the underlying disease, but some, such as dyspnea, fatigue, lethargy, and chest pain, are directly attributable to the SPH. Physical findings include right ventricular hypertrophy and signs of right ventricular failure (increased pulmonic heart sound, right-sided fourth heart sound, peripheral edema, hepatomegaly). Treatment of pulmonary hypertension caused primarily by pulmonary or cardiac disorders consists mainly of treating the underlying disorder. Treatment of SPH is similar to treatment of PPH.

Cor Pulmonale

Cor pulmonale is a hypertrophy of the right side of the heart, with or without heart failure, resulting from pulmonary hypertension. Diseases of the lung or thorax or changes in pulmonary circulation can lead to pulmonary hypertension. Pulmonary hypertension is usually a pre-existing condition in the individual with cor pulmonale. Cor pulmonale may be present with or without overt cardiac failure. The most common cause of cor pulmonale is COPD; however, almost any disorder that affects the respiratory system can cause cor pulmonale. The etiology and pathogenesis of pulmonary hypertension and cor pulmonale are outlined in Figure 30-12.

Clinical Manifestations

Clinical manifestations of cor pulmonale include dyspnea, chronic productive cough, wheezing respirations, retrosternal or substernal pain, and fatigue. Chronic hypoxemia leads to polycythemia and increased total blood volume and viscosity of the blood. (Polycythemia is often present in cor pulmonale secondary to COPD.) Compensatory mechanisms that are secondary to hypoxemia can aggravate the pulmonary hypertension. Episodes of cor pulmonale in a person with underlying chronic respiratory problems are frequently triggered by an acute respiratory tract infection.

If heart failure accompanies cor pulmonale, additional manifestations such as peripheral edema; weight gain; distended neck veins; full, bounding pulse; and enlarged liver will also be

found. (Heart failure is discussed in Chapter 37.) A chest radiograph will show an enlarged right ventricle and pulmonary artery.

Collaborative Care

The primary management of cor pulmonale is directed at treating the underlying pulmonary problem that precipitated the heart problem (Table 30-26). Long-term low-flow O_2 therapy is used to correct the hypoxemia and reduce vasoconstriction in chronic states of respiratory disorders. If fluid, electrolyte, and acid–base imbalances are present, they must be corrected. Diuretics and a low-sodium diet will help decrease the plasma volume and the load on the heart. Bronchodilator therapy is indicated if the underlying respiratory problem is caused by an obstructive disorder. Digitalis may be used if there is left-sided heart failure. Other treatments include those for pulmonary hypertension and comprise vasodilator therapy, calcium channel blockers, and anticoagulants. Theophylline may help because of its weak inotropic effect on the heart. When medical treatment fails, lung transplantation is an option for some patients.

TABLE 30-26

COLLABORATIVE CARE
Cor Pulmonale

Diagnostic	Collaborative Therapy
• History and physical examination • ABGs • Serum and urine electrolytes • Monitoring with ECG • Chest radiographic study	• O_2 therapy • Bronchodilators • Diuretics • Low-sodium diet • Fluid restriction • Antibiotics (if indicated) • Digitalis (if left-sided heart failure) • Vasodilators (if indicated) • Calcium channel blockers (if indicated)

ABGs, arterial blood gases; *ECG,* electrocardiogram; *O_2,* oxygen.

Management of cor pulmonale resulting from COPD is similar to that described for COPD (see Chapter 31). Continuous low-flow O_2

during sleep; exercise; and small, frequent meals may allow the patient to feel better and be more active.

Lung Transplantation

Lung transplantation has evolved as a viable therapy for patients with end-stage lung disease. A variety of pulmonary disorders are potentially treatable with some type of lung transplantation (Table 30-27). Improved selection criteria, technical advances, and better methods of immuno-suppression have resulted in improved survival rates. Various transplant options are available, including single-lung transplant, bilateral-lung transplant, heart–lung transplant, and transplantation of lobes from a living related donor.

TABLE 30-27
INDICATIONS FOR LUNG TRANSPLANTATION

- α_1-Antitrypsin deficiency
- Bronchiectasis
- Cystic fibrosis
- Emphysema
- Idiopathic pulmonary fibrosis
- Interstitial lung disease
- Pulmonary fibrosis secondary to other diseases (e.g., sarcoidosis)
- Pulmonary hypertension

Patients being considered for a lung transplant need to undergo extensive evaluation. The candidate for lung transplantation should not have a malignancy or recent history of malignancy (within the past 2 years), renal or liver insufficiency, or HIV. The typical wait for a lung transplant is longer than 1 year. The candidate and the family undergo psychological screening to determine the ability to cope with a postoperative regimen that requires strict adherence to immuno-suppressive therapy, continuous monitoring for early signs of infection, and prompt reporting of manifestations of infection for medical evaluation.

Postoperative care includes ventilatory support, pulmonary clearance measures (bronchodilators, chest physiotherapy, and deep breathing and coughing), fluid and hemodynamic management, immuno-suppression, detection of early rejection, and prevention or treatment of infection. Infection is the leading cause of morbidity

and mortality. Gram-negative bacterial pneumonia is common. Viral infection with CMV and herpes simplex occur frequently. CMV is a leading cause of mortality, which, if it is going to occur, usually happens 4 to 8 weeks after surgery. Fungal infections are also seen. Empirical antibiotic regimen is routine perioperatively for potential pathogens isolated from donor or recipient.

Immuno-suppressive therapy usually includes a triple-drug regimen of cyclosporine, azathioprine (Imuran), and prednisone. Immuno-suppressive drugs are discussed in Chapter 16 and Table 16-16.

Acute rejection can be seen as soon as 5 to 7 days after surgery. It is characterized by low-grade fever, fatigue, and oxygen desaturation with exercise. Accurate diagnosis is by transtracheal biopsy. Treatment with bolus corticosteroids results in remission of symptoms.

Bronchiolitis obliterans (an obstructive airway disease causing progressive occlusion) is considered to represent chronic rejection in lung transplant patients. The onset is often subacute, with gradual, progressive obstructive airflow defect, including cough, dyspnea, and recurrent lower respiratory tract infection. Treatment involves optimum maintenance immuno-suppression.

Discharge planning begins in the preoperative phase. Patients are placed in an outpatient rehabilitation program to improve physical endurance. The use of home spirometry has been useful in monitoring trends in lung function. Patients are taught to keep logs of medications, laboratory results, and spirometry. Patients need to be able to perform self-care activities, including medication management and ability to identify when to call the physician. Over the past decade, lung transplantation has become an increasingly important mode of therapy for patients with a variety of end-stage lung diseases.

Case Study

Pneumonia and Lung Cancer

Source: Shutterstock.com.

Patient Profile

Jacob Hillen is a 52-year-old man who comes to the emergency department complaining of shortness of breath. He has not seen a health care provider for many years.

Subjective Data

- Has a 38 pack-year history of cigarette smoking
- States he has always been slender but has had 11 kg weight loss despite a normal appetite in the past few months
- Admits to a “smoker's cough” for the past 2 to 3 years; recently coughing up blood
- Is married and the father of three adult children

Objective Data

Physical Examination

- Thin, pale man, looking older than stated age
- Height 182 cm; weight 61.2 kg
- Intermittently confused and anxious with rapid shallow respirations
- Vital signs: temperature 39.2°C, heart rate 120, respiratory rate 36
- Chest wall has limited excursion on right side; auscultation of left side reveals coarse crackles but clear with cough; right side

has diminished breath sounds

Diagnostic Studies

- Arterial blood gases: pH 7.51, PaO_2 58 mm Hg, $PaCO_2$ 30 mm Hg, HCO_3^- 22 mmol/L, O_2 saturation 84% (room air)
- Chest radiograph: consolidation of the right lung, especially in the base with possible mass in the area of right bronchus; pleural effusion on the right side
- Bronchoscopy with biopsy of mass: small cell lung carcinoma

Collaborative Care

- Diagnosis: pneumonia with small cell lung cancer
- Follow-up with patient and family to consider treatment options

Discussion Questions

1. How would Mr. Hillen's pneumonia be classified? Why is classification important?
2. What would the nurse's analysis of Mr. Hillen's arterial blood gas results be?
3. ***Priority decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
4. ***Priority decision:*** What are the priority nursing interventions for Mr. Hillen?
5. The nurse is planning a meeting with Mr. Hillen and his family to discuss their needs. The physician tells the nurse that Mr. Hillen is terminally ill. Who should be included in this meeting?
6. ***Evidence-informed practice:*** Mr. Hillen's children tell the nurse that they are worried they will get lung cancer because their father has it and they grew up around his second-hand

smoke. They want to know what kind of screening is available for them. How should the nurse respond?

7. What is the goal if radiation therapy is used for Mr. Hillen?
8. What issues should be addressed in the nurse's teaching of Mr. Hillen and his wife as he is prepared for discharge and care at home?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. What clinical manifestations should the nurse expect when assessing a client with pneumococcal pneumonia?
   a. Fever, chills, and a productive cough with purulent sputum
   b. Nonproductive cough and night sweats that are usually self-limiting
   c. Gradual onset of nasal stuffiness, sore throat, and purulent productive cough
   d. Abrupt onset of fever, nonproductive cough, and formation of lung abscesses
2. A client with pneumonia has the nursing diagnosis of *ineffective airway clearance* related to *excessive mucus and retained secretions.* What would be an appropriate nursing intervention?
   a. Promote fluid hydration, as appropriate, to help liquefy secretions.
   b. Provide analgesics as ordered to promote client comfort.
   c. Administer oxygen as prescribed to maintain optimal oxygen levels.
   d. Teach the client how to cough effectively to bring secretions to the mouth.
3. A client with tuberculosis (TB) has a history of nonadherence to the medication regimen. What is the most common cause of this behaviour in clients with TB?
   a. Fatigue and lack of energy to manage self-care
   b. Lack of knowledge about how the disease is transmitted
   c. Lack of social support systems for the client and family
   d. Feelings of shame and the response to the social stigma associated with TB
4. A client has been receiving high-dose corticosteroids and broad-spectrum antibiotics for treatment of serious trauma and infection.

Which of the following infections is the client most susceptible to?

a. Aspergillosis

b. Candidiasis

c. Coccidioidomycosis

d. Histoplasmosis

5. Which of the following statements best describes the treatment of lung abscess?

a. It is best treated with surgical excision and drainage.

b. Antibiotics for a prolonged period is the treatment of choice.

c. Abscesses are difficult to treat and usually result in pulmonary fibrosis.

d. Penicillin can effectively eradicate anaerobic organisms.

6. What is a common complication of many types of environmental lung diseases?

a. Benign tumour growth

b. Diffuse airway obstruction

c. Liquefactive necrosis

d. Pulmonary fibrosis

7. What type of lung cancer is generally associated with the best prognosis because it is potentially surgically resectable?

a. Adenocarcinoma

b. Small cell carcinoma

c. Squamous cell carcinoma

d. Undifferentiated large cell carcinoma

8. How does the nurse identify in a client a flail chest caused by trauma?

a. Multiple rib fractures are determined by radiographic study.

b. Tracheal deviation to the unaffected side is present.

c. Paradoxical chest movement occurs during respiration.

d. Decreased movement of the involved chest wall is apparent.

9. The nurse notes tidalling of the water level in the tube submerged in the water-seal chamber in a client with closed chest tube drainage. What should the nurse do?
   a. Continue to monitor this normal finding.
   b. Check all connections for a leak in the system.
   c. Lower the drainage collector further from the chest.
   d. Clamp the tubing at progressively more distal points from the client until the tidalling stops.

10. Which nursing measure should be instituted after a pneumonectomy?
   a. Monitor chest tube drainage and functioning.
   b. Position the client on the operative side or the back.
   c. Perform range-of-motion exercises on the affected upper extremity.
   d. Auscultate frequently for lung sounds on the affected side.

11. What is the cause of respiratory problems in clients with Guillain-Barré syndrome?
   a. Central nervous system depression
   b. Deformed chest-wall muscles
   c. Paralysis of the diaphragm secondary to trauma
   d. Interruption of nerve transmission to respiratory muscles

12. A client with chronic obstructive pulmonary disease asks why the heart is affected by the respiratory disease. Which of the following statements regarding cor pulmonale is the basis for the nurse's response to the client?
   a. Pulmonary congestion secondary to left ventricular failure
   b. Excess serous fluid collection in the alveoli caused by retained respiratory secretions
   c. Right ventricular hypertrophy secondary to increased pulmonary vascular resistance
   d. Right ventricular failure secondary to compression of the heart by hyperinflated lungs

13. Which statement(s) describe(s) the management of a client following lung transplantation? *(Select all that apply)*

a. High doses of oxygen are administered around the clock.

b. The use of a home spirometer will help to monitor lung function.

c. Immuno-suppressant therapy usually involves a three-drug regimen.

d. Most clients experience an acute rejection episode in the first 2 days.

e. The lung is biopsied using a transtracheal method if rejection is suspected.

1. a; 2. a; 3. d; 4. b; 5. b; 6. d; 7. c; 8. c; 9. a; 10. b; 11. d; 12. c 13. b, c, e.

CHAPTER 31

Nursing Management

Obstructive Pulmonary Diseases

Written by, Susan Collazo

Adapted by, Kimberly Hellmer

LEARNING OBJECTIVES

1. Describe the etiology, pathophysiology, and clinical manifestations of asthma, and describe the collaborative care of patients with asthma.
2. Explain the nursing management of patients with asthma.
3. Describe the etiology, pathophysiology, and clinical manifestations of chronic obstructive pulmonary disease (COPD), and describe the collaborative care of patients with COPD.
4. Explain the effects of cigarette smoking on the lungs.
5. Explain the nursing management of patients with COPD.
6. Identify the indications for oxygen therapy, the methods of delivery, and the complications of oxygen administration.
7. Describe the etiology, pathophysiology, and clinical manifestations of cystic fibrosis, and explain the collaborative care of patients with cystic fibrosis.

KEY TERMS

absorption atelectasis, p. 676

α1-antitrypsin (AAT) deficiency, p. 665

asthma, p. 643

chest physiotherapy, p. 687

chronic bronchitis, p. 664

chronic obstructive pulmonary disease (COPD), p. 664

cor pulmonale, p. 668

cough variant asthma, p. 647

cystic fibrosis, p. 685

emphysema, p. 664

oxygen toxicity, p. 676

postural drainage, p. 687

pursed-lip breathing, p. 678

The prevalence of chronic lung disorders in Canada is an important population health concern. Current population health data indicate that the prevalence of asthma among children and youth aged 1 to 19 years is 15.7%; the prevalence of asthma among the population aged 20 years or older is 9.5%; and the prevalence of chronic obstructive pulmonary disease among the population aged 35 years or older is 9.7% (Public Health Agency of Canada [PHAC], 2015a). Among the total population, the rate of mortality due to chronic respiratory diseases is 43.8 per 100 000 (PHAC, 2015a).

Obstructive pulmonary diseases are the most common chronic lung diseases, which include conditions characterized by increased airflow resistance as a result of airway obstruction or narrowing. Airway obstruction may result from accumulated secretions, edema, inflammation of the airways, bronchospasm of smooth muscle, or destruction of lung tissue, or some combination. Asthma, chronic obstructive pulmonary disease (COPD), and cystic fibrosis are obstructive pulmonary diseases and are discussed in further depth in this chapter.

Asthma

Asthma is a chronic inflammatory disorder of the airways. Inflammation causes varying degrees of obstruction in the airways, which leads to recurrent episodes of wheezing, breathlessness, sensation of chest tightness, and cough, particularly at night and in the early morning. The hyper-responsiveness, or "twitchiness," of the airways is directly related to the degree of airway inflammation, in that the more airway inflammation present, the more hyper-responsive the airways are to endogenous or exogenous stimuli or triggers. Asthma occurs as a result of environmental (endogenous or exogenous) effects on the airways that trigger a series of events in the immune system of a genetically predisposed individual. These events lead to airway inflammation and bronchoconstriction (airway narrowing). A key characteristic of asthma is the episodic and reversible nature of the airway obstruction and its associated symptoms (cough, wheeze, sensation of chest tightness, dyspnea), so that an episode may resolve spontaneously or with treatment.

According to Statistics Canada (2015), more than 2.4 million (8.1%) of Canadians older than 12 years were living with asthma (9.2% of all female Canadians and 7.0% of all male Canadians). The morbidity associated with asthma is dramatic. The 2011 *Survey on Living with Chronic Diseases in Canada* identified 11.1% of Canadians with active asthma who reported a minimum of one visit to a hospital emergency room in the previous 12 months because of asthma symptoms (PHAC, 2011). Only one in three (34.4%) of Canadians with active asthma symptoms reported that their asthma was well-controlled (PHAC, 2011). In further investigation, 65.6% of respondents with active asthma were found to have at least one indicator of poorly controlled asthma (PHAC, 2011). The high rate of morbidity related to asthma may be attributed to practice that is inconsistent with the Canadian asthma consensus guidelines, inaccurate assessment of disease severity, a delay in seeking help, inadequate medical treatment, nonadherence to prescribed therapy, an increase in allergens in the environment, limited access to health care, and a lack of knowledge on the part of patients and health care providers.

Triggers of Asthma Attacks

Although the exact mechanisms that cause airway hyper-responsiveness and inflammation remain unknown, multiple stimuli or triggers are

involved (Table 31-1, Figure 31-1). Numerous allergens, chemicals, and infectious pathogens can trigger airway inflammation, which leads to airway narrowing and appearance of symptoms. These triggers are discussed in the following sections.

TABLE 31-1
TRIGGERS OF ASTHMA ATTACKS

Allergens • Animal dander (e.g., from cats, dogs, horses, mice, guinea pigs) • Household dust mites • Cockroaches • Pollens • Moulds • Air pollutants • Diesel particulates • Exhaust fumes • Perfumes • Ozone • Sulphur dioxides • Cigarette smoke • Aerosol sprays Viral upper respiratory infection Sinusitis Exercise Cold, dry air Stress	Hormones or menses Gastro-esophageal reflux disease (GERD) Drugs • Acetylsalicylic acid (ASA; Aspirin) • Nonsteroidal anti-inflammatory medications • β-Adrenergic blockers Occupational exposure • Agriculture • Metal salts • Wood and vegetable dusts • Industrial chemicals and plastics (isocyanates) • Pharmaceutical drugs Food additives • Sulphites (bisulphites and metabisulphites) found in beer, wine, dried fruit, shrimp • Monosodium glutamate • Tartrazine

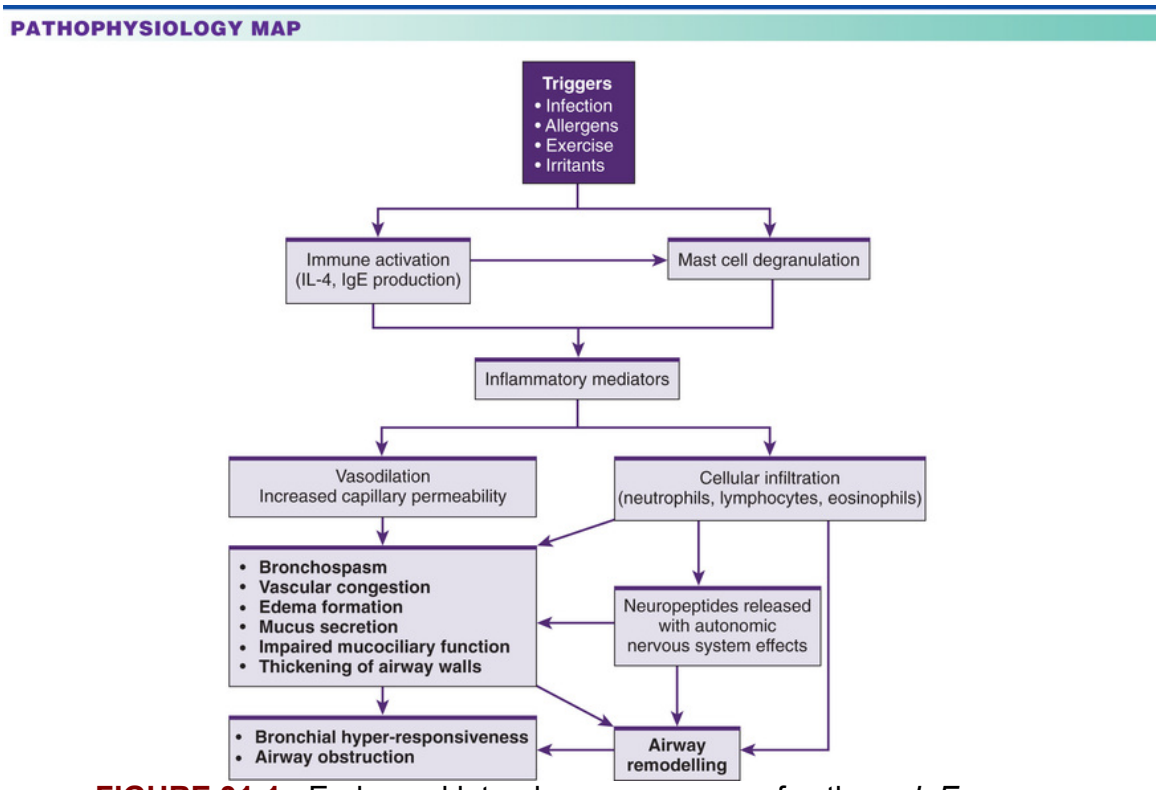

FIGURE 31-1 Early- and late-phase responses of asthma. *IgE,* immunoglobulin E; *IL-4,* interleukin-4.

Allergens.

Some people with asthma have an exaggerated immunoglobulin E (IgE) response to certain allergens (e.g., dust, pollen, grasses, mites, roaches, moulds, animal dander, latex). These allergens attach to IgE receptors on mast cells (Figure 31-2). The IgE–mast cell complexes remain for a long time; thus a second exposure to the allergen triggers mast cell degranulation even years after the initial exposure to the allergen. Patients with allergic rhinitis or atopic dermatitis should be asked specifically about any incidence of respiratory symptoms (Global Initiative for Asthma [GINA], 2015). Allergic reactions are discussed further in Chapter 16.

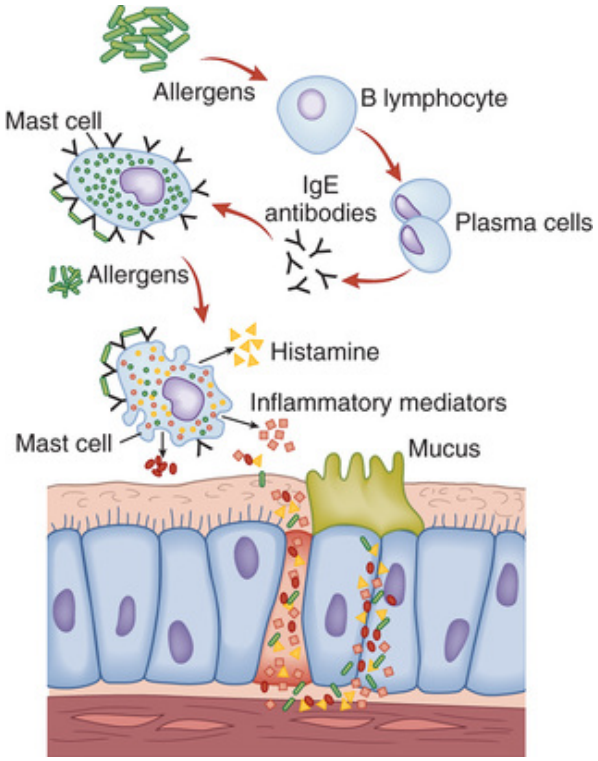

FIGURE 31-2 The early-phase response in asthma is triggered when an allergen or irritant attaches to immunoglobulin E (IgE) receptors on mast cells, which are then activated to release histamine and other inflammatory mediators.

Exercise.

Acute airway narrowing that is induced or exacerbated during physical exertion is referred to as *exercise-induced asthma* or *exercise-induced bronchospasm* (EIB). Although a substantial proportion of patients with an asthma diagnosis experience EIB, other people experience these symptoms but do not have a known diagnosis of asthma (Parsons et al., 2013). Typically, EIB occurs after, not during, vigorous exercise and is characterized by bronchospasm (airway smooth muscle contraction) that causes shortness of breath, cough, wheeze, sensation of chest tightness, or a combination of these. EIB is pronounced during activities in cold, dry air. Airway hyper-responsiveness may result from changes in the airway mucosa caused by the hyperventilation that occurs during exercise with either the cooling or rewarming of air and capillary leakage in the airway wall.

Several strategies can be incorporated to prevent EIB: an adequate warm-up period before the activity begins; breathing through a scarf or

mask during exercise in a cold or dry climate; and using inhaled short-acting β_2-adrenergic agonists either to relieve the symptoms or, 10 to 20 minutes before exercising, to ward off symptoms. Too frequent use of β_2-adrenergic agonists indicates poor asthma control, may mask asthma severity, and may cause a reduction in drug effectiveness. In such cases, patients may need escalation of therapy. (Control criteria and controller therapy are discussed further later in this chapter.) In the American Thoracic Society's clinical practice guideline for EIB, suggestions for the dietary modification are outlined for control of symptoms; these suggestions include low salt intake and dietary supplementation with fish oils and ascorbic acid (Parsons et al., 2013).

Respiratory Infections.

Respiratory infections (particularly viral) are among the most common triggers of worsening asthma. Infections cause increased inflammation in the tracheo-bronchial system, resulting in increased airway hyper-responsiveness, which can last from 2 to 8 weeks after infection both in individuals with asthma and in those without asthma. Patients with asthma should take steps to reduce the possibility of infections by using proper handwashing techniques and receiving an annual influenza vaccination. Influenza vaccines are recommended for patients with asthma aged 6 months and older, especially because of the prevalence of high-risk influenza-related complications in patients with asthma (PHAC, 2015b).

Nose and Sinus Problems.

Some patients with asthma have chronic sinus and nasal problems. Nasal problems include allergic rhinitis, either seasonal or perennial, and nasal polyps. Sinus problems are usually related to inflammation of the mucous membranes, most commonly from noninfectious causes such as allergies. However, bacterial sinusitis may also occur. It is important to treat these comorbid conditions because they often contribute to poor asthma control (Ducharme, Dell, Radhakrishnan, et al., 2015). (Sinusitis is discussed further in Chapter 29.)

Drugs and Food Additives.

Some patients with asthma, especially those with nasal polyps, may have sensitivity to specific drugs. Some people with asthma have what is termed the *asthma triad:* nasal polyps, asthma, and sensitivity to

acetylsalicylic acid (ASA; Aspirin) and nonsteroidal anti-inflammatory drugs (NSAIDs). Salicylic acid can be found in many over-the-counter drugs and some foods, beverages, and flavourings. In some asthmatic patients, wheezing develops within 2 hours after they take ASA (Aspirin) or NSAIDs (e.g., ibuprofen [Motrin]). In addition, most affected patients have profound rhinorrhea, congestion, and tearing. Facial flushing, gastro-intestinal symptoms, and angioedema can also occur. Although sensitivity to salicylates persists for many years, the nature and severity of the reaction can change over time. Such patients should avoid ASA (Aspirin) and NSAIDs. However, patients with ASA (Aspirin) sensitivity can, under the care of an allergist, be desensitized by daily administration of the drug (Simon, Dazy, & Waldram, 2015). Such patients may be more likely to benefit from antileukotriene drugs.

β-Adrenergic blockers in oral form (e.g., metoprolol) or topical eye drops (e.g., timolol [Timoptic]) may trigger asthma episodes because they induce bronchospasm. Angiotensin-converting enzyme inhibitors (e.g., lisinopril) may induce cough in susceptible individuals, thus worsening asthma symptoms. Other irritants that may precipitate asthma symptoms in susceptible patients are tartrazine (yellow dye no. 5, found in many foods) and sulphites (e.g., sodium metabisulphite), widely used in the food and pharmaceutical industries as preservatives and sanitizing agents. Sulphites are commonly found in fruits, beer, and wine and are used extensively in salad bars to protect vegetables from oxidation.

These drugs and food additives are thought to interfere with metabolic pathways, which results in enhanced production of leukotrienes, some of which are potent bronchoconstrictors. The onset of a typical reaction occurs 15 minutes to 3 hours after ingestion and is marked by profuse rhinorrhea, often accompanied by nausea, vomiting, intestinal cramps, and diarrhea. An acute episode of asthma typically begins after the nasal symptoms appear. Pretreatment with corticosteroids does not prevent the reaction. Epinephrine and antihistamines given shortly after the onset of the asthma symptoms usually control the symptoms.

Gastro-esophageal Reflux Disease.

The exact mechanism by which gastro-esophageal reflux disease (GERD) triggers asthma is unknown. It is postulated that reflux of stomach acid into the esophagus can be aspirated into the lungs, which causes reflex vagal stimulation and bronchoconstriction. Although GERD is involved primarily in nocturnal asthma, it can trigger daytime asthma as well. By

monitoring esophageal pH and peak expiratory flow rate (PEFR) simultaneously, the examiner can determine whether GERD is the cause of the asthma symptoms. H_2-histamine blockers or proton pump inhibitors are given to ameliorate symptoms. (GERD is discussed further in Chapter 44.)

Air Pollutants.

Various air pollutants, cigarette or wood smoke, vehicle exhaust, diesel particulate, elevated ozone levels, sulphur dioxide, and nitrogen dioxide can trigger asthma attacks. Ongoing studies are being done to better understand how chronic exposure to urban air pollution and "hotspots" of air pollution within Canadian cities affect people who work and live in these areas (Government of Canada, 2013). The Air Quality Health Index (AQHI) was developed by the Government of Canada (2015) as a tool to help alert the public of health risks posed by air pollution (Figure 31-3).

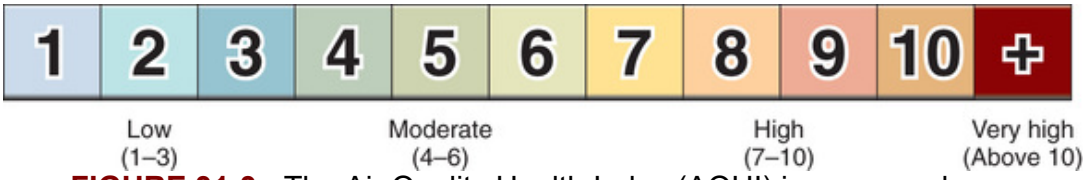

FIGURE 31-3 The Air Quality Health Index (AQHI) is measured on a scale ranging from 1 to 10+. The AQHI index values are also grouped into health risk categories: 1 to 3 indicates low risk; 4 to 6, moderate risk; 7 to 10, high risk; and 10+, very high risk. These categories help patients easily and quickly identify their level of risk.

Emotional Stress.

Asthma is not a psychosomatic disease. However, physiological stress that elicits emotional responses such as crying, laughing, anger, and fear can lead to hyperventilation and hypocapnia, which can cause airway narrowing (GINA, 2015). An asthma exacerbation can produce panic and anxiety, which are not unexpected emotions during this experience. Panic is a normal response to not being able to breathe. The extent to which psychological factors contribute to the induction and continuation of any

given acute exacerbation is unknown, but it probably varies from patient to patient and in the same patient from episode to episode.

Pathophysiology

The hallmarks of asthma are airway inflammation and airway hyper-responsiveness. The degree of bronchoconstriction is related to the degrees of airway inflammation, airway hyper-responsiveness, and exposure to endogenous and exogenous triggers (e.g., infections, allergens, histamine, and other cell mediators). Exposure to allergens or irritants initiates an inflammatory cascade involving multiple cell types, mediators, and chemokines. Typically, there are two possible types of asthmatic responses to stimuli: an early-phase response and a late-phase response.

The early-phase response in asthma is characterized by bronchospasm (see Figure 31-1). This response is triggered when an allergen or irritant attaches to IgE receptors on mast cells found beneath the basement membrane of the bronchial wall (see Figure 31-2). The mast cells become activated, and, subsequently, granules are released and the phospholipids' cell membranes are disrupted. Both processes result in the release of inflammatory mediators, including histamine, bradykinin, leukotrienes, prostaglandins, platelet-activating factor, chemotactic factors, and cytokines (e.g., interleukin-4 and interleukin-5; GINA, 2015). A similar early-phase response process can occur with exercise. These mediators cause intense inflammation in association with bronchial smooth muscle constriction, increased vasodilation and permeability, and epithelial damage. Clinically, the effects are bronchospasm, increased mucus secretion, edema formation, and increased amounts of tenacious sputum (see Figure 31-1), which cause wheeze, cough, sensation of chest tightness, shortness of breath, or a combination of these. This immediate response peaks within 30 to 60 minutes after exposure to the trigger (e.g., allergen, irritant) and subsides in another 30 to 90 minutes.

The late-phase response can be more severe than the early-phase response. It peaks 5 to 12 hours after exposure and may last from several hours to days. Its primary characteristic is inflammation, as opposed to bronchial smooth muscle contraction. Eosinophils and neutrophils, the inflammatory cells involved in asthma, infiltrate the airways. These cells can subsequently release mediators that induce further inflammation and cause mast cells to degranulate, thereby causing the release of histamine and other mediators and initiating a self-sustaining cycle. Corticosteroids are effective in preventing and reversing this cycle.

These inflammatory characteristics of a late-phase response increase airway reactivity, which may lower the threshold of exposure necessary to induce a future asthma attack and cause its symptoms to worsen. The affected person becomes hyper-responsive to allergens and nonspecific stimuli such as air pollution, cold air, and dust. In summary, prominent pathophysiological features of asthma are a reduction in airway diameter and an increase in airway resistance that are related to mucosal inflammation, constriction of bronchial smooth muscle, and excess production of mucus (Figure 31-4). Accompanying these changes are hypertrophy of bronchial smooth muscle, thickening of basement membrane, hypertrophy of mucous glands, secretion of thick and tenacious sputum, hyperinflation, and air trapping in the alveoli, all of which increase the work of breathing. As a consequence of these events, respiratory muscle function may be altered, distribution of both ventilation and perfusion may be abnormal, and arterial blood gas (ABG) values may be altered, depending on severity of the disease. Asthma is considered a disease of the airways, but during an asthma attack, eventually all aspects of pulmonary function are compromised. If airway inflammation is not treated or does not resolve, progressive and irreversible lung damage may eventually occur. This irreversible airway obstruction is thought to be the result of inflammation-induced structural changes called *airway remodelling* (GINA, 2015).

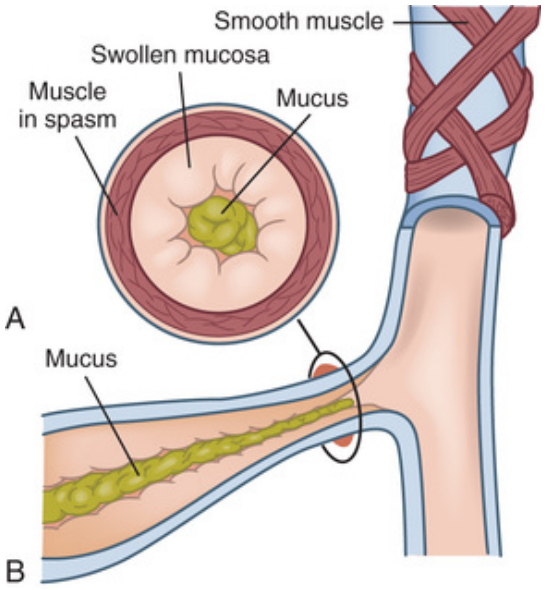

FIGURE 31-4 Factors causing obstruction (especially expiratory obstruction) in asthma. **A,** Cross section of a bronchiole occluded by muscle spasm, swollen mucosa, and mucus in the lumen. **B,** Longitudinal section of a bronchiole. Clinical Manifestations

Asthma has an unpredictable, episodic, and variable course. Recurrent episodes of wheezing, breathlessness, sensation of chest tightness, coughing, or a combination of these, particularly at night and in the early morning (typically between 0200 and 0500 hours), are common features. The onset of an attack or episode of asthma may be abrupt (minutes) or more gradual (1 hour to days). Between attacks, the patient may have no symptoms, with normal or near-normal pulmonary function, depending on the severity of disease. However, in some people, prolonged and uncontrolled asthma may result in compromised pulmonary function and chronic debilitation, resulting in irreversible or fixed airway disease.

The characteristic clinical manifestations of asthma are wheezing, cough, dyspnea, and sensation of chest tightness after exposure to a precipitating factor or trigger. Expiration is often prolonged. The inspiratory–expiratory ratio, instead of being the normal 1 : 2, may be prolonged to 1 : 3 or 1 : 4. As a result of bronchospasm, edema, and mucus in the bronchioles, the airways become narrower; thus it takes longer for the air to move out of

the bronchioles. This produces the characteristic wheezing, air trapping, and hyperinflation.

Wheezing is an unreliable sign for gauging the severity of an attack. Many patients with minor attacks wheeze loudly, whereas others with severe attacks do not wheeze. A patient with a severe asthma attack may have no audible wheezing because of the marked reduction in airflow. For wheezing to occur, the patient must be able to move enough air to produce the sound. Wheezing usually occurs first on exhalation. As an asthma attack progresses, the patient may wheeze during inspiration and expiration. Severely diminished breath sounds or their absence, often referred to as a "silent chest," is an ominous sign of severe obstruction and impending respiratory failure. During an acute attack, the person with asthma usually sits upright or slightly bent forward and uses the accessory muscles of respiration in an attempt to make breathing easier. The more difficult the breathing becomes, the more anxious the patient feels.

Safety Alert

If a patient has been wheezing but the wheeze abruptly disappears (i.e., silent chest) and the patient is obviously in distress, the situation has become life-threatening and may necessitate mechanical ventilation.

In some patients with asthma, cough is the only symptom, which is termed **cough variant asthma.** The bronchospasm may not be severe enough to cause airflow obstruction, but it can increase bronchial tone and cause irritation and stimulation of the cough receptors. The cough may be nonproductive. Mobilizing secretions may be difficult as a result of their thick, tenacious, gelatinous quality.

In patients experiencing an acute attack of moderate or severe asthma, examination usually reveals signs of hypoxemia, which may include restlessness, increased anxiety, inappropriate behaviour, increased pulse and blood pressure, and *pulsus paradoxus* (a drop in systolic pressure during the inspiratory cycle of more than 10 mm Hg). The respiratory rate is significantly increased (usually >30 breaths/minute), and the use of accessory muscles is evident. The patient also has difficulty speaking in complete sentences; typically he or she is able to complete only two to five words without requiring another breath. Percussion of the lungs indicates hyper-resonance, and auscultation indicates the presence of inspiratory or expiratory wheezing.

Asthma Control and Severity

A dynamic continuum of treatment is used to manage asthma. This approach enables drug therapy to be adapted to the severity of the underlying illness and the current level of asthma control. The concepts of asthma "control" and "severity" are related to each other but not correlated (GINA, 2015). For example, even severe asthma may be well controlled, whereas mild disease may remain out of control. *Optimal asthma control* is defined by the absence of both asthma symptoms and the need for rescue bronchodilator, as well as by normal pulmonary function; however, this is difficult to achieve in all patients with asthma. As a result, according to the Canadian Asthma Consensus 2012 guidelines update, treatment needs should be based on achieving acceptable asthma control, determined through clinical and physiological criteria (Lougheed, Lemiere, Ducharme, et al., 2012; Table 31-2). Asthma control is obtained through the use of environmental control measures (reduced exposure to triggers), self-management education, written action plans, and pharmacotherapy tailored to the individual (Lougheed, Lemiere, Ducharme, et al., 2012). Asthma control must be assessed regularly and treatment adjusted accordingly.

TABLE 31-2

ASTHMA CONTROL CRITERIA

Characteristic	Frequency or Value
Daytime symptoms	<4 days/week
Nighttime symptoms	<1 night/week
Physical activity	Normal
Exacerbations	Mild, infrequent
Absence from work or school because of asthma	None
Need for a fast-acting β_2 agonist	<4 doses/week
FEV_1 or PEF	≥90% personal best
PEF diurnal variation*	<10%–15%
Sputum eosinophils†	<2%–3%

*_Diurnal variation_ is calculated as the highest peak expiratory flow (PEF) minus the lowest peak expiratory flow rate (PEFR), divided by the highest PEFR, multiplied by 100 for morning and night (determined over a 2-week period).

†Considered in adults with uncontrolled moderate to severe asthma who are assessed in specialist centres.

FEV_1, forced expiratory volume in 1 second.

Source: Lougheed, M. D., Lemiere, C, Ducharme, F.M., et al. (2012). Canadian Thoracic Society 2012 guideline update: Diagnosis and management of asthma in preschoolers, children and adults. *Canadian Respiratory Journal, 19*(2), 127–164, Table 16.

The severity of asthma is determined from the frequency and duration of symptoms, the presence of persistent airflow limitation, and the medication required to maintain control (Lougheed, Lemiere, Ducharme, et al., 2012). When asthma is well controlled, severity is gauged by level of treatment required to maintain the state of acceptable control (Figure 31-5).

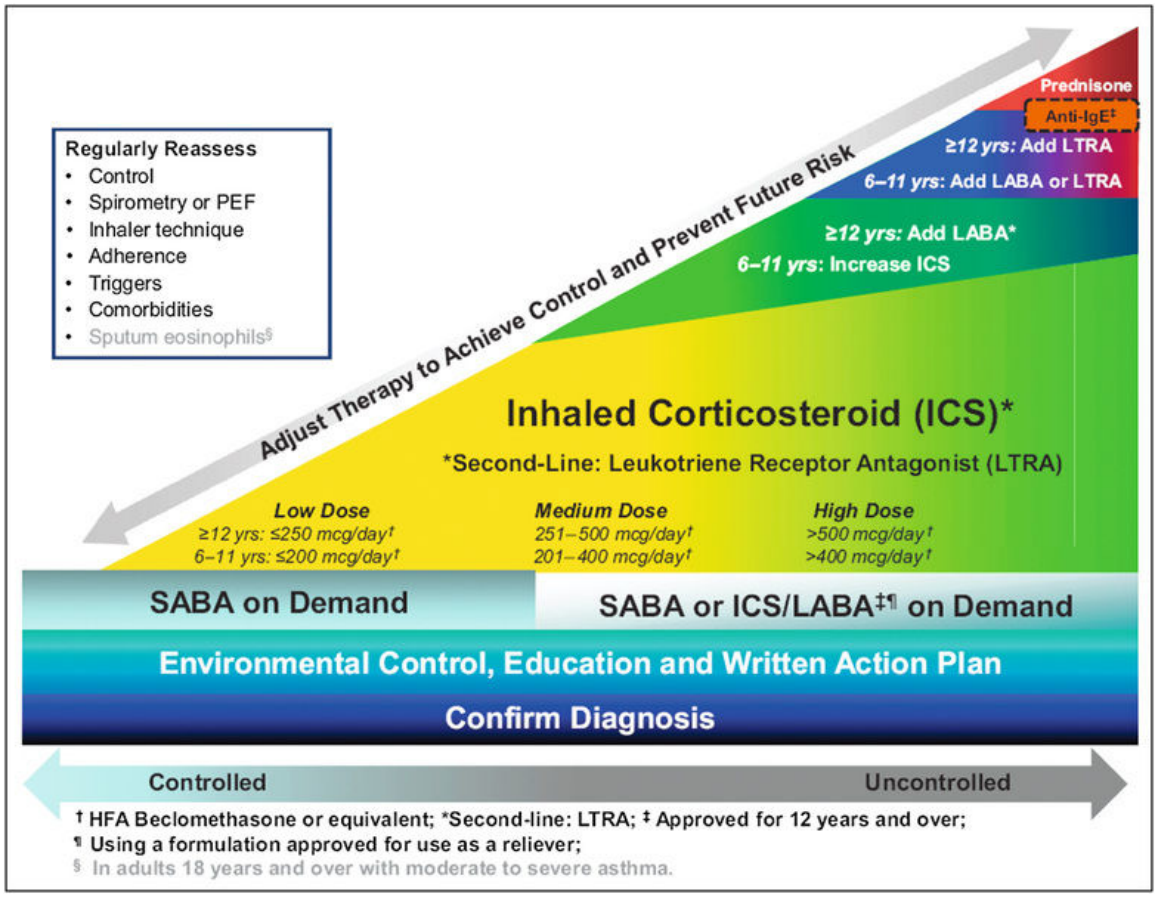

FIGURE 31-5 The 2012 Asthma Management Continuum (for children aged 6 years and older and for adults). *HFA,* hydrofluoroalkane; *IgE,* immunoglobulin E; *LABA,* long-acting β_2 agonist; *PEF,* peak expiratory flow; *SABA,* short-acting β_2 agonist.

Retrieved from *http://www.respiratoryguidelines.ca/guideline/asthma.*

Signs of severe or poorly controlled asthma include a history of a previous near-fatal asthma episode (loss of consciousness, need for intubation); recent hospitalization or recent emergency department visit for asthma; nighttime symptoms; limitations in daily activities; and the need for inhaled β_2 agonists several times each day or night.

Asthma severity levels can change for better or worse over the course of a patient's life. This is particularly true for children with asthma, inasmuch as asthma severity often decreases with age. When asthma control is good, patients have minimal to no symptoms, are able to sleep through the night, and participate in sports, exercise, and strenuous activity. Once asthma control has been maintained for at least a few weeks to months, an

attempt should be made to reduce medication dosages and yet maintain acceptable asthma control (Lougheed, Lemiere, Ducharme, et al., 2010).

Severe Acute Asthma and Life-Threatening Asthma.

Patients who present with a severe acute asthma attack, or one that is life-threatening, often report a history of progressively worsening of asthma control over days or weeks. Of the people with asthma admitted to the hospital, approximately 10% require monitoring or ventilatory assistance in the critical care unit for severe uncontrolled asthma. Common causes of severe acute attacks include viral illnesses, ingestion of ASA (Aspirin) or other NSAIDs, increases in environmental pollutants or other allergen exposure, and discontinuation of drug therapy (especially corticosteroids). The clinical manifestations of a severe attack are a consequence of increased airway resistance that results from edema, mucous plugging, and bronchospasm with subsequent air trapping and hyperinflation. The clinical manifestations are similar to those of nonsevere asthma but are more serious and prolonged. Extreme anxiety, fear of suffocation, severely increased work of breathing, and diaphoresis are common. Absence of diaphoresis may indicate significant dehydration. Sternocleidomastoid, intercostal, and supraclavicular muscle retractions reflect increased work of breathing.

Although wheezing is often audible even without a stethoscope, auscultation may not always be reliable: airflow obstruction may be so severe and airflow so insufficient that audible wheezing or other abnormal lung sounds may not be produced. Absence of a wheeze (i.e., silent chest) represents a life-threatening situation that may necessitate mechanical ventilation. The chest appears fixed in a hyperinflated position and is often described as “tight,” indicating severely decreased movement of air through the constricted bronchial airways.

Forced exhalation with the use of the abdominal musculature can result in increased intrathoracic pressure transmitted to the great vessels and heart. Neck vein distension and pulsus paradoxus with a pressure of 40 mm Hg or higher may result. (Pulsus paradoxus is described in Chapter 39 and Table 39-8.) Hypertension, sinus tachycardia, and ventricular dysrhythmias may occur. These three conditions are related to hypoxemia, to the catecholamines present as a result of an endogenous response to hypoxia, and, in older patients, to underlying coronary artery disease. On the right side of the heart, an electrocardiogram may show sinus

tachycardia or signs of strain secondary to pulmonary vasoconstriction, which may appear as cor pulmonale and a right axis deviation.

Hypoxemia with hypocapnia usually occurs initially as the patient attempts to hyperventilate and maintain adequate oxygenation and ventilation. As the severity of the attack increases, the work of breathing increases, which makes it more difficult for the patient to overcome the increased resistance to breathing. The patient becomes fatigued, which causes more carbon dioxide retention. ABG measurements initially reveal hypocapnia due to increased respiratory rate. Ultimately, these measurements deteriorate to manifest hypercapnia and hypoxemia. The patient must move amounts greater than 150 mL of air for air to participate in gas exchange. A moderate elevation in partial pressure of arterial carbon dioxide ($PaCO_2$) may be tolerated without intubation, and mechanical ventilation may be necessary because of respiratory arrest, altered level of consciousness, or extreme exhaustion (Leatherman, 2015).

Possible complications of a severe asthma attack include pneumothorax, pneumomediastinum, acute cor pulmonale with right ventricular failure, and severe respiratory muscle fatigue that leads to respiratory arrest. Respiratory arrest can be fatal.

Diagnostic Studies for Asthma

"A diagnosis of asthma should be considered in individuals of all age groups with recurrent symptoms" (Lougheed, Lemiere, Dell, et al., 2010, p. 16). Two main features must be considered in the diagnosis of asthma: symptoms and variable airflow obstruction. Several sources of information assist with confirming the diagnosis of asthma along with monitoring severity and control (Table 31-3). A detailed history is important in determining whether a person has had previous attacks of a similar nature, often precipitated by a known cause or trigger, as discussed previously in this chapter. Because asthma and allergies commonly coexist, it is also important to determine whether the patient has a history of nonpulmonary symptoms. Rhinitis, eczema, and conjunctivitis are common but not specific to asthma and indicate a predisposition to allergy.

TABLE 31-3
COLLABORATIVE CARE
Asthma

Diagnostic	Collaborative Therapy
• History and physical examination • Pulmonary function studies (spirometry; methacholine, histamine, exercise challenge test; PEFR) • Chest radiograph • Allergy skin testing • Oximetry and measurement of ABGs during acute episodes when patient is in emergency department or hospital	• Establishing partnerships between health care providers and patients and their families • Identification and avoidance or elimination of triggers • Patient and family teaching • Continuous assessment of asthma control and severity • Appropriate pharmacotherapy (see Tables 31-5 and 31-6) • Asthma action plan (see Figure 31-8) • Regular follow-up

ABG, arterial blood gases; *PEFR*, peak expiratory flow rate.

Of further value is to determine whether the patient has a family history of asthma, allergies, and eczema because such a history increases the likelihood that the patient has asthma. Recurrent symptoms of wheeze, sensation of chest tightness, cough, or breathlessness that improve with treatment are suggestive of asthma. However, wheezing and cough occur with a variety of disorders—COPD, pulmonary embolism, GERD, obesity, vocal cord dysfunction, and heart failure—and their presence can therefore complicate the diagnosis. According to both GINA and the Global Initiative for Chronic Obstructive Lung Disease, differentiating between asthma and COPD can be challenging in a small proportion of patients, and the term *asthma–COPD overlap syndrome* (ACOS) is utilized to clinically describe disease features (GINA, 2015). This is discussed further in the section on COPD later in this chapter.

In all patients who are able to perform pulmonary testing, clinically suspected asthma should be confirmed with objective lung measurements that demonstrate post–bronchodilator therapy reversible obstruction, variable airflow limitation over time, or airway hyper-responsiveness (Lougheed, Lemiere, Dell, et al., 2010). Spirometry is the preferred test for diagnosing asthma; alternative lung testing includes variations in PEFR and bronchoprovocative challenge testing (Lougheed, Lemiere, Dell, et al., 2010; Table 31-4).

TABLE 31-4
DIAGNOSIS OF ASTHMA: PULMONARY FUNCTION CRITERIA

Pulmonary Function Measurement	Children (6 Years of Age and Older)	Adults
Preferred: Spirometry Showing Reversible Airway Obstruction		
Reduced FEV_1/FVC	Less than lower limit of normal based on age, sex, height, and ethnicity (<0.8–0.9)*	Less than lower limit of normal based on age, sex, height, and ethnicity (<0.75–0.8)*
and	*and*	*and*
Increase in FEV_1 after a bronchodilator or after a course of controller therapy	≥12%	≥12% (and a minimum ≥200 mL)
Alternative: Peak Expiratory Flow Variability		
Increase after a bronchodilator or after course of controller therapy	≥20%	60 L/min (minimum ≥20%)
or	*or*	*or*
Diurnal variation†	Not recommended	>8% based on twice daily readings; >20% based on multiple daily readings
Alternative: Positive Challenge Test		
Methacholine challenge	PC_{20} < 4 mg/mL (4–16 mg/mL is borderline; >16 mg/mL is negative)	
or	*or*	
Exercise challenge	≥10%–15% decrease in FEV_1 post-exercise	

*Approximate lower limits of normal ratios for children and adults;

†Difference between minimum morning pre–bronchodilator therapy value in 1 wk and maximum nighttime value as percentage of recent maximum.

FEV_1, forced expiratory volume in 1 second; *FVC*, forced vital capacity; *PC_{20}*, provocative concentration of methacholine producing a 20% fall in FEV_1.

Source: Lougheed, M. D., Lemiere, C., Ducharme, F. M., et al. (2012). Canadian Thoracic Society 2012 guideline update: Diagnosis and management of asthma in preschoolers, children and adults. *Canadian Respiratory Journal, 19*(2), 127–164.

Spirometry performed before and after bronchodilator treatment can best reveal whether airway obstruction is reversible. The ratio of forced expiratory volume in 1 second to the forced vital capacity (FEV_1 to FVC; see Chapter 28, Table 28-15) is a measure of airflow obstruction. For spirometry, the patient is asked to refrain from using bronchodilator medication for 6 to 12 hours before the test. The test is then completed both before and after administration of a bronchodilator to determine the degree of response. Most children 6 years of age and older should be able to perform spirometry, but a standardized clinical score such as the Pediatric Respiratory Assessment Measure (PRAM) can reduce subjectivity of assessment (Ducharme, Dell, Radhakrishnan, et al., 2015).

(The normal values for pulmonary function tests are discussed in Chapter 28.)

An alternative objective pulmonary measurement is peak expiratory flow rate (PEFR), in which variable airflow limitation overtime is measured (see Chapter 28, Table 28-15). The PEFR is a home measurement, which is not as reliable as spirometry but can be used when spirometry or challenge testing is unavailable. To determine an asthma diagnosis through this method, the patient must measure the PEFR four times per day—in the morning and evening both before and after bronchodilator treatment—for several weeks. To determine the PEFR variability, the lowest reading is subtracted from the highest reading, the result is divided by the highest reading, and this answer is then multiplied by 100. Variability in peak expiratory flow of 20% or higher is indicative of asthma.

Determining airway hyper-responsiveness with the use of methacholine, histamine, or exercise challenge testing can be useful in patients with persistent symptoms despite normal spirometry findings and to evaluate work-related asthma (Lougheed, Lemiere, Dell, et al., 2010). Challenge testing must be performed in a controlled environment by trained staff.

Chest radiographs are not necessary to diagnose asthma; however, they may be used to exclude other diagnoses, such as congenital malformations in children and heart failure in adults (Lougheed, Lemiere, Dell, et al., 2010). A chest radiograph in a patient with asthma with no clinical manifestations is usually normal; however, this radiograph should be used as a baseline on initial diagnosis. A chest radiograph obtained during an acute attack usually shows hyperinflation and may reveal other complications of asthma such as mucoid impaction, pneumothorax, atelectasis, or pneumomediastinum.

Allergy assessment is warranted in a patient with asthma and must be interpreted in view of the patient's history of exposure and symptom experience. Allergy skin testing can be helpful in determining sensitivity to specific allergens (antigens). (Allergy testing is discussed further in Chapter 16.)

If a patient is in acute distress, it is not feasible to obtain a detailed health history (although a family member may supply some pertinent information). During an acute asthma attack, bedside spirometry (FEV_1 and FVC are preferred, but usually PEFR is measured) may be used to monitor obstruction. Serial spirometric parameters, oximetry, and measurement of ABGs help provide information about the severity of the attack and the response to therapy. A complete blood cell count and serum

electrolyte measurements are obtained to help monitor the course of therapy because high dosages of inhaled β_2 agonists can cause hypokalemia.

In addition to standard measures of asthma control, monitoring changes in sputum eosinophil counts is a method of measuring airway inflammation, indicating whether treatment for asthma is working (Lougheed, Lemiere, Ducharme, et al., 2012). Sputum eosinophils are not normally present in a healthy individual, but their levels are increased in individuals with known asthma who are exposed to allergens. These measurements have been used in adults and children and are becoming more easily available and reliable. However, they continue to be used most frequently in major research centres.

Collaborative Care

In 1990, Canada became the first country to produce asthma practice guidelines. These guidelines provide a medical approach to diagnosing and managing asthma informed by the best available evidence. The Registered Nurses' Association of Ontario (RNAO) also developed asthma best practice guidelines for adults (RNAO, 2017) and children (Olajos-Clow, Cicutto, Duff Cloutier, et al., 2008) to provide nurses working in diverse settings with an evidence-informed summary of basic asthma care. The RNAO's *Best Practice Guidelines* build on and complement the Canadian Asthma Consensus Report and remain pertinent with the current Canadian Thoracic Society Asthma Management Guidelines Update (Lougheed, Lemiere, Dell, et al., 2012). The focus of the nursing guidelines is on promoting asthma control for adults and children affected by asthma. The overall goal of the guidelines is to achieve asthma control with the minimum level of pharmacotherapy while enhancing the quality of life of individuals living with asthma and reducing the personal and social burdens inflicted by the condition.

Education that builds an active partnership with patients remains the cornerstone of asthma management (see the following "Evidence-Informed Practice" box). Education should start at the time of asthma diagnosis and be integrated into every aspect of clinical asthma care. Asthma self-management should be tailored to the needs of each patient; patients' cultural beliefs and practices should be accounted for. Emphasis should be placed on evaluating outcomes in terms of a patient's level of asthma control and perceptions of improvement, especially quality of life and the ability to engage in activities of normal living such as physical

activity. A listing of centres that provide asthma education to patients can be accessed through the Canadian Network for Respiratory Care (see the Canadian Resources at the end of this chapter).

Evidence-Informed Practice

Research Highlight

Adult Asthma Care Guidelines: Promoting Control of Asthma

Clinical Questions

1. What are the appropriate nursing assessment strategies to use with adults living with asthma to achieve optimal asthma control?
2. What are the appropriate nursing management strategies to use with adults living with asthma to achieve optimal asthma control?
3. What education and training do nurses require to assist people living with asthma to achieve optimal asthma control?
4. What organization or health system–level supports are needed to enable health care providers to assist people living with asthma to achieve optimal asthma control?

Best Available Evidence

Multiple systematic reviews of asthma management practices

Synthesis of Best Available Evidence

Recommendations of Clinical Practice Guideline

Assessment

Recommendation 1.0: All individuals identified as having asthma, or suspected of having asthma, will have their level of asthma control assessed by the nurse.

Recommendation 1.1: At initial encounter, the nurse should identify adults with an asthma diagnosis by reviewing the health record for an established asthma diagnosis,

supported by the use of objective lung function measurements, and by asking the following two questions:

1. Have you ever been told by a health care provider that you have asthma?
2. Have you ever used a puffer or inhaler or asthma medication for breathing problems?

Recommendation 1.2a: At every encounter, the nurse should assess the person's current level of asthma control according to the following criteria:

- Need for a fast-acting β_2 agonist <4 doses/week (including for exercise)
- Daytime symptoms <4 days/week
- Nighttime symptoms <1 night/week
- Normal physical activity levels
- Mild, infrequent exacerbations
- No absences from work or school
- Forced expiratory volume in first second (FEV_1) or peak expiratory flow (PEF) ≥ 90% of personal best*†
- Diurnal PEF variation < 10%–15%*†
- Sputum eosinophil [counts] <2%–3%*

Recommendation 1.2b: For adults with uncontrolled asthma, the nurse should determine whether the person is currently experiencing an asthma exacerbation and, if so, the severity and need for urgent medical attention.

Recommendation 1.3: At every encounter, the nurse should assess the person's risk of future asthma exacerbations according to the following criteria:

- Current control of asthma
- Severe exacerbations experienced
- Exacerbations necessitating systemic corticosteroids
- Use of emergency care or hospitalizations for asthma

Recommendation 1.4: At every encounter, the nurse should identify factors affecting the complexity of asthma management for the person, including age, sex, smoking habits, social determinants of health, triggers, and comorbid conditions.

Asthma Planning

Recommendation 2.0: The nurse should develop an individualized, person-centred asthma education plan that addresses the following:

- Learning needs
- Culture
- Health literacy
- Empowerment

Implementation

Recommendation 3.1a: The nurse should provide asthma education as an essential component of care.

Recommendation 3.1b: The nurse should educate the person on the essential skills and self-management of asthma based on the person's learning needs, including the following:

- Pathophysiology of asthma
- Medications and device technique
- Self-monitoring
- Action plans
- Trigger identification and management
- Smoking cessation (if applicable)

Recommendation 3.2: The nurse should evaluate nonpharmacological interventions for effectiveness and for potential interactions with pharmacological interventions

Recommendation 3.3a: At every encounter, the nurse should actively educate on correct inhaler device technique through observation, feedback, physical demonstration, and written instructions.

Recommendation 3.3b: The nurse should engage the person with asthma in shared decision making with regard to the selection of an inhaler device.

Recommendation 3.3c: The nurse should educate the person with asthma on the difference between controller and reliever medications, their indications, and their potential adverse effects.

Recommendation 3.4: When appropriate, the nurse should assist and educate persons with asthma to measure their peak expiratory flow.

Recommendation 3.5: To support self-management, the nurse should collaborate with the person with asthma to develop and review a documented asthma action plan, in one or a combination of the following formats:

- In writing, on paper
- Electronically
- Pictorally

Recommendation 3.6: The nurse should provide integrated asthma self-management support to adults with uncontrolled asthma who are at risk for severe exacerbations through multiple modalities/formats, such as one of the following:
- Home-care visits
- Telehealthcare

Recommendation 3.7: The nurse should refer and connect persons with asthma to one of the following:
- Primary care provider
- Certified asthma educator or certified respiratory educator

Evaluation

Recommendation 4.1: At every encounter, the nurse should evaluate the effectiveness of the overall plan of care in achieving asthma control.

Education

Recommendation 5.1a: At every encounter, the nurse should evaluate the effectiveness of the overall plan of care in achieving asthma control.
- Health care providers
- Students entering health care professions

Recommendation 5.1b: At every encounter, the nurse should evaluate the effectiveness of the overall plan of care in achieving asthma control.

Recommendation 5.3: The nurse should provide a quality assurance program and standardized training for health care providers who perform spirometry.

Organization and Policy

Recommendation 6.1: Organizations establish a corporate priority focused on the integration and evaluation of best practice asthma care across all care settings.

Recommendation 6.2: Organizations provide the resources and professional training necessary to integrate best practices for the assessment and management of adult asthma across all care settings.

PEFR, peak expiratory flow rate.

*Indicates important objective information for a complete assessment of asthma control, but may not be available.

†Performed and interpreted within health care provider's scope of practice (including appropriate knowledge and skills) and in alignment with organizational policies and procedures.

General Management Approach.

Several components enable successful management of asthma: (a) establishment of a confirmed diagnosis through the use of objective measures; (b) development of a partnership between health care providers and the patients and families affected by asthma; (c) limited exposure to triggers; (d) education of patients; (e) appropriate pharmacotherapy; (f) continuous assessment and monitoring of asthma control and severity; (g) implementation of a written action plan; and (h) ensuring regular follow-up.

In Canada, asthma treatment is based on the Asthma Management Continuum (see Figure 31-5), which reflects the key concepts pertaining to asthma diagnosis and management for children 6 years of age and older and for adults. Controlling the disease in order to prevent complications, morbidity, and mortality is the primary goal of asthma management (Lougheed, Lemiere, Dell, et al., 2010; Lougheed, Lemiere, Ducharme, et al., 2012). The continuum accounts for the fact that the level of control and severity of asthma change over time and that constant assessment and adjustment of therapy is necessary to achieve and maintain control. The general management approach to asthma includes confirming the diagnosis, monitoring the level of asthma control (see Table 31-3), reducing exposure to environmental triggers, providing appropriate medications, providing asthma education, and providing a written action plan.

All individuals with asthma need to have access to "a rescue medication," sometimes referred to as a *fast-acting β_2 agonist (FABA);* such medications most commonly consist of an inhaled short-acting β_2 agonist (SABA), specifically salbutamol. In rare cases, a select subgroup of individuals 12 years of age and older with moderately severe asthma but poor control and prone to exacerbations are already receiving a fixed maintenance of a FABA; this may consist of a combination of an inhaled corticosteroid (ICS) and a long-acting β_2 agonist (LABA), specifically budesonide/formoterol, for quick relief of symptoms (Lougheed, Lemiere, Ducharme, et al., 2012).

If symptoms are infrequent and lung function measurements are normal, a SABA used on an as-needed basis to relieve symptoms is all that is required. However, an ICS is also required if one or more indicators of poor control are identified in a child 6 years of age or older or in an adult (see Table 31-2; Lougheed, Lemiere, Ducharme, et al., 2012). The guidelines emphasize that most patients with asthma, unless it is very mild and manifests infrequently, require daily use of ICS in addition to a SABA as necessary (Lougheed, Lemiere, Dell, et al., 2010). If symptoms persist and are outside the limits of acceptable asthma control, the next step recommended on the Asthma Management Continuum in children 6 to 11 years old is advancement to a moderate-dosage ICS. In children 12 years of age and older and in adults, however, the appropriate second-line therapy is the addition of a LABA in the form of a combination inhaler; the third-line therapy is an increase to a moderate-dosage ICS or addition of leukotriene receptor antagonists (LTRAs). For children 6 to 11 years old in whom asthma is not controlled on a moderate-dosage ICS, the addition of a LABA or LTRA, or both, is recommended. A fourth-line therapy—addition of theophylline—may be considered for adults.

In a minority of patients, symptoms persist despite the use of these therapies. If the FEV_1 is below 60% of predicted levels or of their best value, treatment with an oral corticosteroid (prednisone) should be initiated (GINA, 2015). Long-term prednisone use may be indicated and effective for asthma that is difficult to control, but it should be avoided, if at all possible, because of its adverse effects. An anti-IgE antagonist, omalizumab (Xolair), may be considered in patients 12 years of age and older with atopic asthma that is poorly controlled despite high-dosage ICS and additional therapies, either with or without prednisone. The Asthma Management Continuum also stresses the importance of assessing symptom control, lung function, inhaler technique, adherence to therapy, avoidance of exposure to asthma triggers, the presence of comorbid

conditions, and examination of sputum eosinophils (where available) on a regular basis and before therapy is advanced (Lougheed, Lemiere, Ducharme, et al., 2012).

Acute Asthma Episode.

Many patients with an acute asthma episode come to the emergency department. The choice of treatment of acute asthma depends on the severity of a patient's condition and the response to initial therapy. The examiner can assess the degree of severity by measuring FEV_1 or PEFR, by identifying the degree of change in objective measurements, and by evaluating the baseline pulse oximetry value. Inhaled SABA (e.g., salbutamol) should be administered immediately and supplemental oxygen provided to keep arterial oxygen saturation (SaO_2) above 92%. In more severe cases, ABG measurements may be used to monitor SaO_2.

Inhaled β_2-adrenergic agonists are preferably administered through a metered-dose inhaler (MDI) with a spacer (a holding chamber that holds the medication for a few seconds after it has been released from the inhaler) at a frequency of four to eight puffs every 15 to 20 minutes, usually repeated three times. If the FEV_1 or PEFR is below 40% of predicted, one puff every 30 to 60 seconds (up to 20 puffs) may be administered, depending on the patient's response to and tolerance of treatment (Hodder, Lougheed, Rowe, et al., 2010). Ipratropium bromide (four to eight puffs inhaled every 15 to 20 minutes, repeated three times) may be added to salbutamol during moderate and severe acute asthma episodes. In some emergency departments, bronchodilators are administered via a nebulizer, but a meta-analysis of study results revealed that the MDI with a spacer works faster, is less costly, and is more effective in reducing hospitalization and improving clinical scores (GINA, 2015).

Oral corticosteroids are indicated for treatment of an acute exacerbation that necessitates a visit to the emergency department. Intravenous corticosteroids are generally administered to patients who have difficulty with swallowing. Therapy should be continued until the patient is breathing comfortably, wheezing has disappeared, and pulmonary function measurements are near baseline values.

On occasion, an asthma attack is so severe and unresponsive to treatment that the patient requires mechanical ventilation. Indications for mechanical ventilation are persistent or progressive carbon dioxide retention and respiratory acidosis, clinical deterioration (indicated by fatigue, hypersomnolence), metabolic acidosis, and cardiopulmonary

arrest. In life-threatening asthma exacerbation, the goals of initiating mechanical ventilation are to achieve a partial pressure of arterial oxygen (PaO_2) of 60 mm Hg or higher, an SaO_2 of 90% or higher, and a normal pH.

Audible wheezing may occur in the airways, which indicates a response to therapy as airflow increases. As the patient begins to respond to therapy and symptoms begin to subside, it is important to remember that despite the reversibility of most of the bronchospasm, the edema and cellular infiltration of the airway mucosa and the viscous mucous plugs are still present, and improvement may take several days. Thus intensive therapy includes corticosteroids and must be continued even after clinical improvement has occurred. Patients with moderate or severe acute asthma are typically discharged home with an inhaled SABA, an added LABA or LRTA, high-dosage ICS, and an oral corticosteroid, and the addition of an anti-IgE drug should be considered as well (Lougheed, Lemiere, Dell, et al., 2010). In addition, discharge instructions should include an action plan detailing the use of the medications and the criteria for returning to the emergency department for immediate medical assistance. It is important that patients follow up with their primary asthma care provider after an emergency department visit.

Drug Therapy

Medications used to treat asthma are divided into two categories: (a) relievers and (b) controllers (Table 31-5). They are available in several forms, and various delivery devices are used to administer them. The inhaled route is preferred because the drug is delivered directly to the lungs, which minimizes systemic absorption and thus the number and intensity of adverse events. Relievers, used to ease asthma symptoms, are also known as "rescue medication" and are used intermittently as required. Controllers are maintenance therapy used on a daily basis, typically twice a day. Because inflammation is considered an early and persistent component of asthma, drug therapy is directed toward long-term suppression of inflammation (Table 31-6).

TABLE 31-5

CATEGORIES OF ASTHMA MEDICATIONS: RELIEVERS VERSUS CONTROLLERS

Reliever Medications
Bronchodilators
• Short-acting inhaled β_2-adrenergic agonists (e.g., salbutamol)
Anticholinergics
• Ipratropium, for example*
Controller Medications
Anti-Inflammatory Drugs

• Corticosteroids
  • Inhaled (e.g., fluticasone)
  • Oral (e.g., prednisone)
• Leukotriene modifiers (e.g., montelukast)
• Anti-IgE (e.g., omalizumab)

Bronchodilators
• Long-acting inhaled β_2-adrenergic agonists (e.g., salmeterol inhalation) • Long-acting oral β_2-adrenergic agonists (e.g., oral salmeterol) • Methylxanthines (e.g., theophylline)

*Not considered a rescue medication if used alone; commonly used in combination with salbutamol in the emergency department for severe exacerbations.

TABLE 31-6

DRUG THERAPY
Asthma and Chronic Obstructive Pulmonary Disease

Drug	Route of Administration	Mechanisms of Action	Adverse Effects	Comments
Bronchodilators				
Short-Acting β_2-Adrenergic Agonists				
Salbutamol (Airomir, Apo-Salvent, Ventolin)	Diskus DPI, MDI, nebules	Selectively stimulates β_2 receptors on airway smooth muscle, causing relaxation and producing bronchodilation	Tremor, tachycardia, headache, nervousness, palpitations, insomnia; excessive use can cause hypokalemia	Asthma "rescue medication" (FABA) Rapid onset of action: 1–3 min Duration of action: up to 6 hr Peak effect: 60–90 min
Terbutaline (Bricanyl)	Turbuhaler DPI	Same as for salbutamol	Same as for salbutamol	Rapid onset of action: within minutes Duration of action: 4–7 hr Peak effect: 15–60 min
Long-Acting β_2-Adrenergic Agonists				
Formoterol (Foradil, Oxeze)	Aerolizer DPI, Turbuhaler DPI	Selectively stimulates β_2 receptors on airway smooth muscle, causing relaxation and producing bronchodilation	Tremor, tachycardia, headache, nervousness, palpitations, insomnia	Rapid onset of action: 1–3 min Duration of protection: 8–12 hr Peak effect: 15 min Typically taken twice daily Oxeze has approval to be used as an asthma reliever (FABA) in asthma only in specified patients, and only when used in combination with inhaled steroid (specifically budesonide)

Drug	Route of Administration	Mechanisms of Action	Adverse Effects	Comments
Salmeterol (Serevent)	Diskus DPI	Same as above	Same as above	Onset of action: 10–20 min Duration of action: 8–12 hr Typically taken twice daily; not to exceed 50 mcg q12h Not used for relief of acute exacerbations
Anticholinergics				
Ipratropium bromide (Apo-Ipravent, Atrovent HFA)	MDI, nebulizer	Blocks action of acetylcholine, resulting in bronchodilation; competitive inhibitor of muscarinic receptors	Dry mouth, cough, bad taste in mouth, nausea, headache, flushed skin; blurred vision if sprayed in eyes	Onset: 5–15 min Duration: 4–6 hr Peak effect: 1–2 hr Should be used with caution by individuals with narrow-angle glaucoma, prostatic hyperplasia, or bladder neck obstruction
Ipratropium and salbutamol (Combivent) Ipratropium and fenoterol (Duovent)	Nebulizer	Combination of anticholinergic and β_2 agonist preparations produces bronchodilation	Same as for ipratropium and short-acting β_2 agonists	Same as for ipratropium and short-acting β_2 agonists
Tiotropium bromide (Spiriva)	HandiHaler DPI	Blocks action of acetylcholine, resulting in bronchodilation; competitive inhibitor of muscarinic receptors on bronchial smooth muscle	Dry mouth, cough, bad taste in mouth, nausea, headache, constipation, urinary retention	Onset: 30 min Peak: 1–4 hr Duration: 24 hr Should be used only once per day Should be used same time each day Contact with eyes should be avoided Powder capsules sensitive to light and moisture
Anti-Inflammatory Drugs				
Steroidal Anti-Inflammatory Drugs				
Hydrocortisone (Cortef Tab, Solu-Cortef)	Oral, intravenous	Potent anti-inflammatory and immuno-suppressive effects; interferes with inflammatory cascade; decreases edema in bronchial airways;	Short-term use (<2 wk): weight gain, increased appetite, Cushingoid appearance,	Onset: Some effects within 2–4 hr In acute severe asthma, 4–12 hr may be
Methylprednisolone (Medrol, Solu-Medrol)	Oral, intravenous			

Drug	Route of Administration	Mechanisms of Action	Adverse Effects	Comments
Prednisone (Winpred) Prednisolone (Pediapred) Dexamethasone	Oral	increases number and affinity of β_2 receptors; abolishes and prevents tolerance induced with chronic use of inhaled β_2 agonists; decreases mucus secretion; effective in late-phase reaction of asthma	menstrual changes, mood changes, skin changes (acne, striae, bruising) Longer term use (>2 wk): adrenal suppression, immuno-suppression, osteoporosis, hyperglycemia, obesity, peptic ulcers, hypertension, hypokalemia, cataracts, glaucoma, muscle weakness, catabolism, growth retardation, avascular necrosis, dysphonia	required before clinical response noted Reversal of bronchial hyper-responsiveness requires approximately 1 wk Alternate-day or morning therapy may minimize the intensity of adverse drug events Should be taken with food When drug is given in high doses, patient should be assessed for epigastric pain Histamine (H_2) blockers and antacids may minimize the intensity of GI effects Patient should be counselled about how to prevent osteoporosis If taken for <2 wk or <2 bursts in 1 year, no tapering of dosage required; otherwise dosage should be tapered gradually If symptoms recur during tapering, asthma care provider should be notified

Drug	Route of Administration	Mechanisms of Action	Adverse Effects	Comments
Beclomethasone (QVAR, Rivanase AQ)	MDI, nasal spray	Same as for hydrocortisone and others Acts locally in respiratory tract with relatively little systemic absorption at low to medium dosages	Oral candidiasis infection, hoarseness, irritated throat, dry mouth, cough	Mouth should be rinsed after use to reduce the risk for oral fungal infections, hoarseness, and dry mouth If an MDI is used, a spacer should also be used to reduce the intensity of adverse effects Nasal spray form used for allergic rhinitis Typically taken twice daily
Budesonide (Pulmicort, Rhinocort NS)	Turbuhaler DPI, nasal spray, nebulizer	Same as for beclomethasone	Same as for beclomethasone	Mouth should be rinsed after use Nasal spray form used for allergic rhinitis Typically taken twice daily
Ciclesonide (Alvesco, Omnaris NS)	MDI, nasal spray	Same as for beclomethasone	Same as for beclomethasone	Same as for budesonide
Fluticasone (Avamys NS, Flonase NS, Flovent DPI, MDI)	Diskus DPI, MDI, nasal spray	Same as for beclomethasone but with higher potency (approximately double); as a result, dosages tend to be lower	Same as for beclomethasone; bruising with higher dosages	Mouth should be rinsed after use If an MDI is used, a spacer also needed to reduce the intensity of adverse effects Nasal spray form used for allergic rhinitis Typically taken twice daily
Mometasone (Nasonex NS)	Metered-dose manual pump spray	Exact mechanism of action unknown	Headache, viral infection, pharyngitis	Treatment may be required for 2 wk before improvement noted
Combination Inhalers: Inhaled Corticosteroid and Inhaled Long-Acting β_2 Agonist (LABA)				

Drug	Route of Administration	Mechanisms of Action	Adverse Effects	Comments
Budesonide and formoterol (Symbicort) Fluticasone and salmeterol (Advair) Mometasone and formoterol (Zenhale)	Turbuhaler DPI, diskus DPI, MDI	See text sections pertaining to inhaled corticosteroid and inhaled LABAs	See text sections pertaining to inhaled corticosteroid and inhaled LABAs	Commonly used for moderate and severe asthma Combination therapy products may simplify treatment regimen In COPD, ICS is recommended only in combination with LABA and is initiated when a person has had >1 acute exacerbation in a year
Antileukotrienes				
Montelukast (Singulair)	Oral tablets, chewable tablets for children, granules	Blocks the action of leukotrienes released by inflammatory cell membranes; has bronchodilator and anti-inflammatory effects	Headache, indigestion, nausea, vomiting, diarrhea, fatigue, abdominal pain, respiratory infections	Prevents exercise-induced asthma Affects metabolism of erythromycin and theophylline Not used to relieve acute asthma episodes
Zafirlukast (Accolate)	Oral tablets	Same as for montelukast	Same as for montelukast	Same as for montelukast Bioavailability is reduced when it is taken with food
Anti–IgE Antagonist				

Drug	Route of Administration	Mechanisms of Action	Adverse Effects	Comments
Omalizumab (Xolair)	Subcutaneous injection	Binds free IgE and therefore prevents IgE from binding to receptors on its effector cells, primarily mast cells and basophils, which, in turn, prevents allergens from triggering acute allergic reactions	Reaction at injection site (pain, bruising, redness, warmth)	Only for moderate to severe persistent allergic asthma with symptoms not inadequately controlled by ICS Not for acute bronchospasm Administered under direct medical supervision; patient is observed for a minimum of 2 hr after administration because anaphylaxis has been reported with use
Methylxanthines				
Theophylline (Uniphyl, Theolair) Aminophylline	Oral, intravenous	Relieves bronchoconstriction and its accompanying symptoms by dilating the muscles around the bronchi	Tachycardia, blood pressure changes, dysrhythmias, anorexia, nausea, vomiting, nervousness, irritability, headache, muscle twitching, flushing, epigastric pain, diarrhea, insomnia, palpitations	Wide variety of responses to drug metabolism Half-life: ↓ by smoking and ↑ by heart failure and liver disease Cimetidine, ciprofloxacin, erythromycin, and other drugs may rapidly ↑ theophylline levels The effect of these medications is proportionate to their concentration in the blood To be effective, they must be taken regularly, and blood concentrations should be monitored
Phosphodiesterase 4 Inhibitor				

Drug	Route of Administration	Mechanisms of Action	Adverse Effects	Comments
Roflumilast (Daxas)	Oral	Selective phosphodiesterase 4 inhibitor Nonsteroidal anti-inflammatory drug that targets systemic and pulmonary inflammation associated with COPD	Diarrhea, nausea, anorexia, weight loss, headache, insomnia, anxiety; may resolve after 4 wk of continuous treatment	Indicated for use in severe COPD as a therapeutic addition to long-acting bronchodilators for patients with chronic cough, chronic sputum findings, and history of frequent exacerbations Not currently indicated for asthma Not indicated for acute bronchospasm

COPD, chronic obstructive pulmonary disease; *DPI,* dry powder inhaler; *FABA,* fast-acting β_2 agonist; *GI,* gastro-intestinal; *ICS,* inhaled corticosteroids; *IgE,* immunoglobulin E; *MDI,* metered-dose inhaler.

Anti-Inflammatory Drugs

Corticosteroids.

Chronic inflammation is a primary component of asthma. Corticosteroids are anti-inflammatory medications that reduce bronchial hyper-responsiveness by blocking the late-phase reaction and that inhibit migration of inflammatory cells. Corticosteroids are more effective than any other long-term drug in improving asthma control. ICSs are the mainstay therapy for the long-term control of asthma (GINA, 2015). Usually, ICSs must be administered for 1 to 2 weeks before maximum therapeutic effects can be observed. However, some ICSs (e.g., fluticasone and budesonide) begin to have a therapeutic effect in 24 hours. These drugs must be administered on a fixed schedule.

For children 6 years of age and older and adults with newly diagnosed asthma, low-dosage ICS is recommended (see Figure 31-5) and for ICS-naive patients with mild loss of control (see Table 31-2). In children 6 years of age and older and adults presenting with an asthma exacerbation necessitating a short-term regimen of systemic corticosteroids, a daily low- to moderate-dosage ICS should be initiated as maintenance therapy. In children 6 years of age and older, if low-dosage ICS is not adequate in

achieving or maintaining control, then increasing to moderate-dosage ICS (see Figure 31-5) is the preferred approach. To minimize the intensity of adverse effects, however, add-on therapy should be considered in patients 12 years of age and older before ICS therapy is increased to moderate dosages and certainly before high dosages are prescribed (GINA, 2015).

When ICSs are administered, asthma can usually be controlled without significant systemic adverse events because only minimal amounts of drugs are absorbed systemically. However, ICSs administered at the highest dosage levels have been associated with adverse events such as easy bruising and accelerated bone loss (GINA, 2015). Oropharyngeal candidiasis, hoarseness, and dry cough are local adverse effects caused by ICS (GINA, 2015). Occurrence of these oropharyngeal adverse events can be reduced by mouth rinsing and gargling after every inhalation treatment. If an MDI is used, absorption can be improved, and the intensity of adverse events is reduced with the use of a spacer (Figure 31-6). However, newer drugs (e.g., ciclesonide) that are activated in the lungs (not in the pharynx) appear to minimize the intensity of these adverse events without the need for a spacer or mouth rinsing (Lougheed, Lemiere, Dell, et al., 2010).

FIGURE 31-6 Example of an AeroChamber spacer used with a metered-dose inhaler. Source: Potter, P. A., Perry, A. G., Stockert, P., et al. (2011). *Basic nursing: Essentials for practice* (7th ed.). St. Louis: Mosby.

In acute asthma exacerbations, short courses of orally administered corticosteroids are indicated for gaining prompt control (Lougheed, Lemiere, Dell, et al., 2010). In a minority of cases, maintenance dosages of oral corticosteroids are necessary to control severe chronic asthma. However, long-term use should be avoided in all age groups if possible, especially children, because of adverse effects (Lougheed, Lemiere, Dell, et al., 2010). If long-term use is indicated, a single dose in the morning, to coincide with endogenous cortisol production, and alternate-day dosing should be considered; these schedules are associated with fewer adverse effects. Long-term corticosteroid therapy is discussed further in Chapter 51.

Adults using maintenance oral corticosteroids or high dosages of ICS (>500 mcg of fluticasone and beclomethasone; >800 mcg of budesonide), or both, should be monitored for osteoporosis with bone densitometry. Patients should take adequate amounts of calcium and vitamin D and participate in regular weight-bearing exercise. (Osteoporosis is discussed in Chapter 66.)

Antileukotrienes.

In Canada, two leukotriene receptor antagonists (zafirlukast, montelukast), which block the action of leukotrienes (Lougheed, Lemiere, Dell, et al., 2010), are available. Leukotrienes are produced as a result of arachidonic acid metabolism (see Chapter 14, Table 14-3). Some leukotrienes are potent bronchoconstrictors, causing airway edema and inflammation, and thus contribute to the symptoms of asthma. The anti-inflammatory action of antileukotrienes is not as potent as that of ICS, and thus they are not recommended as a single drug in the treatment of persistent asthma (Lougheed, Lemiere, Dell, et al., 2010). These drugs are used as adjuvant or add-on therapy for individuals experiencing symptoms (uncontrolled asthma) or significant adverse events while using higher dosage ICS. Antileukotrienes may be considered as an alternative to increasing dosages of ICS. They are not used to reverse bronchospasm in acute asthma attacks. An advantage of these drugs is that they are administered orally.

Anti–Immunoglobulin E Antagonists.

Omalizumab (Xolair) is a monoclonal antibody to IgE that decreases circulating free IgE levels (Kuhl & Hanania, 2012). Omalizumab prevents IgE from attaching to mast cells, which thus prevents the release of chemical mediators. Health Canada has approved this drug for use by

patients who have moderate to severe persistent allergic asthma and are 12 years of age and older. This medication is expensive and therefore should be reserved for specific patients: those with asthma that is difficult to control despite adherence to a regimen of high-dosage ICS and at least one additional controller therapy; those who have objectively confirmed asthma; those who have documented allergic perennial asthma; and those whose serum IgE level is 30 to 700 IU/mL. The medication is administered subcutaneously every 2 to 4 weeks and should be part of a well-controlled therapeutic trial supervised by an asthma specialist (Lougheed, Lemiere, Dell, et al., 2010).

Bronchodilators.

Three classes of bronchodilator drugs are currently used in asthma therapy: β_2-adrenergic agonists, anticholinergic drugs, and methylxanthines.

β_2-Adrenergic Agonists.

These drugs may be SABAs or LABAs. These medications work by binding to β_2 receptors located on airway smooth muscle, causing relaxation of the bronchial smooth muscle and thus bronchodilation. Fast-acting β_2-adrenergic agonists are the drug of choice for relief of acute symptoms of asthma (Lougheed, Lemiere, Dell, et al., 2010) and are used as rescue or reliever medication for quick relief of symptoms; therefore, they should be carried by the patient at all times. They are also used to prevent bronchospasm precipitated by exercise, with administration 10 to 15 minutes before exercise. In Canada, several SABAs are approved for this indication, including salbutamol and terbutaline (Lougheed, Lemiere, Dell, et al., 2010). These drugs begin to work within a few minutes and cause maximum dilation within 10 to 15 minutes. The duration of effect varies according to the drug, but airflow rates remain significantly elevated for 2 to 6 hours after inhalation. Adverse events from SABAs are few; they include mild tremor and tachycardia, which diminish with repeated use without loss of bronchodilator effect. However, frequent daily use of inhaled SABAs may be associated with decreased control of asthma and provides the rationale for as-needed dosage. The frequency of use of reliever medications is a good indicator of a patient's level of asthma control (Lougheed, Lemiere, Dell, et al., 2010).

LABAs provide sustained bronchodilation (approximately 12 hr) and include formoterol and salmeterol. LABAs should be considered as add-on

therapy in adults who have persistent symptoms despite low-dosage ICS and in children 6 to 11 years of age who have persistent symptoms despite use of moderate-dosage ICS (Lougheed, Lemiere, Dell, et al., 2010). Both formoterol and salmeterol can help patients reduce the amount of ICS necessary to control asthma and are useful in controlling nocturnal asthma symptoms. However, LABAs are to be used not as monotherapy but rather in combination with an ICS (Lougheed, Lemiere, Dell, et al., 2010). Neither salmeterol nor formoterol causes major adverse events when used in conjunction with ICS. Immediate adverse events are similar to those of SABAs. Salmeterol and formoterol cannot be considered interchangeable. Formoterol has a greater bronchopulmonary protective effect and is rapid acting; thus it can be used as rescue therapy for prompt relief of symptoms when taken in combination with only an ICS (Lougheed, Lemiere, Ducharme, et al., 2012). Salmeterol has a narrower therapeutic window, and dosage should stay within the recommended range.

Combination therapy inhalers that contain both a LABA and an ICS are available and commonly used. The three products available in Canada are Advair, which is a combination of salmeterol and fluticasone; Symbicort, which is a combination of formoterol and budesonide; and Zenhale, which is a combination of formoterol and mometasone. Evidence suggests that combination therapy inhalers can replace the two separate inhalers, thus simplifying therapy and probably increasing adherence to the medication regimen. There is no superior effect over using the two inhalers separately; however, using the two medications in a combination inhaler is preferred for asthma, inasmuch as it the LABA is always used with the ICS (GINA, 2015).

Anticholinergic Drugs.

The parasympathetic division of the autonomic nervous system controls airway diameter. The effects of acetylcholine on the airways are increased smooth muscle contraction and mucus secretion, which result in bronchoconstriction. Anticholinergic drugs inhibit bronchoconstriction that is related to the parasympathetic nervous system. Anticholinergic bronchodilators are not recommended as first-line therapy in asthma, primarily because their action does not peak until 30 minutes to 1 hour after ingestion; therefore, they are inferior to SABAs as rescue or reliever inhalers. Anticholinergic drugs, as rescue inhalers, may be useful only in patients who are unable to tolerate SABAs (Lougheed, Lemiere, Dell, et al., 2010). The combination of ipratropium bromide with salbutamol (Combivent; a nebulized preparation) is commonly used for the

emergency management of acute asthma. This combination appears to produce greater bronchodilation than does either drug used alone. The most common adverse effect of anticholinergic drugs is dry mouth. Systemic adverse events are uncommon because it is poorly absorbed.

Methylxanthines.

Sustained-release methylxanthine (theophylline) preparations should be used only as controller medication for asthma that is difficult to control, after ICS, LABA, and LTRAs. Methylxanthines are bronchodilators with mild anti-inflammatory effects. Theophylline should be prescribed only by an asthma specialist because of its narrow toxic/therapeutic ratio and frequent adverse events (Lougheed, Lemiere, Dell, et al., 2010), which include nausea, headache, insomnia, gastro-intestinal distress, tachycardia, dysrhythmias, and seizures. Blood levels must be monitored regularly to determine whether the drug levels are in the therapeutic range.

Patient Education Related to Drug Therapy.

Education about asthma medication is an essential component of asthma care (GINA, 2015). Information about medications with which the patient should be familiar includes name, dosage, method of administration, frequency of use, indications, adverse effects, consequences of improper use, and the importance of adherence. Specifically, with regard to asthma, patients need to be taught about the different roles and indications for using relievers and controllers. In addition to providing information, it is essential that the nurse assess a patient's ability to use inhaler devices accurately and provide coaching in the proper use of the device. Thus all nurses should know the correct use of the various devices and feel confident in their ability to assess and coach patients and their families about their proper use.

Most asthma drugs are administered by inhalation. Inhalation of drugs is preferred to oral administration because a lower dosage is required and systemic adverse events are fewer and less intense. The onset of action of bronchodilators is faster when they are delivered via inhalation. Inhalation devices include MDIs with or without spacers, dry powder inhalers (DPIs), and wet nebulizers (see Table 31-6).

Wet nebulizers are used primarily to deliver large bronchodilator doses during acute asthma attacks in emergency department and other hospital settings. In the home, they are used as a last resort for patients unable to use other inhalation devices. A trial of wet nebulization in infants and

young children at home may be appropriate if an MDI with a spacer is ineffective. In response to the outbreak of severe acute respiratory syndrome (SARS), the use of wet nebulization has decreased in emergency departments and hospitals because when wet nebulization is used, aerosol is released into the environment, not just to a patient's airways; thus everyone in the room is breathing in the aerosol. MDIs with spacers are as effective as nebulizers in delivering large doses of bronchodilators during acute asthma attacks because the amount of drug delivered to the lungs is enhanced with the spacer.

Inadequate technique in the use of MDIs is widespread, and many patients demonstrate common errors (Table 31-7). If an inhaler technique can be improved and sustained, clinical benefits are likely to result (Table 31-8). Some patients need to add a spacer to the MDI or switch to a DPI to acquire a good technique. Spacers (e.g., AeroChamber, OptiChamber; see Figure 31-6) are used when patients do not have the coordination necessary to use a MDI. In addition, spacers enhance the delivery of medication to the airways and decrease the intensity of adverse events from ICS because less medication is delivered to the mouth. MDIs with spacers can be considered for all age groups and should be used when ICSs are delivered via MDI. A spacer with a face mask is recommended for young children and older adults. When spacers with face masks are used in children, however, a conversion to a spacer with a mouthpiece is encouraged as soon as the child is old enough and able to cooperate.

TABLE 31-7

PROBLEMS ENCOUNTERED WITH USE OF METERED-DOSE INHALER (MDI)

1. Failing to coordinate activation with inspiration
2. Activating MDI in the mouth while breathing through nose
3. Inspiring too rapidly
4. Not holding the breath for 10 sec (or as close to 10 sec as possible)
5. Holding MDI upside down or sideways
6. Inhaling more than one puff with each inspiration
7. Not shaking MDI before use
8. Not waiting a sufficient amount of time between each puff
9. Not opening mouth wide enough, which causes medication to bounce off teeth, tongue, or palate
10. Not having adequate strength to activate MDI
11. Being unable to perform all the necessary steps

TABLE 31-8

PATIENT & CAREGIVER TEACHING GUIDE
How to Use a Metered-Dose Inhaler (MDI) Correctly

The nurse must teach the patient that the key to using all inhaled medications is proper technique. Patients should receive the following instructions to ensure that every puff of the MDI delivers the most medication possible into the lungs, rather than to the back of the throat.
1. Firmly place the metal container into the mouthpiece. Remove the cap, and shake the inhaler vigorously. 2. Breathe out only to the end of a normal breath (not a forced breath). 3. Position the mouthpiece end of the inhaler approximately 4 cm (1.5 inches) from your mouth. 4. Open your mouth widely, and tilt your head back slightly. (Another way of doing this is to close your lips around the mouthpiece, keeping teeth apart and tongue flat so the medication can flow freely into the lungs.) 5. At the same time that you start to breathe in slowly, depress the metal container into the mouthpiece to release one puff of medication. 6. Continue breathing in slowly until your lungs are full (approximately 5 seconds). • Once you have breathed in fully, hold your breath for 10 seconds (or as long as comfortable). • If you need a second puff, wait 30–60 seconds before repeating the preceding steps.
Is the Inhaler Full?
The patient needs to know the correct way to determine whether the MDI must be replaced. Shaking the canister is not a reliable method because the patient may be hearing only the propellant move in the canister when the MDI is nearly empty. The only reliable method, if the MDI does not have a counter, is to count each puff. Alternatively, the patient can plan the length of use on the basis of prescribed puffs per day: for example, if the patient uses two puffs, twice-a-day use means that the inhaler must be replaced in 50 days. Most canisters contain 200 doses. It is a good practice to keep a spare inhaler on hand.
Special Instructions for Children
Most children younger than 9 years cannot use an MDI properly. For these children, a spacer should be used with the MDI. Regardless of the child's age, spacers are recommended when a steroid inhaler is used, to reduce the risk of developing a yeast infection in the mouth or the throat and to enhance the distribution of the medication to the small airways.
How to Use a Metered-Dose Inhaler With a Spacer
Some people, no matter how hard they try, still have trouble coordinating an MDI. Fortunately, spacers (holding chambers), which hold the medication for a few seconds after it has been released from the inhaler, are available. The patient's physician or Certified Respiratory Educator may recommend one if the patient has trouble with an MDI or is using an ICS.
Spacers may also reduce occurrence of adverse drug events such as hoarseness or sore throat if the patient is taking higher dosages of ICS. Spacers can be used with most aerosol inhalers and are very easy to use. Following are instructions for using a spacer with an MDI:
1. Remove the plastic cap from the inhaler mouthpiece and the spacer mouthpiece. 2. Insert the inhaler mouthpiece into the large opening of the spacer. 3. Hold the spacer and inhaler together and shake well. 4. Forcibly exhale. 5. Put the mouthpiece of the spacer into your mouth, close your lips around it; do not cover the small slots. 6. Press the metal canister down into the inhaler to spray the medication into the spacer. Then, breathe in slowly and deeply through your mouth (for approximately 5 seconds). 7. Hold your breath for as long as you comfortably can (approximately 10 seconds). 8. Breathe out slowly through your mouth or nose. 9. If more puffs are prescribed, wait 1 minute and then repeat these steps, starting from step 3.
Caring for the Spacer
Spacers must be cleaned weekly because powder collects on the walls of a spacer with repeated use. To clean, agitate the spacer device carefully in warm tap water mixed with dish soap. Shake off excess water, do not rinse, and allow it to air dry overnight; do not dry with a towel. The soap residue left on the chamber, as well as not using a towel to dry, will prevent static cling and therefore prevent medication from clinging to the inside of the chamber.

ICS, inhaled corticosteroids; *MDI,* metered dose inhaler.

http://www.asthma.ca/adults/treatment/spacers.php.

The DPI contains dry, powdered medication and is breath-activated (Figure 31-7). No propellant is used; instead, an aerosol is created when the patient inhales quickly and forcefully through a reservoir containing a dose of powder. Patients find DPIs easier to use than MDIs with no spacer. There are several advantages to using DPIs: (a) less manual dexterity is required; (b) the patient does not need to coordinate depressing the canister with inhaling; (c) an easily visible colour or number system indicates the number of doses left in the device; and (d) no spacer is necessary. The biggest problem with DPIs is that the medication may clump if exposed to humidity, and so they should be stored in a dry place. The care of DPIs involves wiping off the mouthpiece with a dry tissue. Water or other liquids should never be used to clean the device, which could cause clumping of the medication and cause the device to work improperly.

FIGURE 31-7 Example of a dry powder inhaler (DPI). Source: From Potter, P. A., Perry, A. G., Stockert, P., et al. (2011). *Basic nursing: Essentials for practice* (7th ed.). St. Louis: Mosby.

Various inhalation devices are used to deliver medications to the airways. It is important to work with patients individually to identify the inhalation device that best fits their needs.

Poor adherence to asthma therapy regimens is a major challenge in the long-term management of asthma. Patients commonly rely too heavily on

their reliever inhalers because they provide immediate relief of symptoms and gratification, whereas no immediate benefit is felt with anti-inflammatory therapy, which must be sustained on a daily basis. It is important to explain to patients the importance and purpose of taking controller therapy regularly, emphasizing that maximum improvement may take more than 1 week. It is also important to emphasize that without regular use, the inflammation in the airways may progress and the asthma is likely to worsen over time.

Nursing Management Asthma

Nursing Assessment

If a patient can speak and is not in acute distress, a detailed health history, including identification of any precipitating factors and what has helped alleviate attacks in the past, should be documented. If a patient is in acute distress, some of the information may be obtained from the person accompanying the patient. Subjective and objective data to obtain from a patient with asthma are presented in Table 31-9.

TABLE 31-9

NURSING ASSESSMENT
Asthma

Subjective Data
Important Health Information
Current health: Assess the level of asthma control (see Table 31-2); frequency and severity of asthma symptoms (wheeze, cough, sensation of chest tightness, dyspnea) in the past week, both during the day and in early morning hours and night; need for reliever medication during the past week; and usual pattern of asthma symptoms. Determine whether the patient experienced a recent worsening of asthma and how it was handled. Identify recent exposure to triggers (e.g., upper respiratory tract infection, pollen, animals, mould, dust, inhaled irritants, weather changes, exercise, smoke). *Past health history:* One or more previous asthma attacks and response to treatment; previous visits to the emergency department or hospitalizations for asthma and the need for ICU admission and intubation; recent exposure to pollen, dander, feathers, mould, dust, inhaled irritants, weather changes, exercise, smoke; allergic rhinitis and eczema; sinus infections; gastroesophageal reflux; family history of asthma and allergies *Medications:* Last time the reliever medication was used, what level of relief was provided, duration of relief, and frequency of the reliever use in the past week; pattern of use for controller medications; recent use of antibiotics; use of medications that may precipitate asthma, such as ASA (Aspirin), NSAIDs, β-adrenergic blockers; allergies to medications
Symptoms
• Wheezing, cough, sensation of chest tightness, dyspnea • Decreased level of activity or exercise because of symptoms • Interrupted sleep, fatigue; fear, anxiety, panic, depression, emotional distress
Objective Data
General
Restlessness or exhaustion, confusion, upright or forward-leaning body position
Integumentary
Eczema, diaphoresis, cyanosis (circumoral, nail beds)
Respiratory
Wheezing, crackles, diminishment or absence of breath sounds on auscultation; hyper-resonance on percussion; sputum character and quantity; increased work of breathing, demonstrated by use of accessory muscle, intercostal and supraclavicular retractions; tachypnea; prolonged expiration
Cardiovascular
Tachycardia, pulsus paradoxus, jugular venous distension, hypertension or hypotension, premature ventricular contractions
Possible Diagnostic Findings
Abnormal results of pulmonary function tests: decreased flow rates; FVC, FEV_1, PEFR, and FEV_1/FVC ratio that improve with bronchodilators and between exacerbations ↓ O_2 saturation and abnormal ABG values during moderately severe to life-threatening attacks Serum and sputum eosinophilia Positive results of skin tests for allergens and allergies to medication

ABG, arterial blood gas; *FEV_1,* forced expiratory volume in 1 second; *FVC,* forced vital capacity; *ICU,* intensive care unit; *NSAIDs,* nonsteroidal anti-inflammatory drugs; *PEFR,* peak expiratory flow rate.

Nursing Diagnoses

Nursing diagnoses for the patient with asthma may include, but are not limited to, the following:

- *Ineffective airway clearance* related to *excessive mucus, retained secretions*
- *Anxiety* related to *threat to current status, threat of death* (difficulty breathing)
- *Deficient knowledge* related to *insufficient information, insufficient knowledge of resources* (asthma education)

Additional information on nursing diagnoses is presented in Nursing Care Plan 31-1.

Nursing Care Plan 31-1

Asthma

NURSING DIAGNOSIS	***Ineffective airway clearance*** related to *excessive mucus, retained secretions* as evidenced by *ineffective cough, adventitious breath sounds*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Maintains open airways • Has normal breath sounds and respiratory rate • Has normal or personal best objective lung function measurements (PEFR, FEV_1, FEV_1/FVC) • Participates in normal life activities, including exercise and physical activity (identifying activity that is meaningful to the patient is helpful)	• Position patient to maximize ventilation potential *allowing for adequate chest expansion.* • Monitor respiratory (including spirometry) and oxygenation status *to determine need for intervention or to note improvement.* • Administer medications (e.g., bronchodilators, corticosteroids), as appropriate, *to improve respiratory function.* • Teach patient proper use of prescribed inhalers (see Table 31-8) *to deliver adequate medication to the lungs.* • Auscultate lung sounds after treatments *to note improvement.* • Regulate fluid intake to optimize fluid balance and liquefy secretions *to facilitate removal.* • Provide asthma education *to help patient understand condition and avoid triggers, when possible.* • Establish a written asthma action plan with patient to manage exacerbations., and educating the patient about it *to ensure that patient is prepared for emergency situations.*
NURSING DIAGNOSIS	***Anxiety*** related to *threat to current status* (difficulty breathing, perceived or actual loss of control, fear of suffocation) as evidenced by *restlessness, increase in heart rate, respiratory rate, and blood pressure*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Reports reduced anxiety or no anxiety	• Explore patterns of anxiety and feelings, perceptions, and fears *to identify precipitating factors and problem areas so that planning can be concentrated.* • Use a calm, supportive approach *to provide reassurance.* • Stay with patient *to promote safety and reduce fear.* • Provide factual information concerning diagnosis, treatment, and prognosis *to help patient know what to expect.* • Instruct patient on the use of relaxation techniques *to relieve muscle tension and slow respirations.*
NURSING DIAGNOSIS	***Deficient knowledge*** related to *insufficient information, insufficient knowledge of resources* (asthma and treatment) as evidenced by *inaccurate follow-through of instruction*
Expected Patient Outcomes	**Nursing Interventions and *Rationales****
• Demonstrates appropriate use of inhalers, peak flowmeters, spacers, and nebulizers (if used) • Maintains good asthma control • Manages personal triggers • Recognizes worsening asthma and initiates early treatment • Actively participates in management decisions with the asthma care team	• Appraise patient's current level of knowledge and skills related to asthma management *to identify learning needs.* • Teach patient to identify and manage triggers *to prevent asthma attacks.* • Encourage patient to verbalize feelings about diagnosis, treatment, and effect on lifestyle *to offer support and increase adherence to medication regimen to improve asthma control.* • Ensure that patient has an asthma action plan and understands its use *to enhance patient's ability to identify worsening asthma and respond appropriately.* • Instruct the patient about the proper administration of each medication* (e.g., inhalers, spacers) *to ensure proper use.* • Evaluate the patient's inhaler techniques *to assess correct technique and ensure maximum benefit.* • Instruct the patient on purpose, action, dosage, indication, and duration of each medication *to promote understanding of effects and use.* • Instruct patient about strategies to decrease the intensity of adverse drug events *to prevent or minimize the intensity of adverse drug events and enhance adherence.* • Assist patient to identify strategies that incorporate taking medications into daily life, such as taking inhaled steroids

	before brushing teeth in the morning and at night, *to enhance adherence.* • Include the family and significant others as appropriate *to ensure that a knowledgeable person is available to help when the patient needs it*

*Refer to Figures 31-6 and 31-7 and to Patient & Caregiver Teaching Guides (see Tables 31-8, 31-10, and 31-11).

FEV_1, forced expiratory volume; *FVC*, forced vital capacity; *PEFR*, peak expiratory flow rate.

Planning

The overall goals are that patients with asthma will (a) be able to participate in activities of normal life (including exercise and other physical activity) with little to no interference; (b) have normal or near-normal pulmonary function; (c) have the asthma under control; (d) experience as few adverse effects from asthma medication as possible while taking the lowest dosage of medication necessary to keep the asthma under control; and (e) possess the knowledge and skills necessary to participate in the management of the asthma.

Nursing Implementation

Asthma Education.

Nurses play an essential role in preventing and controlling asthma symptoms by developing a partnership with the patient and family, providing information and education, and helping the patient and family develop the necessary skills for controlling asthma. Education is an essential component of asthma care and should occur at every encounter with patients, families, and caregivers. In order to be effective, asthma education must provide information, help develop and refine asthma-related skills, assist with problem solving, and cause behaviour change. In addition, findings of meta-analyses suggest that self-management asthma education programs can reduce the number of emergency department visits, hospitalizations, urgent care visits, nocturnal awakenings related to asthma, and days of interrupted activity and can improve quality of life (PHAC, 2011). Asthma education programs can also be cost effective. Table 31-10 details basic asthma education to be provided.

TABLE 31-10

PATIENT & CAREGIVER TEACHING GUIDE
Basic Asthma Education

Basic asthma education for patients and caregivers should include:
Basic Facts About Asthma
• Basic anatomical and physiological characteristics of the lungs • Pathophysiological changes of asthma • Relationship of pathophysiological changes to signs and symptoms • Asthma control criteria (signs and symptoms)
Trigger Control
• Identification of possible triggers and management strategies • Avoidance of allergens and other triggers
Medications
• Differences between relievers and controllers • Indications for using reliever as opposed to controller medication • Establishing medication schedule • Adverse effects and strategies to reduce their frequency and intensity
Device Technique
• Good inhaler technique • Good peak flowmeter and monitoring technique (if applicable)
Self-Monitoring and Action Plan
• Development of an individualized asthma action plan • Early recognition of worsening asthma • Actions to take in response to worsening asthma
Follow-Up Care
• Understanding and accepting the need for regular follow-up care

Environmental Control.

Environmental control strategies focus on reducing exposure to asthma triggers specific to the individual. Triggers can be divided into two groups: allergens and irritants. Patients should be taught to identify known personal triggers for asthma and to reduce exposure to them (see Table 31-1). Sensitization to environmental allergens is clearly linked to asthma in children and adults (PHAC, 2011). However, before patients and families are advised to use environmental control strategies to reduce or manage exposure to allergens, it is important to understand the allergen to which they are sensitized.

House dust mites produce a common allergen that can trigger asthma. House dust mites are sightless, eight-legged microorganisms. They excrete food and digestive enzymes as a fecal particle, which is the major form of mite allergen. House dust mites require dead skin and water to survive, and thus the bed provides a perfect environment because when humans sleep, they slough off dead skin and provide humidity. As a result, control strategies focus on the bedroom and include keeping the relative humidity below 50%; encasing the mattress, box springs, and pillows in covers that

are impermeable to mites and mite allergens; laundering bed linen in hot water and hot (55°C) air to dry it; and possibly removing carpets (PHAC, 2011).

Pet dander is another common allergen, and strategies to reduce exposure have been evaluated. The removal of the pet is the most effective means to reduce exposure. However, this is often not a realistic option for patients and families. As a result, numerous alternative strategies have been evaluated to minimize or reduce exposure. These strategies include excluding the pet and its dander from the bedroom by keeping the door and heating register closed; frequent vacuuming (including furniture) with a high-efficiency particulate air (HEPA)–filtered vacuum; removing carpets; and washing the pet at least twice a week (none of these actions to be performed by the person with the allergies).

Environmental tobacco smoke is the most harmful indoor air irritant and should be avoided. Environmental tobacco smoke is a risk factor for the development of childhood asthma and frequently causes the worsening of asthma in children and adults. Among children with asthma, those whose parents smoke have more severe disease than do those whose parents do not smoke. When parents of a child with asthma stop smoking, the child's asthma improves. Nurses must encourage patients and their family members to stop smoking and assist them with identifying smoking cessation strategies.

Exercise and cold air are very common asthma triggers. Strategies to prevent exposure to cold air include the use of scarves and face masks. Exercise is just as important for individuals with asthma as those without it because it provides multiple health benefits. Asthma is not an excuse for avoiding exercise. If a form of exercise provokes asthma symptoms, the nurse can advise the patient to use a warm-up period and an inhaled SABA 10 to 15 minutes before the activity to prevent bronchospasm.

Occupational asthma, defined as asthma symptoms induced by exposure to a specific irritant in the workplace, is the most common occupational lung disease. Exposure to irritants in the occupational environment resulting in occupational asthma has been reported in 10% or less among current workers in cross-sectional studies (Tarlo & Lemiere, 2014). Objective lung function tests, along with a detailed occupational exposure history, are necessary to confirm the diagnosis of occupational asthma. If occupational asthma is suspected, the patient should be referred to his or her primary care provider, a specialist, or an occupational hygienist.

Self-Monitoring and Action Plans.

According to the Canadian Asthma Consensus Guidelines (Lougheed, Lemiere, Dell, et al., 2010), every person with asthma should have an asthma action plan (Figure 31-8). An action plan is a written plan developed to provide the patient with a framework for monitoring and determining his or her level of asthma control and making treatment changes to achieve and maintain control. Often, action plans are designed according to a traffic-light analogy: green, yellow, and red "zones." The green zone represents good asthma control and signals "go" with current therapy. The yellow zone is a time of worsening or uncontrolled asthma and signals "caution" and the need for enhanced anti-inflammatory therapy. The red zone represents a time of danger during which the asthma is severe enough to necessitate urgent medical attention; it signals "stop" current activities in order to address this need.

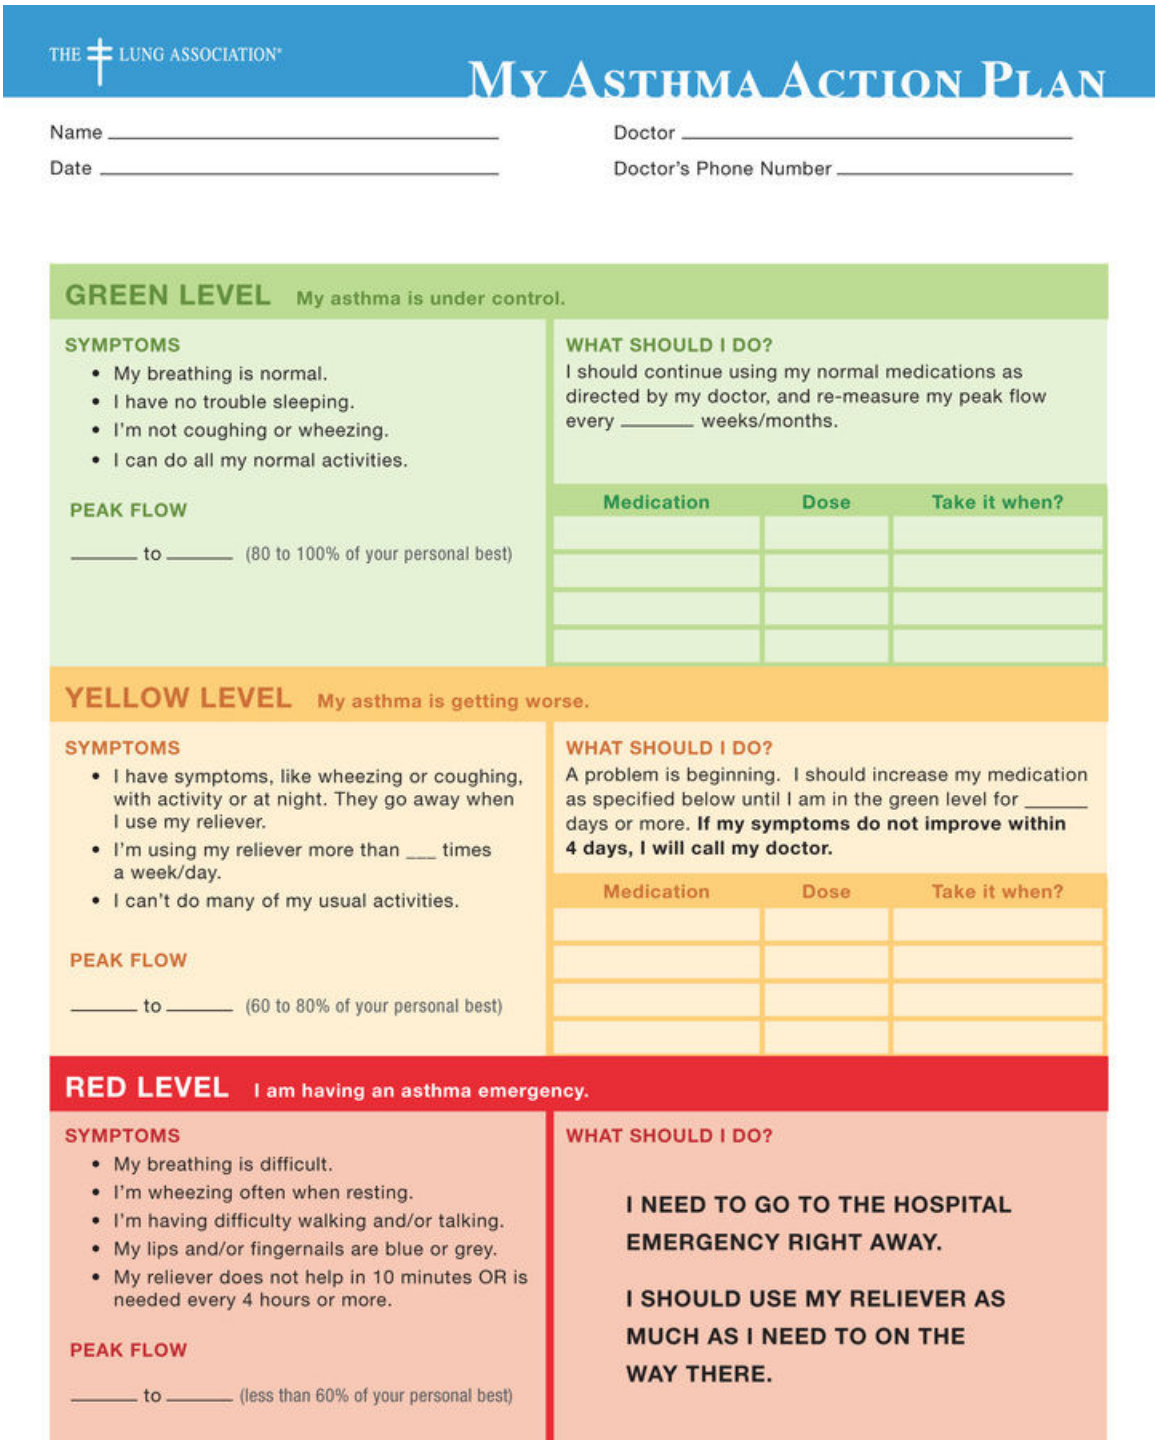

FIGURE 31-8 Example of an asthma action plan. Source: Modified from the Canadian Lung Association (n.d.). *Asthma action plan*. Retrieved from *https://www.lung.ca/sites/default/files/media/asthma_action_plan.pdf*.

Nurses must develop a partnership with patients and their families, their primary asthma care provider, and the rest of the asthma care team in order to help patients attain and effectively use an individualized

asthma action plan. Systematic reviews concluded that self-management programs that included self-monitoring, either by symptoms or peak flow, combined with a written action plan and regular medical review, resulted in reduced need for health care services, fewer days lost from work, and fewer episodes of nocturnal asthma (GINA, 2015). Self-monitoring based on symptom experience alone was compared with self-monitoring based on both symptom experience and peak expiratory flow monitoring; comparable outcomes were reported (GINA, 2015). PEFR provides an objective measurement of lung function (Table 31-11). As a result, it has been advocated for detecting asthma exacerbations; however, for most people, asthma symptoms are a more sensitive measure and change earlier in the course of an exacerbation than does PEFR. The choice of whether an action plan is based on PEFR or symptom monitoring may be made according to a patient's ability to perceive symptoms and airflow limitation, the availability of peak flowmeters, and, of most importance, the patient's preferences.

TABLE 31-11

PATIENT & CAREGIVER TEACHING GUIDE
How to Use a Peak Flowmeter

Follow these five steps to use a peak flowmeter: 1. Move the indicator to the bottom of the numbered scale. 2. Stand up, or sit upright. 3. Take a deep breath in, and fill your lungs completely. 4. Place the mouthpiece in your mouth and close your lips around it. 5. Blow out as hard and fast as possible in a single blow. 6. Write down the value. If coughing occurred, the value is inaccurate; do not record that value. Repeat the test. 7. Repeat steps 1 through 5 twice more. 8. Record the highest result of the three.
Finding the Personal Best Peak Flow Number

• The patient's personal best peak flow number is the highest peak flow number achieved over a 2- to 3-week period when asthma is under good control.
• Each patient's manifestations of asthma are different, and the "best" peak flow value may be higher or lower than that of another person of the same height, weight, and sex. The action plan must be based on the patient's personal best peak flow value.
• To identify the patient's personal best peak flow number, the patient should record peak flow readings
  • At least twice a day for 2 to 3 weeks
  • Upon awakening and before bed
  • Before and 15 minutes after taking a short-acting inhaled bronchodilator (reliever)

Source: Registered Nurses' Association of Ontario. (2004). Appendix I: How to use a peak flow meter. In *Adult asthma care guidelines for nurses: Promoting control of asthma* (p. 94). Toronto: Author. Retrieved from *http://rnao.ca/sites/rnao-ca/files/Adult_Asthma_Care_Guidelines_for_Nurses_-_Promoting_Control_of_Asthma.pdf*. Reprinted with permission of the Registered Nurses' Association of Ontario.

The level of detail in the plan depends on the patient's understanding of asthma and preferences for monitoring (PEFR or symptoms). Key components for teaching patients and their families how to use an action plan include the signs and symptoms of worsening asthma, knowing the level of asthma control and how to adjust medications, and when to seek medical attention. The green zone represents a time when a patient's asthma is under good control (see Table 31-2); peak flow rates are usually 80% or more of predicted or of the patient's personal best (see Table 31-11). When asthma status is in the green zone, the patient should continue with the current therapeutic plan. If asthma status has been in the green zone for a couple of months, an attempt to reduce medication dosages may be warranted. The potential risk of a medication reduction is worsening asthma that necessitates an increase in medications to regain control.

The yellow zone represents a time of uncontrolled asthma, as demonstrated by symptom occurrence, the need for an inhaled short-acting bronchodilator (reliever), and, if measured, PEFR between 50% (some authorities use 60%) and 79% of predicted or personal best (see Table 31-2). In response to worsening asthma, some patients are advised to see their primary asthma care providers, whereas others are advised to increase dosages of anti-inflammatory medication. Typically, this involves initiating the use of an inhaled corticosteroid, doubling, tripling, or quadrupling the dosage of inhaled corticosteroid, or initiating a short burst of oral corticosteroids. Not all patients feel comfortable adjusting medications without seeing their asthma care provider, which highlights the importance of tailoring the type of action plan to meet the individual's needs and preferences.

The red zone represents a time of severe asthma and the need for immediate medical assistance. Indications of the red zone are difficulty completing a sentence without needing another breath; incomplete relief from reliever inhaler or use more frequently than every 2 hours; or, if the patient is using a peak flowmeter, a PEFR between less than 50% and 60% of predicted or personal best value. Affected patients are advised to use their short-acting inhaled β_2 agonists on their way to the emergency department.

In developing a management plan, it is important to involve the patient's family. Family members and friends should be taught how to help the patient during an asthma exacerbation. They should know where the patient's inhalers and emergency phone numbers are located. Family members can help patients identify deteriorating levels of asthma control,

inasmuch as they may notice an increase in symptoms or avoidance of certain activities before the patient notices.

It is particularly important to provide asthma education, which should occur at every encounter with the patient and family, during emergency department visits, and during hospitalization because this is a time when patients are highly motivated to learn and do not have to schedule an additional visit. The Canadian Lung Association develops and distributes several excellent resources for individuals affected by asthma. (See the Resources at the end of this chapter.)

Evaluation.

The expected outcomes for the patient with asthma are presented in Nursing Care Plan 31-1.

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) is a preventable disease, characterized by persistent airflow limitation that is usually progressive. It is associated with an enhanced chronic inflammatory response in the airways and lungs, caused primarily by cigarette smoking and other noxious particles and gases. COPD exacerbations and other coexisting illnesses or comorbid conditions contribute to the overall severity of the disease (Global Initiative for Chronic Obstructive Lung Disease [GOLD], 2017).

Cardinal symptoms experienced by patients with COPD are dyspnea, difficulty breathing, or shortness of breath and limitations in activity. Symptoms are usually insidious in onset and progressive. Dyspnea is the subjective experience of shortness of breath and is the most disabling symptom in COPD (GOLD, 2017). Initially, COPD is confined to the lungs, but when disease is advanced, skeletal muscle dysfunction, right-sided heart failure, secondary polycythemia, depression, and altered nutrition are commonly observed. Past definitions of COPD included the terms *emphysema* and *chronic bronchitis.* **Emphysema** describes only one pathological change present in COPD: destruction of the alveoli. **Chronic bronchitis,** which is the presence of chronic productive cough for 3 months in 2 successive years, remains a useful epidemiological term but it, too, does not convey how airway limitation so severely affects morbidity and mortality in patients with COPD (GOLD, 2017). People with COPD often display characteristics of both chronic bronchitis and emphysema (GOLD, 2017).

The PHAC (2015a) reported that the prevalence of COPD among the population aged 35 years and older was 9.7%. The prevalence among men (9.8%) and women (9.6%) are currently comparable, although rates of COPD and of subsequent hospitalization and death are rising more rapidly among women. Hospitalization may be required in the treatment of COPD, particularly when symptoms worsen from infection. The *Survey on Living with Chronic Diseases in Canada* (SLCDC) revealed that 20% of respondents reported one or more visits to the emergency department in the previous 12 months and 8% reported one or more nights in the hospital in the previous 12 months because of COPD (PHAC, 2011). Overall, 21% of respondents to the SLCDC reported that breathing problems affect their daily life activities "quite a bit or extremely" (PHAC, 2011). COPD accounts for approximately 4.4% of all deaths in Canada,

which is probably an underestimation because the primary cause of death may be listed as pneumonia or heart failure (Bryan & Navaneelan, 2015).

Causes

Cigarette Smoking.

Exposure to tobacco smoke is the primary cause of 80% to 90% of COPD cases in Canada (Bryan & Navaneelan, 2015). In 2012, 16% of Canadians older than 15 years were smoking (Health Canada, 2012). Although the prevalence of cigarette smoking has decreased, it is still a major public health concern.

Clinically significant airway obstruction develops in 15% to 20% of smokers. For most Canadians who die of lung diseases related to cigarette smoking, death is preceded by a long period of debilitation characterized by frequent hospitalizations and loss of many years of productivity. Cigarette smoking remains the most preventable cause of premature death in Canada.

When cigarettes are smoked, approximately 4 000 chemicals and gases are inhaled into the lungs. Over 60 carcinogens have been isolated from cigarette smoke, including cyanide, formaldehyde, and ammonia. Nicotine is probably not a carcinogen, but it has deleterious effects. It acts by stimulating the sympathetic nervous system, resulting in increases in heart rate, peripheral vasoconstriction, blood pressure, and cardiac workload. These effects of nicotine compound the problems in a person with coronary artery disease. (The effects of nicotine are discussed further in Chapter 11.)

Cigarette smoke has several direct effects on the respiratory tract. It simulates an inflammatory response in the lung, which is most evident late in the course of COPD. The irritating effect of the smoke causes hyperplasia of goblet cells, which subsequently results in increased production of mucus and is the basis of chronic cough and sputum accumulation. In airways smaller than 2 mm in diameter, injury leads to narrowing and obstruction of the airways. Smoking reduces ciliary activity and accelerates loss of ciliated cells. Smoking also produces abnormal dilation of the distal air space with destruction of alveolar walls. Many cells develop large, atypical nuclei, which is considered a precancerous condition. Removal of the inciting stimulus is of greatest benefit early in the process but may be less effective in late disease. However, smoking cessation can prevent or delay the development of airflow limitation or slow its progression.

Carbon monoxide is a component of tobacco smoke. Carbon monoxide has a high affinity for hemoglobin and combines with it more readily than does oxygen, thereby reducing the smoker's oxygen-carrying capacity. Smokers inhale a lower percentage of oxygen than normal; as a result, less oxygen is available at the alveolar level. The heart's need for oxygen is increased because of the stimulatory effect of nicotine on the sympathetic nervous system. Because the blood's oxygen-carrying capacity is reduced, the heart must pump more rapidly to adequately supply tissues with oxygen. Carbon monoxide also seems to impair psychomotor performance and judgement.

Passive smoking (also known as *environmental tobacco smoke* or *second-hand smoke*) is the exposure of nonsmokers to cigarette smoke. In adults, involuntary smoke exposure is associated with decreased pulmonary function, increased risk for lung cancer, and increased rates of mortality from ischemic heart disease.

Occupational Chemicals and Dusts.

High levels of urban air pollution are harmful to people with existing lung disease. However, the effect of outdoor air pollution as a risk factor for the development of COPD is unclear. In a person who has intense or prolonged exposure to various dusts, vapours, irritants, or fumes in the workplace, COPD can develop independently of cigarette smoking (PHAC, 2011). If the person also smokes, the risk of COPD increases (GOLD, 2017).

Infection.

Recurring respiratory tract infection is a major factor contributing to the aggravation and progression of COPD (GOLD, 2017). The pathological destruction of lung tissue and the ensuing progression of COPD results from the recurring infections, which impair normal defence mechanisms, making the bronchioles and alveoli more susceptible to injury, and increase inflammation (GOLD, 2017). The most common causative organisms are *Haemophilus influenzae, Streptococcus pneumoniae,* and *Moraxella catarrhalis,* and in patients with severe to very severe COPD, *Pseudomonas aeruginosa* is probably a causative organism (GOLD, 2017). Retained secretions constitute a good medium for their proliferation.

Severe recurring respiratory tract infections in childhood have been associated with reduced lung function and increased respiratory symptoms in adulthood. It is unclear whether the development of COPD

can be related to recurrent infections in adults. People who smoke and also have human immunodeficiency virus (HIV) infection have an accelerated development of COPD. Tuberculosis is also a risk factor for COPD development.

Heredity.

α_1-Antitrypsin (AAT) deficiency is currently the only known genetic abnormality that leads to COPD; however, research is ongoing to identify other genes that predispose a person to developing this disease (GOLD, 2017). AAT (also termed *α_1-protease inhibitor*) is the major antiprotease in plasma, and its primary function is to inhibit neutrophil elastase. It is produced by the liver and is normally found in the lungs, where it inhibits the action of proteolytic enzymes from neutrophils (neutrophil elastase) and macrophages. Lower levels of AAT result in insufficient inactivation of neutrophil elastase, and the subsequent lysis of lung tissue causes destruction of the alveoli. Severe AAT deficiency leads to early-onset COPD. Smoking greatly exacerbates the disease process in affected patients (GOLD, 2017).

Intravenous or nebulizer-administered AAT (Prolastin) replacement therapy is available for people with AAT deficiency (GOLD, 2017). Infusions are administered weekly. Such therapy should be restricted to AAT-deficient patients who do not smoke and whose postbronchodilator FEV_1 is between 35% and 50% of predicted. Its effectiveness in slowing the progression of the disease continues to be evaluated.

Genetics in Clinical Practice

α_1-Antitrypsin (AAT) Deficiency

Genetic Basis

- Described as an autosomal recessive and codominant genetic disorder; >120 alleles.
- Gene for AAT located on chromosome 14.
- Several allelic variants of AAT gene.

Incidence and Prevalence

- Severe AAT deficiency occurs in 1 in 5 000 to 1 in 5 500 of Canadian and North American population.
- Exact prevalence of AAT deficiency in patients with diagnosed COPD: unknown, but estimated prevalence is 1%–5%.
- Severe AAT deficiency occurs in approximately 1 in 1 600 of the Scandinavian population.
- AAT deficiency is found in equal numbers of male and female patients.

Genetic Testing

- Targeted testing for AAT deficiency is recommended for individuals with COPD diagnosed before the age of 65 yr or with a smoking history of <20 pack-years.
- DNA testing is available.
- Screening of siblings is useful.
- Serum assay is available to test for AAT deficiency.

Clinical Implications

- Genetic disorder is linked to COPD.
- AAT deficiency is associated with cirrhosis, hepatitis, panniculitis, and anti–proteinase 3 antibody vasculitis.
- Treatment may include AAT replacement (Prolastin).
- Predisposes patients to early-onset COPD (in the third or fourth decade of life)
- Participation in AAT Canadian Registry is encouraged.

Aging.

Aging results in changes in the lung structure and respiratory muscles that cause a gradual loss of the elastic recoil of the lung. As a result, the lungs

become smaller and stiffer. The number of functional alveoli decreases as a result of the loss of the alveolar supporting structures. Thoracic cage changes result from osteoporosis and calcification of the costal cartilages. The thoracic cage becomes stiff and rigid, and the ribs are less mobile. These changes result in a decreased compliance of the chest wall and an increase in the work of breathing. These changes are similar to those in patients with emphysema. With fewer capillaries available for gas exchange, arterial oxygen levels decrease. Clinically significant emphysema is usually not caused by aging alone.

Pathophysiology

COPD is characterized by chronic inflammation found in the airways, lung parenchyma (respiratory bronchioles and alveoli), and pulmonary blood vessels (Figure 31-9). The pathogenesis of COPD is complex and involves many mechanisms. The defining features of COPD are (a) airflow limitations during forced exhalation that are caused by loss of elastic recoil and are not fully reversible and (b) airflow obstruction caused by mucus hypersecretion, mucosal edema, and bronchospasm.

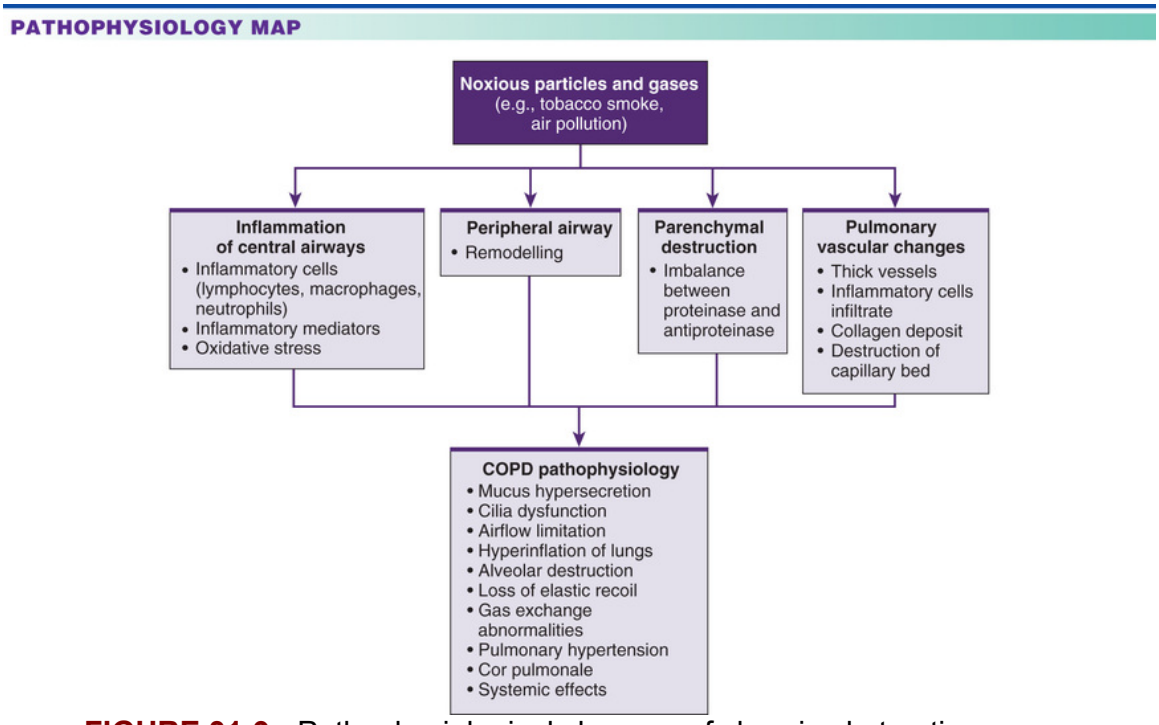

FIGURE 31-9 Pathophysiological changes of chronic obstructive pulmonary disease (COPD).

In COPD, airflow limitation, air trapping, gas exchange abnormalities, mucus hypersecretion, and, in severe disease, pulmonary hypertension and systemic abnormalities are among the various disease processes that occur (see Figure 31-9). The inflammatory process starts with inhalation of noxious particles and gases (e.g., cigarette smoke) but is magnified in people with COPD. The abnormal inflammatory process causes tissue destruction and disrupts the normal defence mechanisms and repair processes of the lungs.

The predominant inflammatory cells in COPD are neutrophils, macrophages, and lymphocytes. This pattern of inflammatory cells is different from that in asthma. The inflammatory cells in COPD attract other inflammatory mediators (e.g., leukotrienes, interleukins). This cascading inflammatory process results in the activation of proinflammatory cytokines such as tumour necrosis factor. In addition, growth factors are recruited into the area and activated, which results in structural changes in the lungs.

The inflammatory process may also be magnified by oxidative stress. Oxidants are produced by cigarette smoke and other inhaled particles and are released from the inflammatory cells, such as macrophages and neutrophils, during inflammation. The oxidative stress adversely affects the lungs as it inactivates antiproteases (which prevent the natural destruction of the lungs), stimulates mucus secretion, and increases fluid in the lungs (GOLD, 2017).

After the inhalation of oxidants in tobacco or air pollution, the activity of proteases (which break down the connective tissue of the lungs) increases, and the antiproteases (which protect against the breakdown) are inhibited. Therefore, the natural balance of protease/antiprotease is tipped in favour of destruction of the alveoli and loss of the elastic recoil of the lung (GOLD, 2017).

Inability to expire air is a main characteristic of COPD. The airflow limitation occurs primarily in the smaller airways and is caused by remodelling. As the peripheral airways become obstructed, air is progressively trapped during expiration. The residual air becomes significant in severe disease as alveolar attachments to small airways (similar to rubber bands) are destroyed. The residual air, combined with the loss of elastic recoil, makes passive expiration of air difficult, and air is trapped in the lungs. The chest hyperexpands and becomes barrel-shaped because the respiratory muscles cannot function effectively. The functional residual capacity is increased, and at this stage, the patient is trying to

breathe in when the lungs are in an "overinflated" state; thus the patient appears dyspneic, and exercise capacity is limited (GOLD, 2017).

As the disease progresses, abnormal gas exchange may occur and results in hypoxemia (decreased oxygen in the blood) and hypercapnia (increased carbon dioxide). As the air trapping worsens and alveoli are destroyed, bullae (large air spaces in the parenchyma) and blebs (air spaces adjacent to pleurae) can form (Figure 31-10). Bullae and blebs are not effective in gas exchange because the capillary bed that normally surrounds each alveolus does not exist in the bullae and bleb. Therefore, there is a significant ventilation–perfusion (VQ) mismatch, and hypoxemia results. Peripheral airway obstruction also results in VQ imbalance and, in combination with the respiratory muscle impairment, can lead to carbon dioxide retention, particularly in severe disease (GOLD, 2017).

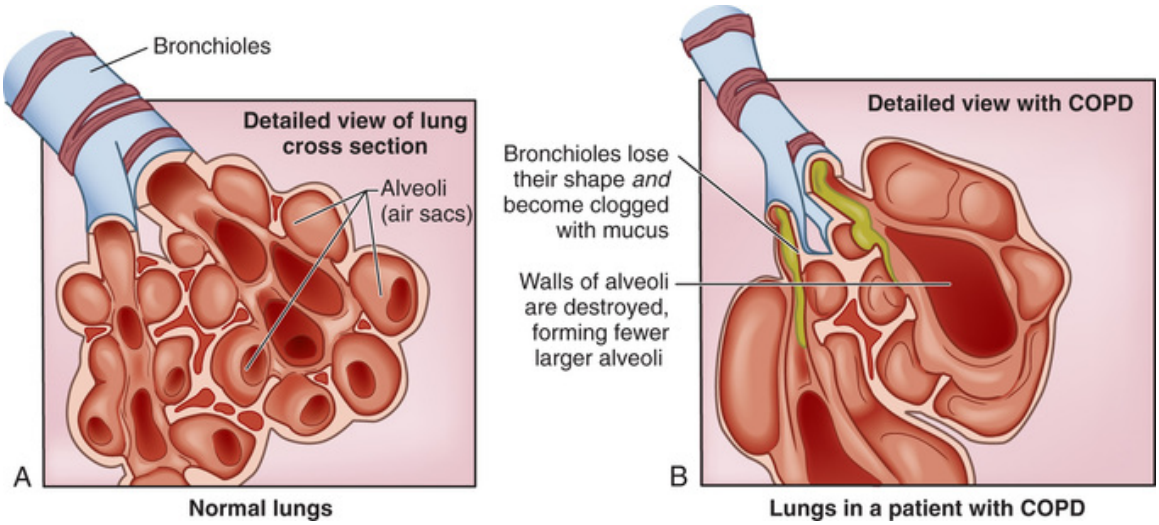

FIGURE 31-10 Illustrations of bronchioles and alveoli in the lungs. **A,** Appearance in normal lungs. **B,** Appearance as a result of changes in the lungs of a patient with chronic obstructive pulmonary disease (COPD).

Excess mucus production, resulting in a chronic productive cough, is a feature of predominant chronic bronchitis and is not necessarily associated with limitation in airflow. However, not all patients with COPD produce sputum. Excess mucus production is a result of an increased number of mucus-secreting goblet cells and enlarged submucosal glands, which respond to the chronic irritation of smoke or other inhalants. In addition, dysfunction of cilia leads to chronic cough and sputum production. Some of the inflammatory mediators also stimulate mucus production.

Pulmonary vasculature changes that result in mild to moderate pulmonary hypertension may occur late in the course of COPD. The small pulmonary arteries undergo vasoconstriction as a consequence of hypoxemia, and their structure changes, which results in thickening of the vascular smooth muscle as the disease advances. Because of the loss of alveolar walls and the capillaries surrounding them, the pressure in the pulmonary circulation increases. Affected patients typically do not have difficulty with hypoxemia at rest until late in the disease. However, hypoxemia may develop during exercise, and such patients may benefit from supplemental oxygen.

Pulmonary hypertension may progress and lead to hypertrophy of the right ventricle of the heart or to cor pulmonale, with or without right-sided heart failure. COPD has been shown to have effects on other body systems, especially in severe disease. These extrapulmonary changes contribute greatly to the clinical findings in affected patients and affect their survival and management. The mechanisms that cause the changes are unclear and are probably multifaceted, but systemic inflammation and inactivity of the patients are probably key factors (GOLD, 2017). Cachexia is common with a loss of skeletal muscle mass (sarcopenia), and weakness probably results from increased apoptosis (programmed cell death), muscle disuse, or a combination of both (GOLD, 2017). Patients may have weakness in all muscles of the upper and lower extremities, and the progression of muscle wasting may be gradual or accelerated, depending on the underlying disease state, and it may be accelerated at times of acute exacerbation or during recovery from illness and a time of deconditioning (GOLD, 2017). Consideration must also be given to the presence of exercise intolerance, deconditioning, and osteoporosis. Patients with severe COPD also may develop chronic anemia, anxiety, and depression. The incidence of cardiovascular disease is increased among such patients, probably as a result of an increase in C-reactive protein (another inflammatory marker linked to cardiovascular disease; GOLD, 2017).

Clinical Manifestations

Several common aspects of asthma and COPD cause diagnostic confusion. However, there are clinically important differences between COPD and asthma (Table 31-12). In addition, some patients have a mixture of asthma and COPD (e.g., those with asthma who have a significant smoking history), and it is important to identify such patients because they may benefit from combination therapy of ICS/LABA and anticholinergic

medications. In addition, earlier introduction of ICS may be justified if the asthma component is prominent.

TABLE 31-12

COMPARISON OF CLINICAL FEATURES OF COPD AND ASTHMA

Feature	COPD	Asthma
Age at onset	Usually >40 yr	Usually <40 yr
Smoking history	Usually >10 pack-years	Not causal but can be a trigger
Clinical symptoms	Persistent	Intermittent and variable
Sputum production	Often	Infrequent
Allergies	Infrequent	Often
Spirometry	Findings may improve but never normalize	Findings often normalize
Disease course	Progressive worsening with exacerbations	Stable with exacerbations

COPD, chronic obstructive pulmonary disease.

Source: Adapted from O'Donnell, D. E., Hernandez, P., Kaplan, A., et al. (2008). Canadian Thoracic Society recommendations for the management of chronic obstructive pulmonary disease—2008 Update—Highlights for primary care. *Canadian Respiratory Journal*, *15*(Suppl. A), 1–8A.

A diagnosis of COPD should be considered when a person experiences symptoms of cough, sputum production, or dyspnea; has a history of smoking or exposure to risk factors for the disease; or demonstrates both. An intermittent cough, often the earliest symptom, usually occurs in the morning with the expectoration of small amounts of mucus. A productive cough (coughing that brings up mucus) during winter months is also a common early symptom that is often exacerbated by respiratory irritants; by cold, damp air; and by respiratory infections. Patients usually seek medical help when they have an acute respiratory infection, dyspnea being the main concern. Dyspnea on exertion may also be one of the earliest symptoms. Dyspnea becomes progressively more severe to the point that it occurs at rest. Patients may dismiss the importance of dyspnea, rationalizing that “I'm just getting older.” They change behaviours to avoid dyspnea and adapt, such as by using the elevator instead of stairs. The dyspnea gradually interferes with daily activities, such as carrying grocery bags, bathing, and cooking. People with COPD have described acute dyspnea as an experience inextricably related to anxiety and emotional functioning. Patients may describe dyspnea in various terms: “My breath does not go out all the way”; “It's hard work to breathe”; or that breathing feels like “heaviness” or “gasping.”

Progressive dyspnea occurs as more alveoli become overdistended, trapping increasing amounts of air. This causes the diaphragm to flatten and the anteroposterior diameter of the chest to increase; as a result, the

chest assumes the typical barrel shape. Effective abdominal breathing is decreased because of the flattening of diaphragm, which forces the person to rely on intercostal and accessory muscles. This type of breathing, however, is not very effective because the ribs become fixed in an inspiratory position.

Many people with advanced COPD experience weight loss and anorexia. The exact cause of these developments is not well understood. One possibility is that such patients are in a hypermetabolic state with increased energy requirements, partly because of the increased work of breathing. Even when caloric intake is adequate, weight loss still occurs. Many patients with COPD have protein-calorie malnutrition, with loss of lean muscle mass and subcutaneous fat (Langen, Gosker, Remels, et al., 2013). (Malnutrition is discussed in Chapter 42.) Fatigue is a highly prevalent symptom that affects the patient's activities of daily living (ADLs).

During physical examination, a prolonged expiratory phase of respiration, wheezes, or decreased breath sounds, or some combination is noted in some or all lung fields. The patient may sit upright with arms supported on a fixed surface such as a table (tripod position). The patient may naturally purse lips on expiration (pursed-lip breathing) and use accessory muscles, such as those in the neck, to aid with inspiration. Edema in the ankles may be a clue to right-sided heart involvement.

Over time, hypoxemia (PaO_2 <60 mm Hg or SaO_2 <88%) may develop with hypercapnia ($PaCO_2$ >45 mm Hg) later in the disease. The bluish-red colour of the skin results from polycythemia and cyanosis. Polycythemia develops as a result of increased production of red blood cells secondary to the body's attempt to compensate for chronic hypoxemia. Hemoglobin concentrations may reach 200 g/L or more. Cyanosis develops in the presence of at least 50 g/L or more of circulating unoxygenated hemoglobin.

Classification of Chronic Obstructive Pulmonary Disease.

The diagnosis of COPD should be considered in any person with exposure to risk factors such as tobacco smoke, environmental or occupational pollutants, chronic cough and dyspnea, or a combination of these. The diagnosis of COPD is confirmed by spirometry, regardless of whether the patient has chronic symptoms. The FEV_1/FVC ratio of less than 70% establishes the diagnosis of COPD. COPD can be classified as mild,

moderate, severe, and very severe (Table 31-13), and this classification is based on the severity of obstruction (as indicated by FEV_1). The management of COPD is based primarily on a patient's symptoms, but the staging provides a general guideline for the type of interventions.

TABLE 31-13

CANADIAN THORACIC SOCIETY CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD) CLASSIFICATION OF SEVERITY BY SYMPTOMS, DISABILITY,* AND IMPAIRMENT OF LUNG FUNCTION

COPD Stage	Classification of Function	
	Symptoms	**Spirometry (After Bronchodilator Treatment)**
Mild	Shortness of breath from COPD† when hurrying on the level or walking up a slight hill (MRC grade 2)	$FEV_1 \geq 80\%$, $FEV_1/FVC < 0.7$
Moderate	Shortness of breath from COPD† causing the patient to stop after walking approximately 100 m (or after a few minutes) on the level (MRC grades 3 to 4)	$50\% \leq FEV_1 < 80\%$ predicted, $FEV_1/FVC < 0.7$
Severe	Shortness of breath from COPD† resulting in the patient being too breathless to leave the house, breathless when dressing or undressing (MRC grade 5), or the presence of chronic respiratory failure or clinical signs of right heart failure	$30\% \leq FEV_1 < 50\%$ predicted, $FEV_1/FVC < 0.7$
Very severe		$FEV_1 < 30\%$ predicted, $FEV_1/FVC < 0.7$

*Postbronchodilator FEV_1/FVC ratio of less than 0.7 is required for the diagnosis of COPD to be established.

†In the presence of non-COPD conditions that may cause shortness of breath (e.g., cardiac dysfunction, anemia, muscle weakness, metabolic disorders), symptoms may not appropriately reflect COPD disease severity. Classification of COPD severity should be undertaken with care in patients with comorbid disease or other possible contributors to shortness of breath.

Complications

Cor Pulmonale.

Cor pulmonale is hypertrophy of the right side of the heart, with or without heart failure, that results from pulmonary hypertension. In COPD, pulmonary hypertension is caused primarily by constriction of the pulmonary vessels in response to alveolar hypoxia; acidosis further potentiates the vasoconstriction (Figure 31-11). Chronic alveolar hypoxia causes pulmonary arteriolar muscle hypertrophy. Chronic hypoxia also stimulates erythropoiesis, which causes polycythemia and increases the viscosity of the blood. Cor pulmonale is a late manifestation of COPD with a poor prognosis.

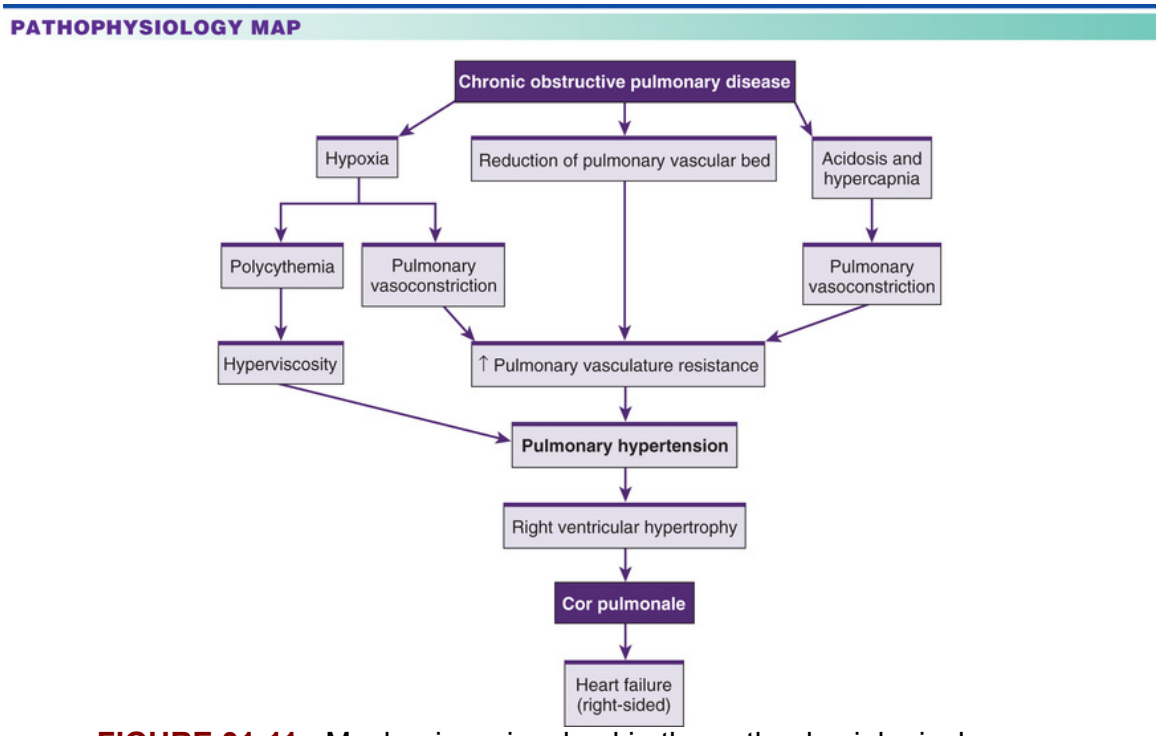

FIGURE 31-11 Mechanisms involved in the pathophysiological process of cor pulmonale secondary to chronic obstructive pulmonary disease.

Normally, the right ventricle and the pulmonary circulatory system are low-pressure systems in comparison with the left ventricle and the systemic circulation. When pulmonary hypertension develops, the pressures on the right side of the heart must increase to push blood into the lungs. Eventually, right-sided heart failure develops.

The clinical manifestations of cor pulmonale are related to dilation and failure of the right ventricle with subsequent intravascular volume expansion and systemic venous congestion. Lung sounds are normal, or

crackles may be heard in the bases of the lungs. Heart sound changes include accentuation of the pulmonic component of the second heart sound, presence of a right-sided third heart sound (right ventricular gallop), and early systolic ejection click along the left sternal border. Overt manifestations of right-sided heart failure may develop, which include distension of neck veins (jugular venous distension), hepatomegaly with right upper quadrant tenderness, ascites, epigastric distress, peripheral edema, and weight gain.

Management of cor pulmonale includes continuous administration of low-flow oxygen. Long-term oxygen therapy can slow but not reverse the progression of pulmonary hypertension in patients with COPD. Diuretics are generally used, but serum creatinine level, blood urea nitrogen level, and electrolytes must be monitored because diuretics can cause volume depletion and electrolyte imbalance. (Cor pulmonale is discussed further in Chapter 30.)

Acute Exacerbations of Chronic Obstructive Pulmonary Disease.

Acute exacerbations are the most frequent cause of medical visits, hospitalizations, and death among people with COPD (Abascal-Bolado, Novotny, Sloan, et al., 2015). Frequent exacerbations contribute to decreases in lung function and deterioration in quality of life. An acute exacerbation of COPD (AECOPD) is defined as a sustained worsening of respiratory symptoms, such as dyspnea, cough, or sputum production that leads to an increased use of maintenance medications or supplementation with additional medications (Beghé, Verduri, Roca, et al., 2013). The term *sustained* implies a change from baseline that lasts 48 hours or longer. Exacerbations should be characterized as purulent or nonpurulent to assist with determining the need for antibiotic therapy; purulent exacerbations necessitate antibiotic therapy. The frequency of AECOPD is, in part, related to the underlying severity of airflow obstruction, and patients with a history of frequent exacerbations are more likely to continue experiencing frequent exacerbations. The cause of AECOPD is often difficult to determine. Noninfectious triggers for exacerbations include exposure to allergens, irritants, cold air, and air pollution.

At least half of all exacerbations are thought to be infectious in nature; many of these are viral in origin, whereas the remainder are caused by bacterial infection. The most common organisms causing AECOPD are *H. influenzae, M. catarrhalis,* and *S. pneumoniae.* As COPD becomes more

severe, *Pseudomonas* organisms, *Klebsiella pneumoniae,* and *Escherichia coli* are frequent causes of infection (GOLD, 2017). The antibiotics most commonly given are amoxicillin, cefuroxime, cefixime, azithromycin, clarithromycin, trimethoprim-sulphamethoxazole, doxycycline, moxifloxacin, levofloxacin, and amoxicillin with clavulanic acid. Some patients are provided with a written action plan and instructed to self-manage exacerbations by beginning antibiotics at the first signs of change in sputum production and colour. In concept, the COPD action plan is similar to the action plan used for patients with asthma (see Figure 31-8); however, the COPD action plan is specific to COPD and AECOPD. Many action plans are available. An example of an action plan can be downloaded from the website of the Canadian Lung Association (see the Resources at the end of this chapter).

Pneumonia is a frequent complication of COPD. The most common causative pathogens are *S. pneumoniae, H. influenzae,* and viruses. The most common manifestation is purulent sputum. Systemic manifestations such as fever, chills, and leukocytosis may not be present. (Treatment of pneumonia is discussed in Chapter 30.)

No diagnostic tests currently define AECOPD. A complete history and physical examination are needed to rule out other causes of increased symptoms. In patients who are very dyspneic, SaO_2 and ABGs should be measured (if oxygen saturation as measured by oximetry is low). Chest radiography should be performed for patients in the emergency department or who are admitted to the hospital because they may have pneumonia, heart failure, or pneumothorax. Increased inhaled bronchodilator dosages (β_2 agonists and anticholinergics) are administered to all patients with AECOPD; oral or systemic corticosteroids, to patients with moderate to severe airflow obstruction ($FEV_1 < 50\%$ of predicted); and antibiotics, to those with purulent sputum. Annual influenza vaccination and pneumococcal vaccination should be encouraged unless the patient has a contraindication.

Acute Respiratory Failure.

An acute exacerbation leads to increased decline in overall lung function, deterioration in health status, and risk of death (GOLD, 2017). Frequently, patients with COPD wait too long to contact their health care provider when they develop fever, increased cough and dyspnea, or other symptoms suggestive of AECOPD. An exacerbation of cor pulmonale may lead to acute respiratory failure. Discontinuing bronchodilator or

corticosteroid medication may also precipitate respiratory failure. The use of β-adrenergic blockers (e.g., propranolol [Inderal]) may exacerbate acute respiratory failure. However, cardioselective β-adrenergic blockers (e.g., atenolol, metoprolol) should not be withheld from patients with mild to moderate diseases because they do not produce clinically significant problems with respiration (Etminan, Jafari, Carleton, et al., 2012).

Indiscriminate use of sedatives and opioids, especially before or after surgery in a patient who retains carbon dioxide, may suppress ventilatory drive and lead to respiratory failure. The patient with COPD who retains carbon dioxide should be treated with low-flow rates of oxygen, and ABG values should be monitored carefully. Surgery or severe, painful illness involving the chest or abdomen may lead to splinting, ineffective ventilation, and respiratory failure. Careful preoperative screening, which includes pulmonary function tests and ABG monitoring, is important in patients with a history of heavy smoking and COPD to prevent postoperative pulmonary complications. (Respiratory failure is defined and discussed in Chapter 70.)

Depression, Anxiety, and Panic.

People with COPD experience higher rates of depression, anxiety, and panic (Yohannes & Alexopoulos, 2014). Of the respondents to the SLCDC, 15% rated their mental health as "fair or poor" (PHAC, 2011). Approximately 40% of patients with COPD report clinically significant anxiety or depression (Long, Bekelman, & Make, 2014). Depression may be related to feelings of loss and grief that accompany the progressive course of the disease, as well as an overall decrease in quality of life (Long, Bekelman, & Make, 2014). A heightened experience of dyspnea is probably related to both anxiety and depression (Long, Bekelman, & Make, 2014). When a person is exceptionally dyspneic, particularly if the condition occurs suddenly, the person becomes anxious and tries to breathe faster, which affects oxygenation status. Proper screening for anxiety and depression and assessment of coping strategies and supports by health care providers are needed to reduce the intensity of these symptoms and improve quality of life.

Clinical Assessment

Goals of the clinical assessment are to determine the severity of the disease and the effect of disease on a patient's quality of life. Identification of these

and other factors enable the health care provider to design an individualized treatment plan (GOLD, 2017).

Clinical assessment begins with a thorough history. Tobacco consumption should be quantified and is typically expressed in pack-years. Pack-years are calculated by multiplying the number of cigarette packs smoked daily by the number of years smoked. Nurses should ask each patient about the experience of symptoms and their effect on the individual's life. A series of probing questions is often necessary to uncover the extent of the patient's breathing difficulty and exercise curtailment. The severity of breathlessness is determined by identifying the magnitude of the task (often an ADL) necessary to cause discomfort in breathing. The Medical Research Council (MRC) Dyspnea Scale is used to assess the level of shortness of breath and disability in COPD (Figure 31-12). The history also should include an assessment of the frequency and severity of exacerbations because the findings may guide treatment choices. In addition, nurses should include an assessment of symptoms associated with comorbid conditions or complications of COPD (ankle swelling, weight loss, anxiety, depression) and the current medical treatment.

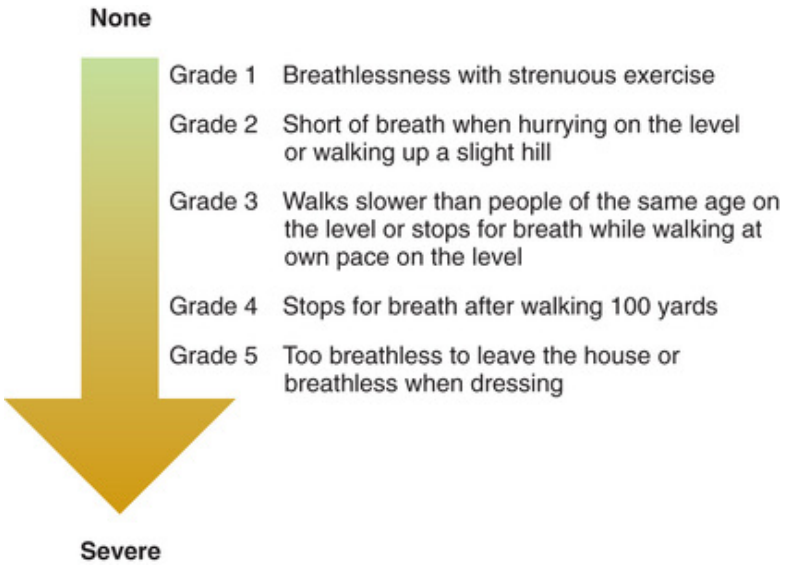

FIGURE 31-12 Medical Research Council (MRC) Dyspnea Scale. This scale can be used to assess shortness of breath and disability in chronic obstructive pulmonary disease. Source: O'Donnell, D. E., Aaron, S., Bourbeau, J., et al. (2004). State of the art compendium: Canadian Thoracic Society recommendations for the management of chronic obstructive pulmonary disease. *Canadian Respiratory Journal, 11*(Suppl. B), 1B–59B, Table 1. Reprinted with permission of D. E. O'Donnell.

Physical examination is important for patients with COPD but is not diagnostic. Pulmonary function studies are needed to determine airflow obstruction and therefore to determine a diagnosis of COPD and to assess the severity of lung impairment (GOLD, 2017). Spirometry is ordered before and after bronchodilator therapy; when the post-therapy FEV_1/FVC ratio is less than 70% of the predicted value, it confirms the presence of airway obstruction (GOLD, 2017).

Chest radiographic studies are not diagnostic of COPD but are often necessary to confirm or rule out comorbid conditions. This also applies to high-resolution computed tomography, which is not routinely required. Pulse oximetry should be used to assess all patients with an FEV_1 of less than 35% of predicted, and ABGs should be monitored in patients who have a low SaO_2 (<92%) on oximetry, especially in patients in whom respiratory failure is suspected (GOLD, 2017). In the later stages of COPD, typical findings are low PaO_2, elevated $PaCO_2$, decreased pH, and increased bicarbonate levels. The 6-minute walking test is a useful test of functional disability and provides prognostic information. It includes determination of changes in the SaO_2 with exercise.

Collaborative Care

Primary COPD management goals are the following (O'Donnell, Aaron, Bourbeau, et al., 2007; O'Donnell, Hernandez, Kaplan, et al., 2008):

1. Prevent disease progression (smoking cessation)
2. Reduce the frequency and severity of exacerbations
3. Alleviate breathlessness and other respiratory symptoms
4. Improve exercise tolerance and daily activity
5. Treat exacerbations and complications of the disease
6. Improve health status and quality of life
7. Reduce the risk of mortality

AECOPD and complications such as respiratory failure, pneumonia, and heart failure necessitate hospitalization, but otherwise patients are treated on an outpatient basis and manage their condition at home. Therapy is expected to escalate in intensity as a patient's disability progresses from MRC Dyspnea Scale grade 2 to grade 5; those with grade of 3 or higher require more intensive management, including pharmacological and nonpharmacological interventions (O'Donnell, Aaron, Bourbeau, et al., 2007). Collaborative care guidelines are presented in Table 31-14.

TABLE 31-14

COLLABORATIVE CARE
Chronic Obstructive Pulmonary Disease

Diagnostic
• History and physical examination
• Pulmonary function tests
• Serum α_1-antitrypsin levels
• Chest radiography (if indicated)
• Sputum specimen for Gram stain and culture (if indicated)
• ABG measurements (if indicated)
• Exercise testing with oximetry (if indicated)
• Electrocardiography (if indicated)
• Echocardiography or cardiac nuclear scans (if indicated)
Collaborative Therapy
• Smoking cessation
• Bronchodilator therapy (see Table 31-8)
• β_2-Adrenergic agonists
• Anticholinergic drugs
• Long-acting theophylline preparations (rarely used)
• Prompt treatment of exacerbations
• Corticosteroids (oral for exacerbations)
	• Nonsteroidal anti-inflammatory drugs (roflumilast)
	• Antibiotics for exacerbations with purulent sputum
	• Influenza immunization (yearly)
	• Pneumovax immunization (every 5–10 years)
	• Pulmonary rehabilitation program
	• Progressive plan of exercise, especially walking and upper body strengthening
	• Breathing exercises
	• Airway clearance techniques
	• Hydration of 3 L/day (if not contraindicated)
	• Relaxation techniques
	• Appropriate pacing and planning of activities
	• Patient and family teaching
	• Long-term oxygen (if indicated)
	• Nutritional supplementation if BMI is low
	• Surgery in severe and advanced COPD
	  • Lung volume reduction
	  • Lung transplantation

ABG, arterial blood gas; *BMI,* body mass index; *COPD,* chronic obstructive pulmonary disease.

Environmental and occupational irritants and triggers should be assessed for a possible negative effect, and ways to control or avoid them should be determined. Patients with COPD should receive an annual influenza vaccination and a pneumococcal vaccine (pneumococcal revaccination is recommended every 5–10 years; O'Donnell, Hernandez, Kaplan, et al., 2008). (See the "Evidence-Informed Practice: Translating Research Into Practice" box.)

Evidence-Informed Practice

Translating Research Into Practice

Physical Activity and Chronic Obstructive Pulmonary Disease

A nurse in the pulmonary clinic is working with a 65-year-old man who has been recently discharged from the hospital after receiving a new

diagnosis of COPD. He tells the nurse that he has been mostly inactive for the past few months because his breathing seems to worsen with activity.

Best Available Evidence	Clinician Expertise	Patient Preference and Values
Patients with COPD who participate in regular moderate physical activity (e.g., brisk walking) have fewer severe flare-ups and are less likely to be readmitted to the hospital.	Physical inactivity is common in patients with COPD. Persistent inactivity may place a patient at greater risk for hospital readmissions.	The patient tells the nurse that he misses taking walks every day with his wife and is wondering whether he would be able to resume this activity at a slow pace.

Decisions and Actions

1. What important factors should be discussed with the patient about physical activity and COPD?
2. How would the nurse assess the patient's willingness and motivation to engage in physical activity?
3. How would the nurse involve the interprofessional team members to assist the patient in regular physical activity?

Reference for Evidence

Nguyen H, Chu L, Liu I, et al. Associations between physical activity and 30-day readmission risk in chronic obstructive pulmonary disease. *Annals of the American Thoracic Society*. 2014;11:695.

Smoking Cessation.

Cessation of cigarette smoking is the most significant factor in slowing the progression of COPD. After a patient stops smoking, not only does the accelerated decline in pulmonary function slow but also pulmonary function usually improves. Thus the sooner the patient stops smoking, the less pulmonary function is lost and the sooner the symptoms decrease, particularly cough and sputum production. (See the RNAO's Best Practice Guideline: *Integrating Smoking Cessation Into Daily Practice* in the Resources at the end of this chapter.)

Drug Therapy.

Medications for COPD can reduce the intensity of symptoms or abolish them altogether, increase the capacity for exercise, improve overall health, and reduce the number and severity of exacerbations. Bronchodilators are the mainstay of pharmacological therapy for COPD (GOLD, 2017). Bronchodilator drug therapy relaxes smooth muscles in the airway, reduces airway resistance and dynamic hyperinflation of the lungs, and improves the ventilation of the lungs, thus reducing the degree of breathlessness. Although patients with COPD do not respond to bronchodilator therapy as dramatically as do those with asthma, a reduction in dyspnea and an increase in FEV_1 are usually achieved. As with asthma, the preferred route of administration is inhalation because it targets the lungs directly.

Bronchodilator medications commonly used are β_2-adrenergic agonists, anticholinergic drugs, and methylxanthines (see Table 31-6). Short-acting bronchodilators, both β_2-adrenergic agonists and anticholinergic drugs, improve pulmonary function, symptoms, and exercise function (O'Donnell, Hernandez, Kaplan, et al., 2008). SABAs and anticholinergic drugs can be used separately, but together they produce superior bronchodilation than does either drug alone. These medications are also available in nebulized combination (salbutamol and ipratropium

[Combivent]). For most patients with COPD, bronchodilator therapy is best used as maintenance therapy (three or four times per day) with extra puffs on an as-needed basis for breakthrough symptoms.

Long-acting bronchodilators also play a role in COPD and are typically indicated for patients with more severe COPD who experience persistent symptoms. Like short-acting bronchodilators, long-acting bronchodilators include both β_2-adrenergic agonists (formoterol [Oxeze; Foradil], salmeterol [Serevent]), and anticholinergic drugs (tiotropium [Spiriva]). The long-acting anticholinergic drugs and LABAs produce more sustained improvements in pulmonary function, activity-related dyspnea, and quality of life than do the short-acting bronchodilators. Tiotropium reduces the frequency of hospitalization and exacerbation, improves health status and hyperinflation, and is taken only once daily. In comparison with LABAs, tiotropium provides greater improvements in dyspnea and health status (GOLD, 2017). These two classes of long-acting bronchodilators can be used separately or in combination.

The use of theophylline in the treatment of COPD is controversial. Although it has some weak bronchodilator effects, its main value may be to improve contractility of the diaphragm and decrease diaphragmatic fatigue. The addition of theophylline to inhaled bronchodilator therapy may provide some benefit in some patients. However, the benefits and the risks need to be weighed because theophylline produces serious cardiovascular and neurological adverse effects. (Bronchodilator drugs are described in Table 31-6.)

The role of ICS in stable COPD has not been found to modify the long-term decline of FEV_1 or overall patient mortality (GOLD, 2017). ICS monotherapy does not have consistent effects on important outcomes (e.g., pulmonary function, symptoms, exacerbations). However, ICS in combination with a LABA has been found to reduce the frequency of exacerbations and to improve lung function and health status (GOLD, 2017). In Canada, two ICS and LABA combination products are currently used in the management of COPD: budesonide-formoterol (Symbicort) and fluticasone-salmeterol (Advair). The Canadian Thoracic Society Guidelines (O'Donnell, Aaron, Bourbeau, et al., 2007) suggest the addition of an ICS in combination with a LABA when the patient has moderate to severe lung impairment and has frequent AECOPD (defined as one or more per year).

A new medication, approved for the treatment of COPD in 2011, is a phosphodiesterase 4 inhibitor, roflumilast (Daxas). This drug is indicated

as add-on therapy with bronchodilators for the maintenance of COPD in patients with chronic cough and sputum and frequent exacerbations.

Oral or parenteral corticosteroids are used for the treatment of AECOPD. They speed recovery time, reduce relapse rates, reduce the need for hospitalization, and improve FEV_1 and partial pressure of oxygen. The dosage and duration should be individualized, but treatment periods between 7 and 14 days are recommended for people with moderate to severe COPD (O'Donnell, Hernandez, Kaplan, et al., 2008). Continuous use of oral corticosteroids is not recommended for routine use in managing COPD because it can produce deleterious effects.

Oxygen Therapy.

Oxygen therapy is frequently used in the treatment of COPD and other problems associated with hypoxemia. Oxygen is a colourless, odourless, tasteless gas that constitutes 20.95% of the atmosphere. Administering supplemental oxygen raises the partial pressure of oxygen in inspired air.

Indications for Use.

Oxygen is usually administered to treat hypoxemia caused by respiratory disorders such as COPD, acute exacerbations of COPD, cor pulmonale, pneumonia, atelectasis, and lung cancer. Long-term oxygen therapy (15 hours/day or more to achieve an oxygen saturation of 90% or greater) prolongs life in patients with hypoxemia. Hypoxemia is defined as a PaO_2 lower than 55 mm Hg or lower than 60 mm Hg in the presence of cor pulmonale with a hematocrit higher than 56%. Patients with COPD are at risk of developing hypoxemia during an exacerbation.

Methods of Administration.

The goal of oxygen administration is to supply the patient with adequate oxygen to maximize the oxygen-carrying ability of the blood. There are various methods of oxygen administration (Table 31-15, Figures 31-13 through 31-16). The method selected depends on factors such as the fraction of inspired oxygen, mobility of the patient, humidification requirement, patient cooperation, comfort, cost, and available financial resources.

TABLE 31-15
METHODS OF OXYGEN ADMINISTRATION

Advantages	Disadvantages	Nursing Interventions
Nasal Cannula		
May be used by a mobile or restless patient Safe and simple method that is relatively comfortable and acceptable Used for patients requiring low O_2 concentrations Can be used while patient eats, talks, or coughs (see Figure 31-13, *E*)	Difficult to maintain in position and can be easily dislodged Patient alertness necessary to keep cannula in proper place Dryness of nasal membranes and possible pain in frontal sinuses with high flow rates (>5 L/min) Can cause pressure necrosis or excoriation of nares	Stabilize cannula during care for a restless patient. Flow rate of 2 L/min produces an O_2 concentration of approximately 28%. Amount of O_2 inhaled depends on room air and patient's breathing pattern. Most patients with COPD can tolerate 2 L/min via cannula.
Simple Face Mask		
Delivers O_2 quickly for short periods O_2 concentrations of 35%–50% achievable with flow rates of 6–12 L/min Provides adequate humidification of inspired air (see Figure 31-13, *A*)	Not as well tolerated as nasal cannula; lack of patient tolerance results in inadequate therapy. May be uncomfortable because a tight seal must be maintained between face and mask May produce pressure necrosis of the skin and confines heat radiating from the face to the area around the nose and mouth Must be removed to eat or drink	Wash and dry under mask q2h. Mask must fit snugly. Nasal cannula may be provided while patient is eating. Watch for pressure necrosis at the top of ears from elastic straps. (Gauze or other padding may be used to alleviate this problem.) Method requires at least 5-L/min flow to prevent accumulation of expired air in the mask.
Nasal Catheter		
Allows continuous, uninterrupted O_2 therapy Delivers O_2 even if patient is a mouth breather Does not interfere with patient care Rarely used except for short-term procedures (e.g., bronchoscopy)	Inserted into nasopharynx through a nostril and can produce excoriation of the nostril Dryness of nasal membranes with high flow rates (>6 L/min). Stomach distension with inadvertent gas flow High degree of humidification not delivered easily; catheter must be taped to patient's face	Catheter should be changed q8h, alternating the nostrils. Distance that catheter is to be inserted is measured from distance between tip of nose and earlobe. A flow rate of 5–6 L/min produces O_2 concentration of ≈30%. This method is best for short-term therapy.
Partial Rebreathing Mask		
Lightweight and easy to use. O_2 conserved by reservoir bag. Concentrations of 40%–60% achievable with flow rates of 6–10 L/min	Cannot be used when patient requires a high degree of humidity	This method is useful when blood O_2 concentrations must be raised. It is not recommended for patients with COPD and should never be used with a nebulizer. Bag should not be allowed to deflate during inspiration.
Nonrebreathing Mask		

Advantages	Disadvantages	Nursing Interventions
Accurate delivery of high concentrations of O_2 O_2 flow into bag and mask during inhalation. Valve in place to prevent expired air from flowing back into bag Concentrations of 60%–90% achievable	Cannot be used when patient requires a high degree of humidity	Mask should fit snugly. Flow rate must be sufficient to keep bag from collapsing during inspiration. Bag should not be allowed to deflate during inspiration.
Oxygen-Conserving Cannula		
Has a built-in reservoir that increases O_2 concentration delivered and allows patient to use lower flow rates, usually 30%–50%, which increases comfort and lowers cost Reported to be more comfortable than standard nasal cannulas (see Figure 31-15)	Cannot be cleaned: changing cannula weekly recommended More expensive than standard cannulas and requires evaluation with measurement of ABGs and oximetry to determine correct flow Highly visible and heavy on ears	This method is generally indicated when long-term O_2 therapy is used at home rather than during hospitalization. It may be "moustache" or "pendant" type. Cannula may cause necrosis over the tops of the ears; can be padded.
Transtracheal Catheter		
Less visible than cannula. Flow requirement possibly reduced 60%–80%, which greatly increases amount of time available from portable source of O_2 Less nasal irritation occurs (see Figure 31-14)	Necessary for patient and family to learn entire program of care for tracheostoma and how to replace catheter Procedure invasive Equipment more costly	Method may not be appropriate for patient with excessive mucus production from mucous plugging.
Tracheostomy Collar		
Can deliver high humidity and O_2	Possible for condensed fluid in tubing to drain into tracheostomy Water traps usually inserted Collection of secretions inside collar and around tracheostomy O_2 concentration lost into atmosphere because collar does not fit tightly	Collar attaches to neck with elastic strap and should be removed and cleaned at least q4h to prevent aspiration of fluid and infection.
Tracheostomy T Bar		
Better O_2 and humidity delivery than by tracheostomy collar because of tight fit	Possible for condensed fluid in tubing to drain into tracheostomy Water traps usually inserted	T bar must be removed for suctioning. T bar may pull on patient's tracheostomy tube, causing irritation and potential tissue damage. The nurse should monitor this closely.
Tent or Incubator		
Has ability to control temperature and humidity	Limited usefulness Difficult to maintain adequate concentrations of O_2 Isolates patient from environment	Tent should be flushed with O_2 every time it is opened. Nurse should assess for leaks around canopy.
Venturi Mask		

Advantages	Disadvantages	Nursing Interventions
Delivers precise, high flow rates of O_2 Lightweight, cone-shaped plastic device fitted to face Available for delivery of 24%, 28%, 31%, 35%, 40%, and 50% O_2 Possible to apply adaptors to increase humidification (see Figure 31-13, *C*)	Uncomfortable and must be removed when patient eats Possible to talk while wearing mask, but voice may be muffled Other disadvantages: same as those for the simple face mask	Entrainment device on mask must be changed to deliver higher concentrations of O_2. Method is especially helpful for administering low, constant O_2 concentrations to patients with COPD. Air entrainment ports must not be occluded.

ABGs, arterial blood gases; *COPD*, chronic obstructive pulmonary disease.

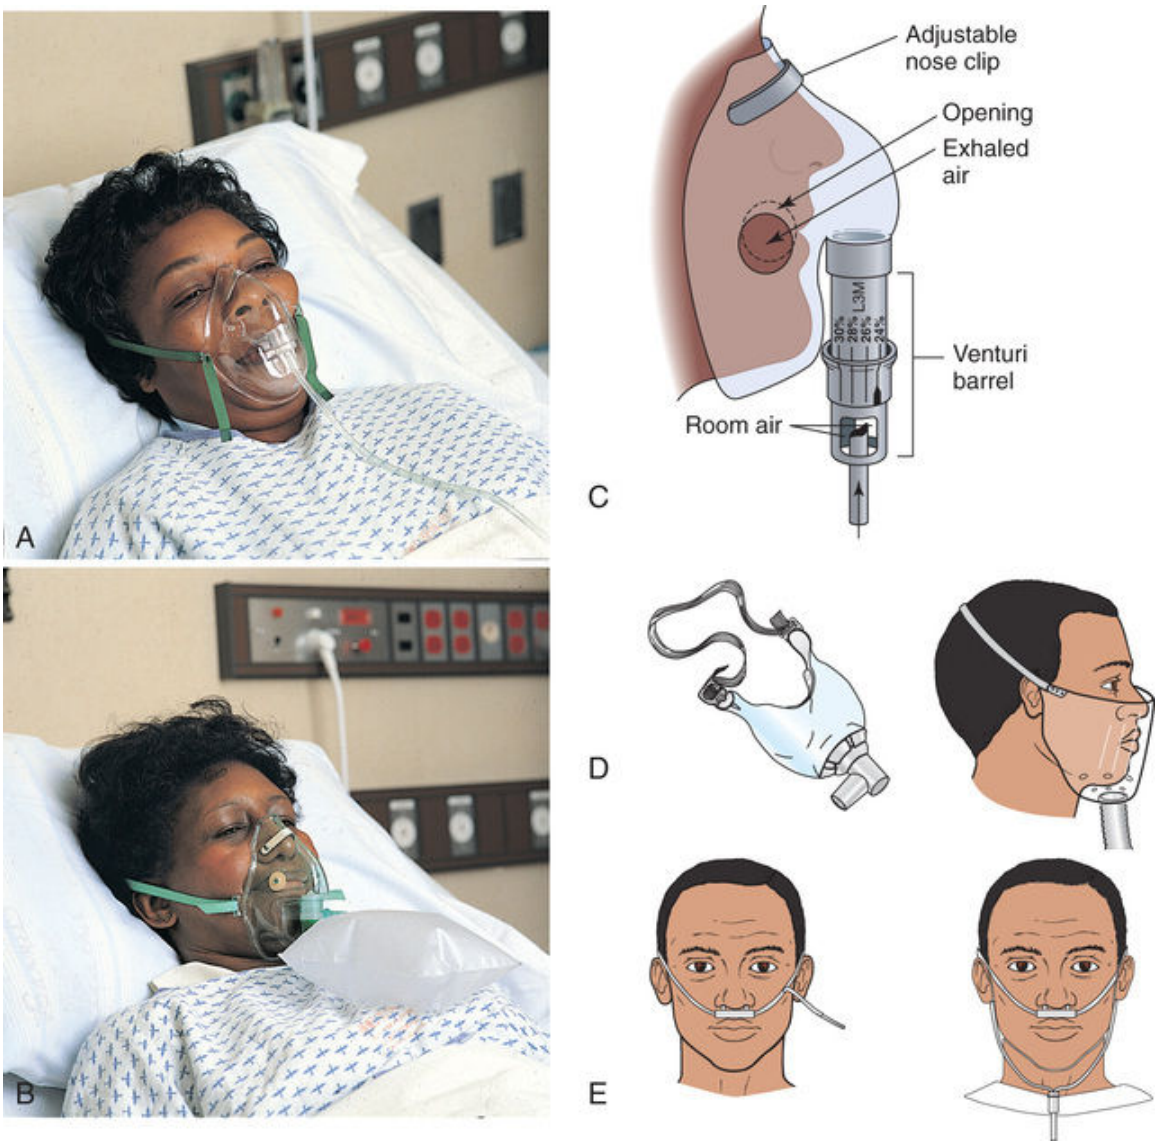

FIGURE 31-13 Methods of oxygen administration. **A,** Simple face mask. **B,** Plastic face mask with reservoir bag. **C,** Venturi mask. **D,** Tracheostomy mask. **E,** Standard nasal cannulas. Source: Adapted from Potter, P. A., & Perry, A. G. (2009). *Fundamentals of nursing* (7th ed., pp. 958–959, Figures 40-15, 40-16, and 40-17). St. Louis: Mosby.

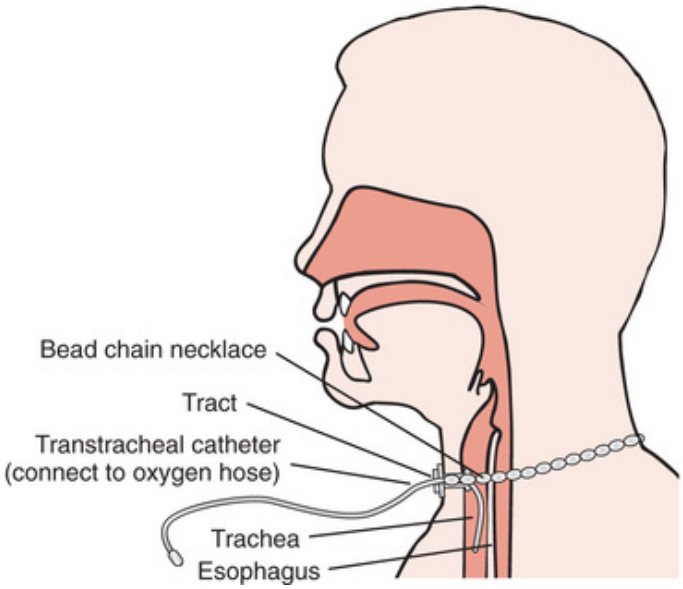

FIGURE 31-14 Transtracheal catheter for oxygen administration.

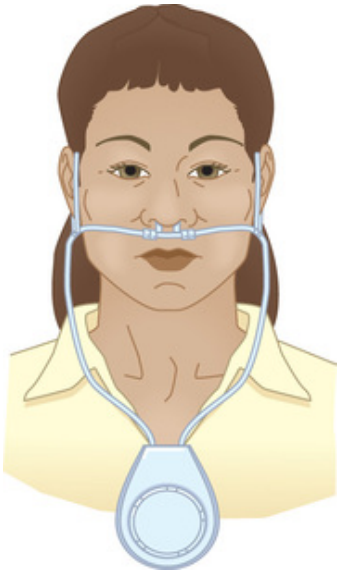

FIGURE 31-15 Pendant type of oxygen-conserving cannula.

FIGURE 31-16 Golfer using Helios liquid portable oxygen system.

Oxygen delivery systems are classified as low- or high-flow systems. Because room air is mixed with oxygen, the percentage of oxygen delivered to the patient is not as precise in low-flow systems as in high-flow systems. Most methods of oxygen administration are low-flow devices that deliver oxygen in concentrations that vary in accordance with the patient's respiratory pattern. In contrast, the Venturi mask is a high-flow device that delivers fixed concentrations of oxygen independent of a patient's respiratory pattern. With the Venturi mask, oxygen is delivered to a small jet (Venturi device) in the centre of a wide-based cone (see Figure 31-13, *C*). Air is entrained (pulled) through openings in the cone as oxygen flows through the small jet. The mask has large vents through which exhaled air can escape. The degree of restriction, or narrowness, of the jet determines the amount of entrainment and the dilution of pure oxygen with room air and thus the concentration of oxygen.

Humidification.

Oxygen obtained from cylinders or wall systems is dry. Dry oxygen has an irritating effect on mucous membranes and dries secretions. Therefore, it is important that oxygen be humidified when administered, either by humidification or by nebulization. A device commonly used for humidification when the patient has a catheter, cannula, or low-flow mask is a bubble-through humidifier. It is a small plastic jar filled with sterile

distilled water that is attached to the oxygen source by means of a flowmeter. Oxygen passes into the jar, bubbles through the water, and then goes through tubing to a patient's catheter, cannula, or mask. The purpose of the bubble-through humidifier is to restore the humidity conditions of room air. However, the need for bubble-through humidifiers at flow rates between 1 and 4 L/min is debatable when humidity in the environment is adequate.

Complications

Combustion.

Oxygen supports combustion and increases the rate of burning; thus it is important that smoking be prohibited in an area where supplemental oxygen is being used. A “No Smoking” sign should be prominently displayed on patients' doors and in their homes and cars. Patients should also be cautioned against smoking cigarettes when using oxygen.

Carbon Dioxide Narcosis.

The drive to breathe is guided by arterial and central chemoreceptors in the respiratory centre that respond to changes in carbon dioxide and oxygen levels. Normally, accumulation of carbon dioxide is the major stimulant of the respiratory centre. Over time in COPD, the respiratory centre loses its sensitivity to the elevated carbon dioxide levels, and some patients with COPD develop a tolerance for high carbon dioxide levels. In theory, for these individuals, the “drive” to breathe is hypoxemia. Thus administering oxygen to patients with COPD has been thought to weaken their drive to breathe. This has been a pervasive myth but is not a serious threat. In fact, not providing adequate oxygen to these patients is much more detrimental. Although oxygen administration should be titrated to the lowest effective dosage, many patients who have end-stage COPD require high-flow rates. They may, in fact, exhibit higher than normal levels of carbon dioxide in their blood, but this is of little concern. What is important is careful, ongoing physical and cognitive assessment when oxygen is provided to these patients.

Oxygen Toxicity.

Pulmonary **oxygen toxicity,** a condition of oxygen overdosage, may result from prolonged exposure to a high level of oxygen (PaO_2). Although relatively rare, the development of oxygen toxicity is determined by patient tolerance, exposure time, and dosage. High concentrations of

oxygen damage alveolar–capillary membranes, inactivate pulmonary surfactant, cause interstitial and alveolar edema, and decrease lung compliance; all these changes ultimately lead to acute respiratory distress syndrome (see Chapter 70). Early manifestations of oxygen toxicity are reduced vital capacity, cough, substernal chest pain, nausea and vomiting, paresthesia, nasal stuffiness, sore throat, and malaise. Prevention of oxygen toxicity is important in patients who are receiving oxygen. The amount of oxygen administered should be just enough to maintain the PaO_2 within a normal or acceptable range for each patient. A safe limit of oxygen concentrations has not yet been established. All levels above 50% and supplemental oxygen used for longer than 24 hours should be considered potentially toxic. Levels of 40% and below may be regarded as relatively nontoxic if the exposure period is short.

Absorption Atelectasis.

Normally, nitrogen constitutes 79% of the air that is breathed, but it is not absorbed into the bloodstream. Its presence in the alveoli prevents alveolar collapse. When high concentrations of oxygen are given, nitrogen is washed out of the alveoli and replaced with oxygen. If airway obstruction occurs, the oxygen is absorbed into the bloodstream and the alveoli collapse. This process is called **absorption atelectasis.**

Infection.

Infection can be a major hazard of oxygen administration. Heated nebulizers present the highest risk. The constant use of humidity supports bacterial growth, the most common infecting organism being *P. aeruginosa.* Disposable equipment that operates as a closed system should be used. The hospital should have a policy about the required frequency of equipment changes, based on the type of equipment used, and about the use of Gram staining and culturing of both equipment and respiratory secretions.

Long-Term Oxygen Therapy at Home.

Improved survival and enhanced quality of life are observed in patients with COPD who receive long-term oxygen therapy to treat hypoxemia. The improved prognosis results from preventing both progression of the disease and subsequent cor pulmonale. The benefits of long-term oxygen therapy include improvements in neuro-psychological function and sleep, increase in exercise tolerance, decrease in hematocrit, and reduced rates of pulmonary hypertension. Short-term home oxygen therapy (1 to 30 days)

may be indicated for patients in whom hypoxemia persists after discharge from the hospital. For example, a patient with underlying COPD who develops a serious respiratory infection may demonstrate continued hypoxemia for 4 to 6 weeks after discharge. It is important to measure oxygenation status by pulse oximetry 2 to 3 months after an acute episode to determine whether long-term oxygen therapy is still warranted: At that point, up to 50% of patients requiring oxygen during an exacerbation no longer meet the requirements for long-term oxygen therapy (O'Donnell, Aaron, Bourbeau, et al., 2007).

Patients whose disease is stable with a PaO_2 of 55 mm Hg or lower (corresponding to an SaO_2 of 88% or lower) should receive long-term oxygen therapy. A patient whose PaO_2 is between 55 and 59 mm Hg (SaO_2 of 89%) and who exhibits signs of tissue hypoxia, such as cor pulmonale, erythrocytosis, and peripheral edema from right-sided heart failure, should also receive long-term oxygen therapy. In cases in which desaturation occurs only during exercise or sleep, the use of oxygen therapy specifically during exercise or sleep is controversial and must be assessed individually. The need for oxygen during these periods should be evaluated with oximetry or a 6-minute walk test. (Pulse oximetry is discussed in Chapter 28.) Several issues in Canada related to funding and eligibility criteria vary greatly across jurisdictions. Periodic re-evaluations are necessary for patients who are using long-term supplemental oxygen. In general, the recommendation is that such patients be re-evaluated every 30 to 90 days during the first year of therapy and annually after that, as long as patients remain stable.

Nasal cannulas, either regular or the oxygen-conserving type (see Figures 31-13, *E* and 31-15 and Table 31-15) are usually used to deliver oxygen from a central source in the home. The source may be a liquid oxygen storage system, compressed oxygen in tanks, or an oxygen concentrator or extractor, depending on home environment, insurance coverage, activity level, and proximity to an oxygen supply company (Table 31-16). To increase mobility in the home, the patient can use extension tubing (up to 15 m [≈50 ft]) without adversely affecting the oxygen flow delivery if the flowmeter is the back pressure–compensated type. Small portable systems, such as that for liquid oxygen, may be provided for the patient who remains active outside the home.

TABLE 31-16
HOME OXYGEN DELIVERY SYSTEMS

Advantages	Disadvantages	Comments
Liquid Oxygen		
Portable unit* can be refilled by patient from reservoir. Portable unit holds 6- to 8-hr supply at 2 L/min; reservoir will last approximately 7–10 days when 2 L/min is used continuously.	Liquid system is slightly more expensive, depending on location and is not available everywhere; its use is generally limited to urban areas.	As liquid warms to gas, some is vented from the system. In summer, evaporation is accelerated and may decrease reservoir duration to <1 wk.
Compressed Oxygen Tanks or Cylinders		
Availability is good in most areas. Portability is possible with a cart. Aluminum cylinders available in varying sizes (e.g., D, E, M, H, J) are markedly lighter than steel and easier to manoeuvre.	Duration of large (H or J) tank at 2 L/min flow is approximately 50 hr; storage of four or five large cylinders in the home is necessary to have 7- to 10-day supply; portable cylinder on cart is cumbersome and heavy. Duration of E cylinder when 2 L/min is used is approximately 4–5 hr.	Some smaller tanks (D or M) may be used; these can be refilled from large cylinders and weigh approximately 4.5 kg (10 lb). Tank can be carried on shoulder strap, backpack, or fanny pack or placed on portable cart.
Concentrator or Extractor		
Because the O_2 supply is made from room air, these devices never need to be "filled." These devices are on wheels, movable from room to room. They provide compact, excellent systems for rural or homebound patients. They are convenient, safe, and reliable (assuming electricity source is reliable).	—	Concentrator should be kept in room other than bedroom if noise disturbs sleep.
Portable Oxygen Concentrator		
These are light-weight devices (3.9–17.7 kg [8.5–17 lb]) that are portable via carts or shoulder straps. Batteries last up to 8 hr with recharging in either AC or DC (e.g., car) outlets. These devices provide patient with exceptional freedom and are beneficial to an active patient who may use more than the allotted requirement of O_2 cylinders each month.	These devices can be costly. Patient must meet qualifications of O_2 company to use.	—
Pulse or Demand Delivery System (Oxygen-Conserving Device)		

Advantages	Disadvantages	Comments
These devices deliver a pulse of O_2 only during inhalation to conserve O_2. They attach to cylinders. Their use increases duration of O_2 supply. There is less drying or irritation to nasal mucosa. These devices save O_2.	These devices may not be able to provide sufficient oxygen during exertion; are costly; are less efficient at higher O_2 flow rates; are best for low activity levels. Audible pulses may be annoying. Patient must be a nose-breather to trigger the flow of O_2.	Monitor O_2 saturation during rest and exercise to determine whether oxygenation is acceptable. Consult with vendor or respiratory therapist if O_2 saturation is below desired level.

**Portable* usually refers to units weighing more than 4.5 kg (10 lb); ambulatory units weigh less than 4.5 kg (10 lb).

Reservoir cannulas operate on the principle of storing oxygen in a small reservoir during exhalation. The oxygen is then delivered to the patient during the subsequent inhalation, in a manner similar to a bolus effect. The reservoir cannulas can reduce flow requirements by approximately 50%. A pendant type is available (see Figure 31-15). Other delivery devices for chronic oxygen therapy include transtracheal oxygen delivery and intermittent-demand oxygen delivery systems. Transtracheal oxygen delivery necessitates a surgical procedure to insert the small oxygen catheter into the patient's trachea (see Figure 31-14). Nursing care involves teaching the patient and caregivers how to care for the stoma and the transtracheal catheter. The transtracheal catheter is less visible than nasal cannulas, and there is no nasal irritation. It also reduces the oxygen flow requirement by 30% to 50%.

Intermittent-demand delivery systems or conserver devices are mechanically complex devices that most commonly attach to the oxygen cylinders. They deliver “pulses” of oxygen to the patient, usually during inspiration, and thus eliminate waste of oxygen during exhalation, as is experienced during continuous flow.

Home oxygen systems are usually rented from a company that sends a respiratory therapist or respiratory nurse specialist to the patient's home to teach how to use and care for the oxygen system and how to recognize when the supply is running low and must be reordered. A patient and caregiver teaching guide for the use of oxygen at home is presented in Table 31-17.

TABLE 31-17

PATIENT & CAREGIVER TEACHING GUIDE
Home Oxygen Use

Mask or Cannula
• Ensure that the straps are not too tight. • Remove two or three times per day to wash and dry skin where straps are placed. • Pad any pressure points. • Observe tops of ears for skin breakdown from pressure points.
Oral and Nasal Mucous Membranes
• Assess oral and nasal mucous membranes two or three times per day. • Use water-based gel on lips and nasal mucosa. • Practise frequent oral hygiene. • Avoid dry ambient air; humidity is required whenever oxygen is used.
Decreasing Risk for Infection
• Remove mask or collar, and clean with water two or three times per day. • Clean skin carefully and observe for cuts, scratches, and bruises. • Change disposable equipment frequently. • Remove secretions that are expectorated.
Decreasing Risk of Fire Injuries
• Post "No Smoking" signs in home where they can be seen. • Do not use electric razors, portable radios, open flames, wool blankets, or mineral oils in the area where oxygen is in use. • Do not allow smoking in the home or car.

Note: The Canadian Lung Association has good resources for patients using oxygen at home. See the Resources at the end of this chapter.

A patient who uses home oxygen should be encouraged to remain active and to travel. If long-distance travel is by automobile, arrangements can be made for oxygen to be available at the destination point. Oxygen-supply companies can often assist with these arrangements. If a patient wishes to travel by bus, train, or airplane, the patient must notify the transportation company of the need for oxygen during travel when reservations are made. A high-altitude simulation test may be performed or a mathematical formula calculated in a hospital pulmonary function laboratory to determine the oxygen prescription required. Because airplane cabins are pressurized to an elevation of 2 100 or 2 400 m (7 000 or 8 000 ft), a passenger who uses supplemental oxygen should have oxygen provided during flight. The plane's oxygen system must be used. Passengers may not use their own oxygen system during flight because it is not properly pressurized. Airlines allow patients to bring their oxygen system to be carried in the baggage compartment for use at the point of destination, but the reservoirs (liquid or tank) must be empty and the valves left open. Some patients may need to avoid prolonged exposure to high elevations during travel unless they are instructed by their health care provider how to adjust their oxygen flow to attempt to compensate for altitude.

Surgical Therapy.

Two different surgical procedures have been used in management of severe COPD. One type of surgery is *lung volume reduction surgery* (GOLD, 2017). The rationale for the surgery is that by reducing the size of the hyperinflated emphysematous lungs, airway obstruction is decreased and room for the remaining normal alveoli to function is increased. The procedure reduces volume by approximately 20% to 35% of the most emphysematous lungs and improves lung and chest wall mechanics. The most common postoperative complication is pneumonia. For a subgroup of patients with severe COPD, however, lung volume reduction surgery may offer improvements in lung function, exercise capacity, quality of life, and possibly length of survival.

The second surgical procedure is *lung transplantation* for selected patients with advanced, severe COPD. In Canada between 2004 and 2013, 445 lung transplantations (double-lung, single-lung, or heart-lung) were performed in patients with COPD (Canadian Institute for Health Information [CIHI], 2015). Recipients of lung transplants who have COPD tend to have better outcomes than do those with other conditions (O'Donnell, Aaron, Bourbeau, et al., 2007). The major complications affecting long-term morbidity and mortality are (a) chronic graft dysfunction associated with obliterative bronchiolitis and (b) opportunistic infection (GOLD, 2017). Patients with COPD who receive lung transplants can achieve substantial improvements in exercise capacity and improved quality of life, and most no longer need supplemental oxygen. (Lung transplantation is discussed in Chapter 30.)

Informatics in Practice

Texting for Patients With Chronic Obstructive Pulmonary Disease (COPD)

- Sometimes patients with COPD or those requiring O_2 therapy experience difficulty speaking because of shortness of breath.
- Patients should be encouraged to use typed messages displayed on a monitor to communicate.
- Texting and instant messaging family and friends are good alternatives to having phone conversations.

Pulmonary Rehabilitation Programs.

All patients with COPD should be encouraged to maintain an active lifestyle. Pulmonary rehabilitation programs (PRPs) are used to optimize the functional status of patients with COPD—as well as their quality of life, experience of dyspnea, exercise endurance, psychosocial functioning, and overall autonomy—and to reduce health care costs (Camp, Hernandez, Bourbeau, et al., 2015). The benefits observed with PRPs are often superior to the benefits of pharmacological therapy. These benefits are largely attributable to exercise. In addition, patients who attend a PRP within 1 month of an exacerbation are shown to have improved outcomes (Marciniuk, Goodridge, Hernandez, et al., 2011).

Specific components of a PRP can include exercise conditioning (aerobic conditioning and upper and lower body conditioning), breathing exercises, energy conservation, nutrition, smoking cessation, environmental factors, health promotion, patient education and self-management, psychological support, psychological counselling, and vocational rehabilitation. PRPs can be provided as inpatient, outpatient, or in-home programs. The duration of the program is typically 4 to 12 weeks or longer.

Exercise training involves both lower and upper extremity training and improves dyspnea and exercise performance. Lower extremity training focuses on aerobic training and includes walking, treadmill walking, bicycling, and cycling ergometry. Upper extremity training focuses on improving arm strength and endurance. Peripheral muscle wasting and weakness affects approximately 25% of patients with COPD. Exercise training should be performed more than three times per week. Health care providers working in PRPs assess the individual's limitations and conditioning status and develop a customized exercise program that is monitored over the length of the rehabilitation program.

Breathing Exercises.

In patients with COPD, the respiratory rate increases and expiration is prolonged, to compensate for airflow obstruction and dyspnea. The accessory muscles of breathing, located in the neck and the upper part of the chest, are used excessively to promote chest wall movement. These muscles are not adapted to long-term use for breathing and, as a result, become fatigued. Breathing exercises can assist the patient during rest and activity (e.g., lifting, walking, stair climbing). The main types of breathing exercises are (a) pursed-lip breathing and (b) diaphragmatic breathing.

Pursed-lip breathing is used to prolong exhalation, prevent bronchiolar collapse and air trapping, and assist with dyspnea. Exhalation should be at least three times longer than inhalation. It is important to demonstrate and teach patients how to use this technique and for them to practise until it works for them and they feel comfortable using it. Patients should be instructed to follow this sequence:

1. Relax neck and shoulder muscles.
2. Inhale slowly through the nose to the count of 2.
3. Pucker lips as if whistling.
4. Exhale slowly and gently through the lips while mentally counting to 6.
5. Always exhale longer than inhaling.

Diaphragmatic (abdominal) breathing focuses on using the diaphragm instead of accessory muscles to achieve maximum inhalation and to slow the respiratory rate. There has been an overall lack of evidence in controlled studies to either support or refute the use of diaphragmatic breathing in pulmonary rehabilitation programs.

Effective Coughing.

Many patients with COPD have developed ineffective coughing patterns that do not adequately clear their airways of sputum. In addition, they fear they may develop spastic coughing, which would increase dyspnea. *Huff coughing* is an effective technique that the patient can be taught easily; guidelines are presented in Table 31-18. The main goals of effective coughing are to conserve energy, reduce fatigue, and facilitate removal of secretions.

TABLE 31-18

PATIENT & CAREGIVER TEACHING GUIDE
Huff Coughing

1. Patient assumes a sitting position with neck slightly flexed, shoulders relaxed, knees flexed, and forearms supported by pillow and, if possible, with feet on the floor.
2. Patient then drops head and bends forward while using slow, pursed-lip breathing to exhale.
3. Sitting up again, patient uses diaphragmatic breathing to inhale slowly and deeply.
4. Patient repeats steps 2 and 3 another three or four times to facilitate mobilization of secretions.
5. Before initiating a cough, patient should take a deep abdominal breath, bend slightly forward, and then cough three or four times on exhalation (huff coughing). Patient may need to support or splint the thorax or the abdomen to achieve a cough of maximum effectiveness.

Nutritional Therapy.

Weight loss and malnutrition are common among people with severe COPD and are a result of multiple factors. In these patients, energy expenditure is increased as a result of increased work of breathing (they spend 30%–50% more energy on breathing than does the average person); oxygen consumption is increased; gas exchange is inefficient; and dead space ventilation is increased. Other factors contributing to weight loss and malnutrition are decreased food intake, the effects of certain drugs, and a high systemic inflammatory response (Remels, Gosker, Langen, et al., 2013). Other factors further affecting patients' nutritional status may be dyspnea, dysphagia, dyspepsia, depression, anxiety, physical limitations, social or financial considerations, decreased sense of smell and taste, and drug and alcohol consumption. Eating becomes an effort as a result of dyspnea, especially in the later stages of COPD. In addition, a full stomach presses up on the flattened diaphragm, further increasing dyspnea and causing discomfort. It is difficult for some patients to eat and breathe at the same time; therefore, they eat inadequate amounts of food. The role of a registered dietitian is critical for nutritional screening and intervention.

Patients with COPD should try to keep body mass index (BMI) between 21 and 25 kg/m^2. Being either overweight or underweight can cause further problems in conjunction with COPD. However, a reduced BMI or weight loss is especially associated with poor outcomes in acute exacerbations and with increased rates of morbidity and mortality among patients with COPD. To decrease dyspnea and conserve energy, patients may need to rest (30 minutes) before eating, use a bronchodilator before meals, and select foods that can be prepared in advance. Eating five to six small meals per day helps avoid feelings of bloating and early satiety. Patients may want to avoid foods that form intestinal gas, such as cabbage, Brussels sprouts, and beans. Cold foods produce less of a sense of fullness than do hot foods. Foods that require a great deal of chewing can be served in another manner (e.g., grated, pureed). The use of frozen foods and a microwave oven may help conserve a patient's energy in food preparation. Exercises should be avoided for at least 1 hour before and after eating. In patients with late-stage or severe COPD, nutritional requirements for protein and calories may be greater than normal. They may need 1.2 to 1.3 times the normal kilocalorie requirement to even maintain their weight. A high-calorie, high-protein diet is recommended. High-protein, high-calorie nutritional supplements can be offered between meals. (Nutritional supplements are discussed in Chapter 42.)

Fluid intake should be at least 2 to 3 L per day unless contraindicated for other medical conditions, such as heart failure. Fluids should be taken between meals (rather than with them) to prevent excess stomach distension and to decrease pressure on the diaphragm. Sodium restriction may be indicated if a patient also has heart failure. In older patients, corticosteroid use increases the risk of or leads to osteoporosis. As a result, it is important to stress the necessity for adequate calcium and vitamin D intake.

Age-Related Considerations

Chronic Obstructive Pulmonary Disease

Older adults have physiological changes, including reduced lean body mass and decreased respiratory muscle strength that may increase the burden of disease from COPD, including more dyspnea and less tolerance of exercise (Kobayashi, Yanai, Hanagama, et al., 2014). This causes a poorer ADL status and a higher incidence of acute exacerbations, which necessitate hospitalization. Smoking cessation is a key intervention but can be difficult to achieve.

COPD is frequently complicated by the presence of comorbid conditions such as cardiovascular disease, serious infections, osteoporosis, psychological problems (depression, anxiety), impaired cognition, and lung cancer (Areias, Carreira, & Anciães, 2014). The presence of comorbid conditions can make it difficult for patients to cope with the stress of an exacerbation. Thus assessment of comorbid conditions can assist in ensuring comprehensive and safe management, especially during an exacerbation.

Older patients may have difficulty in handling the increased secretions during an acute COPD exacerbation. The use of additional medications to manage the acute exacerbation can complicate disease management and increase the likelihood of adverse events. The nurse should assess for potential drug–drug interactions, especially in patients being treated for comorbidities.

Some medications used to treat common disorders in older adults, such as hypertension, can worsen COPD symptoms. Nonspecific beta blockers should be avoided because they can also block the α_2 receptors in the airway and cause bronchoconstriction. Angiotensin-converting enzyme inhibitors may cause a dry cough or worsen a current cough.

Older adults may not adhere to drug therapies because of cognitive impairment and complexity of the polypharmacy prescribed. Arthritis in the hands can hinder the patient from using proper technique for MDIs. It is important to review MDI technique during clinic visits and have DPI or spacers prescribed (if possible) because they are easier to use. For patients with poor memory and visual impairment, an attempt should be made to simplify the medication regimen with written large-font action plans. Long-term use of ICSs has the potential of causing local and systemic side effects, including cataracts, glaucoma, and osteoporosis. Monitoring of

ocular pressures, bone densitometry, and using the lowest possible ICS dose should be recommended (Battaglia, Cardillo, Lavorini, et al., 2014).

Older adult patients with COPD generally have impaired quality of life (Rinaudo, Ferrer, Terraneo, et al., 2015). An important role for the nurse is to focus on things that will improve these patients' quality of life. Psychological and emotional support becomes imperative to help them achieve successful outcomes. In the later stages of COPD, the nurse should get palliative and hospice care involved to help manage symptoms and improve the quality of the remainder of the patients' lives (Batzlaff, Karpman, Afessa, et al., 2014).

Nursing Management Chronic Obstructive Pulmonary Disease

Nursing Assessment

Subjective and objective data that should be obtained from a patient with COPD are listed in Table 31-19.

TABLE 31-19

NURSING ASSESSMENT
Chronic Obstructive Pulmonary Disease (COPD)

Subjective Data
Important Health Information
Current health: The nurse should assess patient's experience of dyspnea (with activity and at rest) and cough. If cough is productive, the nurse should determine colour, consistency, and quantity of secretions. Current dyspnea should be measured on a quantitative scale such as a visual analogue or a numeric rating scale. (See Chapter 28 with regard to dyspnea.) The usual level of dyspnea that a patient experiences should be measured against the Medical Research Council Dyspnea Scale (see Figure 31-12). *Past health history:* The nurse should note whether the patient has had long-term exposure to chemical pollution, respiratory irritants, occupational fumes, and dust; the history and frequency of respiratory infections; previous hospitalizations and emergency department visits related to breathing and cardiac problems; smoking exposure (pack-years, exposure to secondary smoke, previous attempts at cessation); and personal and family history of respiratory and cardiac conditions. *Medications:* The nurse should record the use and duration of supplemental O_2, bronchodilators, anticholinergics, corticosteroids, antibiotics, OTC drugs, complementary therapies; effectiveness of bronchodilators and experience of adverse effects
Symptoms
• Anorexia, weight loss or gain, early satiety, difficulty eating • Decreased level of activity and ability to perform ADLs or exercise. Dyspnea, palpitations, recurrent cough, use of sitting-up position for sleeping, paroxysmal nocturnal dyspnea, orthopnea, swelling of feet • Constipation, gas, bloating • Headache, loss of memory, inability to concentrate • Fatigue, insomnia, depression, anxiety, panic
Objective Data
General
Height, weight, BMI Distress, increased work of breathing, use of compensatory mechanisms for breathing (upright position, pursed-lip breathing), anxiety, depression, restlessness
Integumentary
Cyanosis (bronchitis), pallor or ruddy colour, poor skin turgor, thin skin, easy bruising, peripheral edema (cor pulmonale)
Respiratory
Rapid, shallow breathing; accessory muscle use; inability to speak at all; prolonged expiratory phase; pursed-lip breathing; wheezing, crackles, diminished breath sounds; ↓ chest excursion and diaphragmatic movement; use of accessory muscles; hyper-resonant or dull chest sounds on percussion
Cardiovascular
Tachycardia, dysrhythmias, jugular vein distension, right-sided third heart sound (cor pulmonale), edema (especially in feet)
Gastro-intestinal
Ascites, hepatomegaly (cor pulmonale)
Musculo-skeletal
Muscle atrophy, ↑ anteroposterior diameter (barrel chest)
Possible Diagnostic Findings
Pulmonary function test results demonstrating airflow obstruction (e.g., ↓ FEV_1, FEV_1/FVC ratio, and PEFR; ↑ RV), ↓ SaO_2 as measured by pulse oximetry, abnormal arterial blood gas values, polycythemia Chest radiograph showing flattened diaphragm and hyperinflation or infiltrates ECG showing dysrhythmias

ADLs, activities of daily living; *BMI,* body mass index; *ECG,* electrocardiogram; *FEV_1,* forced expiratory volume in one second; *FVC,* forced vital capacity; *OTC,* over-the-counter; *PEFR,* peak expiratory flow rate; *RV,* residual volume; *SaO_2,* arterial oxygen saturation.

Nursing Diagnoses

Nursing diagnoses for patients with COPD may include, but are not limited to, the following:

Ineffective breathing pattern related to *hyperventilation, body position that inhibits lung expansion*
Ineffective airway clearance related to *excessive mucus, retained secretions* (expiratory airflow obstruction)
Impaired gas exchange (related to alveolar hypoventilation)

Additional information on nursing diagnoses is presented in Nursing Care Plan 31-2.

Nursing Care Plan 31-2

Chronic Obstructive Pulmonary Disease (COPD)

NURSING DIAGNOSIS	***Ineffective breathing pattern*** related to *body position that inhibits lung expansion, fatigue, respiratory muscle fatigue* as evidenced by *use of three-point position, pursed-lip breathing, use of accessory muscles to breathe*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Returns to baseline respiratory function • Demonstrates an effective rate, rhythm, and depth of respirations	***Ventilation Assistance*** • Monitor respiratory and oxygenation status *to assess need for intervention.* • Auscultate breath sounds, noting areas of decreased or absent ventilation and presence of adventitious sounds, *to obtain ongoing data on patient's response to therapy.* • Encourage slow, deep breathing; turning; and coughing *to promote effective breathing techniques and secretion mobilization.* • Administer medications (e.g., bronchodilators, inhalers) *that promote airway patency and gas exchange.* • Position to minimize respiratory efforts (i.e., elevate head of the bed and provide overbed table for patient to lean on) *to save energy for breathing and promote chest expansion.* • Monitor for respiratory muscle fatigue *to detect a need for ventilatory assistance.* • Initiate a program of respiratory muscle strength and/or endurance training *to establish effective breathing patterns and techniques.*
NURSING DIAGNOSIS	***Ineffective airway clearance*** related to *excessive mucus, retained secretions* as evidenced by *ineffective cough, absence of cough, diminished breath sounds*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Has normal breath sounds for patient • Demonstrates effective coughing • Reports decreased dyspnea • Maintains clear airway	• Facilitate deep breathing by sitting patient up *to maximize use of diaphragm and prolong expiratory phase.* • Ensure adequate hydration (oral intake approximately 2–3 L/day, humidified ambient air) *to liquefy secretions for easier expectoration.* • Teach effective cough techniques *to minimize the extent of airway collapse and to enhance airway clearance.* • Assist with inhaled bronchodilator administration *to facilitate clearance of retained secretions.*
NURSING DIAGNOSIS	***Impaired gas exchange*** (related to alveolar hypoventilation as evidenced by headache on awakening, $PaCO_2$ of ≥45 mm Hg and abnormal for patient's baseline, PaO_2 of <60 mm Hg, or SaO_2 of <90% at rest)
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Has $PaCO_2$ of 35–45 mm Hg or usual compensated baseline value • Experiences return of PaO_2 to normal range for patient • Reports improved mental status • Reports decreased dyspnea • Performs ADLs	• Monitor respiratory and oxygenation status *to assess need for intervention.* • Teach pursed-lip breathing *to prolong expiratory phase and slow respiratory rate.* • Assist patient to assume position of comfort (e.g., tripod position, elevated back rest, support of upper extremities to fix shoulder girdle) *to maximize respiratory excursion.* • Administer and teach appropriate use of bronchodilators *to open the airways.* • Teach signs, symptoms, and consequences of hypercapnia (e.g., confusion, somnolence, headache, irritability, decrease in mental acuity, increase in respiration, facial flush, diaphoresis) *to recognize problem early and initiate treatment.* • Teach avoidance of central nervous system depressants *because they further depress respirations.* • Administer O_2 if appropriate *to increase SaO_2 saturation.* • Select O_2 supply systems and devices (e.g., nasal cannula, mask) that are appropriate for patient's ADLs (rest, sleep, exercise) *to minimize effect on preferred lifestyle.*
NURSING DIAGNOSIS	***Imbalanced nutrition: less than body requirements*** related to *insufficient dietary intake, inability to ingest food* (decreased energy level, shortness of breath, gastric distention) as evidenced by *food intake less than recommended daily allowance*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Maintains body weight within normal range for	• Monitor caloric intake, weight, and serum albumin and protein levels *to determine adequacy of intake.*

sex, height, and age • Has normal serum protein and albumin levels	• Provide menu suggestions for high-protein, high-calorie foods *to ensure maintenance of weight.* • Give patient high-protein, high-calorie liquid supplements if necessary *to provide adequate calories and protein to prevent weight loss and muscle wasting.* • Plan periods of rest before and after food intake *to assist with controlling fatigue and to compensate for blood flow diversion to the gastro-intestinal tract for digestion.* • Refer to agency for financial or nutritional assistance as necessary (e.g., Meals-On-Wheels, home care) *to ensure nutritional adequacy after discharge.* • Discuss benefit of five to six small meals throughout the day *because this reduces bloating.*
NURSING DIAGNOSIS	***Disturbed sleep pattern*** related to *nonrestorative sleep pattern* (dyspnea, orthopnea, paroxysmal nocturnal dyspnea) as evidenced by *unintentional awakening, feeling unrested*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Sleeps at least 5 hr over a 24-hr period • Reports improved sleep pattern • Reports feeling rejuvenated on awakening	• Identify usual sleep habits and elicit reasons for difficulty sleeping *to provide baseline data.* • Monitor patient's sleep pattern, and note physical circumstances (e.g., pain or discomfort and urinary frequency) and psychological circumstances (e.g., fear or anxiety) that interrupt sleep *to initiate appropriate interventions.* • Observe for signs and symptoms of sleep apnea such as frequent awakenings at night or excessive daytime sleepiness, or noting a partner who complains of the patient's snoring or gasping for air *to initiate appropriate diagnostic tests and interventions.* • Identify patient-specific methods of relaxation, and teach patient relaxation methods *to foster sleep.* • Encourage exercise and activity during daylight hours *to ensure improved sleep at night.* • Provide patient with activity that promotes wakefulness *to limit daytime sleep.* • Instruct patient in arranging surroundings (e.g., clothing, temperature, position, noise level) *to produce an environment conducive to sleep.* • Teach patient to avoid alcoholic beverages, caffeine products, or other stimulants before bedtime *to reduce interference with sleep.*
NURSING DIAGNOSIS	***Risk for infection*** as evidenced by *insufficient knowledge to avoid exposure to pathogens, smoking, malnutrition, stasis of body fluid* (increased secretions)
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Uses behaviours that minimize risk of infection • Experiences fewer or no respiratory infections	• Monitor for systemic and localized signs and symptoms of infection *to determine whether an infection is present.* • Teach patient to assess indicators of infection: change in sputum colour, quantity, odour, and viscosity; increase in cough and dyspnea; experience of fever, chills, diaphoresis, excessive fatigue; increase in respiratory rate; and abnormal breath sounds (gurgles, wheezing) *to determine whether an infection is present.* • Teach patient to use good handwashing and hygiene techniques and to avoid contact (when possible) with people with respiratory infections *to minimize sources of infection.* • Encourage patient to obtain vaccination for influenza and pneumococcal pneumonia *to decrease occurrence or severity of influenza or pneumonia.* • Teach proper care and cleaning of home respiratory equipment *to eliminate this source of infection.* • Instruct patient to seek medical attention for manifestations of early infection *to initiate treatment promptly.* • Teach patient to follow plan of care for managing exacerbations (e.g., increase fluid intake, initiate antibiotics and oral corticosteroid) *to initiate appropriate self-care promptly.*

ADLs, activities of daily living; $PaCO_2$, partial pressure of arterial carbon dioxide; PaO_2, partial pressure of arterial oxygen; SaO_2, arterial oxygen saturation.

Planning

Overall goals for patients with COPD include (a) the prevention of disease progression, (b) the ability to perform ADLs, (c) relief from breathlessness

and other respiratory symptoms, (d) improvement in exercise tolerance, (e) the prevention and treatment of exacerbations, (f) improved overall quality of life, and (g) reduction in premature mortality.

Nursing Implementation

Health Promotion.

The best way to prevent COPD is never to smoke, and the next best step is to stop smoking immediately. (See the "Nursing Management: Lung Cancer" section in Chapter 30.) Avoiding or controlling exposure to occupational and environmental pollutants and irritants is another preventive measure to maintain healthy lungs. (These factors are discussed in the section on environmental lung diseases in Chapter 30.) Early detection of airway disease is important and is the rationale for the use of spirometry or pulmonary function tests. Early identification and treatment of respiratory tract infections is important for improving the long-term prognosis of COPD. Avoiding exposure to large crowds in the peak influenza periods may be necessary, especially for older adults and patients with a history of respiratory problems. Patients should also be taught good handwashing technique, to avoid sharing food and drinks, and to keep their hands away from their nose, mouth, and ears. Influenza and pneumococcal pneumonia vaccinations are recommended.

Families with a history of both COPD and AAT deficiency should be aware of the genetic nature of the disease. Genetic counselling may be appropriate for such patients and their families.

Education.

An important aspect in the long-term care of the patient with COPD is education (Table 31-20). (Patient teaching is discussed in Chapter 4.) One component of education may involve preparation of an advance care plan (see the "Ethical Dilemmas: Advance Directives" box).

TABLE 31-20

PATIENT & CAREGIVER TEACHING GUIDE
Chronic Obstructive Pulmonary Disease

Goal: To assist patient and caregivers in improving quality of life through education and to promote lifestyle practices that support successful living with chronic obstructive pulmonary disease (COPD).	
Teaching Topic	**Strategies and Resources**
• Overall guide to COPD, including topics listed below	Global Initiative for Chronic Obstructive Lung Disease (GOLD): *Patient guide: What you can do about a lung disease called COPD*, available at *http://goldcopd.org/wp-content/uploads/2016/04/GOLD_PatientGuide_2012.pdf* Canadian Lung Association: *COPD BreathWorks Plan*, available at *http://www.lung.ca/lung-health/lung-disease/chronic-obstructive-pulmonary-disease-copd/resources* or toll-free helpline at 1-866-717-COPD (2673) Living Well With COPD program: available online (see the Resources at the end of this chapter)
What Is COPD?	
• Basic anatomy and physiology of lung • Basic pathophysiological changes of COPD • Signs and symptoms of COPD, exacerbations, cold, flu, pneumonia • Tests to assess breathing	Models and posters of the lungs
Nonpharmacological Therapy	
• Breathing exercises • Combating breathlessness and shortness of breath with "rescue breathing" techniques • Pursed-lip breathing • Relaxation techniques • Energy conservation techniques • Pacing and planning throughout the day for ADLs (pacing activity and using pursed-lip breathing with activities) • Regular exercise (upper and lower extremity)	Demonstration and return demonstration RNAO dyspnea guidelines Developing and using a schedule of daily and weekly activities Pulmonary rehabilitation program
• Smoking cessation	See Chapter 11 Smoking cessation guidelines for nurses (e.g., the RNAO's Best Practice Guideline *Integrating Smoking Cessation into Daily Practice*); Quit Smoking helplines
Medications	
Types (include mechanism of action) • β_2-Adrenergic agonists • Anticholinergics • Corticosteroids • Methylxanthines • Phosphodiesterase 4 inhibitor • Antibiotics Reviewing medication schedule and indications for use Adverse drug events	Written medication list and schedule Having patients explain purpose of the medication and show the medication they are referring to Knowing the various colours of the inhalers because patients typically refer to them by colour
Correct Use of Inhalation Devices	
• Metered-dose inhalers with and without spacers	See Figures 31-6 and 31-7 Canadian Lung Association

• Dry powder inhalers	• Handouts • Inhalation device videos Placebo and demonstration units (provided by pharmaceutical companies) to assist with hands-on training Having patients demonstrate inhaler technique, and providing feedback about technique Checking periodically to ensure maintenance of proper technique Repeating process until accurate technique is demonstrated Exploring alternative delivery devices for patients who cannot demonstrate accurate technique
Home Oxygen	
• Explaining need for O_2 • Explaining equipment and rationale for use • Guidance for home O_2 and ambulatory use • Care of oxygen equipment	Canadian Lung Association website (see the Resources at the end of this chapter) See Tables 31-16 and 31-17
Psychosocial/Emotional Issues	
Concerns about interpersonal relationships • Dependency • Intimacy Emotional difficulties • Depression • Anxiety and panic Treatment decisions • Support and rehabilitation groups	Canadian Lung Association website (see the Resources at the end of this chapter) Open discussion (sharing with patient, significant other, and family) Exploring idea of attending social support groups or speaking to another person with COPD
COPD Management Plan	
• Focusing on self-management • A written action plan • Monitoring signs and symptoms • Reporting changes in symptoms • Understand causes of flares or exacerbations • Recognizing signs and symptoms of respiration infection, heart failure • Reducing the number of risk factors, especially smoking • Pulmonary rehabilitation program • Yearly follow-up	COPD management plan, developed and agreed upon by nurse and patient, that meets individual needs Assessment of patient's confidence level in managing COPD, and enhancement of skill development and confidence as necessary
Healthy Nutrition	
• Strategies to lose weight (if patient is overweight) • Strategies to gain weight (if patient is underweight)	Consultation with dietitian
End-of-Life and Advance Planning	
• Identifying concerns and preferences for end-of-life care • Support of problem solving, decision making, and planning	End-of-life planning module in the Living Well With COPD program (see the Resources at the end of this chapter) Open discussion (health care team, patient, and family)

ADLs, activities of daily living; *RNAO*, Registered Nurses Association of Ontario.

Exercise.

Walking is by far the best physical exercise for patients with COPD. Coordinated walking with slow, pursed-lip breathing without breath holding is a difficult task that requires conscious effort and frequent

reinforcement. During coordinated walking and breathing, the patient is taught to breathe in through the nose while taking one step, then to breathe out through pursed lips while taking two to four steps (the number depends on a patient's tolerance). Walking should occur at a slow pace with rest periods when necessary. If supplemental oxygen has been prescribed, the patient needs to use oxygen while walking or exercising. By walking with the patient, the nurse helps decrease anxiety and helps maintain an appropriate pace. Walking also enables the nurse to observe the patient's actions and physiological responses to the activity. Many patients with moderate or severe COPD are anxious and fearful of walking or performing exercise. These patients and their families require much support while they build the confidence they need to walk or to perform daily exercises (GOLD, 2017).

Patients should be encouraged to walk 15 to 20 minutes a day and gradually increase this time. Patients can begin at a slower pace by walking for 2 to 5 minutes three times a day and slowly building up to 20 minutes a day, if possible. Adequate rest periods should be allowed. Some patients benefit from using a SABA (see Table 31-6) approximately 10 minutes before exercise. Parameters to monitor with exercise include resting pulse and pulse rate after activity. Pulse rate after exercise should not exceed 75% to 80% of the maximum heart rate (maximum heart rate = 220 − age in years). Dyspnea is usually the limiting factor, rather than increased heart rate, for exercise; therefore, the patient's perceived sense of dyspnea should be used as an indication of exercise tolerance. The patient can use the MRC Dyspnea Scale (see Figure 31-12) to determine the intensity of dyspnea.

Patients should be informed that shortness of breath often increases during exercise (as it does for a healthy individual). The activity is not being overdone unless the increased dyspnea does not return to baseline within 5 minutes after the cessation of exercise. Patients should wait approximately 5 minutes after completion of exercise, and if the dyspnea has not returned to baseline levels, then a SABA should be used. During the recovery time, the patient should use pursed-lip breathing. If dyspnea takes longer than 5 minutes to return to baseline levels, the patient has probably overdone the exercise and should proceed at a slower pace during the next exercise period. Keeping a diary or log of the exercise program may be beneficial. Diaries provide a realistic evaluation of progress, help motivate, and add to a sense of accomplishment. Stationary bicycles and treadmills can also be used and are particularly valuable when weather prevents walking outside.

Energy-Conserving Strategies.

Energy conservation is another important component in COPD rehabilitation. Exercise training of the upper extremities improves function and reduces dyspnea. Many patients have already adapted alternative energy-saving practices for ADLs. Alternative or modified methods of hair care, shaving, showering, and other activities that necessitate over-the-head reaching must be explored. Assuming a tripod posture (elbows supported on a table, chest in fixed position) and placing a mirror on the table while using an electric razor or hair dryer conserves energy in comparison with standing in front of a mirror to perform these activities. If the patient uses home oxygen therapy, it must be used during activities of hygiene because these activities consume energy. Another energy-saving tip is to exhale when pushing, pulling, or exerting effort during an activity and to inhale during rest. Patients should also try to sit as much as possible when performing activities.

Sexual Activity.

Modifying but not abstaining from sexual activity can contribute to a feeling of well-being. Using a SABA before sexual activity can help control dyspnea. Patients with COPD also need less energy if these guidelines are followed: (a) have sexual activity during the part of the day when breathing is best, (b) use slow pursed-lip breathing, (c) refrain from sexual activity after eating or other strenuous activity, (d) do not assume a dominant position, and (e) do not prolong foreplay. These aspects of sexual activity require open communication between partners regarding their needs and expectations and the changes that may be necessary as the result of a chronic disease (e.g., changes in body image, role reversal).

Sleep.

Adequate sleep is extremely important. Getting adequate amounts of sleep can be difficult for patients with COPD. Medications may cause restlessness and insomnia. If patients experience cough during the night, the use of long-acting bronchodilators may help. Postnasal drip may cause coughing at night and can be treated with nasal saline sprays or rinses, nasal steroids, or both before sleep and in the morning. If a patient snores, stops breathing, or makes gasping breaths while sleeping and has a tendency to fall asleep during the day, the patient may need to be tested for sleep apnea (see Chapter 9).

Psychosocial Considerations.

Healthy coping is often challenging for patients with COPD. Such patients frequently have to deal with many lifestyle changes that may involve a decreased ability to care for themselves and their condition, decreased energy for performing day-to-day activities and social activities, and the loss of a job. These lifestyle changes can put the patient at risk for social isolation.

When a patient first receives a diagnosis of COPD or experiences complications, the nurse should expect a variety of emotional responses. Emotions frequently encountered include guilt, depression, anxiety, social isolation, denial, and dependence. Among patients who still or used to smoke, guilt may result from the knowledge that the disease was caused largely by tobacco smoking. The patient may experience depression as he or she realizes the severity and chronicity of the disease. The nurse should convey a sense of understanding and caring to the patient. Relaxation techniques may provide benefit in terms of relief of dyspnea for some patients, but the evidence for this is unclear. Relaxation techniques include progressive muscular relaxation, positive thinking and visualization, use of music, yoga, massage, and humour (see Chapters 8 and 12). Progressive relaxation techniques are performed by having the patient listen to music, or to his or her own or another voice, and then gradually begin to slowly tense and relax muscle groups. Support groups at local chapters of the Canadian Lung Association, at hospitals, and at clinics can also be helpful.

End-of-Life Issues.

Nurses have a responsibility to discuss with and plan for end-of-life care with patients and their families or caregivers to make sure that the necessary supports are in place to assist them through this critical terminal phase. Patients, their families, and health care providers should be involved in writing advance directives. Nurses must explore and understand the issues facing patients and their families through empathic, honest, and informative conversations. Discussions that highlight the importance of palliative care services and alleviation of terminal dyspnea lessen anticipatory fear and anxiety. The following "Ethical Dilemmas" box discusses advance directives.

Evaluation

The expected outcomes for the patient with COPD are presented in Nursing Care Plan 31-2.

Ethical Dilemmas

Advance Directives

Situation

A 79-year-old man with chronic obstructive pulmonary disease is admitted to the hospital with respiratory failure. He is placed on a mechanical ventilator and responds to stimuli occasionally by opening his eyes. His living will was written 5 years ago, and a copy was given to his wife and health care provider at that time. The wife brings the document to the critical care unit and tells the nurse that the hospital must stop treating her husband and allow him to die as he requested. However, the oldest son is threatening the hospital with a lawsuit if the staff does not provide full care to his father.

Important Points for Consideration

- A living will is one type of an advance directive.
- A living will is prepared by the person in advance, indicating the person's treatment wishes should he or she become terminally ill or in a situation in which there is no hope of recovery.
- Health care providers must determine whether this respiratory crisis is reversible.
- Power of attorney for health care is another form of advance directive in which one person names another person to make health care decisions in the event that the first person is no longer able to do so.
- An advance directive respects the patient's autonomy: that is, the right to self-determination regarding health care at the end of life.
- A legally written living will is legally binding.
- Health care providers are obligated to follow the patient's advance directive when the patient is no longer able to speak for himself or herself.
- Health care providers are protected from liability when they adhere to advance directives.

Clinical Decision-Making Questions

1. What should the nurse do next with the information provided by the wife?
2. How should the nurse address the needs of each member of this family in the patient's plan of care?
3. What resources can the nurse use to facilitate decision making in this situation?

Cystic Fibrosis

Cystic fibrosis (CF) is an autosomal recessive, multisystem disease characterized by altered function of the exocrine glands involving primarily the lungs, the pancreas, and the sweat glands. (Autosomal recessive disorders are discussed in Chapter 15.) Abnormally thick, abundant secretions from mucous glands leads to a chronic, diffuse, obstructive pulmonary disorder in almost all affected patients. Exocrine pancreatic insufficiency is associated with most cases of CF. Sweat glands excrete increased amounts of sodium and chloride.

CF is a chronic fatal respiratory disease. According to the Canadian Cystic Fibrosis Registry, nearly 4 200 Canadians have cystic fibrosis (representing about 1 in 3 600 live births); the numbers of male and female patients are approximately equal, and the majority (92.7%) of CF patients are White (Cystic Fibrosis Canada, 2017). This autosomal recessive disease has a carrier rate of 1 per 25. If both parents carry the gene, the chance that their offspring will have the disease is 25%. The first signs and symptoms typically occur in early childhood, and in most patients, the disease is diagnosed by the age of 5 years. However, some patients tend to have less severe disease, and their cases are not diagnosed until they are adults.

The severity and the progression of the disease vary from person to person. Since the 1990s, the prognosis of this disease has improved dramatically as a result of early diagnosis and improvements in therapy. CF survival has improved at a rate of 1.8% per year with a median survival age of 39 years in 2010 (MacKenzie, Gifford, Sabadosa, et al., 2014). Of the 47 patients with CF who died in Canada in 2015, the median age at death was 29.7 years of age (Cystic Fibrosis Canada, 2017) and the median age of survival for Canadians with CF is currently estimated to be 52.1 years of age (Cystic Fibrosis Canada, 2017).

Etiology and Pathophysiology

CF results from mutations in a gene located on chromosome 7. The most common genetic mutation in CF occurs in what is known as the cystic fibrosis transmembrane regulator (CFTR) gene. The CFTR protein localizes to the lining of the exocrine portion of particular organs such as airways, pancreatic duct, sweat gland duct, and reproductive tract. The CFTR gene regulates sodium and chloride channels. Mutations in the CFTR gene alter this protein in such a way that the channels are blocked. As a result, cells

that line the passages of the lungs, the pancreas, and other organs produce abnormally thick, sticky mucus. This mucus obstructs the airways and glands. The glands distal to the duct eventually undergo fibrosis. The high concentrations of sodium and chloride in the sweat of the patient with CF result from decreased chloride resorption in the sweat duct.

In the respiratory system, both upper and lower respiratory tracts can be affected. Upper respiratory tract manifestations include chronic sinusitis and nasal polyposis. The hallmark of respiratory involvement in CF is its effect on the airways. From being a disease of the small airways (chronic bronchiolitis), CF progresses to an entity that eventually involves the larger airways and finally causes destruction of lung tissue. Thick secretions obstruct bronchioles and lead to air trapping and hyperinflation of the lungs. The stasis of mucus provides an excellent growth medium for bacteria, which makes the airways more susceptible to serious lower respiratory tract infections. CF is thus characterized by chronic airway infection. The organisms most commonly cultured from the sputum of a patient with CF are *Staphylococcus aureus, H. influenzae,* and *P. aeruginosa* (Esther, Lin, Kerr, Miller, & Gilligan, 2014). These infections increase the rate of lung destruction through inflammatory mediators such as interleukins, tumour necrosis factor, and leukotrienes.

Lung disorders that can result from this pathological process include pneumonia, bronchiolitis, bronchitis, bronchiectasis, atelectasis, and emphysema. Lung tissue is progressively destroyed by inflammation and scarring, and the resultant chronic hypoxia leads to pulmonary hypertension and cor pulmonale. Blebs and large cysts in the lung are further severe manifestations of lung destruction. Other pulmonary complications include hemoptysis, which can sometimes be fatal, and pneumothorax. The degree of hemoptysis may range from scant streaking to major bleeding.

Initially, CF is an obstructive lung disease caused by the overall obstruction of the airways with mucus. Later, CF also progresses to a restrictive lung disease because of the fibrosis, lung destruction, and thoracic wall changes. Death usually results from loss of pulmonary function. Cor pulmonale is a common late complication caused by extensive loss of lung tissue and chronic hypoxia.

Pancreatic insufficiency is caused primarily by mucous plugging of the pancreatic duct and its branches, which results in fibrosis of the acinar glands of the pancreas and leads to the loss of exocrine function. Pancreatic enzymes such as trypsinogen, lipase, and amylase do not reach the intestine to digest ingested nutrients. Fat, protein, and fat-soluble

vitamins (vitamins A, D, E, and K) are malabsorbed. Fat malabsorption results in steatorrhea, and protein malabsorption results in malnutrition, failure to grow, and failure to gain weight.

Diabetes mellitus may occur if the islets of Langerhans become fibrotic. CF-related diabetes mellitus affects approximately 15% of all patients with CF. It differs from type 1 diabetes in that some insulin is secreted, the disease is nonketotic, and it is slow in onset. It differs from type 2 diabetes in that affected individuals are underweight (as opposed to being obese), the onset is in a younger age population, and affected individuals are hypoinsulinemic. Routine screening of serum glucose levels is recommended. Insulin may be required for treatment of CF-related diabetes.

The sweat glands of the patient with CF secrete normal volumes of sweat but are unable to absorb sodium and chloride from sweat as it moves through the sweat duct. Therefore, these patients excrete four times the normal amount of sodium and chloride in sweat. This abnormality does not seem to affect the general health of the person, but it is useful as a diagnostic indicator.

Individuals with CF often have gastrointestinal problems. Intestinal obstruction resulting in meconium ileus is present in 10% to 15% of newborns with CF. GERD, distal intestinal obstructive syndrome (DIOS), and constipation are common. GERD is a major problem in individuals with CF. The relationship between reflux and exacerbation of respiratory disease is not known, but it is known that these two entities worsen each other.

DIOS is a syndrome that results from intermittent obstruction in the ileocecal area in patients with pancreatic insufficiency. The degree to which the bowel is obstructed may vary with each episode, and a partial obstruction may progress to a complete obstruction. Complete obstruction necessitates gastric decompression and a surgical consultation; partial and uncomplicated episodes of DIOS are treated with ingestion of a balanced polyethylene glycol electrolyte solution. Constipation develops in the sigmoid colon and progresses proximally, whereas DIOS develops in the ileocecal area and progresses distally. Careful monitoring of bowel habits and patterns is essential.

The liver may become involved. Biliary cirrhosis may not be recognized until late in the disease. Hepatobiliary disease is common in adult patients with CF. Chronic cholestasis, inflammation, fibrosis, and portal hypertension can occur.

Clinical Manifestations

The clinical manifestations of CF vary in accordance with the severity of the disease. As mentioned, meconium ileus is present in 10% to 15% of newborns with CF. Early childhood manifestations are failure to grow, digital clubbing, persistent cough with mucus production, tachypnea, and large, frequent bowel movements. The abdomen may become large and protuberant, and the extremities may develop an emaciated appearance.

The first symptom of CF in adults is frequently cough. With time, the cough becomes persistent and produces viscous, purulent, and often greenish sputum. Other respiratory problems that may be indicative of CF are recurring lung infections such as bronchiolitis, bronchitis, and pneumonia. As the disease progresses, periods of clinical stability are interrupted by exacerbations characterized by increased cough and sputum production, weight loss, and decreases in pulmonary function. Over time, the exacerbations become more frequent and lost lung function is less completely recovered, which ultimately leads to respiratory failure.

DIOS causes pain in the right lower quadrant, loss of appetite, and emesis, and a mass is often palpable. Insufficient pancreatic enzyme release causes the typical pattern of protein and fat malabsorption with frequent, bulky, foul-smelling stools.

The function of the reproductive system is altered. This finding is important because increasing numbers of people with CF are living to adulthood. Nearly all men with CF have reproductive issues because the vas deferens, which transports the sperm from the storage in the testes to the penile urethra, is congenitally absent. However, men with CF make sperm normally and thus, with assisted reproductive technology, have the capability of fathering children. In women with CF, menarche is usually delayed. During exacerbations, menstrual irregularities and secondary amenorrhea are fairly common. Affected women may be unable to become pregnant because of the increased viscosity of the cervical mucus. Many women with CF do have children, but the fertility rate is lower than among healthy women (Ahmad, Ahmed, & Patrizio, 2015). The baby of such a patient is heterozygous for CF (and hence a carrier of the CFTR gene) if the father is not a carrier. If the father is a carrier, the baby has a 50% chance of having CF. Genetic counselling can assist couples in deciding whether they want to have children and whether they want to use assisted reproductive technology to have a baby without the risk of CF. Screening of newborns can identify who will develop CF. Debate about the usefulness of this technology continues. (See Chapter 15, Figures 15-7, 15-9, and 15-11, for an explanation of genetic transmission of CF.)

Complications

Pneumothorax is a relatively uncommon but serious complication that is caused by the formation of bullae and blebs. A small amount of blood in the sputum is common in patients with CF because of chronic infection. Massive hemoptysis is life-threatening. With advanced lung disease, digital clubbing becomes evident. Respiratory failure and cor pulmonale are late complications of CF.

Diagnostic Studies

Diagnostic criteria for CF are evidence of CFTR protein malfunction on the sweat chloride test and characteristic respiratory or gastrointestinal symptoms. The sweat chloride test is performed with the pilocarpine iontophoresis method, which yields abnormal results in more than 90% of adults with CF. Pilocarpine carried by a small electric current is used to stimulate sweat production. The sweat is collected on filter paper or gauze and then analyzed for sodium and chloride concentrations. The test takes approximately 40 to 60 minutes. Values higher than 65 mEq/L for both sodium and chloride are suggestive of CF, especially in a person who has other clinical features of the disease. A second sweat chloride test is recommended to confirm the diagnosis unless two CF mutations have been identified by genetic testing (Ooi, Castellani, Keenan, et al., 2015). The degree of sodium and chloride elevation is not necessarily correlated with the severity of the disease. Secondary diagnostic studies include chest radiography, pulmonary function tests, fecal analysis for fat, and duodenoscopy for quantitative determination of pancreatic enzymes.

Because of the large number of CF mutations, DNA analysis is not used for the primary diagnostic test. A positive result of DNA analysis does, however, corroborate the diagnosis. Fetal diagnosis can be performed from specimens obtained by amniocentesis or chorionic villus sampling.

Collaborative Care

A multidisciplinary team should be involved in patients' care and should include nurses, physicians, respiratory and physical therapists, dietitians, pharmacists, and social workers. The major objectives of therapy in CF are to (a) promote clearance of secretions, (b) control infection in the lungs, and (c) provide adequate nutrition. Management of pulmonary problems in CF is directed at relieving airway obstruction and controlling infection. Drainage of thick bronchial mucus is assisted by aerosol and nebulized

forms of medications to liquefy mucus and to facilitate coughing. The abnormal viscosity of secretions in CF results primarily from mucus glycoproteins and DNA from degenerated neutrophils. Drugs that degrade the high concentrations of DNA in CF sputum (e.g., DNase [Pulmozyme]) decrease sputum viscosity and increase airflow. Bronchodilators (e.g., β_2-adrenergic agonists, theophylline) may be used.

Airway clearance techniques are critical in reducing mucus. These techniques include chest physiotherapy, postural drainage, and positive expiratory pressure breathing. **Chest physiotherapy** (CPT) consists of percussion, vibration, and postural drainage. Percussion and vibration are manual or mechanical techniques used to augment postural drainage. In **postural drainage,** the principle of gravity is used to assist in bronchial clearance (Figure 31-17). Percussion and vibration are used after the patient has assumed a postural drainage position to assist in loosening the mobilized secretions. Percussion, vibration, and postural drainage may assist in bringing secretions into larger, more central airways. Effective coughing is then necessary to help raise these secretions. After each drainage position change, the patient should be given time to cough and breathe deeply. These techniques are individualized on the basis of the patient's pulmonary condition and response to the initial treatment. Sometimes it takes several hours after CPT for secretions to be expectorated. It is important to evaluate the effectiveness of CPT and its relief of symptoms; a physiotherapist who is trained in the proper technique often performs CPT. Complications associated with improperly performed CPT include fractured ribs, bruising, hypoxemia, and discomfort. CPT may not be beneficial and can be stressful for some patients. Some patients may develop hypoxemia and bronchospasm with CPT.

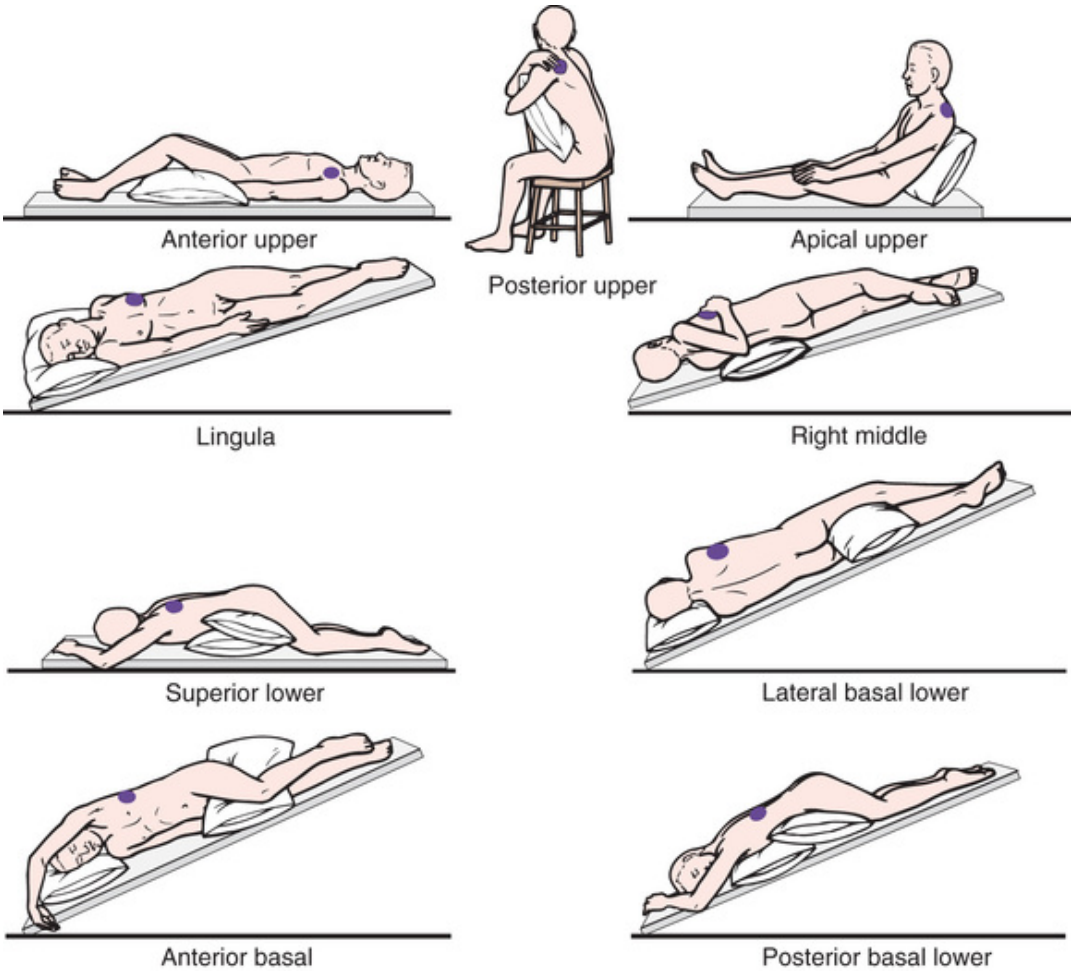

FIGURE 31-17 Representative positions for postural drainage. *Shaded areas* in each illustration indicate the segment of the lung in which drainage is promoted.

Various *airway clearance devices* are available to mobilize secretions, are easier to tolerate than CPT, and take less time than conventional CPT sessions. These devices include the Flutter device, Acapella device, and TheraPEP Therapy System. These devices involve the use of the principle of positive expiratory pressure (PEP) and may provide greater benefit to patients with COPD than other airway clearance techniques.

The Flutter mucus clearance device is also effective in promoting mucus removal (Figure 31-18). It is a handheld device that provides positive expiratory pressure. The flutter valve works by (a) causing the airways to vibrate, which loosens mucus from airway walls; (b) intermittently increasing the endobronchial pressure, which helps maintain the patency of the airway; and (c) accelerating expiratory airflow. It helps move mucus up through the airways to the mouth, where the mucus can be expectorated.

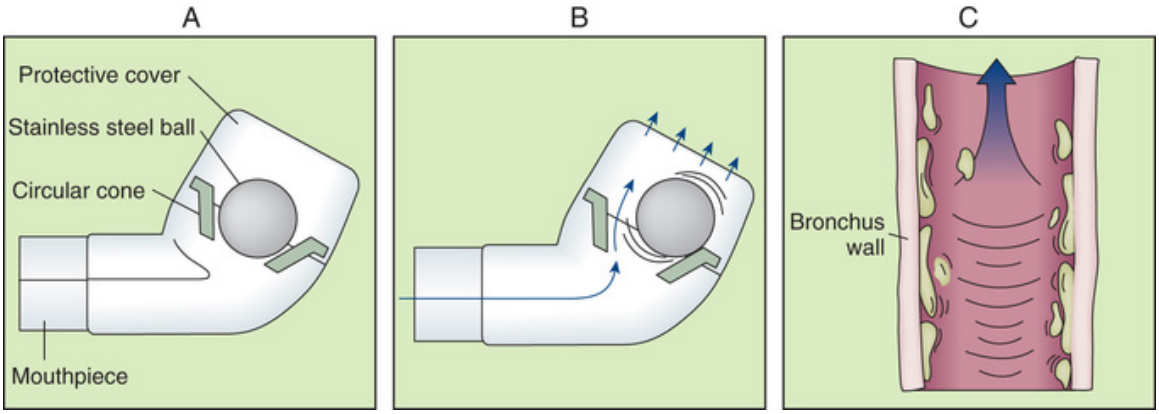

FIGURE 31-18 The Flutter mucus clearance device is a small, handheld tool that provides positive expiratory pressure therapy. It is used to facilitate removal of mucus from the lungs. **A,** It consists of a hard plastic mouthpiece, a plastic perforated cover, and a high-density stainless steel ball resting in a circular cone. **B,** The flutter effect occurs during expiration. Before exhalation, the steel ball blocks the conical canal of the Flutter device. During exhalation, the position the steel ball occupies is the result of equilibrium between the pressure of the exhaled air, the force of gravity on the ball, and the angle of the cone where the contact with the ball occurs. As the steel ball rolls and moves up and down, it creates an opening-and-closing cycle that repeats itself many times throughout each exhalation. The net result is that vibrations occur in the airways, resulting in the "fluttering" sensation. **C,** These vibrations loosen mucus from the airway walls and facilitate its movement up the airways. Source: Axcan Scandipharm, Inc., Birmingham, Alabama.

The Acapella device is another small hand-held tool that combines the benefits of both PEP therapy and airway vibrations to mobilize pulmonary secretions. It can be used in virtually any setting, inasmuch as patients are free to sit, stand, or recline while using it.

TheraPEP Therapy System can also provide sustained PEP and can simultaneously deliver aerosols so that the patient can inhale and exhale through it. TheraPEP has a mouthpiece attached to tubing connected to a small cylindrical resistor and a pressure indicator. The pressure indicator provides visual feedback about the pressure that the patient needs to hold in an exhalation to receive the PEP. (See the Resources section at the end of this chapter for a description and photo of this system.)

It is important to work collaboratively with families and patients because individuals with CF may have a preference for a certain technique that works well for them. Aerobic exercise seems to be effective in clearing the airways. Important needs to consider in planning an aerobic exercise

program for a patient with CF are (a) frequent rest periods interspersed throughout the exercise regimen, (b) meeting increased nutritional demands of exercise, (c) being alert for manifestations of hyperthermia, and (d) drinking large amounts of fluid and replacing salt losses.

Most CF patients die of complications resulting from lung infection. According to current data, antimicrobial treatment used for prophylaxis of *P. aeruginosa* has not been found beneficial and therefore is not a recommended prevention strategy (Doring, Flume, Heijerman, et al., 2012). Rigorous, early treatment of early *P. aeruginosa* colonization/infection is of great benefit to CF patients because of high eradication rates of the pathogen (Doring, Flume, Heijerman, et al., 2012). Prolonged high-dosage therapy may be necessary because many drugs are abnormally metabolized and rapidly excreted by patients with CF. Results of pharmacokinetic and kidney function studies should be monitored closely.

Although combination oral and aerosolized antimicrobial therapy is usually adequate, some patients require a 2- to 4-week course of intravenous antimicrobial therapy. If home care supports are adequate, the patient and family may choose parenteral therapy at home. The usual treatment for an acute infectious exacerbation is either an aminoglycoside combined with penicillin or a third-generation cephalosporin. Aerosolized bronchodilators may be used in selected patients, particularly before CPT. Patients with cor pulmonale or hypoxemia may require oxygen therapy. (Oxygen therapy is discussed earlier in this chapter.) Sclerosing of the pleural space or partial pleural stripping and pleural abrasion performed surgically are usually indicated for recurrent episodes of pneumothorax. (See the section on collaborative care of pleural effusions in Chapter 30.)

CF has become a leading indication for bilateral lung transplantation, accounting for 24.5% of these operations from 2004 to 2013 (CIHI, 2015). Also during this period, 356 people with cystic fibrosis received bilateral lung transplants (CIHI, 2015). (Lung transplantation is discussed in Chapter 30.) Lung transplantation for people with CF has resulted in significant improvements in pulmonary function and quality of life, as well as longer life expectancy. The survival rate among lung transplant recipients, including all primary diagnoses, is 86.8% at 1 year and 65.9% at 5 years (CIHI, 2015). The rate of survival after lung transplantation is higher among people with CF than among those with other pulmonary diseases such as COPD.

The management of pancreatic insufficiency includes pancreatic enzyme replacement of lipase, protease, and amylase (e.g., pancrelipase [Cotazym,

Creon, Ultrase, Viokase] and zymase, an enzyme complex) administered before each meal and snack. A high-calorie, high-protein diet and multivitamin supplementation are recommended. Fat restriction usually is not necessary. Fat-soluble vitamin supplementation (vitamins A, D, E, and K) is necessary. Use of caloric supplements improves nutritional status. Added dietary salt is indicated whenever sweating is excessive, such as during hot weather, in the presence of fever, or from intense physical activity.

Gene therapy has been used as an experimental therapy for treating CF, but more research is still required (Mitomo, Griesenbach, Inoue, et al., 2010). (Gene therapy is discussed in Chapter 15.)

Nursing Management Cystic Fibrosis

Nursing Assessment

Subjective and objective data that should be obtained from a patient with cystic fibrosis are listed in Table 31-21.

TABLE 31-21

NURSING ASSESSMENT
Cystic Fibrosis (CF)

Subjective Data
Important Health Information
Current health: Experience of cough and mucus production (quantity, colour, consistency), dyspnea, and wheeze *Past health history:* Past respiratory and sinus infections: typical pattern, how treated, how responded to treatment; past hospitalizations and emergency department visits; when CF was diagnosed; family history of CF *Medications:* Use of bronchodilators, antibiotics, enzymes, herbs, and complementary therapies; adverse effects experienced; and adherence to treatment regimen *Nonpharmacological therapies:* Use of postural drainage, percussion, and vibration
Symptoms
• Runny nose; increased work of breathing; thick, tenacious sputum • Dietary intolerances, voracious appetite, weight loss, intestinal gas, bulky and foul-smelling stools, abdominal pain • Fatigue, restlessness, decreased exercise tolerance • Anxiety, depression • Delayed menarche, menstrual irregularities, and secondary amenorrhea; fertility issues
Objective Data
General
Restlessness, failure to thrive
Integumentary System
Cyanosis (circumoral, nail beds), digital clubbing, salty skin
Eyes
Scleral icterus
Respiratory System
Runny nose, diminished breath sounds, sputum (amount, colour, tenacious), hemoptysis, increased work of breathing evidenced by use of accessory muscles of respiration, barrel chest
Cardiovascular System
Tachycardia
Gastro-intestinal System
Possibility of protuberant abdomen and abdominal distension and of foul, fatty stools
Possible Diagnostic Findings
Abnormal results of the following: pulmonary function tests, sweat chloride test, chest radiography, fecal fat analysis for fatty stools

Nursing Diagnoses

Nursing diagnoses for a patient with CF may include, but are not limited to, the following:

- *Ineffective airway clearance* related to *excessive mucus, retained secretions*
- *Ineffective breathing pattern* related to *fatigue, respiratory muscle fatigue*
- *Impaired gas exchange* (related to recurring lung infection)
- *Imbalanced nutrition: less than body requirements* related to insufficient dietary intake, inability to digest food
- *Ineffective coping* related to *high degree of threat* (decreased life expectancy, cost of treatment, limitation of career choices)

Planning

Overall goals for patients with CF include (a) adequate airway clearance, (b) reduction in number of risk factors associated with respiratory infections, (c) ability to perform ADLs, (d) minimizing complications related to CF, (e) adequate nutritional support to maintain appropriate BMI, and (f) active participation in planning and implementing a therapeutic regimen.

Nursing Implementation

Nurses and other health care providers can help young adults with CF obtain independence by helping them assume responsibility for their care. An important issue that should be discussed is sexuality. Delayed or irregular menstruation is not uncommon. There may be delayed development of secondary sex characteristics such as breasts in girls. A patient may use CF as a reason to avoid certain events or relationships. In contrast, healthy individuals may hesitate to make friends with someone who is sick, which can present a challenge for individuals with CF. Normal life transitions can present larger challenges to young adults with CF, such as building confidence and self-respect on the basis of

achievements, persevering with employment goals and opportunities, developing motivation to set and achieve goals, learning to cope with the intensity and chronicity of the treatment program, and adjusting to losing independence when health fails. Disclosing the CF diagnosis to friends, potential spouses, or employers may pose challenges emotionally and financially.

For patients with CF, respiratory intervention targets relief of bronchoconstriction, airway obstruction, and airflow limitation through the use of aggressive CPT, antibiotics, and bronchodilators. Good nutrition, nutritional supplements, and pancreatic enzymes are also important. Advances in long-term vascular access (e.g., implanted ports) have made intravenous access and administration of medication much easier and has eased the transition for intravenous treatment from hospital to home.

CPT is the mainstay of intervention for airway clearance. Home management of CF includes an aggressive plan of postural drainage with percussion and vibration, aerosol nebulization therapy, and breathing retraining. The patient is taught controlled coughing techniques and deep-breathing exercises and is encouraged to perform progressive exercise conditioning, such as a bicycling program.

Individuals and families affected by CF need significant support to cope with the many stresses imposed by the condition. Education and assistance can help them maintain a normal family life while coping with the huge physical demands associated with the condition. It is not uncommon for a person with CF to spend 2 hours a day performing CPT and 1 hour receiving nebulized medication (often antibiotics).

The family and the person with CF have a great financial and emotional burden. The cost of drugs, special equipment, and health care is often a financial hardship. Financial support for medications varies considerably across provinces. Some provinces provide complete support, whereas others have much lower levels of subsidy. In addition, some provinces cover only the cost of medications in childhood but stop coverage when the patient becomes an adult. The Canadian Cystic Fibrosis Foundation has established cystic fibrosis centres across the country to provide a comprehensive range of services to patients and families. A major advantage of the centres is the multidisciplinary team of nurses, physiotherapists, respiratory therapists, nutritionists, and doctors who work very closely with the family to tailor care to meet the family's needs.

As the person continues toward and into adulthood, the nurse and other skilled health professionals should be available to help the patient and

family cope with complications resulting from the disease.

Case Study

Chronic Obstructive Pulmonary Disease

Source: Jeroen van den Broek/ Shutterstock.com.

Patient Profile

Hazel Merrick is a 68-year-old married, female, retired police officer. She has been in the hospital for 3 days with an acute COPD exacerbation and will be discharged tomorrow.

Subjective Data

- Before admission, had 7 days of exceptional shortness of breath and increased volume of sputum, which turned greenish
- Had increased salbutamol use at home to five or six times a day for dyspnea
- Had jitters and racing heart
- Had three or four bouts of exacerbations of COPD in the past year that she treated at home
- Thirty pack-year history of smoking; smokes half a pack per day now to "clear out lungs" in the morning
- Eats a regular diet but "gets full fast"
- Cannot climb one flight of stairs without stopping; walks down the flat driveway 10 yards without difficulty
- Awakens two or three times per night coughing and short of breath

Objective Data

Physical Examination

- Weight, 58.5 kg (129 lb); height, 1.73 m (5 ft 8 in.); BMI, 20 kg/m^2
- Blood pressure, 136/76 mm Hg; pulse, 86; respiratory rate, 28
- Increased anteroposterior diameter of chest (barrel-shaped)
- Slight use of accessory (neck) muscles with breathing
- Diminished breath sounds with occasional wheezes
- No peripheral edema

Diagnostic Studies

- Last spirometry: decreased FEV_1 (48%) and FEV_1/FVC ratio (62%)
- ABG measurements on admission: pH, 7.34; $PaCO_2$, 49 mm Hg; HCO_3^-, 27 mmol/L; PaO_2, 70 mm Hg
- WBC count: 14 × 10^9/L, on admission
- Chest radiograph: hyperinflation, flat diaphragm, no sign of pneumonia
- Sputum: negative for *P. aeruginosa*

Collaborative Care

- COPD stage: severe COPD with acute exacerbation
- O_2, 2 L via nasal catheter while in hospital
- Prednisone, 40 mg daily PO for 5 days
- Levofloxacin, 750 mg PO
- Ipratropium HFA MDI, 2 puffs four times a day
- At discharge: fluticasone, 250 mcg, and salmeterol, 50 mcg (Advair) Diskus 250/50, one inhalation q12hr

Discussion Questions

1. What classic manifestations indicate the patient had a COPD exacerbation?

2. What are some likely causes of her COPD?
3. What symptoms indicate the overuse of inhalers, and which drug would cause the symptoms described?
4. What is the only way Ms. Merrick can halt the progression of her lung disease?
5. Why would Ms. Merrick “feel full fast” when eating? What could the nurse do to minimize this issue?
6. Interpret the ABG values. What pattern can be seen?
7. ***Priority decision:*** What are nursing priorities for discharge planning and teaching?
8. ***Priority decision:*** In view of the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
9. ***Evidence-informed practice:*** Ms. Merrick's son has been trying to persuade his mother to quit smoking for many years without success. He asks the nurse to tell his mother the results of her spirometry to convince her it is time to quit. Will this approach work?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. A client is concerned that he may have asthma. Of the following symptoms that he relates to the nurse, which ones suggest asthma or risk factors for asthma? *(Select all that apply)*
   a. Allergic rhinitis
   b. Prolonged inhalation
   c. History of skin allergies
   d. Cough, especially at night
   e. Gastric reflux or heartburn
2. In evaluating an asthmatic client's knowledge of self-care, the nurse recognizes that additional instruction is needed when the client says which of the following?
   a. "I use my corticosteroid inhaler when I feel short of breath."
   b. "I get a flu shot every year and see my health care provider if I have an upper respiratory tract infection."
   c. "I use my inhaler before I visit my aunt who has a cat, but I visit for only a few minutes because of my allergies."
   d. "I walk 30 minutes every day but sometimes I have to use my bronchodilator inhaler before walking to prevent me from getting short of breath."
3. Which of the following clinical manifestations would the nurse recognize as a key feature of COPD?
   a. Age at onset of younger than 40 years
   b. Smoking history of more than 10 pack-years
   c. History of atopic dermatitis
   d. Infrequent sputum production
4. When teaching clients about the common adverse effects of cigarette smoke on the respiratory system, the nurse would include which of the following?
   a. Increased proliferation of ciliated cells
   b. Hypertrophy of the alveolar membrane
   c. Destruction of all alveolar macrophages

d. Hyperplasia of goblet cells and increased production of mucus

5. A plan of care for the client with COPD could include which of the following? *(Select all that apply)*
   a. Exercise, such as walking
   b. High flow rate of O_2 administration
   c. Low-dose long-term oral corticosteroid therapy
   d. Use of peak flowmeter to monitor the progression of COPD
   e. Breathing exercises such as pursed-lip breathing that focus on exhalation
6. The nurse is preparing a client for transport for a diagnostic test and selects a Venturi mask for oxygen delivery. What is the rationale for choosing a Venturi mask?
   a. It can deliver up to 80% oxygen.
   b. It can provide continuous 100% humidity.
   c. It can deliver a precise concentration of oxygen.
   d. It can be used while a patient eats and sleeps.
7. Which studies would the nurse anticipate that the health care provider would order to diagnose cystic fibrosis?
   a. Pulmonary function test and sweat test
   b. Insulin tolerance and blood glucose
   c. Pancreatic enzymes and hormones
   d. Sweat test and vitamin B tolerance test

1. a, c, d, e; 2. d; 3. b; 4. d; 5. a, e; 6. c; 7. a.

CHAPTER 32

Nursing Assessment

Hematological System

Written by, Sandra Irene Rome

Adapted by, Bridgette Lord

LEARNING OBJECTIVES

1. Describe the structures and functions of the hematological system.
2. Differentiate among the different types of blood cells and their functions.
3. Explain the process of hemostasis.
4. Understand how age-related changes in the hematological system may result in differences in findings of hematological studies.
5. Describe the significant subjective and objective assessment data related to the hematological system that should be obtained from a patient.
6. Describe how to conduct a physical assessment of the hematological system.
7. Differentiate normal from abnormal physical findings of the hematological system.
8. Describe the purpose, the significance of results, and the nursing responsibilities related to diagnostic studies of the hematological system.
9. Differentiate between common normal and abnormal blood laboratory studies.

KEY TERMS

ecchymosis, p. 703
erythropoiesis, p. 697
fibrinolysis, p. 699
hematopoiesis, p. 695
hemoglobin, p. 697
hemolysis, p. 697
leukopenia, p. 708
neutropenia, p. 708
pancytopenia, p. 707
petechiae, p. 703
phagocytosis, p. 698
polycythemia, p. 707
purpura, p. 705
stem cell, p. 695
thrombo-cytopenia, p. 708
thrombo-cytosis, p. 708

Hematology is the study of blood and blood-forming tissues. The hematological system includes the bone marrow, blood, spleen, and lymph system. A basic knowledge of hematology is useful in clinical settings to evaluate a patient's ability to transport oxygen (O_2) and carbon dioxide (CO_2), coagulate blood, and combat infections. Assessment of the hematological system is based on the patient's health history, physical examination, and results of diagnostic studies.

Structures and Functions of the Hematological System

Bone Marrow

Blood cell production (hematopoiesis) occurs within the bone marrow. *Bone marrow* is the soft material that fills the central core of bones. There are two types of bone marrow (yellow [adipose] and red [hematopoietic]). The red marrow actively produces blood cells. In adults, the red marrow is located primarily in the flat and the irregular bones, such as the ends of long bones, pelvic bones, vertebrae, sacrum, sternum, ribs, flat cranial bones, and scapulae.

All three types of blood cells (red blood cells, white blood cells, and platelets) develop from a common hematopoietic stem cell within the bone marrow. This hematopoietic stem cell is best described as an immature blood cell that is able to self-renew and to differentiate into hematopoietic progenitor cells. As blood cells mature and differentiate, several different types of cells are formed (Figure 32-1). The marrow responds to increased demands for various types of blood cells by increasing production by means of a negative feedback system. The bone marrow is stimulated by various factors (e.g., erythropoietin, granulocyte colony–stimulating factor, thrombopoietin) that cause differentiation of the stem cells into one type of the committed hematopoietic cells. For example, when tissue hypoxia occurs, erythropoietin is secreted primarily by the kidney. It circulates to the bone marrow and causes differentiation of proerythroblasts in the bone marrow (Zhang, Wang, Dey, et al., 2014).

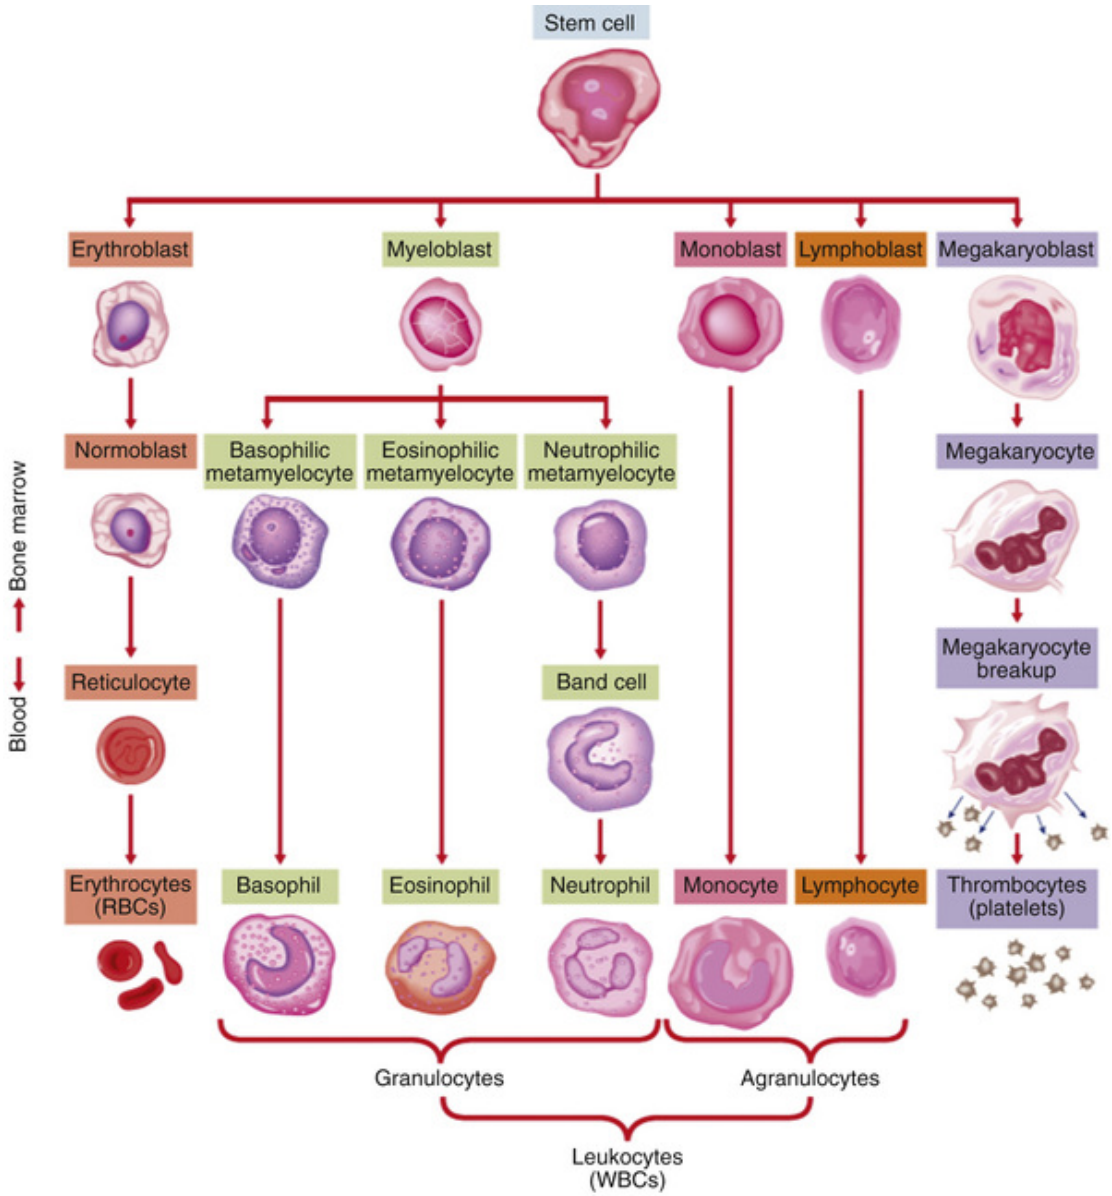

FIGURE 32-1 Development of blood cells. *RBCs*, red blood cells; *WBCs*, white blood cells.

Blood

Blood is a type of connective tissue that performs three major functions: transportation, regulation, and protection (Table 32-1). Blood is responsible for the *transportation* of oxygen, nutrients, hormones, and waste products around the body. Blood also plays a role in the *regulation* of temperature, fluid and electrolyte balance, and acid–base balance. Finally, blood plays a

protective role in its ability to coagulate (or clot) and combat infections. Blood has two major components: plasma and blood cells.

TABLE 32-1
FUNCTIONS OF BLOOD

Function	Examples
Transportation	• Oxygen from lungs to cells • Nutrients from gastro-intestinal tract to cells • Hormones from endocrine glands to tissues and cells • Metabolic waste products (e.g., CO_2, ammonia, urea) from cells to lungs, liver, and kidneys
Regulation	• Fluid and electrolyte balance • Acid–base balance • Body temperature
Protection	• Combating invasion of pathogens and other foreign substances • Maintaining homeostasis of blood coagulation

Plasma.

Approximately 55% of blood is plasma (Figure 32-2). Plasma is composed primarily of water, but it also contains proteins, electrolytes, gases, nutrients, and waste. Plasma proteins include albumin, globulin, and clotting factors, mostly fibrinogen (McCance & Huether, 2015). The term *serum* refers to plasma without its clotting factors.

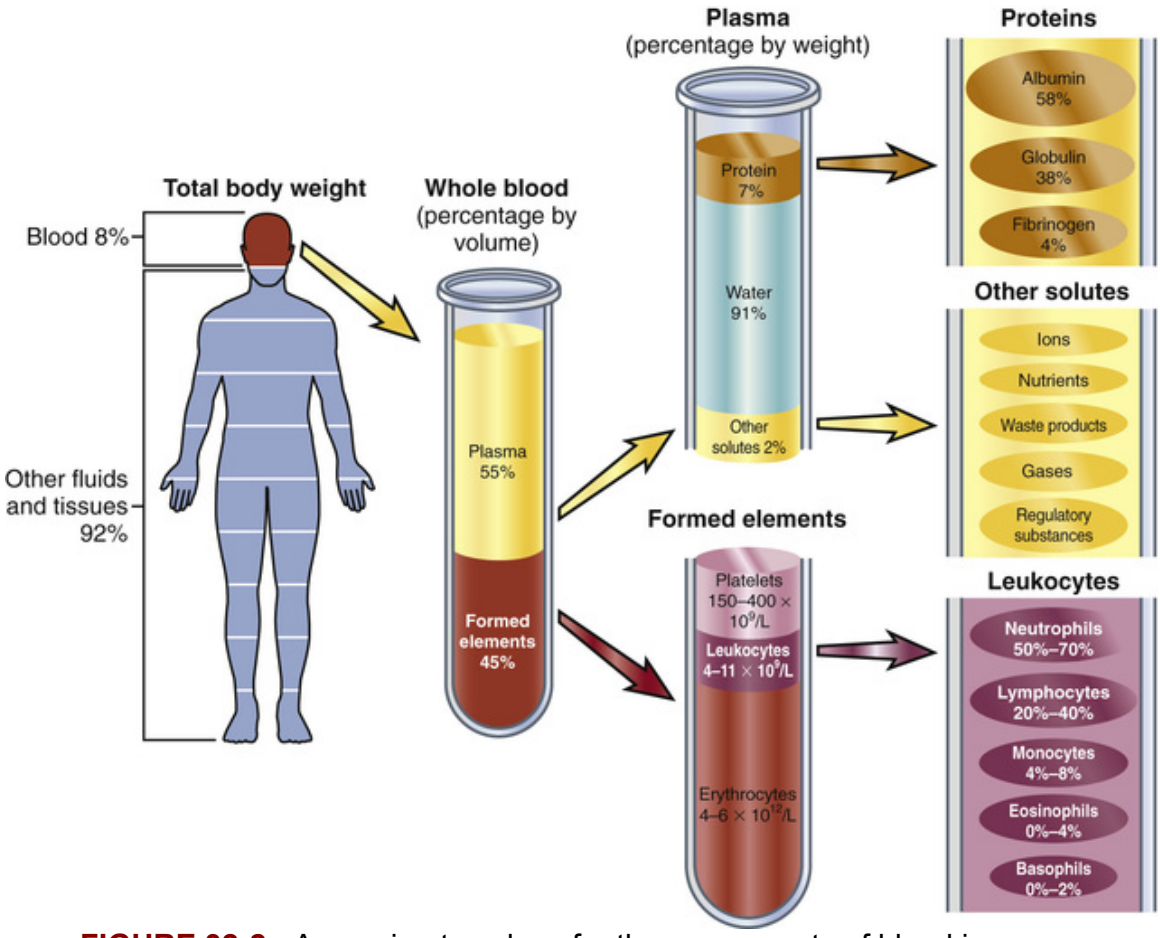

FIGURE 32-2 Approximate values for the components of blood in the adult. Normally, 45% of the blood is composed of blood cells, and 55% is composed of plasma.

Blood Cells.

About 45% of the blood (see Figure 32-2) is composed of formed elements, or blood cells. There are three types of blood cells: *erythrocytes,* or red blood cells (RBCs); *leukocytes,* or white blood cells (WBCs); and *thrombocytes,* or platelets. The primary function of erythrocytes is oxygen transportation, whereas the leukocytes are involved in protection of the body from infection. Platelets mainly function to promote blood coagulation.

Erythrocytes.

The primary functions of erythrocytes (RBCs) include transport of gases (both O_2 and CO_2) and assistance in maintaining acid–base balance. The composition and features of an erythrocyte are ideal for its role in gas

transportation. It is a flexible cell with a unique biconcave shape. Flexibility enables the cell to alter its shape so that it can easily pass through tiny capillaries. The cell membrane is also very thin, which facilitates the diffusion of gases. Erythrocytes are composed primarily of a large molecule called hemoglobin, a complex compound composed of heme (an iron compound) and globin (a simple protein) that binds with O_2 and CO_2. As erythrocytes circulate through the capillaries surrounding the alveoli within the lungs, O_2 attaches to the iron on the hemoglobin. The O_2-bound hemoglobin is referred to as *oxyhemoglobin* and is responsible for the bright-red appearance of arterial blood. As erythrocytes flow to body tissues, O_2 detaches from the hemoglobin and diffuses from the capillary into tissue cells. CO_2 diffuses from tissue cells into the capillary, attaches to the globin portion of hemoglobin, and is transported to the lungs for removal. Hemoglobin also acts as a buffer and plays a role in maintaining acid–base balance. This buffering function is described further in Chapter 19.

Erythropoiesis (the process of RBC production) is regulated by cellular O_2 requirements and general metabolic activity. Erythropoiesis is stimulated by hypoxia and controlled by *erythropoietin*, a glycoprotein growth factor synthesized and released primarily by the kidneys. Erythropoietin stimulates the bone marrow to increase erythrocyte production. Approximately 2.5 million erythrocytes are produced per second, and the normal lifespan of an erythrocyte is about 120 days. Erythropoiesis is also influenced by the availability of nutrients. Many essential nutrients are necessary for erythropoiesis, including protein, iron, copper, folate (folic acid), cobalamin (vitamin B_{12}), riboflavin (vitamin B_2), pyridoxine (vitamin B_6), pantothenic acid (vitamin B_5), niacin (vitamin B_3), ascorbic acid (vitamin C), and vitamin E. Erythrocyte production is also affected by endocrine hormones, such as thyroxine, corticosteroids, and testosterone.

Several distinct cell types evolve during erythrocyte maturation (see Figure 32-1). The *reticulocyte* is an immature erythrocyte. The reticulocyte count is a measure of the rate at which new RBCs appear in the circulation. Reticulocytes can develop into mature erythrocytes within 48 hours of their release into circulation. Therefore, assessing the number of reticulocytes is a useful means of evaluating the rate and adequacy of erythrocyte production.

Hemolysis (destruction of RBCs) by monocytes and macrophages removes abnormal, defective, damaged, and old RBCs from circulation.

Hemolysis occurs in the bone marrow, liver, and spleen and results in increased levels of bilirubin that must be processed by the body. When hemolysis occurs under normal conditions, the liver is able to conjugate and excrete the bilirubin produced.

Leukocytes.

Leukocytes (WBCs) appear white when separated from blood. Like erythrocytes, leukocytes originate from stem cells within the bone marrow (see Figure 32-1). There are five different types of leukocytes, each of which has a different function. Leukocytes that contain granules within the cytoplasm are called *granulocytes* (also known as *polymorphonuclear leukocytes*). Granulocytes include three types: neutrophils, basophils, and eosinophils. Leukocytes that do not have granules within the cytoplasm are called *agranulocytes* and include lymphocytes and monocytes (Table 32-2). Lymphocytes and monocytes are also referred to as *mononuclear cells* because they have only one discrete nucleus. The lifespan of leukocytes varies widely: granulocytes may live for only a few hours, whereas some lymphocytes may live for many years.

TABLE 32-2
TYPES AND FUNCTIONS OF LEUKOCYTES

Type	Cell Function
Granulocytes	
Neutrophil	Phagocytosis, especially during the early phase of inflammation
Basophil	Inflammatory response and allergic response; release of bradykinin, heparin, histamine, serotonin; limited phagocytosis
Eosinophil	Phagocytosis (not as effective as neutrophil); allergic response; protection from parasitic infections
Agranulocytes	
Lymphocyte	Cellular and humoral immune response
Monocyte	Phagocytosis; cellular immune response

Granulocytes.

The primary function of the granulocytes is phagocytosis**,** a process by which WBCs ingest or engulf an unwanted organism and then digest and kill it. The *neutrophil* is the most common type of granulocyte, accounting for 50% to 70% of all WBCs. Neutrophils are the primary phagocytic cells involved in acute inflammatory responses. Once they engulf the pathogen, they die in 1 to 2 days. Neutrophil production and maturation are stimulated by hematopoietic growth factors (e.g., granulocyte colony–stimulating factor [G-CSF] and granulocyte-macrophage colony–stimulating factor [GM-CSF]) (Hamilton & Achuthan, 2013).

A mature neutrophil is called a *segmented neutrophil* ("seg") because the nucleus is segmented into two to five lobes connected by strands. An immature neutrophil is called a *band* (for the bandlike or rodlike appearance of the nucleus). Although band cells are sometimes found in the peripheral circulation of normal people and are capable of phagocytosis, the mature neutrophils are more effective. An increase in neutrophils in the blood is a common diagnostic indicator of infection or tissue injury. The existence of many immature cells is termed a *shift to the left* and may be indicative of active infection or inflammation. (Shift to the left is explained further in the "White Blood Cells" section later in this chapter.)

Eosinophils account for only 2% to 4% of all WBCs. They have a similar but reduced ability for phagocytosis. One of their primary functions is to engulf antigen–antibody complexes formed during an allergic response. Elevated levels of eosinophils are also seen in some neoplastic disorders, such as lymphoma, as well as in various skin and connective tissue disorders (Lebeaux & Sene, 2012). Eosinophils are able to defend against parasitic infections.

Basophils constitute less than 2% of all leukocytes. These cells have cytoplasmic granules that contain chemical mediators such as heparin, serotonin, and histamine. If a basophil is stimulated by an antigen or by tissue injury, it responds by releasing substances from the granules. This is part of the response in allergic and inflammatory reactions. *Mast cells* are similar to basophils, but they reside in connective tissue and play a central role in inflammation, permeability of blood vessels, and smooth muscle contraction.

Agranulocytes.

Agranulocytes differ from granulocytes in that their cytoplasm does not contain lysosomal granules. *Lymphocytes*, one type of agranular leukocyte, constitute 20% to 25% of the WBCs. Lymphocytes originate from stem cells in the bone marrow, and their main function is related to the immune response. Two lymphocyte subtypes are B cells and T cells. Although T-cell precursors originate in the bone marrow, these cells migrate to the thymus gland for further differentiation into T cells. (Details of lymphocyte function are presented in Chapter 16.)

Monocytes are the other type of agranular leukocyte. These cells are usually larger than other WBCs and account for approximately 3% to 8% of all WBCs. Monocytes are potent phagocytic cells. They can ingest small or large masses of matter, such as bacteria, dead cells, tissue debris, and

old or defective RBCs. These cells are present in the bone marrow for only a short time before they migrate into the tissues and become macrophages. In addition to macrophages that have differentiated from monocytes, resident macrophages can also be found in tissues. These resident macrophages are further differentiated; they include Kupffer cells in the liver, osteoclasts in the bone, and alveolar macrophages in the lungs. These macrophages protect the body from pathogens at these entry points and are more phagocytic than monocytes. Macrophages also interact with lymphocytes to facilitate the humoral and cellular immune responses.

Thrombocytes.

The primary function of thrombocytes (platelets) is to initiate the clotting process by producing an initial "platelet plug" in the early phases of the clotting process. Platelets must be available in sufficient numbers and must be structurally and metabolically sound for blood clotting to occur. When capillaries are damaged, platelets adhere to the damaged capillary wall, and platelet activation is initiated. Increasing numbers of platelets accumulate to form the platelet plug, which is stabilized with clotting factors. Platelets are also important in the process of clot shrinkage and retraction.

Platelets, like other blood cells, originate from stem cells within the bone marrow (see Figure 32-1). The stem cell undergoes differentiation by transforming into a *megakaryocyte*, which fragments into platelets. Platelet production is partly regulated by *thrombopoietin*, a growth factor that acts on bone marrow to stimulate platelet production (Kaushansky, 2015).

Thrombopoietin is produced in the liver, kidneys, smooth muscle, and bone marrow. Typically, platelets have a lifespan of 8 to 10 days.

Iron Metabolism

Iron is obtained from foods and dietary supplements. On average, only 5% to 10% of the dietary iron that is consumed is absorbed by the body. Absorption primarily takes place in the duodenum and the upper jejunum. Approximately two-thirds of the body's iron is found as the heme part of the hemoglobin molecule in RBCs. The other third of iron is stored as ferritin and hemosiderin in the bone marrow, spleen, liver, and macrophages (Figure 32-3). When stored iron is not replaced, hemoglobin production is reduced.

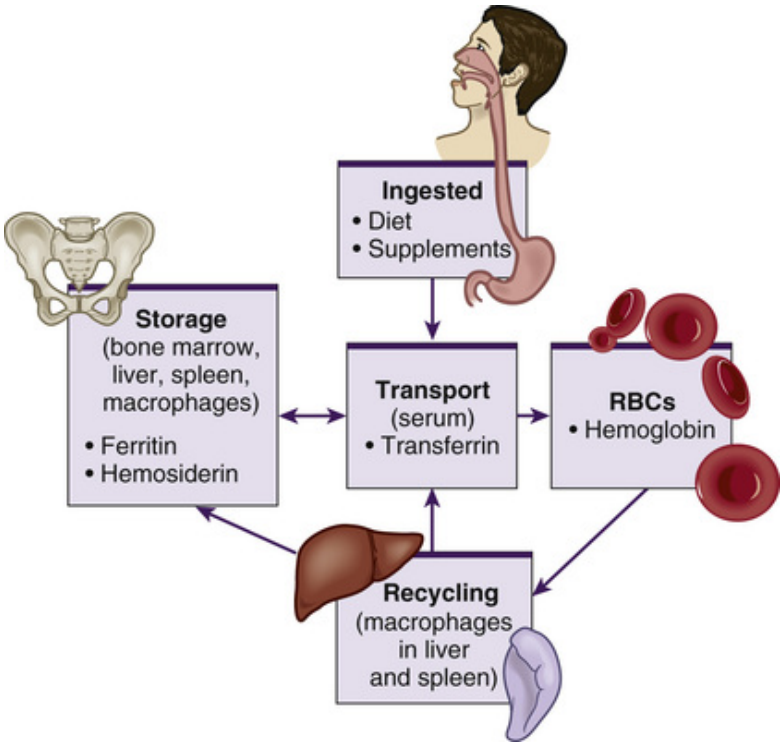

FIGURE 32-3 Iron metabolism. Iron is ingested in the diet or from supplements. Macrophages break down ingested red blood cells. Iron is returned to the blood bound to transferrin or stored as ferritin or hemosiderin. *RBC*, red blood cell.

Transferrin, which is synthesized in the liver, serves as a carrier plasma protein for iron. The degree to which transferrin is saturated with iron is a reliable indicator of the iron supply for developing RBCs.

Iron is recycled in the body after old and damaged RBCs are *phagocytized* (i.e., ingested and destroyed) by macrophages in the liver and spleen. Iron is released into the plasma and transported by transferrin to the bone marrow for RBC production. Alternatively, iron may be stored as ferritin or hemosiderin (see Figure 32-3). Only about 3% of iron is lost daily in urine, sweat, bile, and epithelial cells in the gastro-intestinal tract. Therefore, there is normally very little iron loss except with blood loss.

Clotting Mechanisms

Hemostasis is a term used to describe the blood clotting process. This process is important in minimizing blood loss when body structures are injured. The sequence of events is as follows: (1) vascular injury and subendothelial exposure; (2) platelet plug formation involving adhesion,

aggregation, and activation; (3) fibrin clot development; and (4) clot retraction and dissolution.

Vascular Injury and Subendothelial Exposure.

When a blood vessel is injured, an immediate local vasoconstrictive response occurs. Vasoconstriction reduces the leakage of blood from the vessel not only by restricting the vessel size but also by pressing the endothelial surfaces together. The latter reaction enhances vessel wall stickiness and maintains closure of the vessel even after the vasoconstriction subsides. Vascular spasm may last for 20 to 30 minutes, allowing time for the platelet response and plasma clotting factors to be activated.

Platelet Plug Formation (Adhesion, Aggregation, Activation).

Damage to the endothelial lining of blood vessels exposes glycoproteins such as collagen and von Willebrand factor (vWF), to which platelets adhere. The stickiness is termed *adhesiveness,* and the formation of clumps is termed *aggregation*. As platelets adhere to the collagen fibres of a wound, platelets become spiked and much stickier. They stick to one another because of fibrin linking their glycoprotein IIb/IIIa receptors. The adhesion process causes platelets to undergo an *activation* process whereby they release their stored granules that contain adenosine diphosphate (ADP), prostaglandin, thromboxane A_2 (TXA_2), and other factors that enhance platelet plug formation and limit bleeding (Porteus & Mantanona, 2012).

In addition to their contribution in forming a platelet plug, platelets also facilitate the reactions of the plasma clotting factors within the coagulation cascade. Platelet lipoproteins stimulate necessary conversions in the clotting process (Figure 32-4).

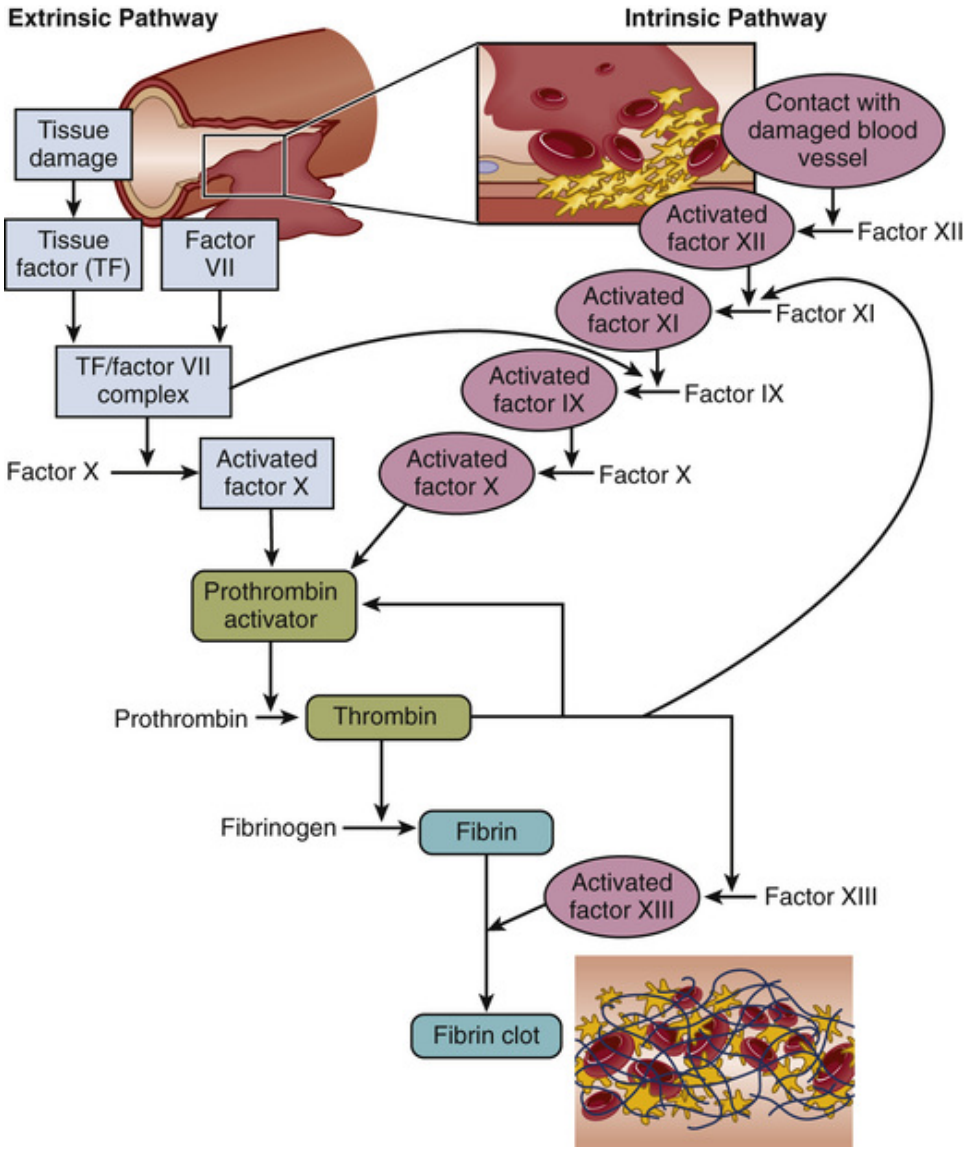

FIGURE 32-4 Coagulation mechanism showing steps in the intrinsic and the extrinsic pathways as they would occur in the test tube.

Fibrin Clot Development.

The formation of a fibrin clot interlaced with the platelet plug is the conclusion of a complex series of reactions involving different clotting factors. The plasma clotting factors are labelled with both names and Roman numerals (Table 32-3). Plasma proteins circulate in inactive forms until stimulated to initiate clotting through one of two pathways: intrinsic or extrinsic. The *intrinsic pathway* is activated by collagen exposure from endothelial injury when the blood vessel is damaged. The *extrinsic pathway*

is initiated when tissue thromboplastin is released extravascularly from injured tissues.

TABLE 32-3

COAGULATION FACTORS

Coagulation Factor	Action
I Fibrinogen	Source of fibrin to form a clot. Made in liver.
II Prothrombin	Converted to thrombin, which then activates fibrinogen into fibrin, as well as activating factors V, VII, VIII, XI, XIII; protein C; and platelets.
III Tissue factor, tissue thromboplastin	Released from damaged endothelial cells; activates the extrinsic pathway by reacting with factor VII.
IV Calcium	Required cofactor at several points in the coagulation cascade.
V Labile factor	Binds with factor X to activate prothrombin.
VI	Not in use (now obsolete).
VII Stable factor, proconvertin	Forms a complex with factor III and activates factors IX and X.
VIII Antihemophilic factor	Works with factor IX and calcium to activate factor X.
IX Christmas factor	Together with factor VIII, activates factor X.
X Stuart–Prower factor	Activates conversion of factor II (prothrombin) into thrombin.
XI Plasma thromboplastin antecedent	Activates factor IX when calcium is present.
XII Hageman factor	Activates factor XI, which starts the intrinsic pathway.
XIII Fibrin-stabilizing factor	Cross-links fibrin strands and stabilizes fibrin clot.

Regardless of whether clotting is initiated by substances inside or outside the blood vessel, coagulation ultimately follows the same final common pathway of the clotting cascade. Thrombin, in the common pathway, is the most powerful enzyme in the coagulation process (Figure 32-5). It converts fibrinogen to fibrin, which is an essential component of a blood clot.

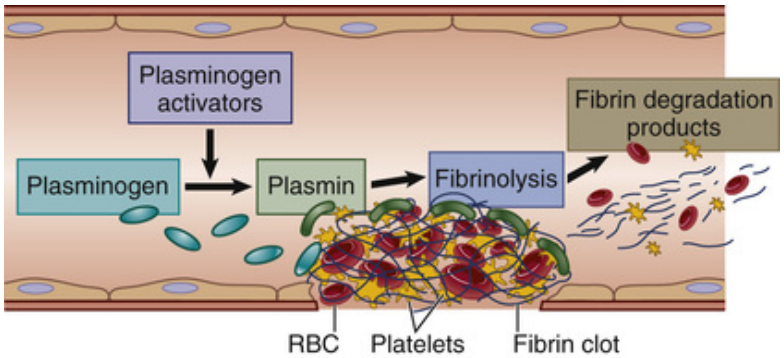

FIGURE 32-5 Fibrinolytic system. *RBC*, red blood cell.

Clot Retraction and Dissolution.

Just as some blood elements foster coagulation *(procoagulants),* others interfere with clotting *(anticoagulants).* This counter-mechanism to blood clotting serves to keep blood in its fluid state. Anticoagulation may be achieved by several means: antithrombin activity, fibrinolysis, and vessel and platelet activity. As the name implies, antithrombins keep blood fluid by antagonizing thrombin, a powerful coagulant. Endogenous heparin, protein C, and protein S are examples of anticoagulants.

Another method of maintaining blood in its fluid form is fibrinolysis**,** a continual process resulting in the dissolution of fibrin and thus clots. The fibrinolytic system is initiated when plasminogen is converted to plasmin (see Figure 32-5). Thrombin is one of the substances that can activate the conversion of plasminogen to plasmin, thereby promoting fibrinolysis. The plasmin attacks either fibrin or fibrinogen by splitting the molecules into smaller elements known as *fibrin split products* (FSPs) or *fibrin degradation products* (FDPs). (More information about FSPs can be found in Table 32-8 later in this chapter and in the discussion of disseminated intravascular coagulation in Chapter 33.)

If fibrinolysis is excessive, the patient is predisposed to bleeding. In such a situation, bleeding results from the destruction of fibrin in platelet plugs or from the anticoagulation effects of increased amounts of FSPs. Increased FSPs lead to impairment in platelet aggregation, reduction in prothrombin, and an inability to stabilize fibrin.

Spleen

Another component of the hematological system is the spleen, which is located in the upper left quadrant of the abdomen. The role of the spleen can be classified into the following four general functions:

1. *Hematopoietic function:* The spleen produces RBCs during fetal development.
2. *Filter function:* The spleen filters the blood. It removes old and defective RBCs from circulation by means of the mononuclear phagocyte system. Filtration also involves the reuse of iron—the spleen is able to catabolize hemoglobin released by hemolysis and return the iron component of the hemoglobin to the bone marrow for reuse. The spleen also plays an important role in filtering circulating bacteria, especially encapsulated organisms such as Gram-positive cocci.

3. *Immune function:* The spleen contains a rich supply of lymphocytes, monocytes, and stored immunoglobulins.
4. *Storage function:* The spleen serves as a storage site for platelets and RBCs. More than 300 mL of blood and one-third of platelets can be stored in the spleen.

Lymph System

The lymph system—consisting of lymph fluid, lymphatic capillaries, lymphatic ducts, and lymph nodes—carries fluid from the interstitial spaces to the blood. It is by means of the lymph system that proteins and fat from the gastro-intestinal (GI) tract and certain hormones are able to return to the circulatory system. The lymph system also returns excess interstitial fluid to the blood, which is important in preventing the development of edema.

Lymph fluid is a pale-yellow fluid that has diffused through lymphatic capillary walls. It circulates through a special vasculature, much as blood moves through blood vessels. The formation of lymph fluid increases when interstitial fluid increases, thereby forcing fluid into the lymph system. When too much interstitial fluid forms or when something interferes with the reabsorption of lymph, *lymphedema* develops. Lymphedema may occur as a complication following surgery (for example, when axillary lymph nodes are removed as part of a radical mastectomy) or if lymph drainage is disrupted following radiation to an area. The lymphatic capillaries are thin-walled vessels that have an irregular diameter. They are somewhat larger than blood capillaries and do not contain valves. Lymphatic capillaries unite to form lymphatic vessels that carry all lymph fluid to either the right lymphatic duct or to the thoracic duct. These large lymphatic ducts drain into the subclavian veins of the neck.

The *lymph nodes* are round, oval, or bean-shaped and vary in size according to their location. Structurally, lymph nodes are small clumps of lymphatic tissue and are found in groups along lymph vessels at various sites in the body. The body contains more than 200 lymph nodes, with the greatest number in the abdomen surrounding the GI tract. Lymph nodes are situated both superficially and deep. The superficial nodes can be palpated, but evaluation of the deep nodes requires radiological examination. A primary function of lymph nodes is the filtration of pathogens and foreign particles that are carried by lymph fluid to the nodes.

Liver

The liver functions as a filter. It also produces procoagulants that are essential for hemostasis and blood coagulation. In addition, when the amount of iron exceeds tissue needs (which can occur with frequent blood transfusions or with diseases that cause iron overload), the excess is stored in the liver. *Hepcidin*, a protein produced by the liver, is a key regulator of iron balance. The synthesis of hepcidin is regulated by a variety of stimuli, including existent iron stores in the body, inflammation, hypoxia, and RBC requirements (Kautz & Nemeth, 2014). Hepcidin reduces the release of stored iron from enterocytes (in the intestines) and macrophages. Thus, when iron is deficient, hepatocytes produce less hepcidin, releasing stored iron and increasing dietary absorption. Other functions of the liver are described in Chapter 46.

Age-Related Considerations

Hematological System

Physiological aging is a gradual process that involves cell loss and organ atrophy. Aging leads to a decrease in bone marrow mass and cellularity and an increase in bone marrow fat (Ershler, Artz, & Kanapuru, 2015). Although older adults are still capable of maintaining adequate blood cell levels, the lower reserve capacity leaves them more vulnerable to possible problems with clotting, transporting O_2, and fighting infection. The result is a diminished ability to compensate for an acute or chronic illness. In addition, age-related changes result in an increased risk for clonal myeloid cancers.

Hemoglobin levels begin to decrease in both men and women after middle age. Although iron deficiency is often responsible for the low hemoglobin levels, the cause of anemia in approximately one-third of older patients is unknown. Inadequate nutritional intake of iron may be a factor, as may occult inflammation, low testosterone levels, impaired renal function, or incipient myelodysplasia (Ershler, Artz, & Kanapuru, 2015). Older adults are also not as able as younger adults to produce reticulocytes in response to hemorrhage or hypoxemia. Also, the RBC plasma membranes are more fragile in the older person. This fragility may account for a slight increase in mean corpuscular volume (MCV) and a slight decrease in mean corpuscular hemoglobin concentration (MCHC) of RBCs in some older individuals.

The total WBC count and differential are generally not affected by aging (Ershler, Artz, & Kanapuru, 2015). However, humoral antibody response and T-cell function may decrease (Bueno, Sant'Anna, & Lord, 2014). During an infection, an older adult may have only a minimal elevation in the total WBC count. This laboratory finding suggests that the bone marrow reserve of granulocytes is diminished in older adults and reflects the possible impairment in stimulation of hematopoiesis.

The number of platelets is unaffected by the aging process, but functionally the platelets may have increased adhesiveness. More important, the levels of proteins critical to coagulation change with age. There is an age-related activation of coagulation and fibrinolytic pathways that favours clot formation. The effects of aging on hematological studies are presented in Table 32-4. Immune changes related to aging are described in Chapter 16.

TABLE 32-4

AGE-RELATED DIFFERENCES IN ASSESSMENT
Effects of Aging on Hematological Studies

Study	Changes
CBC Studies	
Hemoglobin	Normal; possibly slightly decreased
MCV	May be slightly increased
MCHC	May be slightly decreased
WBC count	Diminished response to infection
Platelets	Unchanged
Clotting Studies	
Partial thromboplastin time	Decreased
Fibrinogen	May be elevated
Factors V, VII, VIII, IX	May be elevated
ESR	Increased significantly
D-dimers	Increased
Iron Studies	
Serum iron	Decreased
Total iron-binding capacity	Decreased
Ferritin	Increased
Erythropoietin	May be decreased

CBC, complete blood cell count; *ESR,* erythrocyte sedimentation rate; *MCHC,* mean corpuscular hemoglobin concentration; *MCV,* mean corpuscular volume; *WBC,* white blood cell.

Assessment of the Hematological System

Much of the evaluation of the hematological system is based on a thorough health history. Key questions to ask a patient with a hematological problem are presented in Table 32-5.

TABLE 32-5

HEALTH HISTORY
Hematological System: Subjective Data

Past History
• Have you had any previous problems with anemia, bleeding disorders, and blood diseases such as leukemia?*
• Have you ever received a blood transfusion?*
• Have you undergone any surgical procedures?
Family History
• Has anyone in your family had anemia, cancer, bleeding, or clotting problems?*
Social and Occupational History
• Does your occupation bring you into contact with hazardous substances?*
• Have you had any past or current occupational or household exposures to radiation or chemicals?*
• Have you had any past exposure to radiation as a medical treatment?
• Do you have a support system to assist you when needed?
• What coping strategies do you use when your symptoms get worse?
Self-Care History
• Do you smoke or drink alcohol?*
• Do you take any prescribed or over-the-counter medications?*
• Are you having or have you ever had chemotherapy?*
• Do you take any herbal products?* Home remedies?*
• Have you in the past or are you currently consuming illegal drugs? What agents? What route? How frequently? When did you last use them?
• Do you exercise regularly? What type of exercise do you do, and how frequently?*
Activities of Daily Living
• Do you have any difficulty performing daily activities because of a lack of energy?*
• Have you experienced excessive fatigue recently?*
• Do you have any shortness of breath at rest? With activity?*
Nutrition–Metabolic History
• Do you have any difficulties with eating, chewing, or swallowing?*
• Have you had a sore tongue or any mouth sores, swollen or sore gums, or excessive oral bleeding?
• How has your appetite been?
• What kind of diet do you follow? If vegetarian, do you eat eggs, milk products, fish, or chicken? Do you follow a vegan diet?
• Do you take any vitamins, nutritional supplements, or iron?*
• Have you had any changes in your weight in the past year?*
• Are nausea and vomiting a problem for you?*
• Have you ever experienced any unusual bleeding or bruising?*
• Have there been recent changes in the condition of your skin?*
• Have you noticed any swelling in your armpits, neck, or groin?*
• Have you experienced night sweats or cold intolerance?*
Elimination
• Have you had black or tarry stools?* Have you had light- or clay-coloured stools?
• Do you ever have diarrhea or a change in your bowel habits?*
• Have you noticed any blood or a dark tea colour in your urine?*
• Have you been urinating less?*
• Has your urine had a foul odour or cloudiness?
Neurological History
• Do you have any pain, such as bone, joint, or abdominal pain, or abdominal fullness?*
• Do you have pain when moving your joints?*
• Have your muscles been sore or achy recently?*
• Do you have any limitations in joint motion?*
• Do you have a problem with unsteady gait?* Have you fallen recently?*
• Have you experienced any numbness or tingling?*
• Have you had any problems with your vision, hearing, or taste?*
• Have you noticed any changes in your mental functions?*
Sleep History
• Do you feel fatigued? Are you more fatigued than usual?*

• Do you feel rested on awakening? If no, explain.
Sexual–Reproductive History
• Has your hematological problem caused any sexual or intimacy problems that concern you?*
• *Women:* When was your last menses? Is your cycle regular? How long does your bleeding usually last? How heavy is the flow? Have you had any increase in cramping or clotting?* Have there been any changes in the amount of flow?
• *Men:* Do you experience erectile dysfunction?*
• Have you had unprotected sex in the past 6 months?* Was your partner someone new or a person with whom you have had a long-term sexual relationship?
Other
• Has your current illness caused a change in your roles and relationships?*
• Does your health problem make you feel differently about yourself?*
• Do you have any other physical changes that cause you distress?*
• Do you have any personal or religious objection to receiving blood or blood products?*
• Do you have any conflicts between your planned therapy and your value–belief system?*

*If yes, describe.

Case Study

Patient Introduction

Source: Image Point Fr/Shutterstock.com

Allison Jobena is a 73-year-old woman who is brought to the emergency department by her husband. He found his wife at home, weak and lying in bed after she had returned from work. She says she has been slowly getting more "cold and tired" but "that is what happens when you continue to work at this age." Her husband states that she has become more tired over the past couple of weeks and gets short of breath when doing simple errands. She recently developed a "bad cold and sinus infection" that improved only after two courses of antibiotics. Ms. Jobena also states, "I've noticed I've had a lot of bruising lately."

Discussion Questions

Throughout this assessment chapter, think about Ms. Jobena with the following questions in mind:

1. What are the possible causes of Ms. Jobena's weakness, pallor, and shortness of breath?
2. What would be the nurse's priority assessment?
3. What questions should the nurse ask Ms. Jobena?
4. What should be included in the physical assessment? What would the nurse be looking for?
5. What diagnostic studies might be ordered?

Ms. Jobena and her condition will be followed throughout this assessment chapter. See pp. 704, 705, and 711 for more information on Ms. Jobena.

Subjective Data

Important Health Information

Past Medical History.

It is important to learn whether the patient has had prior hematological problems or whether the patient's family has any hereditary disorders. Hematological disorders that have a strong genetic link include sickle cell anemia, hemophilia, thalassemia, and hemochromatosis. The nurse should also document other related medical conditions such as mononucleosis, malabsorption, and liver disorders (e.g., hepatitis, cirrhosis), as well as kidney or spleen disorders. A patient may have received a kidney transplant, may have lost a spleen to traumatic injury, or may have a history of intravenous drug use that may affect the risk for hematological disorders. A history of recurrent infection or problems with blood clotting should also be noted. In addition, it is important to determine how many, if any, blood transfusions a patient has had, as well as any complications experienced during administration, since the risk for transfusion reactions and iron overload increase with the number of blood transfusions.

Medications.

A complete medication history that includes both prescription and over-the-counter drugs taken is an important component of a hematological assessment. The use of vitamins, herbal products, or dietary supplements should specifically be addressed because many patients may not consider

these to be drugs. Many drugs and supplements interfere with normal hematological functions. For example, herbal therapies such as *Panax* ginseng can alter clotting times (Li, Wang, & Xu, 2013). Chemotherapeutic drugs used to treat cancer and antiretroviral agents used to treat human immunodeficiency virus (HIV) infection may cause bone marrow depression (see Chapters 17 and 18). A patient previously treated with chemotherapeutic drugs, particularly alkylating agents, is at a higher risk of developing a secondary malignancy such as leukemia or lymphoma. A patient receiving long-term anticoagulation therapy (e.g., warfarin [Coumadin]) may be at increased risk for bleeding.

Surgery or Other Treatments.

The patient should be asked about specific past surgical procedures, specifically, splenectomy, tumour removal, prosthetic heart valve placement, surgical excision of the duodenum (in which iron absorption occurs), partial or total gastrectomy (in which parietal cells are removed, thus reducing intrinsic factor needed for the absorption of cobalamin [vitamin B_{12}]), gastric bypass (in which the duodenum may be bypassed and parietal cell surface area decreased), and ileal resection (in which cobalamin absorption takes place). The nurse should also ascertain how wound healing progressed postoperatively and if and when any bleeding problems occurred related to the surgery. Wound healing and bleeding as responses to past injuries (including minor trauma) and to dental extractions should be documented.

Approach to Obtaining a Hematological History

Social and Occupational History.

The patient should be questioned about any past or current occupational or household exposures to radiation or chemicals. If such exposure has occurred, the type, amount, and duration of exposure should be determined. A person who has been exposed to radiation, as a treatment modality or by accident, has a higher incidence of certain hematological problems (see Chapter 18). The same is true of a person who has been exposed to chemicals (e.g., benzene, lead, naphthalene, phenylbutazone). These chemicals are commonly used by potters, dry cleaners, and individuals in occupations involving the use of adhesives. The nurse should assess the effect of the current illness on a patient's usual roles and

responsibilities. The patient's support systems and coping skills should also be assessed.

Self-Care History.

Risk factors that might disrupt the hematological system, such as alcohol and cigarette use, must be assessed. Alcohol is a caustic agent, and damage to the GI tract secondary to alcohol use can cause bleeding. *Hematemesis* (bright-red, brown, or black vomit) can be a symptom of this problem and should be investigated. Alcohol also exerts a damaging effect on platelet function and the liver, in which clotting factors are produced. Consequently, bleeding problems can develop and should be anticipated in patients with a known history of alcohol use disorder. Cigarette smoking increases low-density lipoprotein cholesterol and levels of CO_2, leading to hypoxia and altering the anticoagulant properties of the endothelium. Smoking also increases platelet reactivity, plasma fibrinogen, hematocrit, and blood viscosity, which increases the risk of developing blood clots. Illegal drug use should also be documented because many illegal drugs may affect hematopoiesis.

Activities of Daily Living.

Because fatigue is a prominent symptom in many hematological disorders, the patient should be asked about feelings of tiredness. The nurse should also ask whether the patient experiences weakness and complains of heavy extremities. Symptoms of apathy, malaise, dyspnea, or palpitations should be documented. Any change in a patient's ability to perform activities of daily living (ADLs) should be noted. Whether or not the patient exercises should also be determined.

Nutritional–Metabolic History.

During the patient interview and assessment, the nurse should measure the patient's weight and determine whether the patient has experienced any anorexia, nausea, vomiting, or oral discomfort. A dietary history may provide clues about the cause of anemia. Iron, cobalamin, and folic acid are necessary for the development of RBCs. Iron and folic acid deficiencies are associated with inadequate dietary intake; foods containing these substances include liver, meat (duck, chicken, beef), tofu, eggs, seafood (sardines, oysters), whole-grain and enriched breads, potatoes, leafy green vegetables (kale, spinach, bok choy), dried fruits, lentils, soybeans, and molasses. Folic acid deficiencies may be offset by a diet that includes foods that are also high in iron.

Any changes in the skin's texture or colour should be explored. The patient should be asked about any bleeding of gum tissue. Any petechiae (small, purplish-red lesions) or ecchymosis (bruising) on the skin should be noted; if they are present, the frequency, size, and cause should be documented. The location of petechiae can indicate an accumulation of blood in the skin or mucous membranes. Small vessels leak under pressure, and if platelet numbers are insufficient to stop the bleeding, petechiae may result. Petechiae may also occur in areas where clothing constricts the circulation.

The patient should also be questioned about any lumps or swelling in the neck, the armpits, or the groin. Specifically, the patient must be asked what the lumps feel like (i.e., hard or soft, tender or nontender) and if they are mobile or fixed. Primary lymph tumours are usually not painful. A nontender swollen lymph node may be a sign of Hodgkin's disease or non-Hodgkin's lymphoma. Lymph nodes that are enlarged and tender are usually associated with an acute infection. Any incidents of fever should be explored thoroughly. It should be determined whether the patient currently has a fever, recurring fevers, chills, or night sweats.

Elimination Pattern.

The patient should be asked whether blood has been noted in the urine or stool or whether stools have been black and tarry. The patient should indicate whether he or she has had a recent stool Hemoccult (blood) test or colonoscopy. Also, any decrease in urinary output or diarrhea should be documented.

Neurological History.

Arthralgia (joint pain) may be caused by a hematological problem and should be assessed. Pain in the joint may be indicative of an autoimmune disorder or may be caused by gout secondary to increased uric acid production, which in turn may be secondary to a hematological malignancy or hemolytic anemia. Aching bones may result from pressure of expanding bone marrow with diseases such as leukemia. *Hemarthrosis* (blood in a joint) can occur in patients with bleeding disorders and can be painful.

Paresthesias, numbness, and tingling may be related to a hematological disorder and should be noted. Any changes in vision, hearing, taste, or mental status should also be assessed carefully.

Sleep History.

The patient's feeling of being rested after a night's sleep should be determined. Fatigue secondary to a hematological problem often does not resolve after sleep.

Sexual–Reproductive History.

A careful gynecological history should be obtained from women, including the ages at menarche and menopause, duration and amount of bleeding, incidence of clotting and cramping, and any associated problems. Any intrapartum or postpartum bleeding problems should also be documented. Men should be asked whether they have any problems related to erectile dysfunction, a common occurrence in men with hematological problems. Patients should also be questioned about sexual behaviour because HIV infection is potentially a concern, particularly among populations at high risk for acquiring this disease.

Values and Beliefs.

Some hematological problems are treated with blood transfusions or bone marrow transplantation. Determine whether any treatment plans may conflict with a patient's values or beliefs.

Case Study

Subjective Data

Source: Image Point Fr/Shutterstock.com.

A focused subjective assessment of Allison Jobena revealed the following information:

Past History: History of mild osteoarthritis. Denies any personal history of anemia, cancer, or bleeding. No surgical history. Prefers

to take care of self with "natural therapy" and has not seen a health care provider for 5 years, except for a recent sinus infection.

Medications: Metamucil 1 tbsp. PO daily; vitamins C, E, and D with calcium.

Family History: Ms. Jobena denies any family history of anemia, cancer, or bleeding disorders. She believes she comes from a family with great genes for longevity because they "eat organic foods."

Self-Care History: Ms. Jobena admits to drinking one glass of red wine with her evening meal. She is a nonsmoker and just cannot understand her gradual increase in shortness of breath with exertion. She states she cannot do anything anymore without having to stop and catch her breath. She says, "It's tough getting old."

Activities of Daily Living: Ms. Jobena is having difficulty performing ADLs without having to stop and catch her breath. Denies dyspnea at rest.

Nutritional–Metabolic History: Ms. Jobena and her husband eat a lot of pasta "because it is cheap." She uses a lot of garlic for flavouring and the "health benefit of it." Although not a vegetarian, she states that she eats little meat.

Elimination: Denies black or tarry stool. Occasional constipation. No problems with urination. Urine without odour.

Neurological History: Ms. Jobena states her joints are stiff on arising in the morning and after sitting, but she is able to get around okay and work at her secretarial job. States her walking is steady but weak. No history of falling. Denies any numbness or tingling. Admits to being a little hard of hearing but can still see "pretty good."

Sleep History: Typically sleeps 8 to 9 hr/night with no difficulty falling asleep. However, she still feels tired and needs to nap during her lunch break and on her days off.

Other: Prefers natural therapies over traditional medication.

See pp. 703, 705, 711 for more information on Ms. Jobena.

Objective Data

Physical Examination.

A complete and thorough physical examination is necessary to assess all the body systems that affect or are affected by the hematological system

(see Chapter 3). Disorders of the hematological system can manifest in various ways; thus a patient's presenting symptoms may not immediately point to a hematological problem. For example, paresthesias of the lower extremities may not appear to reflect a hematological problem, but when they are accompanied by other clinical findings or risk factors, cobalamin deficiency and resulting pernicious anemia may be suspected. Although a full examination should be performed on patients suspected of a hematological disorder, certain aspects of the physical examination are specifically relevant in hematological disorders; these include the skin, the lymph nodes, the spleen, and the liver. Examination of the skin is discussed in Chapter 25; spleen and liver examinations are described in Chapter 41.

Lymph Node Assessment.

Lymph nodes are distributed throughout the body. Superficial lymph nodes can be evaluated by light palpation (Figure 32-6). Deep lymph nodes cannot be palpated and are best evaluated with radiological examination. Lymph nodes should be assessed with regard to symmetry in location, size, degree of fixation (i.e., movable, fixed), tenderness, and texture. To assess superficial lymph nodes, lightly palpate the nodes with the pads of the fingers and then gently roll the skin over the area and concentrate on feeling for possible lymph node enlargement. To be considered normal, a palpable node should be small (0.5 to 1 cm), mobile, firm, and nontender. A node that is tender, hard, fixed, or enlarged (regardless of whether it is tender or not) is abnormal and warrants further investigation. Tender nodes are usually a result of inflammation, whereas hard or fixed nodes are suggestive of malignancy (Ball, Dains, Flynn, et al., 2014).

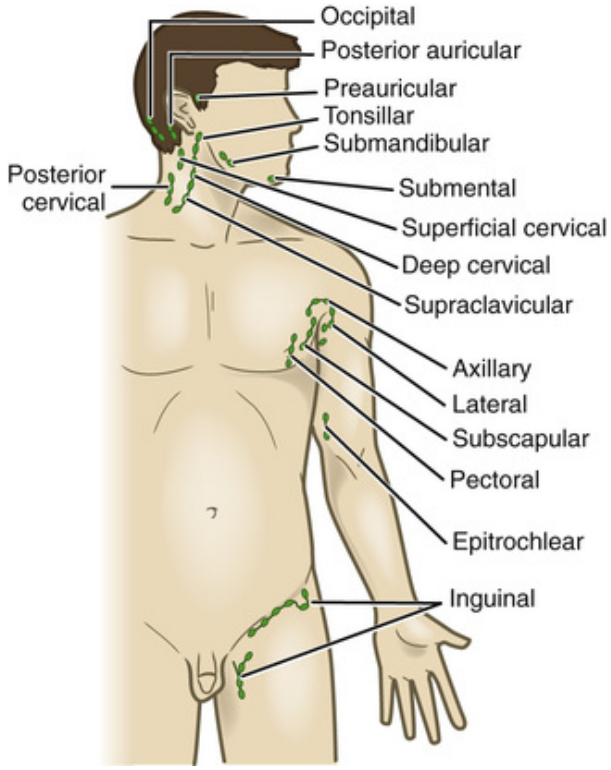

FIGURE 32-6 Palpable, superficial lymph nodes.

It is important to develop a sequence for examining the lymph nodes. A convenient sequence for examination is to start at the head and neck. First, preauricular, posterior auricular, occipital, tonsillar, submandibular, submental, superficial cervical, posterior cervical chain, deep cervical chain, and supraclavicular nodes are palpated. Next, the axillary lymph nodes and pectoral, subscapular, and lateral groups of nodes are palpated. The epitrochlear nodes, located in the antecubital fossa between the biceps and triceps muscles, are then examined. The inguinal lymph nodes, found in the groin, are palpated last.

A focused assessment of the hematological system is used to evaluate previously identified hematological problems and to monitor for signs of new problems. An example of such an assessment is presented in the "Focused Assessment" box below.

Focused Assessment

Hematological System

Use this checklist to make sure the key assessment steps have been performed.

Subjective

Ask the patient about any of the following and note the responses:

Unusual bleeding (e.g., gums) or bruising	Y	N
Black, tarry stool	Y	N
Blood in vomit	Y	N
Swelling in neck, armpits, groin	Y	N
Dark-coloured urine	Y	N
Fatigue	Y	N
Heart palpitations	Y	N

Objective: Diagnostic

Check the following laboratory results for critical values:

CBC	✓
Clotting: PT, INR, aPTT, platelets	✓
Hematocrit and hemoglobin	✓

Objective: Physical Examination

Inspect

Skin for lesions or colour changes	✓

Auscultate

Blood pressure for alteration or orthostasis	✓

Palpate

Pulse for tachycardia	✓
Liver and spleen for enlargement	✓
Lymph nodes for lymphadenopathy	✓

aPTT, activated partial thromboplastin time; *CBC,* complete blood cell count; *INR,* international normalized ratio; *PT,* prothrombin time.

Palpation of the Liver or the Spleen.

The liver and the spleen are normally not detectable through palpation of the abdomen. When they are enlarged, however, they may be detectable through percussion or palpation. The degree of enlargement of the liver is measured by the number of centimetres it extends below the rib border.

The spleen may be more difficult to palpate because of its deep location in the abdomen.

Skin Assessment.

In hematological disorders, assessment of the skin may yield valuable information about the hematological system. The skin should be examined over the entire body in a systematic manner (e.g., starting with the face and oral cavity and moving downward over the body). In patients with RBC disorders, the skin may be pale or, in the case of severe anemia, have a cyanotic or grayish tinge. Erythrocytosis often produces small vessel occlusions, causing a purple, mottled appearance of the face, the nose, the fingers, or the toes. Digital clubbing can occur with conditions of chronic anemia, such as sickle cell disease. Leukocyte disorders may cause infectious skin lesions or malignant nodular lesions. These lesions may occur anywhere and have a variable distribution pattern. During the physical assessment of the skin, the nurse must look carefully for petechiae (small purplish-red lesions), purpura (purplish-red rash), ecchymosis (bruising), and spider nevus (a form of *telangiectasia*) because these can indicate bleeding disorders (Table 32-6).

TABLE 32-6

ASSESSMENT ABNORMALITIES
Hematological System

Finding	Description	Possible Etiology and Significance
Skin		
Pallor of skin or nail beds	Paleness; decrease in or absence of skin coloration (varies with patient's natural skin colour)	Low Hb level (anemia)
Flushing	Transient, episodic redness of skin (usually around face and neck)	Increase in RBC (polycythemia), congestion of capillaries Flushing of the palms of the hands or the soles of the feet may indicate anemia
Jaundice	Yellow appearance of skin and mucous membranes	Accumulation of bile pigment caused by rapid or excessive hemolysis or liver damage
Cyanosis	Bluish discoloration of skin and mucous membranes in lighter-skinned people; greyish/whitish discoloration of skin and mucous membranes in darker-skinned people	Reduced Hb Excessive concentration of deoxyhemoglobin in blood
Excoriation	Scratch or abrasion of skin	Scratching from intense pruritus
Pruritus	Unpleasant cutaneous sensation that provokes the desire to rub or scratch the skin	Hodgkin's lymphoma Cutaneous lymphomas Infiltrative leukemias Increased bilirubin level
Leg ulcers	Prominent on the malleoli on the ankles	Sickle cell disease
Angioma	Benign tumour consisting of blood or lymph vessels	Most are congenital; some may disappear spontaneously
Telangiectasia	Small angioma with tendency to bleed; focal red lesions, coarse or fine red lines	Dilation of small vessels
Spider nevus	Form of telangiectasia characterized by a round red central portion and branching radiations resembling the profile of a spider; usually develop on face, neck, or chest	Elevated estrogen levels as in pregnancy or liver disease
Petechiae	Pinpoint, nonraised, perfectly round area <2 mm; purple, dark-red, or brown in colour	Decreased numbers of platelets or clotting factors, resulting in hemorrhage into the skin Vascular abnormalities Break in blood vessel walls as a result of trauma
Purpura	Small hemorrhages in the surface of the skin or mucous membranes resulting in a rash of purple, red, or brown spots measuring 2–10 mm in diameter	Same as for petechiae
Ecchymosis (bruise)	Small hemorrhagic spot, larger than purpura; nonelevated; round or irregular	Same as for petechiae
Hematoma	A localized collection of blood, usually clotted	Same as for petechiae
Chloroma	A tumour arising from myeloid tissue and containing a pale-green pigment	Acute myelogenous leukemia that has infiltrated the skin
Plasmacytoma	A tumour arising from abnormal plasma cells	Multiple myeloma that has infiltrated tissue
Eyes		
Jaundiced sclera	Yellow appearance of the sclera	Accumulation of bile pigment resulting from rapid or excessive hemolysis or liver disease or infiltration

Finding	Description	Possible Etiology and Significance
Conjunctival pallor	Paleness; decreased or absence of coloration in the conjunctiva	Low Hb level (anemia)
Blurred vision, diplopia, visual field cuts	Decreased visual acuity or areas of blindness (field cuts)	Anemia, extreme leukocytosis, and polycythemia may cause visual abnormalities Thrombo-cytopenia may cause intraocular hemorrhage with visual abnormalities Excessive clotting may cause thromboses in the circulation to the brain that cause visual field cuts
Nose		
Epistaxis	Spontaneous bleeding from the nares	May occur with low platelet counts, especially if the patient bends down for a long period, tries to lift a heavy item, or attempts an intense Valsalva manoeuvre
Mouth		
Gingival and mucous membrane changes	Pallor Gingival or mucosal ulceration, swelling, or bleeding	Low Hb level (anemia) Neutropenia; inability of impaired leukocytes to combat oral infections; thrombo-cytopenia Gingival hyperplasia may be present with some types of leukemia
Smooth tongue	Tongue surface is smooth and shiny; mucosa is thin and red from decreased papillae	Pernicious anemia, iron-deficiency anemia
Lymph Nodes		
Lymphadenopathy	Lymph nodes are enlarged (>1 cm diameter)	Infection, foreign infiltrations, or systemic disease such as leukemia, lymphoma, Hodgkin's lymphoma, or metastatic cancer
Heart and Chest		
Tachycardia	Heart rate >100 beats/min	Compensatory mechanism in anemia to increase cardiac output
Palpitations	Sensation of feeling the heart beat, flutter, or pound in the chest	Anemia, fluid volume overload, hypotension with impending syncope, hypertension, or dysrhythmias may cause palpitations
Altered blood pressure	Orthostasis: >20/min increase in heart rate or >20 mm Hg decrease in blood pressure from baseline value when moving from a lying position to either sitting or standing Hypotension: <90 mm Hg systolic or >40 mm Hg drop in systolic reading from baseline BP Hypertension: >130/90 mm Hg	Orthostasis is a common manifestation in anemia, especially if accompanied by low blood volume Hypotension may indicate an infectious process, blood loss, or compromised cardiovascular compensatory mechanisms Hypertension may occur initially as a compensatory mechanism for anemia
Sternal tenderness	Abnormal sensitivity to touch or pressure on sternum	Leukemia, as a result of increased bone marrow cellularity, which causes an increase in pressure and bone erosion; multiple myeloma, as a result of stretching of periosteum
Low oxygen saturation	Oxygen-carrying capacity is reflected by the oxygen saturation as measured with pulse oximetry	Oxygen saturation may be decreased in cases of severe anemia
Abdomen		
Hepatomegaly	Palpable liver	Leukemia, cirrhosis, or fibrosis secondary to iron overload from sickle cell disease or thalassemia

Finding	Description	Possible Etiology and Significance
Splenomegaly	Palpable spleen	Anemia, thrombo-cytopenia, leukemia, lymphomas, leukopenia, mononucleosis, malaria, cirrhosis, trauma, portal hypertension
Distended abdomen	Distended abdomen is an abdominal profile that is larger than normal; it may be soft or firm, tender or nontender, and accompanied by other symptoms such as nausea, vomiting, or rebound tenderness	Lymphoma may manifest as abdominal adenopathy, mass(es), or bowel obstruction
Nervous System		
Paresthesias of feet and hands; ataxia	Numbness sensation and extreme sensitivity experienced in central and peripheral nerves; impaired muscle movement	Cobalamin (vitamin B_{12}) deficiency or folate deficiency
Weakness	Lacking physical strength or energy	Low Hb level (anemia)
Headache, nuchal rigidity	Pain in the cranium, potentially involving one area or extending from the frontal area to the back of the neck	Generalized headache is a common manifestation of mild to moderate anemia Severe headache with or without visual disturbances may signal intracranial hemorrhage caused by thrombo-cytopenia
Musculo-Skeletal System		
Bone pain	Pain in pelvis, ribs, spine, sternum	Multiple myeloma, in relation to enlarged tumours that stretch periosteum Bone invasion by leukemia cells Bone demineralization that results from various malignancies Sickle cell disease
Joint swelling	Fluid-filled spaces surrounding the joints	Occurs with sickle cell anemia as bleeding into the joint (hemarthrosis) causes inflammation
Arthralgia	Joint pain	Sickle cell disease, as a result of hemarthrosis

Hb, hemoglobin.

Case Study

Objective Data: Physical Examination

Source: Image Point Fr/Shutterstock.com.

Physical examination findings for Allison Jobena are as follows:

BP 100/70 (lying), 88/60 (standing); apical pulse 110 (lying), 124 (standing), but regular in rhythm. Respiratory rate 26, temperature 36°C (96.8°F), O_2 saturation 90% on room air. No jugular venous distension. Weight: 48 kg. Height: 155 cm. Skin pale with two ecchymoses on her arms and one on her left lower leg. A few scattered petechiae on both ankles. No jaundice noted. Conjunctivas pale. Tongue smooth and shiny. Lungs clear but diminished breath sounds in the bases bilaterally. No visible bleeding. No enlarged lymph nodes, spleen, or liver noted. General weakness with dyspnea on exertion. No numbness or tingling or peripheral edema.

Throughout this chapter, consider diagnostic studies that the nurse may order for Ms. Jobena.

See pp. 703, 704, and 711 for more information on Ms. Jobena.

Diagnostic Studies of the Hematological System

The most direct means of evaluating the hematological system is through laboratory analysis and other diagnostic studies. Diagnostic tests of the hematological system are presented in Tables 32-7 through 32-9 and Table 32-11.

TABLE 32-7
COMPLETE BLOOD CELL COUNT STUDIES

Study	Description and Purpose	Normal Values
Hb	Measurement of gas-carrying capacity of RBCs	Women: 117–160 g/L Men: 132–173 g/L
Hct	Measurement of packed cell volume of RBCs, expressed as a percentage of the total blood volume	Women: 0.35–0.47 Men: 0.39–0.50
Total RBC count	Count of number of circulating RBCs	Women: 3.8–5.1 × 10^{12}/L Men: 4.3–5.7 × 10^{12}/L
RBC indices		
• MCV (Hct/RBC)	Determination of relative size of RBC; low MCV reflection of microcytosis, high MCV reflection of macrocytosis	fL
• MCH (Hb/RBC)	Measurement of average weight of Hb/RBCs; low MCH is indication of microcytosis or hypochromia, high MCH is indication of macrocytosis	pg
• MCHC	Evaluation of RBC saturation with Hb; low MCHC is indication of hypochromia, high MCHC is evident in spherocytosis	g/L
• RBC morphology	Examination of the shape and size of RBCs	No variation in RBC structure
• WBC count	Measurement of total number of leukocytes	× 10^{9}/L
• WBC differential	Determination of whether each kind of WBC is present in proper proportion; absolute value is determined by multiplying percentage of cell type by total WBC count and dividing by 100	Neutrophils: 5.0–7.0 × 10^{9}/L Eosinophils: 0.00–0.04 × 10^{9}/L Basophils: 0–0.02 × 10^{9}/L Lymphocytes: 0.2–0.4 × 10^{9}/L Monocytes: 0.04–0.08 × 10^{9}/L
• Platelet count	Measurement of number of platelets available to maintain platelet clotting functions (not measurement of quality of platelet function)	150–400 × 10^{9}/L

Hb, hemoglobin; *Hct,* hematocrit; *MCH,* mean corpuscular hemoglobin; *MCHC,* mean corpuscular hemoglobin concentration; *MCV,* mean corpuscular volume; *RBC,* red blood cell; *WBC,* white blood cell.

TABLE 32-8

CLOTTING STUDIES

Study	Description and Purpose	Normal Values
Activated clotting time (ACT)	Evaluation of intrinsic coagulation status; more accurate than aPTT; used during dialysis, coronary artery bypass procedure, arteriography	70–120 sec
Activated partial thromboplastin time (aPTT)	Assessment of intrinsic coagulation by measuring factors I, II, V, VIII, IX, X, XI, and XII; longer with the use of heparin	25–35 sec
Antithrombin	Naturally occurring protein synthesized by the liver that inhibits coagulation through inactivation of thrombin and other factors; is depleted in DIC	210–300 mg/L or 0.80–1.2 of standard
Capillary fragility test (tourniquet test, Rumpel–Leede test)	Reflection of capillary integrity when positive or negative pressure is applied to various areas of the body; positive result is indication of thrombo-cytopenia, toxic vascular reactions	No petechiae, or negative
D-dimer	Assay to measure a fragment of fibrin that is formed as a result of fibrin degradation and clot lysis; used in diagnosis of hypercoagulable conditions (e.g., DIC, pulmonary embolism)	<250 mcg/L
Fibrin split products (FSP) or fibrin degradation products (FDPs)	Reflection of degree of fibrinolysis and predisposition to bleeding (if present); screening test for DIC; elevated levels associated with DIC, advanced malignancy, severe inflammation	<10 mg/L
Fibrinogen (factor I)	Reflection of level of fibrinogen; increase in fibrinogen may indicate enhancement of fibrin formation, which renders patient hypercoagulable; decrease in fibrinogen indicates that patient may be predisposed to bleeding	2–4 g/L
International normalized ratio (INR)	Standardized system of reporting PT that is based on a reference calibration model and calculated by comparison of the patient's PT with a control value	0.8–1.2
Plasminogen	Assessment of adequacy of plasminogen in patients who have multiple thrombo-embolic episodes	2.4–4.4 units/mL
Platelet count	Count of number of circulating platelets	150×10^9/L to 400×10^9/L
Prothrombin time (PT)	Assessment of extrinsic coagulation by measurement of factors I, II, V, VII, and X	11–16 sec
Thrombin time	Reflection of adequacy of thrombin; prolonged thrombin time indicates that coagulation is inadequate secondary to decreased thrombin activity	17–23 sec

DIC, disseminated intravascular coagulation.

TABLE 32-9

ABO BLOOD GROUP NAMES AND PATIENT/DONOR COMPATIBILITIES*

Recipient's Blood Group	RBC Antigen	Plasma/Serum Antibody	Compatible Donor for RBC Transfusions	Compatible Donor for Plasma Transfusions
A	A	Anti-B	A and O	A and AB
B	B	Anti-A	B and O	B and AB
AB (universal recipient)	Both A and B	Neither anti-A nor anti-B	A, B, AB, and O	AB
O	Neither A nor B	Both anti-A and anti-B	O (universal donor)	A, B, AB, and O

*ABO blood groups are named for the antigen found on the RBCs. Donor compatibility is based on the antibodies present in the serum.

RBC, red blood cell.

TABLE 32-10
MISCELLANEOUS LABORATORY BLOOD STUDIES

Study/Substance Studied	Description and Purpose	Normal Values
Bilirubin	Measurement of degree of RBC hemolysis or liver's inability to excrete normal quantities of bilirubin Increase in indirect bilirubin with hemolytic problems; increase in direct bilirubin with obstructive problems (e.g., gallstones, tumour)	Total: 3.0–21 mcmol/L Direct: 1.7–5.1 mcmol/L Indirect: 1.7–17 mcmol/L
Blood smear (peripheral blood smear)	Reviews colour, size, shape, and quantity of cells in peripheral blood; can provide significant information regarding disorders affecting RBCs, WBCs, or platelets	Normal quantity of each cell type; normal size, shape, and colour of RBCs; normal WBC differential
Coombs test	Differentiation among types of hemolytic anemias; detection of immune antibodies; detection of Rh factor	Negative finding (no agglutination)
• Direct	Detection of antibodies that are attached to RBCs	Negative finding
• Indirect	Detection of antibodies in serum	Negative finding
Cobalamin (vitamin B_{12})	Level of vitamin B_{12} available for production of new RBCs	148–616 pmol/L
Erythrocyte sedimentation rate (ESR)	Measurement of sedimentation, or settling, of RBCs in 1 hr Inflammatory process causes an alteration in plasma proteins, resulting in aggregation of RBCs and making them heavier; the faster the RBCs settle, the higher the ESR is	Female • <50 yr: <20 mm/hr • >50 yr: <30 mm/hr Male • <50 yr: <15 mm/hr • >50 yr: <20 mm/hr
Erythropoietin	Measurement of degree of hormonal stimulation of the bone marrow to release RBCs	5–35 mU/mL
Ferritin	Major iron storage protein; is normally present in blood in concentrations directly related to iron storage	Female: 10–150 mcg/L Male: 12–300 mcg/L
Folic acid (folate)	Amount of folic acid or folate available for RBC production	7–36 nmol/L
Hemoglobin (Hb) electrophoresis	Proteins involved in development of the hemoglobin molecule have a definitive pattern of separation on electrophoresis; this pattern is altered with abnormal Hb synthesis, as occurs in thalassemia or in sickle cell anemia, in which sickle Hb (HbS) is increased	Normal HbA_1: 95%–98% HbA_2: 2%–3% HbF: 0.8%–2% HbS: 0% HbC: 0%
Homocysteine	Amino acid formed from methionine Rapidly metabolized through pathways that require cobalamin (vitamin B_{12}) and folic acid; increased in deficiencies of cobalamin and folic acid	3.7–12.9 mcmol/L (some variation with gender)
Iron		
• Serum iron	Reflection of amount of iron combined with proteins in serum; accurate indication of status of iron storage and use	mcmol/L
• Total iron-binding capacity (TIBC)	Measurement of all proteins available for binding iron Transferrin represents the largest quantity of iron-binding proteins; therefore, TIBC is an indirect measure of transferrin	45–76 mcmol/L
Lactic dehydrogenase (LDH)	Intracellular enzyme that is present in almost all body tissues Levels rise in response to cell damage; increased levels confirm diagnosis of injury or disease May be used as a nonspecific marker of hematological malignancy growth and response to treatment	0.83–2.5 mckat/L

Study/Substance Studied	Description and Purpose	Normal Values
Methylmalonic acid (MMA)	Indirect test for cobalamin: MMA metabolism requires cobalamin; test helps differentiate cobalamin deficiency from folic acid deficiency	<2.4 mcg/dL
Microglobulin (β_2 microglobulin)	Protein that is found on the surface of all cells Increased in patients with malignancies such as lymphoma, leukemia, or multiple myeloma; may be used as a tumour marker	Blood: 0.7–1.8 mcg/mL Urine: ≤300 mcg/L Spinal fluid: ≤2.4 mg/L
Reticulocyte count	Measurement of immature RBCs; reflection of bone marrow activity in producing RBCs	0.5%–1.5% of RBC count (0.005–0.015 of RBC count)
Serum protein electrophoresis (SPEP)	Separates proteins in the blood on basis of electrical charge; helps detect hyperglobulinemic states, as in multiple myeloma or some lymphomas	Normal banding pattern of albumin and globulins; an increase in any protein ("protein spike") is abnormal
Transferrin	The largest of proteins that bind to iron; increased in majority of people with iron-deficiency anemia	1.9–3.8 g/L
Transferrin saturation (%)	Decreased in iron-deficiency anemia and increased in hemolytic and megaloblastic anemia	15%–50%

HbA, hemoglobin alpha; *HbC,* abnormal hemoglobin that shows reduced plasticity of the erythrocyte causing hemoglobinopathy; *HbF,* fetal hemoglobin; *HbS,* sickle hemoglobin; *RBC,* red blood cell.

TABLE 32-11

DIAGNOSTIC STUDIES
Hematological System

Study/Substance Studied	Description and Purpose	Nursing Responsibility
Urine Studies		
Bence Jones protein	An electrophoretic measurement is used to detect the presence of the Bence Jones protein, which is found in most cases of multiple myeloma. Negative finding is considered normal.	Acquire random urine specimen early in the morning. If a 24-hour urine collection is ordered, discard first specimen and collect all urine voided during the 24 hr, keeping on ice or refrigerated.
Radioisotope Studies		
Bone scan	Radioactive isotope is injected by IV. Used for evaluating the structure of the bones. Patient is not a source of radioactivity.	IV access is required. Patient needs to lie still during imaging.
SPECT (**s**ingle-**p**hoton **e**mission **c**omputed **t**omography) scan	Radioactive isotope is injected by IV. Images from the radioactive emissions are used to evaluate the structure of the spleen, liver, bone, and possible tumours. Patient is not a source of radioactivity.	IV access is required. Patient needs to lie still during imaging.
Radiological Studies		
Skeletal radiograph	Radiographic studies performed as a bone survey to detect lytic lesions associated with multiple myeloma. Bone scans do not identify lytic lesions very well in this condition: Because of lack of blood supply, there is no uptake of radioactive isotopes.	No specific nursing responsibilities.
Liver, spleen, or abdominal ultrasonography	Noninvasive probe is lubricated and slid across the abdomen to detect the density and borders of the abdominal organs. Irregular borders, masses, vascular structure, and biliary tree can be detected.	Patients must be comfortable lying flat, and the probe must compress the abdomen.
Positron emission tomography (PET) scan	A nuclear tracer substance is injected and is taken up by metabolically active cells. The follow-up scan shows tissues in different colours based on the metabolic rate. "Hot spots" reflect increased glucose consumption that may reflect tumours.	IV access is required for injection of the tracer substance. Patients should ingest nothing by mouth except water and medications for at least 4 hr before the test. IV solutions containing glucose may be held. Patients who are glucose intolerant or diabetic may need adjustments to their medications. Bowel preparation may also be needed, depending on the area being studied.
Computed tomographic (CT) scan	Noninvasive examination in which computer-assisted radiography is used to evaluate the lymph nodes. Contrast medium often is used in abdominal studies of the liver or the spleen. Spiral CT is used to evaluate lymph nodes.	If contrast medium is used, investigate whether patient has iodine sensitivity. IV, oral contrast, or both may be given prior to the procedure, depending on the area being studied. Patient may need to be NPO.
Magnetic resonance imaging (MRI)	Noninvasive procedure that produces sensitive images of soft tissue without the use of contrast medium. No ionizing radiation is required.	Instruct patient to remove all metal objects and ask about any history of surgical insertion of staples, plates, or other metal appliances. Patient may need to lie still in small chamber.
Biopsies/Procedures		

Study/Substance Studied	Description and Purpose	Nursing Responsibility
Bone marrow aspirate	Removal of bone marrow through a locally anaesthetized site to evaluate the status of the blood-forming tissue. Used to diagnose multiple myeloma, leukemia, and some lymphomas and to stage some solid tumours. Also performed to assess efficacy of leukemia therapy.	Explain procedure to patient. Obtain signed consent form. Ensure that a *time out** is done before procedure. Consider preprocedure analgesic administration to enhance patient comfort and cooperation. Apply pressure dressing after procedure. Assess biopsy site for bleeding.
Lumbar puncture (LP)	Purpose is to obtain cerebro-spinal fluid for testing for malignancy or infection. It may also be used to administer chemotherapy to central nervous system.	Assist in positioning patient and provide support. Observe site for bleeding and signs of infection.
Lymph node biopsy	Purpose is to obtain lymph tissue for histological examination to determine diagnosis and therapy.	Explain procedure to patient. Obtain signed consent form.
• Open	Excision of lymph node and surrounding tissue through an incision. Performed in the operating room or procedure area; either local or general anaesthesia is administered.	Observe site for bleeding, and monitor vital signs, especially if the platelet count is low. The sterile dressing should be changed as ordered, and the wound should be inspected for healing and infection.
• Closed (needle) or fine needle	Performed at patient's bedside or in an outpatient area.	
Molecular, Cytogenic, and Gene Analysis Studies		
Fluorescent in situ hybridization (FISH) Comparative genomic hybridization (CGH) Spectral karyotyping (SKY)	Tests performed on malignant cells, either peripheral blood (e.g., leukemia) or biopsy specimen (bone marrow, lymph node), to assess genetic or chromosomal abnormalities of cancer cells. May be useful in confirming diagnosis and determining treatment modalities and prognosis.	Explain purpose of testing to patient.

*A time out is done just before a surgical procedure starts to verify patient identification, surgical procedure, and surgical site.

IV, intravenous; *NPO,* nothing by mouth.

Laboratory Studies

Complete Blood Cell Count.

The complete blood cell count (CBC) involves several laboratory tests (Table 32-7), each of which serves to assess the three major blood cells formed in the bone marrow. In addition to the CBC, a *peripheral blood smear* may be ordered. The smear is used to look at the morphological features (shape and appearance) of the blood cells and may assist with diagnosis. For example, a large number of immature *blast* WBCs may indicate acute leukemia.

Although the status of each cell type is important, the entire system may be disrupted by diseases, as well as by the treatment of diseases.

Suppression of the entire CBC is termed pancytopenia (marked decrease in the number of RBCs, WBCs, and platelets). In such cases, care is directed toward the management of anemia, infection, and hemorrhage (see Chapter 33).

Red Blood Cells.

Normal values of some RBC tests are reported separately for men and for women because normal values are based on body mass and men usually have a larger body mass than do women.

The *hemoglobin* value is reduced in cases of anemia, hemorrhage, and states of hemodilution, such as those that occur when the fluid volume is excessive. RBCs are increased in polycythemia or in states of hemoconcentration, which can develop from volume depletion (dehydration).

The *hematocrit* value is determined by spinning blood in a centrifuge, which causes erythrocytes (RBCs) and plasma to separate. The RBCs, being the heavier elements, settle to the bottom. The hematocrit value represents the percentage of RBCs in comparison with the total blood volume. The hematocrit value is reduced and elevated in the same conditions that raise and lower the hemoglobin value.

The total RBC count is reported as RBC $\times 10^{12}$/L. However, the total RBC count is not always reliable in determining the adequacy of RBC function. Consequently, other data, such as hemoglobin, hematocrit, and RBC indices, must also be evaluated. The RBC count is altered by the same conditions that raise and lower the hemoglobin and hematocrit values.

RBC indices are special indicators that reflect RBC volume, colour, and hemoglobin saturation (see Table 32-7). These parameters may provide insight into the cause of anemia. (The significance of these parameters is discussed further in Chapter 33.)

White Blood Cells.

The WBC count provides two different sets of information. The first is a total count of WBCs per litre of peripheral blood. Elevations in WBC count to more than 11 $\times 10^9$/L are associated with infection, inflammation, tissue injury or death, and malignancies (e.g., leukemia, lymphoma). Although the degree of WBC elevation is not necessarily predictive of the severity of illness, it can provide clues to the cause. Certain types of leukemias are more likely to produce extremely high WBC counts (e.g., >25 $\times 10^9$/L). A total WBC count lower than 4 $\times 10^9$/L **(**leukopenia**)** is associated with bone marrow depression, severe or chronic illness, and some types of leukemia.

The second aspect of the WBC count, the *differential count*, is the percentage of each type of leukocyte. The information from the WBC differential count provides valuable clues to the cause of illness. When infections are severe, more granulocytes are released from the bone marrow as a compensatory mechanism. To meet the increased demand, many young, immature polymorphonuclear neutrophils (bands) are released into circulation. More mature neutrophils are called *polymorphonuclear segmented neutrophils* ("segs"). The usual laboratory procedure is to report WBCs in order of maturity, with the less mature forms (i.e., band neutrophils) on the left side of the written report; hence, the existence of many immature cells is termed a *shift to the left*. A shift to the left may be indicative of active infection or inflammation (e.g., postsurgically). The WBC differential count is of considerable significance because it is possible for the total WBC count to remain essentially normal despite a marked change in one type of leukocyte. For example, a patient may have a normal WBC count of 8.8×10^9/L, but the differential count may reveal a relative proportion of lymphocytes to be reduced to 10%—an abnormal finding that warrants further investigation.

When the bone marrow does not produce enough neutrophils, neutropenia occurs. Neutropenia is a condition associated with an absolute neutrophil count (ANC) lower than 1×10^9/L to 1.5×10^9/L; severe neutropenia is associated with an ANC lower than 0.5×10^9/L. The ANC is determined as the total WBCs multiplied by the percentage of neutrophils. Neutropenia results from a number of disease processes, such as leukemia, or from bone marrow depression (see Chapter 33) and is associated with an increased risk for infection and death from sepsis.

Platelet Count.

The platelet count is the number of platelets per microlitre of blood. Normal platelet counts are between 150×10^9/L and 400×10^9/L; counts lower than 150×10^9/L signify a condition termed thrombo-cytopenia**.** Bleeding may occur with thrombo-cytopenia. Spontaneous hemorrhage is probable once platelet counts fall below 10×10^9/L. A more extensive description of clotting studies is presented in Table 32-8. Thrombo-cytosis**,** in contrast, is an excess of platelets, a disorder that occurs with inflammation and some malignant diseases. The complication related to thrombo-cytosis that is most likely to occur is excessive clotting.

Blood Typing and Rh Factor.

Blood group antigens (A and B) are found only on RBC membranes and form the basis for the ABO blood typing system. The presence or absence of one or both of the two inherited antigens is the basis for the four blood groups: *A, B, AB,* and *O.* People with blood group A have A antigens, those with group B have B antigens, those with group AB have both A and B antigens, and those with group O have neither A nor B antigens. People with blood types A, B, or O have antibodies in the serum, termed *anti-A* and *anti-B*, that react with A or B antigens. These antibodies are found when the corresponding antigen is absent from the RBC membrane. For example, anti-B antibodies are found in the plasma of people with blood group A (Table 32-9).

Blood reactions caused by ABO incompatibilities result in intravascular hemolysis of the RBCs. RBCs *agglutinate* (or clump) when a serum antibody that reacts with the antigens on the RBC membrane is present. For example, agglutination would occur in the blood of a person with type A blood if he or she received blood from a donor with B antigens (i.e., type B or AB). The anti-B antibodies in the serum of the person with type A blood would react with the B antigens on the donor RBCs, thus initiating the process that results in RBC hemolysis.

The Rhesus (Rh) system is based on a third antigen, D, which is also found on the RBC membrane. Rh-positive people have the D antigen, whereas Rh-negative people do not. Rh-positive blood is indicated with a plus sign after the ABO group name (e.g., "AB+"). A Coombs test is used to evaluate the person's Rh status (Table 32-10).

As a result of transfusion therapy or during childbirth, an Rh-negative person may be exposed to Rh-positive blood. If an Rh-negative mother gives birth to an Rh-positive infant, the mother forms an antibody, anti-D, which acts against Rh antigens. (Rh-positive people normally have no anti-D antibody.) In subsequent pregnancies, the mother's anti-D antibodies can cross the placenta and attack the RBCs of a fetus who is Rh-positive, thus causing hemolysis of the RBCs. A pregnant Rh-negative woman should receive Rho(D) immune globulin (WinRho) injections during pregnancy to prevent anti-D antibodies from forming.

Iron Metabolism.

The laboratory tests used in evaluating iron metabolism include serum iron, total iron-binding capacity (TIBC), serum ferritin, and transferrin saturation. Additional tests for nutritional deficiencies leading to defective RBC production may also be performed (see Table 32-10).

Serum iron is a measurement of the amount of protein-bound iron circulating in the serum. TIBC provides a measurement of all proteins that bind or transport iron between the tissues and the bone marrow. Although this indirect measurement is a general reflection of the amount of transferrin present in the circulation, it overestimates transferrin levels by 16% to 20% because it also measures other proteins that can bind iron. These alternative proteins bind iron only when transferrin is more than half saturated. Also, TIBC varies inversely with tissue iron stores; it is higher when iron stores are low and lower when iron stores are high.

Transferrin saturation is a better indicator of the availability of iron for erythropoiesis than is serum iron because, unlike serum iron, the iron bound to transferrin is readily available for the body to use. To calculate transferrin saturation, the serum iron value is divided by TIBC, and the result is multiplied by 100. For example, a patient with a serum iron level of 18 mcmol/L and a TIBC of 57 mcmol/L would have a transferrin saturation of about 31.6%. Under normal conditions, the serum ferritin concentration is correlated closely with body iron stores.

Radiological Studies

Radiological studies for the hematological system involve primarily the use of computed tomography (CT) or magnetic resonance imaging (MRI) for evaluating the spleen, the liver, and the lymph nodes. Nursing responsibilities related to these studies are presented in Table 32-11.

Biopsy

Biopsy procedures specific to hematological assessment are bone marrow examination and lymph node biopsy. In general, these procedures are performed because a peripheral blood smear is nonspecific and a diagnosis cannot usually be established from a peripheral blood smear. Furthermore, a biopsy provides additional information about a hematological problem; such information is needed for diagnostic purposes, as well as for planning treatment options.

Bone Marrow Examination.

Bone marrow examination is important in the evaluation of many hematological disorders. The examination of the marrow may involve aspiration alone or aspiration with biopsy. The benefits of bone marrow examination include the ability to (a) fully evaluate hematopoiesis and (b)

obtain specimens for cytopathological study and evaluation for chromosomal abnormalities.

The preferred site for both aspiration and biopsy of bone marrow is the posterior superior iliac crest (Pagana & Pagana, 2014). In adults, the anterior superior iliac crest is an alternative site. Bone marrow aspiration and biopsy are performed by a physician or by a nurse with special credentials. Local anaesthesia and sedation may be used to minimize anxiety and pain.

For bone marrow aspiration, the skin over the puncture site is cleansed with a bactericidal agent. The skin, subcutaneous tissue, and periosteum are infiltrated with a local anaesthetic drug (Figure 32-7). The patient may be uncomfortable when the periosteum is penetrated. Once the area is anaesthetized, a bone marrow needle is inserted through the cortex of the bone. The stylet of the needle is then removed, the hub is attached to a 10-mL syringe, and 0.2 to 0.5 mL of the marrow fluid is aspirated. The patient may experience pain with aspiration. Although it generally lasts for only a few seconds, the pain may be quite uncomfortable. After the marrow aspiration, the needle is removed. Pressure is applied over the aspiration site to ensure hemostasis. If the patient is thrombo-cytopenic, pressure may be required for 5 to 10 minutes or longer. With severe thrombo-cytopenia, platelets may be infused before the procedure. If a bone biopsy is required, the preparatory procedure remains the same, but a different needle is used. The needle has a cutting blade that allows a specimen of the bone to be removed.

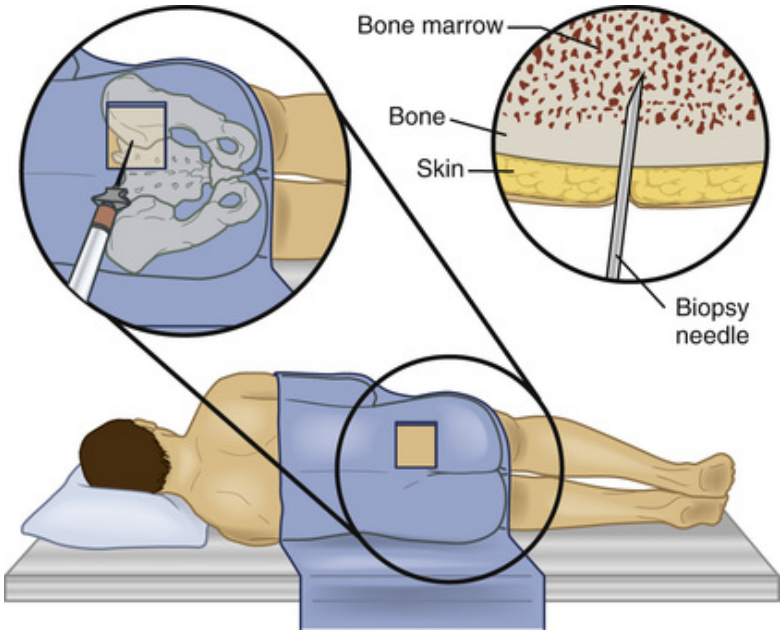

FIGURE 32-7 Bone marrow aspiration from the posterior superior iliac crest.

Although complications of bone marrow aspiration are minimal, there is a possibility of penetrating the bone and damaging underlying structures. Other complications include hemorrhage (particularly if the patient is thrombo-cytopenic) and infection (particularly if the patient is leukopenic).

Lymph Node Biopsy.

Lymph node biopsy involves obtaining lymph tissue for histological examination to determine the diagnosis and to help plan therapy. Lymph tissue may be obtained through either an open biopsy or a closed (needle) biopsy. Negative results from a needle biopsy may indicate only that the cancer cells were not part of the tissue specimen obtained. A repeated needle biopsy or a larger tissue specimen (open biopsy) may be subsequently required.

Case Study

Objective Data: Diagnostic Studies

Source: Image Point Fr/Shutterstock.com.

The health care provider orders the following initial diagnostic studies for Allison Jobena:

- CBC, basic metabolic panel (electrolytes, BUN, creatinine), PT/PTT
- Arterial blood gases
- Chest radiograph

Ms. Jobena's CBC reveals an Hgb of 59 g/L, Hct of 0.18, WBC of 2.6 × 10^9/L, platelet count of 72 × 10^9/L, PT = 18 sec, aPTT = 37. Her arterial blood gases are normal, as is her chest radiograph. The health care provider orders more blood work, including a WBC differential and RBC indices, and admits Ms. Jobena to the hospital for further evaluation.

See pp. 703, 704, and 705 for more information on Ms. Jobena.

Molecular Cytogenetics and Gene Analysis

Testing for specific genetic or chromosomal variations in hematological conditions is often helpful in diagnosis, in determining the treatment options, and in determining prognosis. If a large number of abnormal cells are circulating in the blood, as in acute leukemia, these tests may be performed with peripheral blood samples. However, testing is usually performed on samples from bone marrow and from lymph node biopsies. For example, fluorescent in situ hybridization (FISH) can identify specific genes or portions of genes that are abnormal by attaching a probe to a targeted region of deoxyribonucleic acid (DNA). It may be used to reveal an abnormal extra chromosome 8 that is common in certain leukemias. Spectral karyotyping (SKY) allows for each set of chromosomes to be coloured individually. It can be used to identify the 9;22 translocation in the Philadelphia chromosome of chronic myelogenous leukemia. More information on genetics is available in Chapter 15.

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Why might a client who lives at a high altitude normally have an increased RBC count?
   a. High altitudes cause vascular fluid loss, leading to hemoconcentration.
   b. Hypoxia caused by decreased atmospheric oxygen stimulates erythropoiesis.
   c. The function of the spleen in removing old erythrocytes is impaired at high altitudes.
   d. Impaired production of leukocytes and platelets leads to proportionally higher RBC counts.
2. What is the primary effect of malignant disorders that arise from granulocytic cells in the bone marrow?
   a. Risk for hemorrhage
   b. Altered oxygenation
   c. Decreased production of antibodies
   d. Decreased phagocytosis of bacteria
3. An anticoagulant such as warfarin that interferes with prothrombin production will alter the clotting mechanism during what process?
   a. Platelet aggregation
   b. Activation of thrombin
   c. Release of tissue thromboplastin
   d. Stimulation of factor activation complex
4. When reviewing laboratory results of an 83-year-old client with an infection, what should the nurse expect to find?
   a. Minimal leukocytosis
   b. Decreased platelet count
   c. Increased hemoglobin and hematocrit levels
   d. Decreased erythrocyte sedimentation rate (ESR)
5. What significant information related to the hematological system should be obtained from a client's health history?

a. Jaundice
b. Bladder surgery
c. Early menopause
d. Multiple pregnancies

6. What technique should the nurse use when assessing the lymph nodes?
   a. Applying gentle, firm pressure to deep lymph nodes
   b. Palpating the deep cervical and supraclavicular nodes last
   c. Lightly palpating superficial lymph nodes with the pads of the fingers
   d. Using the tips of the second, third, and fourth fingers to apply deep palpation
7. When a lymph node is palpated, which of the following is a normal finding?
   a. Hard, fixed nodes
   b. Firm, mobile nodes
   c. Enlarged, tender nodes
   d. Hard, nontender nodes
8. Nursing care for a client immediately after a bone marrow biopsy and aspiration includes which of the following? (*Select all that apply*)
   a. Administering analgesics as necessary
   b. Preparing to administer a blood transfusion
   c. Instructing on need to lie still with a sterile pressure dressing intact
   d. Monitoring vital signs and assessing the site for excess drainage or bleeding
   e. Instructing on the need for preprocedure and postprocedure antibiotics
9. A nurse is taking care of a male client who has the following laboratory values from his CBC: WBC 6.5 × 10^9/L, Hb 134 g/L, Hct 40%, platelets 50 × 10^9/L. What should the nurse be most concerned about?
   a. The client is neutropenic.
   b. The client has an infection.
   c. The client is at risk for bleeding.
   d. The client is at risk of falling due to his anemia.

1. b; 2. d; 3. b; 4. a; 5. a; 6. c; 7. b; 8. a, c, d; 9. c

CHAPTER 33

Nursing Management

Hematological Problems

Written by, Sandra Irene Rome

Adapted by, Bridgette Lord

LEARNING OBJECTIVES

1. Describe the general clinical manifestations and complications of anemia.
2. Describe the etiologies, clinical manifestations, diagnostic findings, and nursing and collaborative management of iron-deficiency, megaloblastic, and aplastic anemias and anemia of chronic disease.
3. Explain the nursing and collaborative management of anemia secondary to blood loss.
4. Describe the pathophysiology, clinical manifestations, and nursing and collaborative management of anemia caused by increased erythrocyte destruction, including sickle cell disease and acquired hemolytic anemias.
5. Describe the pathophysiology and nursing and collaborative management of polycythemia.
6. Explain the pathophysiology, clinical manifestations, and nursing and collaborative management of various types of thrombo-cytopenia.
7. Describe the types, clinical manifestations, diagnostic findings, and nursing and collaborative management of hemophilia and von Willebrand disease.
8. Explain the pathophysiology, diagnostic findings, and nursing and collaborative management of disseminated intravascular coagulation.
9. Describe the etiology, clinical manifestations, and nursing and collaborative management of neutropenia.
10. Describe the pathophysiology, clinical manifestations, and nursing and collaborative management of myelodysplastic syndrome.
11. Compare and contrast the major types of leukemia in terms of age of onset, clinical manifestations, and diagnostic findings.
12. Explain the nursing and collaborative management of acute and chronic leukemias.

13. Compare Hodgkin's lymphoma and non-Hodgkin's lymphoma in terms of clinical manifestations, staging, and nursing and collaborative management.
14. Describe the pathophysiology, clinical manifestations, and nursing and collaborative management of multiple myeloma.
15. Describe spleen disorders and related collaborative care.
16. Describe the nursing management of transfusing blood and blood products.

Anemia

Definition and Classification

Anemia is a deficiency in the number of erythrocytes (red blood cells [RBCs]), the quantity or quality of hemoglobin (Hb), the volume of packed RBCs (hematocrit [Hct]), or a combination of these. It is a prevalent condition with many diverse causes such as blood loss, impaired production of erythrocytes, or increased destruction of erythrocytes. Because RBCs transport oxygen (O_2), erythrocyte disorders can lead to tissue hypoxia; this accounts for many of the signs and symptoms of anemia. Anemia is not a specific disease: it is a manifestation of a pathological process.

Anemia is diagnosed based on a complete blood count (CBC), reticulocyte count, and peripheral blood smear. Once anemia is identified, further investigation is done to determine its specific cause (Marks, 2013).

Anemia can result from primary hematological problems or can develop as a secondary consequence of defects in other body systems. There are also biological and genetic factors (see the "Determinants of Health" box). The various types of anemia can be grouped according to either a morphological classification (by cellular characteristics) or an etiological one (by underlying cause). Morphological classification is based on descriptive, objective laboratory information about erythrocyte size and colour (Table 33-1). Etiological classification is related to the clinical conditions causing the anemia (Table 33-2). Although the morphological system is the most accurate means of classifying anemias, it is easier to discuss patient care by focusing on the cause or etiology of the anemia.

TABLE 33-1

RELATIONSHIP OF MORPHOLOGICAL CLASSIFICATION AND ETIOLOGIES OF ANEMIA

Morphology	Etiology
Normocytic, normochromic (normal size and colour) MCV 80–100 fL, MCH 27–34 pg	Acute blood loss, hemolysis, chronic renal disease, chronic disease, cancers, sideroblastic anemia, refractory anemia, diseases of endocrine dysfunction, aplastic anemia, pregnancy
Macrocytic (megaloblastic), normochromic (large size, normal colour) MCV >100 fL, MCH >34 pg	Vitamin B_{12} deficiency, folate deficiency, liver disease (including effects of alcohol use disorder), medications that impair DNA synthesis, hypothyroidism
Microcytic, hypochromic (small size, pale colour) MCV <80 fL, MCH <27 pg	Iron-deficiency anemia, thalassemia, anemia of chronic disease, sideroblastic anemia, lead poisoning

DNA, deoxyribonucleic acid; *MCH*, mean corpuscular hemoglobin; *MCV*, mean corpuscular volume.

TABLE 33-2
ETIOLOGICAL CLASSIFICATION OF ANEMIA

Decreased Red Blood Cell Production
Decreased Hemoglobin Synthesis
• Iron deficiency • Thalassemias (decreased globin synthesis) • Sideroblastic anemia (decreased porphyrin)
Defective DNA Synthesis
• Cobalamin (vitamin B_{12}) deficiency • Folic acid deficiency
Decreased Number of Erythrocyte Precursors
• Aplastic anemia • Anemia of myeloproliferative disorders and myelodysplasia • Chronic diseases or disorders • Medications (e.g., chemotherapy)
Blood Loss
Acute
• Trauma • Blood vessel rupture
Chronic
• Gastritis • Menstrual flow • Hemorrhoids
Increased Red Blood Cell Destruction
Intrinsic
• Abnormal hemoglobin (hemoglobin S—sickle cell anemia) • Enzyme deficiency (G6PD) • Membrane abnormalities (paroxysmal nocturnal hemoglobinuria, hereditary spherocytosis)
Extrinsic
• Physical trauma (prosthetic heart valves, extracorporeal circulation) • Antibodies (isoimmune and autoimmune) • Infectious agents, medications, and toxins (malaria)

DNA, deoxyribonucleic acid; *G6PD*, glucose-6-phosphate dehydrogenase.

Clinical Manifestations

The clinical manifestations of anemia are caused by the body's response to tissue hypoxia. Specific manifestations vary depending on the rate at which anemia evolved, its severity, and the presence of coexisting disease. Hb levels are often used to determine the severity of anemia. Mild states of anemia (Hb 100–120 g/L) may exist without causing symptoms. If symptoms develop, it is because the patient has an underlying disease or is experiencing a compensatory response to heavy exercise. Symptoms include palpitations, dyspnea, and diaphoresis. In cases of moderate anemia (Hb 60–100 g/L), the cardiopulmonary symptoms are increased and the patient may experience them while resting as well as with activity. The patient with severe anemia (Hb <60 g/L) displays many clinical manifestations involving multiple body systems (Table 33-3).

TABLE 33-3
CLINICAL MANIFESTATIONS OF ANEMIA

Body System	Severity of Anemia		
	Mild (Hb 100–120 g/L*)	Moderate (Hb 60–100 g/L*)	Severe (Hb <60 g/L*)
Integument	None	None	Pallor, jaundice,† pruritus†
Eyes	None	None	Icteric conjunctiva and sclera, retinal hemorrhage, blurred vision
Mouth	None	None	Glossitis, smooth tongue
Cardiovascular	Palpitations	Increased palpitations, "bounding pulse"	Tachycardia, increased pulse pressure, systolic murmurs, intermittent claudication, angina, HF, MI
Pulmonary	Exertional dyspnea	Dyspnea	Tachypnea, orthopnea, dyspnea at rest
Neurological	None	"Roaring in the ears"	Headache, vertigo, irritability, depression, impaired thought processes
Gastro-intestinal	None	None	Anorexia, hepatomegaly, splenomegaly, difficulty swallowing, sore mouth
Musculo-skeletal	None	None	Bone pain
General	None	Fatigue	Sensitivity to cold, weight loss, lethargy

*Applies to female values; will be slightly higher in males.

†Caused by hemolysis.

Hb, hemoglobin; *HF*, heart failure; *MI*, myocardial infarction.

Determinants of Health

Anemia

Biology and Genetic Endowment

- Sickle cell disease has a high incidence among people of African descent but may also affect people of Latin, Caribbean, Arabian, Indian, and Mediterranean descent.
- Thalassemia has a higher incidence among people of North African, East Asian, and Mediterranean origin.
- There is a high incidence of pernicious anemia among people of African and Scandinavian descent.
- Indigenous people have a higher incidence of iron-deficiency anemia, primarily caused by inadequate diet, poor living conditions, and high infection rates.*

[*] Khambalia AZ, Aimone AM, Zlotkin SH. Burden of anemia among indigenous populations. *Nutrition Reviews*. 2011;69(12):693–719; 10.1111/j.1753-4887.2011.00437.x.

Integumentary Changes

Integumentary changes include pallor, jaundice, and pruritus. Pallor results from reduced amounts of Hb and reduced blood flow to the skin. Jaundice occurs when hemolysis of RBCs results in an increased concentration of serum bilirubin. Pruritus occurs because of increased serum and bile salt concentrations in the skin. In addition to the skin, the sclera of the eyes and the mucous membranes should be evaluated for jaundice because they reflect the integumentary changes more accurately, especially in dark-skinned individuals.

Cardiopulmonary Manifestations

Cardiopulmonary manifestations of severe anemia result from additional attempts by the heart and lungs to provide adequate amounts of O_2 to the tissues. Cardiac output is maintained by increasing the heart rate and the stroke volume. The low viscosity of the blood contributes to the development of systolic murmurs and bruits. In extreme cases or when concomitant heart disease is present, angina pectoris and myocardial infarction (MI) may occur if myocardial O_2 needs cannot be met. Heart failure (HF), cardiomegaly, pulmonary and systemic congestion, ascites, and peripheral edema may develop if the heart is overworked for an extended period.

Nursing Management Anemia

This section discusses general nursing management of anemia. Specific care related to various types of anemia is discussed later in this chapter.

Nursing Assessment

Subjective and objective data that should be obtained from a patient with anemia are presented in Table 33-4.

TABLE 33-4

NURSING ASSESSMENT
Anemia

Subjective Data
Important Health Information
Past health history: Recent blood loss or trauma; chronic liver, endocrine, or renal disease (including dialysis); GI disease (e.g., malabsorption syndrome, ulcers, gastritis, or hemorrhoids); inflammatory disorders (especially Crohn's disease); smoking, exposure to radiation or chemical toxins (arsenic, lead, benzenes, copper); infectious disease (e.g., HIV) or recent travel suggesting exposure to infection; angina, myocardial infarction; history of falling *Medications:* Use of vitamin and iron supplements, acetylsalicylic acid (ASA; Aspirin), anticoagulants, oral contraceptives, phenobarbital, penicillins, nonsteroidal anti-inflammatory drugs, phenacetin, omeprazole, phenytoin (Dilantin), methyldopa, sulphonamides, herbal products *Surgery or other treatments:* Recent surgery, small bowel resection, gastrectomy, prosthetic heart valves, chemotherapy, radiation therapy *Dietary history:* General dietary patterns, consumption of alcohol
Symptoms
• Nausea, vomiting, anorexia, dysphagia, dyspepsia, heartburn, painful tongue • Night sweats, cold intolerance, weight loss, pruritus, pain • Hematuria, decreased urinary output, diarrhea, constipation, flatulence, tarry stools, bloody stools • Fatigue, muscle weakness, and decreased strength • Dyspnea, orthopnea, cough, hemoptysis, palpitations, shortness of breath with activity • Headache; paresthesias of feet and hands; disturbances in vision, taste, or hearing; vertigo • Menorrhagia, metrorrhagia; recent or current pregnancy in women; male impotence
Objective Data
General
Lethargy, apathy, general lymphadenopathy, fever
Integumentary
Pale skin and mucous membranes; blue sclera, yellowing of the whites of the eyes, or icteric sclera; cheilitis; poor skin turgor; brittle, spoon-shaped fingernails; jaundice; petechiae; ecchymoses; nose or gingival bleeding; poor healing; dry, brittle, thinning hair
Respiratory
Tachypnea
Cardiovascular
Tachycardia, systolic murmur, dysrhythmias; postural hypotension, widened pulse pressure, bruits (especially carotid); intermittent claudication, ankle edema
Gastro-Intestinal
Hepato-splenomegaly; glossitis; beefy, red tongue; stomatitis; abdominal distension; anorexia
Neurological
Headache, roaring in the ears, confusion, impaired judgement, irritability, ataxia, unsteady gait, paralysis, loss of vibration sense
Possible Diagnostic Findings
↓ RBCs; ↓ Hb; ↓ Hct; ↓ or ↑ reticulocytes, MCV; ↓ serum iron, ferritin, folate, or cobalamin (vitamin B_{12}); heme (guaiac)-positive stools; ↓ serum erythropoietin level; ↓ or ↑ LDH, bilirubin, transferrin (see Table 33-6)

GI, gastro-intestinal; *Hb*, hemoglobin; *Hct*, hematocrit; *HIV*, human immunodeficiency virus; *LDH*, lactate dehydrogenase; *MCV*, mean corpuscular volume; *RBCs*, red blood cells.

Nursing Diagnoses

Nursing diagnoses for the patient with anemia include but are not limited to those presented in Nursing Care Plan (NCP) 33-1.

Nursing Care Plan 33-1

Anemia

NURSING DIAGNOSIS	***Fatigue*** related to *anemia* (inadequate oxygenation of the blood) as evidenced by insufficient energy, *increase in physical symptoms* (pulse rate and blood pressure)
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Participates in activities of daily living (e.g., bathing, dressing, grooming, feeding) without abnormal increases in pulse and blood pressure • Reports increased endurance of activity	• Correct physiological status deficits (e.g., chemotherapy-induced anemia) *to help mitigate the underlying cause of anemia.* • Encourage alternate periods of rest and activity *to provide activity without tiring the patient.* • Monitor cardiorespiratory response to activity (e.g., tachycardia, dysrhythmias, dyspnea, diaphoresis, pallor, respiratory rate) *to evaluate activity intolerance.* • Limit environmental stimuli *to reduce demands placed on patient.* • Assist the patient in assigning priority to activities *to accommodate energy levels for important activities.* • Arrange physical activities (e.g., avoid activity immediately after meals) *to reduce competition for O_2 supply to vital body functions.* • Assist with regular physical activities (e.g., ambulation, transfers, turning, personal care) *to minimize fatigue and risk for injury from falls.* • Instruct patient, caregiver(s), and family member(s) to recognize signs and symptoms of fatigue that require reduction in activity *to promote self-care.* • Instruct patient, caregiver(s), and family member(s) to notify health care provider if signs and symptoms of fatigue persist *to review treatment plan.*
NURSING DIAGNOSIS	***Imbalanced nutrition: less than body requirements*** related to insufficient dietary intake as evidenced by *insufficient interest in food, inability to absorb nutrients*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Maintains dietary intake that provides minimum daily requirements of nutrients. • Experiences normal blood values of nutrients necessary to prevent anemia.	• Determine, in collaboration with dietitian, number of calories and type of nutrients needed to meet nutritional requirements *to plan interventions.* • Teach patient how to use a food diary *to help evaluate nutritional intake.* • Monitor recorded intake for nutritional content and calories *to evaluate nutritional status.* • Instruct patient about nutritional needs (i.e., encourage increased intake of protein, iron, vitamin C) *to help ensure patient gets nutrients needed for maximum iron absorption and hemoglobin production.* • Adjust diet, as necessary, *to adapt to changes in nutritional requirements.*
NURSING DIAGNOSIS	***Ineffective health management*** related to *insufficient knowledge of therapeutic regimen* as evidenced by *difficulty with prescribed regimen*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
Verbalizes knowledge necessary to maintain adequate nutrition and management of medication regimen	*Nutritional Counselling* • Facilitate identification of eating behaviours to be changed. • Use accepted nutritional standards *to assist patient in evaluating adequacy of dietary intake.* • Discuss nutritional requirements and patient's perceptions of prescribed or recommended diet. • Provide referral or consultation with other members of the health care team *to help patient achieve goals and make adjustments throughout recovery.* • Review with patient measurements of hemoglobin values *to evaluate response to therapeutic plan.* *Teaching: Prescribed Medication* • Instruct the patient on the purpose and action of each medication. • Instruct the patient on dosage, route, and duration of each medication *to improve adherence.* • Instruct the patient on possible adverse effects of each medication *to ensure early detection of adverse responses to medication.*

Planning

The overall goals are that the patient with anemia will (a) assume normal activities of daily living, (b) maintain adequate nutrition, and (c) develop no

complications related to anemia.

Nursing Implementation

The numerous causes of anemia necessitate different nursing interventions specific to the needs of the patient. Nevertheless, there are certain general components of care for all patients with anemia; these are presented in NCP 33-1.

Correcting the cause of anemia is ultimately the goal of therapy. Acute interventions may include blood or blood product transfusions, drug therapy, volume replacement, and O_2 therapy to stabilize the patient. Dietary and lifestyle changes can reverse some types of anemias. The plan of care should include an ongoing assessment of the patient's knowledge regarding adequate nutritional intake and drug therapies and of the patient's compliance with safety precautions to prevent falls and injury.

Age-Related Considerations

Anemia

Modest changes in RBC mass occur in older adults. In healthy older men, a decline in Hb of about 10 g/L between ages 70 and 88 years is common, in part because of the decreased production of androgens. Only a minimal decrease in Hb occurs between these ages in healthy women (≈2 g/L) (Marks, 2013).

Anemia is not a normal finding in older adults. However, its prevalence increases starting from the seventh decade of life. For the majority of older adults, anemia is related to an underlying cause such as iron or folate deficiency, bleeding, cancer, chronic disease or inflammation, or renal insufficiency. In many older patients with anemia, there is no identifiable cause (Artz & Ershler, 2013). Signs and symptoms of anemia in the older adult may include pallor, confusion, ataxia, fatigue, and worsening cardiovascular and respiratory problems. Unfortunately, anemia may go unrecognized in the older adult because manifestations of anemia may be mistaken as normal aging changes or be overlooked because of another health problem. By recognizing signs of anemia, the nurse can play a pivotal role in appropriate health assessment and related interventions for older adults.

Anemia Caused by Decreased Erythrocyte Production

Normally, RBC production (termed *erythropoiesis*) is in equilibrium with RBC destruction and loss. This balance ensures that an adequate number of erythrocytes are available at all times. The normal lifespan of an RBC is 120 days. Three alterations in erythropoiesis may occur that decrease RBC production: (a) decreased Hb synthesis may lead to iron-deficiency anemia, thalassemia, and sideroblastic anemia; (b) defective deoxyribonucleic acid (DNA) synthesis in RBCs (e.g., cobalamin or folic acid deficiency) may lead to megaloblastic anemias; and (c) diminished availability of erythrocyte precursors may result in aplastic anemia and anemia of chronic disease (see Table 33-2).

Iron-Deficiency Anemia

Iron-deficiency anemia is the most common nutritional disorder in the world. It is a microcytic hypochromic anemia caused by inadequate supplies of the iron needed to synthesize hemoglobin. The people most susceptible to iron-deficiency anemia are the very young, those with poor diets, and women in their reproductive years (World Health Organization, 2016). Normally, 1 mg of iron is lost daily in urine, bile, sweat, sloughing of epithelial cells, and minor bleeding (Rote & McCance, 2014).

Etiology

Iron deficiency may develop from inadequate dietary intake, malabsorption, blood loss, or hemolysis. Iron is obtained from food and dietary supplements. Dietary iron is usually adequate to meet the needs of men and older women, but it may be inadequate for individuals with higher iron needs (e.g., menstruating or pregnant women). Table 33-5 lists nutrients needed for erythropoiesis. Malabsorption of iron may occur after certain types of gastro-intestinal (GI) surgery and in malabsorption syndromes. Surgical procedures may involve removal or bypass of the duodenum. Because iron absorption occurs primarily in the duodenum, malabsorption syndromes may involve disease of the duodenum in which the absorptive surface is altered or destroyed.

TABLE 33-5

NUTRITIONAL THERAPY
Nutrients Needed for Erythropoiesis

Nutrient	Role in Erythropoiesis	Food Sources
Cobalamin (vitamin B_{12})	RBC maturation	Red meats (especially liver), eggs, enriched grain products, dairy, fish, fortified rice and soy beverages
Copper	Mobilization of iron from tissues to plasma	Shellfish, whole grains, beans, nuts, potatoes, organ meats, sesame seeds, kale, fermented soy foods
Folic acid	RBC maturation	Leafy green vegetables, okra, liver, meat, fish, legumes, whole grains, orange juice, peanuts, avocado, lentils
Iron	Hemoglobin synthesis	Liver and muscle meats, eggs, dried fruits, legumes, leafy dark-green vegetables, whole-grain and enriched bread and cereals, beans, tofu
Niacin (vitamin B_3)	RBC maturation	Peanut butter, beans, meats, avocado, enriched and fortified grains, yeast extract
Pantothenic acid (vitamin B_5)	Hemoglobin synthesis	Meats, leafy green vegetables, cereal grains, legumes, eggs, milk, mushrooms
Pyridoxine (vitamin B_6)	Hemoglobin synthesis	Meats, wheat germ, legumes, potatoes, cornmeal, bananas, nuts, fish (salmon, sardines)
Riboflavin (vitamin B_2)	Oxidative reactions	Dairy, enriched bread, salmon, chicken, eggs, leafy green vegetables
Vitamin E	Hemoglobin synthesis, protection against oxidative damage to RBCs	Vegetable oils, meat, eggs, wheat germ, whole-grain products, seeds, nuts (pine nuts, almond butter), fish (salmon, eel)
Amino acids	Synthesis of nucleoproteins	Eggs, meat, milk and milk products, poultry, fish, legumes, nuts, tofu
Ascorbic acid (vitamin C)	Conversion of folic acid to its active forms; contribution to iron absorption	Citrus fruits, leafy green vegetables, strawberries, cantaloupe, kiwi, chili peppers

RBC, red blood cell.

Blood loss is a major cause of iron deficiency in adults. Two millilitres of whole blood contains 1 mg of iron. The major sources of chronic blood loss are from the GI and genito-urinary (GU) systems. GI bleeding is often not apparent and, therefore, may be present for a considerable time before the problem is identified. Loss of 50 to 75 mL of blood from the upper GI tract is required for stools to appear black *(melena).* The black colour results from the iron in the RBCs. Common causes of GI blood loss are peptic ulcer, gastritis, esophagitis, diverticuli, hemorrhoids, and neoplasia. GU blood loss occurs primarily from menstrual bleeding. The average monthly menstrual blood loss is about 45 mL and causes the loss of about 22 mg of iron. Postmenopausal bleeding can contribute to anemia in a susceptible older woman. Pregnancy also contributes to iron deficiency because of the diversion of iron to the fetus for erythropoiesis, blood loss at delivery, and lactation (Cantor, Bougatsos, Dana, et al., 2015). In addition to anemia of chronic kidney disease, dialysis treatment may induce iron-deficiency anemia because of the blood lost in the dialysis equipment and frequent blood sampling.

Clinical Manifestations

In the early course of iron-deficiency anemia, the patient may be symptom free. As the disease becomes chronic, any of the general manifestations of anemia may develop (see Table 33-3). In addition, specific clinical symptoms may occur related

to iron-deficiency anemia. Pallor is the most common finding, and *glossitis* (inflammation of the tongue) is the second most common; another finding is *cheilitis* (inflammation of the lips). In addition, the patient may report headache, paresthesias, and a burning sensation of the tongue, all of which are caused by a lack of iron in the tissues.

Diagnostic Studies

Iron-deficiency anemia will lead to a number of characteristic laboratory abnormalities (Table 33-6). Other diagnostic studies are done to determine the cause of the iron deficiency (e.g., stool occult blood test). Endoscopy and colonoscopy may be used to detect GI bleeding. A bone marrow biopsy may be done if other tests are inconclusive.

TABLE 33-6
LABORATORY RESULTS IN ANEMIA

Etiology of Anemia	Hb/Hct	MCV	Reticulocytes	Serum Iron	TIBC	Transferrin	Ferritin	Bilirubin	Serum B_{12}	Folate
Iron deficiency	↓	↓	N or slight ↓ or ↑	↓	↑	N or ↓	↓	N or ↓	N	N
Thalassemia major	↓	N or ↓	↑	↑	↓	↓	N or ↑	↑	N	↓
Cobalamin deficiency	↓	↑	N or ↓	N or ↑	N	Slight ↑	↑	N or slight ↑	↓	N
Folic acid deficiency	↓	↑	N or ↓	N or ↑	N	Slight ↑	↑	N or slight ↑	N	↓
Aplastic anemia	↓	N or slight ↑	↓	N or ↑	N or ↑	N	N	N	N	N
Chronic disease	↓	N or ↓	N or ↓	N or ↓	↓	N or ↓	N or ↑	N	N	N
Acute blood loss	↓	N or ↓	N or ↑	N	N	N	N	N	N	N
Chronic blood loss	↓	↓	N or ↑	↓	↓	N	N	N or ↓	N	N
Sickle cell anemia	↓	N	↓	N or ↑	N or ↓	N	N	↑	N	↓
Hemolytic anemia	↓	N or ↑	↑	N or ↑	N or ↓	N	N or ↑	↑	N	N

Hb, hemoglobin; *Hct,* hematocrit; *MCV,* mean corpuscular volume; *N,* normal; *TIBC,* total iron-binding capacity.

Collaborative Care

The main goal of the collaborative care of iron-deficiency anemia is to treat the underlying disease that is causing reduced intake or absorption of iron. In addition, efforts are directed toward replacing iron (Table 33-7). The patient should be taught which foods are good sources of iron (see Table 33-5). If nutrition is already adequate, increasing iron intake by dietary means may not be practical. Consequently, oral or, occasionally, parenteral iron supplements are

used. If the iron deficiency is from acute blood loss, the patient may require a transfusion of packed RBCs.

TABLE 33-7
COLLABORATIVE CARE
Iron-Deficiency Anemia

Diagnostic	Collaborative Therapy

• History and physical examination
• Hct and Hb levels
• RBC count, including morphology
• Reticulocyte count
• Serum iron
• Serum ferritin
• Serum transferrin
• TIBC
• Stool examination for occult blood
• Bone marrow aspirate (rarely)
	• Identification and treatment of underlying cause
	• Drug therapy
	  • Oral: ferrous sulphate or ferrous gluconate
	  • IM or IV: iron dextran, iron sucrose, sodium ferric gluconate (Ferrlecit)
	• Nutritional therapy (see Table 33-5)
	• Transfusion of packed RBCs

Hb, hemoglobin; *Hct,* hematocrit; *IM,* intramuscular; *IV,* intravenous; *RBC,* red blood cell; *TIBC,* total iron-building capacity.

Drug Therapy.

Oral iron should be used whenever possible because it is inexpensive and convenient. Many iron preparations are available. The following five factors should be considered in the administration of iron:

1. Iron is absorbed best from the duodenum and the proximal jejunum. Therefore, enteric-coated or sustained-release capsules, which release iron farther down in the GI tract, are counterproductive.
2. The daily dosage should provide 150 to 200 mg of elemental iron. This can be ingested in three or four daily doses, with each tablet or capsule of the iron preparation containing between 50 and 100 mg of iron. Common iron preparations and amounts of elemental iron are provided in Table 33-8.

TABLE 33-8

COMMON IRON PREPARATIONS AND ELEMENTAL IRON PROVIDED

Iron Preparation	Amount of Elemental Iron (mg)
Ferrous sulphate (300-mg tablet)	60
Ferrous gluconate (300-mg tablet)	35
Ferrous fumarate (300-mg tablet)	99
Polysaccharide iron complex	150

Source: Adapted from Canadian Pharmacists Association. (2011). *Iron preparations: Oral*. Retrieved from *https://www.e-therapeutics.ca/cps.showMonograph.action?newSearch=true&simpleIndex=BrandGeneric&simpleQuery=Iron+Preparations%3A+Oral&=#m267400n00027*.

3. Iron is best absorbed as ferrous sulphate (Fe^{2+}) in an acidic environment. For this reason and to avoid binding the iron with food, iron should be

taken about an hour before meals, when the duodenal mucosa is most acidic. Taking iron with vitamin C (ascorbic acid) or orange juice, which contains ascorbic acid, also enhances iron absorption. Gastric effects, however, may necessitate ingesting iron with meals.

4. Undiluted liquid iron may stain the patient's teeth; therefore, it should be diluted and ingested through a straw.
5. GI adverse effects of iron administration may occur, including heartburn, constipation, and diarrhea. If adverse effects develop, the dosage and type of iron supplement may be adjusted. For example, many individuals who need supplemental iron cannot tolerate ferrous sulphate because of the effects of the sulphate base. However, ferrous gluconate may be an acceptable substitute. All patients should know that the use of iron preparations will cause their stools to become black because the GI tract excretes excess iron. Constipation is common, so patients should be started on stool softeners and laxatives if needed when taking iron.

Drug Alert

Iron

- Some preparations of IV iron have a risk of allergic reaction; the patient should be monitored accordingly.
- Oral iron should be taken about 1 hour before meals.
- Vitamin C (ascorbic acid) enhances iron absorption.

In some situations, it may be necessary to administer iron parenterally. Parenteral use of iron is indicated for malabsorption, intolerance of oral iron, a need for iron beyond oral-intake limits, or poor patient compliance in taking the oral preparations of iron. Parenteral iron may be given intramuscularly (IM) or intravenously (IV). Because IM iron solutions may stain the skin, separate needles should be used for drawing up the solution and for injecting the medication. The Z-track method should be used for injection to prevent leakage of the iron solution to the subcutaneous tissue. Some preparations of IV iron have a high risk for an allergic reaction, so the patient should be monitored accordingly.

Nursing Management Iron-Deficiency Anemia

Certain groups of individuals are at an increased risk for the development of iron-deficiency anemia. These include premenopausal and pregnant women, persons from low socioeconomic backgrounds, older adults, and individuals experiencing blood loss. Nutritional education, with an emphasis on foods high in iron and on ways to maximize absorption, is important for these groups, as is adherence to both dietary and drug therapy. The patient should be informed of the need for diagnostic studies to identify the underlying cause, and the Hb and RBC counts should be reassessed periodically to evaluate the response to therapy. To replenish the body's iron stores, the patient needs to continue to take iron therapy for 2 to 3 months after the Hb level returns to normal. Patients who require lifelong iron supplementation should be monitored for potential liver problems related to the iron storage. Appropriate nursing measures are presented in NCP 33-1.

Thalassemia

Etiology

Thalassemia is a group of diseases involving inadequate production of normal Hb, and therefore decreased erythrocyte production. Thalassemia is caused by an absent or reduced globulin protein. Alpha-globulin chains are absent or reduced in alpha thalassemia, and beta-globin chains are absent or reduced in beta thalassemia. Hemolysis also occurs in thalassemia, but insufficient production of normal Hb is the predominant problem. Thalassemia is commonly found in members of ethnic groups whose origins are near the Mediterranean Sea, South East Asia, the Middle East, China, or Africa.

Thalassemia has an autosomal recessive genetic basis. An individual with thalassemia may have a heterozygous or homozygous form of the disease. A person who is heterozygous has one thalassemic gene and one normal gene and is said to have *thalassemia minor* (or *thalassemic trait*), a mild form of the disease. A homozygous person has two thalassemic genes, causing a severe condition known as *thalassemia major* (Porteus & Mantanona, 2012).

Clinical Manifestations

Thalassemia minor is frequently asymptomatic. A patient with thalassemia minor may exhibit mild to moderate anemia with *microcytosis* (small RBCs) and *hypochromia* (pale cells).

Thalassemia major is a life-threatening disease in which growth, both physical and mental, is often affected. The person who has thalassemia major is pale and displays other general symptoms of anemia (see Table 33-3). The symptoms develop by 2 years of age and can cause growth and development deficits. In

addition, the person has pronounced splenomegaly as the spleen continuously tries to remove the damaged RBCs. Jaundice from RBC hemolysis is prominent. Hepatomegaly and cardiomyopathy may occur from iron deposition. As the bone marrow responds to the reduced O_2-carrying capacity of the blood, RBC production is stimulated and the marrow becomes packed with immature erythroid precursors that die. The death of these erythroid precursors stimulates further erythropoiesis, leading to chronic bone marrow hyperplasia and expansion of the marrow space. This expansion may cause thickening of the cranium and the maxillary cavity. Other complications of the disease include endocrinopathies and thromboses.

Collaborative Care

The laboratory abnormalities of thalassemia major are summarized in Table 33-6. No specific drug or diet therapies are effective in treating thalassemia. Thalassemia minor requires no treatment because the body adapts to the reduction of normal Hb; however, genetic counselling is advised.

Thalassemia major is managed with blood transfusions in conjunction with chelating agents that bind to iron: oral deferasirox (Exjade) or deferiprone (Ferriprox) or IV or subcutaneous deferoxamine (Desferal). These agents reduce the iron overloading that occurs with chronic transfusion therapy (Carson & Martin, 2014). Transfusions are administered to keep the Hb level at approximately 100 g/L in order to foster the patient's own erythropoiesis without enlarging the spleen. Zinc supplementation may be needed with transfusion therapy, though supplement amounts are reduced with chelation therapy. During chelation therapy, ascorbic acid supplementation increases urine excretion of iron; ascorbic acid should not otherwise be taken because it increases the absorption of dietary iron. Regular folic acid may be given if the patient's diet is poor. Iron supplements should not be given.

Although hematopoietic stem cell transplantation (HSCT) remains the only cure for thalassemia, issues such as the risk of the procedure, donor availability, access, and cost make HSCT a reasonable option for only a small number of patients. Regular transfusions and proper iron chelation therapy remain the mainstay of therapy for thalassemia major (Goss, Giardina, Degtyaryova, et al., 2014).

Megaloblastic Anemias

Megaloblastic anemias are a group of disorders caused by impaired DNA synthesis and characterized by the presence of large RBCs. When DNA synthesis is impaired, defective RBC maturation results. These abnormal, large RBCs (macrocytic) are referred to as *megaloblasts.* Macrocytic RBCs are easily destroyed because they have fragile cell membranes. Although the overwhelming majority of megaloblastic anemias result from cobalamin (vitamin B_{12}) and folic acid deficiencies, this type of RBC deformity can also occur from suppression of DNA

synthesis by drugs, inborn errors of cobalamin and folic acid metabolism, and *erythroleukemia* (a malignant blood disorder characterized by a proliferation of erythropoietic cells in bone marrow) (Table 33-9).

TABLE 33-9
CLASSIFICATION OF MEGALOBLASTIC ANEMIA

Cobalamin (Vitamin B_{12}) Deficiency

• Dietary deficiency
• Deficiency of gastric intrinsic factor
  • Pernicious anemia
  • Gastrectomy
  • Gastric bypass
  • Celiac disease
  • *Helicobacter pylori*
• Intestinal malabsorption
• Increased requirement (pregnancy)
• Chronic alcoholism

Folic Acid Deficiency

• Dietary deficiency (e.g., leafy green vegetables, citrus fruits)
• Malabsorption syndromes
  • Celiac disease
  • Crohn's disease
  • Small bowel resection
• Drugs interfering with absorption or use of folic acid
  • Methotrexate
  • Antiseizure drugs (e.g., phenobarbital, phenytoin [Dilantin])
• Increased requirement (pregnancy)
• Chronic alcoholism
• Chronic hemodialysis (folic acid lost during dialysis)

Drug-Induced Suppression of DNA Synthesis
• Folate antagonists • Metabolic inhibitors • Alkylating agents
Inborn Errors
• Defective folate metabolism • Defective transport of cobalamin
Erythroleukemia
• Alkylating agents • Ionizing radiation • Familial erythroleukemia • Myelodysplastic syndrome (MDS)

Normally, a protein termed *intrinsic factor* (IF) is secreted by the parietal cells of the gastric mucosa. IF is required for cobalamin (vitamin B_{12}) absorption. Cobalamin is normally absorbed in the distal ileum and if IF is not secreted, cobalamin will not be absorbed.

Etiology

Pernicious Anemia.

The most common cause of cobalamin deficiency is **pernicious anemia,** which is caused by an absence of IF. In pernicious anemia, the gastric mucosa does not secrete IF because of either gastric mucosal atrophy or autoimmune destruction of parietal cells and possibly also because of IF itself. Pernicious anemia is a

disease of insidious onset that begins in middle age or later (usually after age 40), with 60 years being the most common age at diagnosis. Pernicious anemia occurs frequently in people of African or Northern European ancestry (particularly Scandinavians). In people of African descent, the disease tends to begin early, occurs with higher frequency in women, and is often severe.

Other Causes of Cobalamin Deficiency.

Cobalamin deficiency can also occur in patients who have had GI surgery such as gastrectomy or gastric bypass; patients who have had a small bowel resection involving the ileum; and patients with Crohn's disease, ileitis, celiac disease, diverticulitis of the small intestine, chronic atrophic gastritis, or a combination of these. In these cases, cobalamin deficiency results from the loss of IF-secreting gastric mucosal cells or impaired absorption of cobalamin in the distal ileum. Cobalamin deficiency is also found in long-term users of histamine (H_2)-receptor blockers and proton pump inhibitors and in strict vegetarians (Townsley & Rodgers, 2013).

Clinical Manifestations

General symptoms of anemia related to cobalamin deficiency develop because of tissue hypoxia (see Table 33-3). GI manifestations include a sore, red, shiny tongue; anorexia; nausea, vomiting; and abdominal pain. Typical neuro-muscular manifestations include weakness, paresthesias of the feet and hands, reduced vibratory and position senses, ataxia, muscle weakness, and impaired thought processes ranging from confusion to dementia. Because cobalamin deficiency–related anemia has an insidious onset, it may take several months for these manifestations to develop.

Diagnostic Studies

Laboratory data reflective of cobalamin-deficiency anemia are presented in Table 33-6. The RBCs appear large (macrocytic) and have abnormal shapes. This structure contributes to erythrocyte destruction because the cell membrane is fragile. Serum cobalamin levels are reduced. It is important also to know serum folate levels because, if they are normal and cobalamin levels are low, it suggests that megaloblastic anemia is caused by a cobalamin deficiency. A serum test for anti-IF antibodies may be done that is specific for pernicious anemia. Because the potential for gastric cancer is increased in patients with pernicious anemia, a gastroscopy and biopsy of the gastric mucosa may also be done. Testing of serum methylmalonic acid (MMA) (elevated mainly in cobalamin deficiency) and serum homocysteine (elevated in both cobalamin and folic acid deficiencies) helps determine the cause of the anemia.

Collaborative Care

Regardless of how much is ingested, the patient is not able to absorb cobalamin if IF is lacking or if absorption in the ileum is impaired. For this reason, increasing dietary cobalamin does not correct this anemia. However, the patient should be instructed on adequate dietary intake to maintain good nutrition (see Table 33-5). Parenteral or intranasal administration of cobalamin (cyanocobalamin or hydroxocobalamin) is the treatment of choice. Without cobalamin administration, these individuals will die in 1 to 3 years. A typical treatment schedule consists of 1 000 mcg of cobalamin IM daily for 2 weeks and then weekly until the Hct is normal and then monthly for life. High-dose oral cobalamin and sublingual cobalamin are also available for those whose GI absorption is intact. As long as supplemental cobalamin is used, the anemia can be reversed. However, any longstanding neuro-muscular complications a patient has experienced may not be reversible.

Folic Acid Deficiency

Folic acid (folate) deficiency also causes megaloblastic anemia. Folic acid is required for DNA synthesis leading to RBC formation and maturation. Common causes of folic acid deficiency are listed in Table 33-9.

The clinical manifestations of folic acid deficiency are similar to those of cobalamin deficiency. The disease develops insidiously, and the patient's symptoms may be attributed to other, coexisting problems such as cirrhosis or esophageal varices. GI disturbances include dyspepsia and a smooth, swollen, beefy red or shiny tongue. The absence of neurological problems is an important diagnostic finding and differentiates folic acid deficiency from cobalamin deficiency (Stabler, 2013).

The diagnostic findings for folic acid deficiency are presented in Table 33-6. In addition, the serum folate level is low (normal is 11–57 mmol/L), and the serum cobalamin level is normal. Folic acid deficiency is treated by replacement therapy. The usual dose is 1 mg/day by mouth. In malabsorption states, up to 5 mg/day may be required. The duration of treatment depends on the reason for the deficiency. In addition to supplements, the patient should be encouraged to eat foods containing large amounts of folic acid (see Table 33-5).

Nursing Management Megaloblastic Anemia

Because there is a familial predisposition for pernicious anemia (the most common type of cobalamin deficiency), patients who have a positive family history of pernicious anemia should be evaluated for symptoms. Although disease development cannot be prevented, early detection and treatment can help reverse symptoms more easily. Signs and symptoms of other possible causes of megaloblastic anemia should be brought to the attention of the primary health care provider.

The nursing measures presented in NCP 33-1 for the patient with anemia are appropriate for the patient with cobalamin-deficiency anemia. In addition to these measures, the nurse should ensure protection against injuries such as falls, burns, and trauma because the patient will have diminished sensations to heat and pain resulting from the neurological impairment. If heat therapy is required, the patient's skin must be evaluated at frequent intervals to detect redness.

Ongoing care is focused on ensuring good patient compliance with treatment. There must also be careful follow-up to assess for neurological difficulties that were not fully corrected by adequate cobalamin replacement therapy. Because the potential for gastric cancer may be increased in patients with atrophic gastritis–related pernicious anemia, the patient should have frequent and appropriate screening.

Anemia of Chronic Disease

Chronic inflammation, autoimmune, infectious, or malignant diseases can lead to anemia of chronic disease. *Anemia of chronic disease* is associated with an underproduction of RBCs and mild shortening of RBC survival. The RBCs are usually normocytic, normochromic, and hypoproliferative. The anemia is usually mild, but it can be more severe if the underlying disorder is not treated. This type of anemia is primarily immune driven. Cytokines released with inflammatory, autoimmune, infectious, or malignant disease cause an increased uptake and retention of iron within macrophages. This leads to a diversion of iron from the circulation into storage sites and subsequent limitation of the availability of iron for erythropoiesis.

In the case of any chronic disease, additional factors may contribute to the anemia. For example, with renal disease, the primary factor causing anemia is decreased erythropoietin, a hormone made in the kidneys that is necessary for erythropoiesis. With impaired renal function, erythropoietin production is decreased (see Chapter 49).

Anemia of chronic disease must first be recognized and differentiated from anemias of other etiologies. Findings of elevated serum ferritin and increased iron stores distinguish it from iron-deficiency anemia. Normal folate and cobalamin

blood levels distinguish it from megaloblastic anemias secondary to folate and cobalamin deficiencies.

The best treatment of anemia of chronic disease is correction of the underlying disorder. Unless the anemia is severe, blood transfusions are rarely indicated. Erythropoietin therapy may be used for anemia related to renal disease (see Chapter 49) or anemia related to cancer therapies. However, erythropoietin therapy is used conservatively because of the increased risk for thrombo-embolism and mortality in some patients (Bejjani, 2015).

Aplastic Anemia

Aplastic anemia is a disease in which the patient has peripheral blood *pancytopenia* (decrease of all blood cell types—RBCs, white blood cells [WBCs], and platelets) and hypocellular bone marrow. The spectrum of the anemia can range from a chronic condition managed with erythropoietin or blood transfusions to a critical condition with hemorrhage and sepsis.

Etiology

The incidence of aplastic anemia is low, affecting approximately four of every 1 million people every year. There are various etiological classifications for aplastic anemia, but they can be divided into two major groups: *congenital* and *acquired* (Table 33-10). Most of the acquired aplastic anemias are idiopathic and thought to have an autoimmune basis (Scheinberg, Young, & Liu, 2013).

TABLE 33-10
CAUSES OF APLASTIC ANEMIA

Congenital (Chromosomal Alterations)	Acquired
• Fanconi's syndrome • Congenital dyskeratosis • Amegakaryocytic thrombo-cytopenia • Schwachman-Diamond syndrome	• Chemical agents and toxins (e.g., benzene, arsenic) • Drugs (e.g., gold, antimicrobials) • Idiopathic/autoimmune • Radiation • Viral and bacterial infections

Clinical Manifestations

Aplastic anemia can manifest acutely (over days) or insidiously over weeks to months and can vary from mild to severe. Clinically, the patient may have symptoms caused by suppression of any or all bone marrow elements. General manifestations of anemia, such as fatigue and dyspnea, as well as cardiovascular and cerebral responses may be seen (see Table 33-3). Patients with neutropenia (low neutrophil counts) are susceptible to infection and are at risk for septic shock. Even a low-grade fever should be considered a medical emergency. Thrombo-cytopenia manifests as a predisposition to bleeding (e.g., petechiae, ecchymosis, epistaxis).

Diagnostic Studies

The diagnosis is confirmed by laboratory studies. Because all marrow elements are affected, Hb, WBC, and platelet values are often decreased in aplastic anemia. Other RBC indices are generally normal (see Table 33-6). The condition is, therefore, classified as a normocytic, normochromic anemia. The reticulocyte count is low.

Aplastic anemia can be further evaluated by assessing various iron studies. The serum iron and total iron-binding capacity (TIBC) may be elevated as initial signs of erythropoiesis suppression. Bone marrow biopsy, aspiration, and pathological examination may be done for any anemic state. However, the findings are especially important in aplastic anemia because the marrow is hypocellular, with increased yellow marrow (fat content).

Nursing and Collaborative Management Aplastic Anemia

Management of aplastic anemia is based on identifying and removing the causative agent (when possible) and providing supportive care until the pancytopenia reverses. Nursing interventions appropriate for the patient with pancytopenia from aplastic anemia are presented in NCP 33-1, earlier in this chapter. (See also NCP 33-2 for thrombo-cytopenia and NCP 33-3 for neutropenia, both available on the Evolve website.) Nursing actions are directed at preventing complications from infection and hemorrhage.

The prognosis for severe untreated aplastic anemia is poor. However, advances in medical management, including HSCT and immuno-suppressive therapy with antithymocyte globulin (ATG) and cyclosporin (Neoral), have improved outcomes significantly. ATG is a horse or rabbit serum that contains polyclonal antibodies against human T cells. The rationale for this therapy is that aplastic anemia is an immune-mediated disease resulting from the upregulation of T cells actively targeting and destroying the patient's own hematopoietic stem cells. ATG can cause anaphylaxis, but with premedications and careful infusion, most patients can complete the prescribed course of treatment.

The treatment of choice for younger adults who have a human leukocyte antigen (HLA)–matched donor is bone marrow transplantation. (Bone marrow transplants are discussed in Chapter 18.) The best results occur in younger patients (Bacigalupo, 2014). Prior transfusions increase the risk of graft rejection.

For the older adult or the patient without an HLA-matched donor, the treatment of choice is immuno-suppression with ATG or cyclosporine. High-dose corticosteroids may also be used. However, this therapy may be only partially beneficial.

Anemia Caused by Blood Loss

Anemia resulting from blood loss may be caused by either acute or chronic problems.

Acute Blood Loss

Acute blood loss occurs as a result of sudden hemorrhage. Causes of acute blood loss include trauma, complications of surgery, and conditions or diseases that disrupt vascular integrity. There are two clinical concerns in such situations. First, there is a sudden reduction in the total blood volume that can lead to hypovolemic shock. Second, if the acute loss is more gradual, the body maintains its blood volume by slowly increasing the plasma volume. Although the circulating fluid volume is preserved, the number of RBCs available to carry O_2 is significantly diminished.

Clinical Manifestations

The clinical manifestations of anemia from acute blood loss are caused by the body's attempts to maintain an adequate blood volume and meet O_2 requirements. Table 33-11 summarizes the clinical manifestations of patients with varying degrees of blood volume loss. It is essential to understand that the clinical signs and symptoms the patient is experiencing are more important than the laboratory values. For example, an adult with a bleeding peptic ulcer who had a 750-mL hematemesis (15% of a normal total blood volume) within the past 30 minutes may have postural hypotension but have normal values for Hb and Hct. Over the ensuing 36 to 48 hours, most of the volume deficit will be repaired by the movement of fluid from the extravascular into the intravascular space. Only at these later times will the Hb and Hct reflect the blood loss.

TABLE 33-11

MANIFESTATION OF ACUTE BLOOD LOSS

Volume Lost*		
%	**mL**	**Manifestations**
10	500	None or rare vasovagal syncope
20	1 000	No detectable signs or symptoms at rest; tachycardia with exercise and slight postural hypotension
30	1 500	Normal supine blood pressure and pulse at rest; postural hypotension and tachycardia with exercise
40	2 000	Blood pressure, central venous pressure, and cardiac output below normal at rest; air hunger; rapid, thready pulse and cold, clammy skin
50	2 500	Shock, lactic acidosis, and potential death

*Based on an adult with a total blood volume of 5 L.

The nurse should be alert to the patient's expression of pain when assessing for blood loss. Internal hemorrhage may cause pain because of tissue distension, organ displacement, and nerve compression. Pain may be localized or referred. In the case of retroperitoneal bleeding, for example, the patient may not experience abdominal pain. Instead, the patient may have numbness and pain in a lower extremity secondary to compression of the lateral cutaneous nerve, which is located in the region of the first to third lumbar vertebrae.

The major complication of acute blood loss is shock. (Shock and its management are discussed in Chapter 69.)

Diagnostic Studies

When blood volume loss is sudden, plasma volume has not yet had a chance to increase, the loss of RBCs is not reflected in laboratory data, and values may seem normal or high for 2 to 3 days. However, once the plasma is replaced, the RBC mass is less concentrated. At this time, RBC, Hb, and Hct levels are low, reflecting the blood loss.

Collaborative Care

Collaborative care is initially concerned with (a) replacing blood volume to prevent shock and (b) identifying the source of the hemorrhage and stopping the blood loss. IV fluids used in emergencies include dextran, hetastarch, albumin, and crystalloid electrolyte solutions such as lactated Ringer's. The amount of infusion varies with the solution used. (Management of shock is discussed in Chapter 69.)

Once volume replacement is established, attention can be directed to correcting the RBC loss. The body needs 2 to 5 days to manufacture more RBCs in response to increased erythropoietin. Consequently, blood transfusions (packed RBCs) may be needed if the blood loss is significant. In addition, if the bleeding is related to a platelet or clotting disorder, replacement of that deficiency must be addressed. If a large volume of blood is lost, platelets, plasma, and possibly cryoprecipitate will also be infused, because large volumes of RBCs would dilute the patient's own coagulation system.

The patient may also need supplemental iron because the availability of iron affects the marrow production of erythrocytes. When anemia exists after acute blood loss, dietary sources of iron will probably not be adequate to maintain iron stores. Therefore, oral or parenteral iron preparations are administered.

Nursing Management Acute Blood Loss

In the case of trauma, it may be impossible to prevent loss of blood. For the postoperative patient, carefully monitor the blood loss from various drainage tubes and dressings and implement appropriate actions. The NCP for the patient with anemia resulting from acute blood loss will most likely include administration of blood products (described at the end of this chapter).

Once the source of hemorrhage is identified, blood loss is controlled, and fluid and blood volumes are replaced, the anemia should begin to correct itself. There should be no need for long-term treatment of this type of anemia.

Chronic Blood Loss

The sources of chronic blood loss are similar to those of iron-deficiency anemia (e.g., bleeding ulcer, hemorrhoids, menstrual and postmenopausal blood loss). The effects of chronic blood loss are usually related to the depletion of iron stores and are usually considered as iron-deficiency anemia. Management of chronic blood loss anemia involves identifying the source and stopping the bleeding. Supplemental iron may be required. The nursing measures presented in NCP 33-1 are relevant to anemia of chronic blood loss.

Anemia Caused by Increased Erythrocyte Destruction

The third major cause of anemia is termed **hemolytic anemia,** a condition caused by the destruction or hemolysis of RBCs at a rate that exceeds production. Hemolysis can occur because of problems intrinsic or extrinsic to the RBCs. Intrinsic hemolytic anemias result from defects in the RBCs themselves caused by abnormal Hb (e.g., sickle cells), enzyme deficiencies that alter glycolysis (glucose-6-phosphate dehydrogenase [G6PD] deficiency), or RBC membrane abnormalities. Intrinsic hemolytic anemias are usually hereditary. More common are the extrinsic hemolytic anemias, which are acquired. In this type of anemia, the patient's RBCs are normal; damage is caused by external factors (see Table 33-2). The spleen is the primary site of the destruction of RBCs that are old, defective, or moderately damaged. Figure 33-1 indicates the sequence of events involved in extravascular hemolysis.

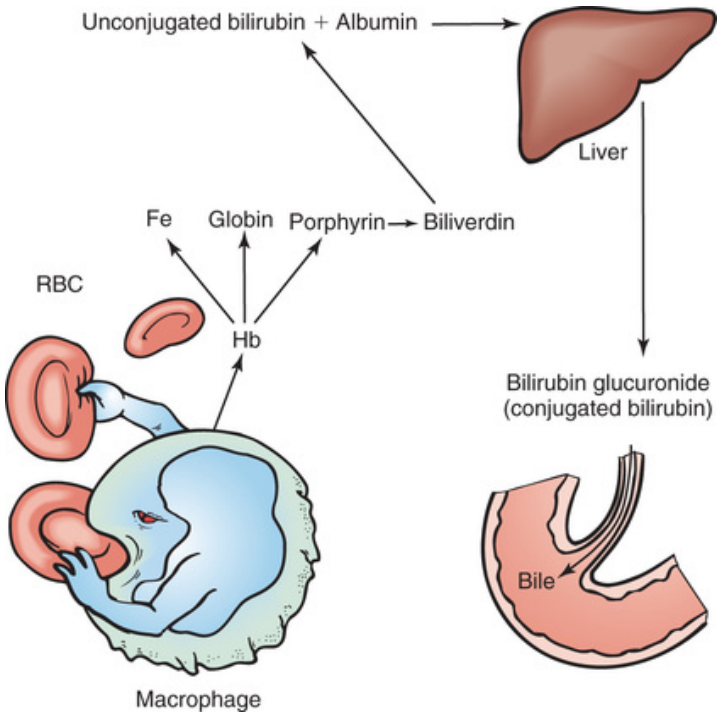

FIGURE 33-1 Sequence of events in extravascular hemolysis. *Fe,* iron; *Hb,* hemoglobin; *RBC,* red blood cell.

The patient with hemolytic anemia manifests the general symptoms of anemia and clinical manifestations specific to this type of anemia (see Table 33-3). Jaundice is likely because the increased destruction of RBCs causes an elevation

in bilirubin levels. The spleen and the liver may enlarge because of their hyperactivity, which is related to macrophage phagocytosis of the defective erythrocytes.

A major focus of treatment of hemolysis, no matter its cause, is to maintain renal function. When an RBC is hemolyzed, the Hb molecule is released and filtered by the kidneys. The accumulation of Hb molecules can obstruct the renal tubules and lead to acute tubular necrosis (see Chapter 49).

Sickle Cell Disease

Sickle cell disease (SCD) is a group of inherited, autosomal recessive disorders characterized by the presence of an abnormal form of Hb in the RBC. (Autosomal recessive genetic disorders are discussed in Chapter 15.) This abnormal Hb, *hemoglobin S* (HbS), causes the erythrocyte to stiffen and elongate and take on a sickle shape in response to low levels of O_2 in the blood. HbS results from substitution of valine for glutamic acid on the beta-globin chain of Hb. Because it is a genetic disorder, SCD is usually identified during infancy or early childhood. It is an incurable disease that is often fatal by the time the affected individual reaches middle age. Death usually results from renal and pulmonary failure, infection, or stroke (Kline, 2014).

SCD is common in the African-descended population of Canada. It affects millions of people around the world, mainly those whose ancestors come from sub-Saharan Africa, Spanish-speaking regions (South America, Cuba, Central America), Saudi Arabia, India, and Mediterranean countries.

Etiology and Pathophysiology

Types of Sickle Cell Disease.

Types of SCD disorders include sickle cell anemia, sickle cell–thalassemia, sickle cell–HbC disease, and sickle cell trait. *Sickle cell anemia,* the most severe of the SCD syndromes, occurs when a person is homozygous for HbS (HbSS), meaning the person has inherited HbS from both parents. *Sickle cell–thalassemia* and *sickle cell–HbC* occur when a person inherits HbS from one parent and another type of abnormal Hb (such as thalassemia or HbC) from the other parent. Both of these forms of SCD are less common and less severe than sickle cell anemia. *Sickle cell trait* occurs when a person is heterozygous for hemoglobin S (HbAS), meaning the person has inherited HbS from one parent and normal Hb (HbA) from the other parent. Sickle cell trait is typically a very mild or even asymptomatic condition.

Sickling Episodes.

The major pathophysiological event of SCD is the sickling of RBCs. Sickling episodes are most commonly triggered by low O_2 tension in the blood. Hypoxia or deoxygenation of the RBCs can be caused by viral or bacterial infection, high

altitude, emotional or physical stress, surgery, or blood loss. Infection is the most common precipitating factor. Other events that can trigger or sustain a sickling episode include dehydration, increased hydrogen ion concentration (acidosis), increased plasma osmolality, decreased plasma volume, and low body temperature. A sickling episode can also occur without an obvious cause.

Sickled RBCs become rigid and take on an elongated, crescent shape (Figure 33-2). Sickled cells cannot easily pass through capillaries or other small vessels and can cause vascular occlusion, leading to acute or chronic tissue injury. The resulting hemostasis promotes a self-perpetuating cycle of local hypoxia, deoxygenation of more erythrocytes, and more sickling. Circulating sickled cells are hemolyzed by the spleen, leading to anemia. Initially, the sickling of cells is reversible with reoxygenation, but it eventually becomes irreversible owing to cell membrane damage from recurrent sickling.

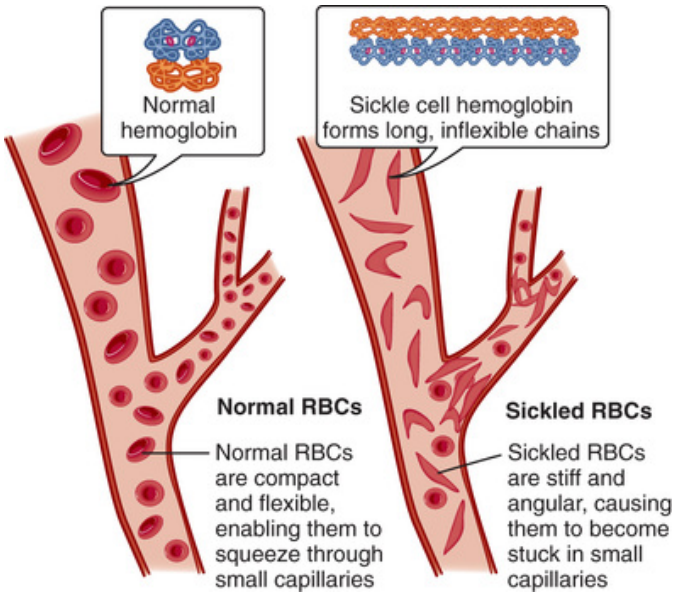

FIGURE 33-2 Sickle cell hemoglobin aggregates into long chains and alters the shape of the red blood cell.

Sickle cell crisis is a severe, painful, acute exacerbation of RBC sickling causing a vaso-occlusive crisis. As blood flow is impaired by sickled cells, vasospasm occurs, further restricting blood flow. Severe capillary hypoxia causes changes in membrane permeability, leading to plasma loss, hemoconcentration, the development of thrombi, and further circulatory stagnation. Tissue ischemia, infarction, and necrosis eventually occur from lack of O_2. Shock is a possible life-threatening consequence of sickle cell crisis owing to severe O_2 depletion of the tissues and a reduction of the circulating fluid volume. Sickle cell crisis can begin suddenly and persist for days to weeks.

The frequency, extent, and severity of sickling episodes are highly variable and unpredictable but are largely dependent on the percentage of HbS present. Individuals with sickle cell anemia have the most severe form because the erythrocytes contain a high percentage of HbS.

Clinical Manifestations

The effects of SCD vary greatly from person to person, with their severity believed to result from genetic polymorphisms. Many people with sickle cell anemia are in reasonably good health the majority of the time. However, they may have chronic health problems and pain because of organ tissue hypoxia and damage (e.g., involving the kidneys or liver). The typical patient is anemic but asymptomatic except during sickling episodes. Because most individuals with sickle cell anemia have dark skin, pallor is more readily detected by examining the mucous membranes. The skin may have a greyish cast. Because of the hemolysis, jaundice is common and patients are prone to gallstones (cholelithiasis).

The primary symptom associated with sickling is pain. The pain can range from mild to excruciating. The episodes can affect any area of the body or several sites simultaneously, with the back, chest, extremities, and abdomen most commonly affected. Pain episodes are often accompanied by objective clinical signs such as fever, swelling, tenderness, tachypnea, hypertension, nausea, and vomiting.

Complications

With repeated episodes of sickling, there is gradual involvement of all body systems, especially the spleen, lungs, kidneys, and brain. Organs that have a high need for O_2 are most often affected, and their involvement forms the basis for many of the complications of SCD (Figure 33-3). Infection is a major cause of morbidity and mortality in patients with SCD. One reason for this is the failure of the spleen to phagocytize foreign substances as it becomes infarcted and dysfunctional (usually by 2 to 4 years of age) from the sickled RBCs. The spleen becomes small because of repeated scarring, a phenomenon termed *autosplenectomy*.

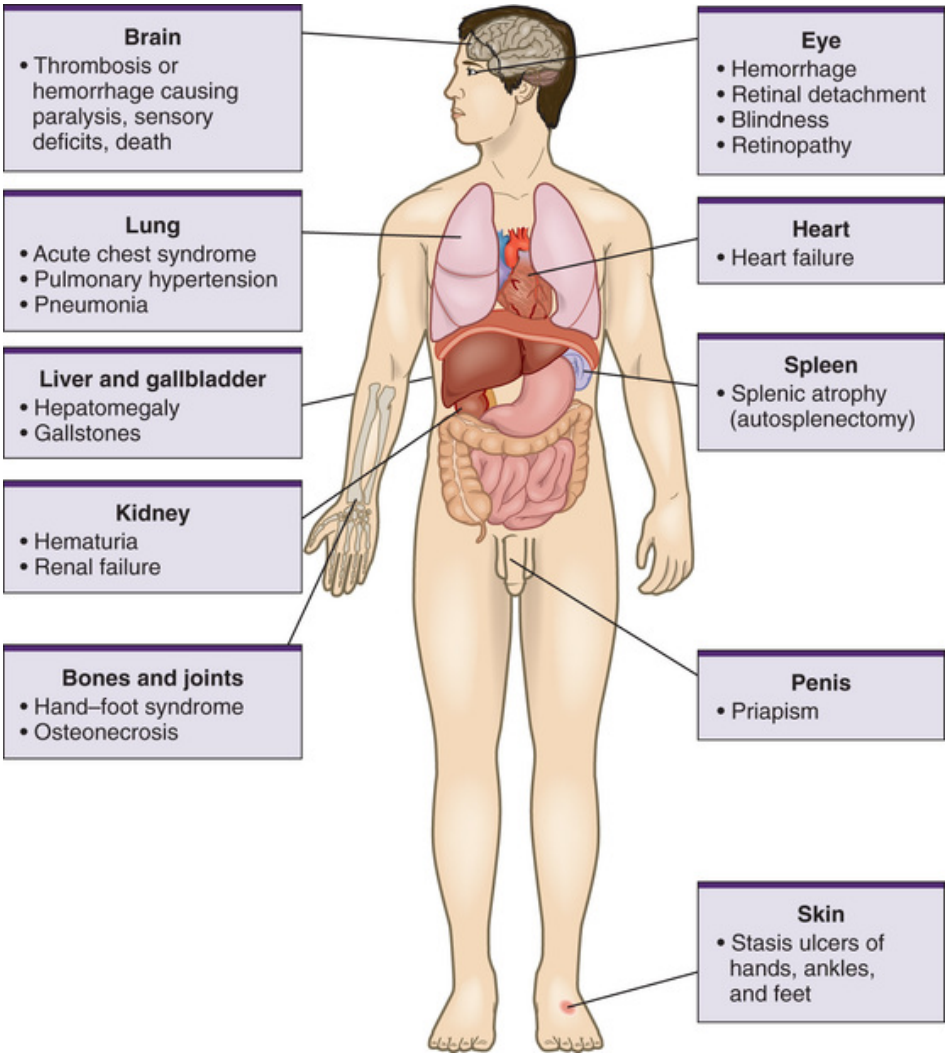

FIGURE 33-3 Clinical manifestations and complications of sickle cell disease. Source: Modified from McCance, K.L., & Huether, S. E. (2014). *Pathophysiology: The biologic basis for disease in adults and children* (7th ed.). St Louis: Mosby.

Pneumonia is the most common infection and often is of pneumococcal origin. Infections can be severe enough to cause an aplastic and hemolytic crisis and gallstones. In turn, an *aplastic crisis* can be so severe as to cause a temporary shutdown of RBC production in the bone marrow.

Acute chest syndrome is a term used to describe acute pulmonary complications that include pneumonia, tissue infarction, and fat embolism. It affects 30% of patients with SCD; is characterized by fever, chest pain, cough, pulmonary infiltrates, and dyspnea; and may be life-threatening. Pulmonary infarctions may cause pulmonary hypertension, MI, HF, and ultimately cor pulmonale. The heart may become ischemic and enlarged, leading to HF. Retinal vessel obstruction may result in hemorrhage, scarring, retinal detachment, and blindness. The kidneys may be injured from the increased blood viscosity and the lack of O_2, which can lead to renal failure. Pulmonary embolism or stroke can result from

thrombosis and infarction of blood vessels. Bone changes may include osteoporosis and osteosclerosis after infarction. Chronic leg ulcers can result from hypoxia and are especially prevalent around the ankles. *Priapism* (persistent penile erection) may occur if penile veins become occluded.

Diagnostic Studies

A peripheral blood smear may reveal sickled cells and abnormal reticulocytes. The presence of HbS can be diagnosed by the sickling test, which uses RBCs (in vitro) and exposes them to a deoxygenation agent. As a result of the accelerated RBC breakdown, the patient has characteristic clinical findings of hemolysis (jaundice, elevated serum bilirubin levels) and abnormal laboratory test results. Hb electrophoresis may be done to determine the proportion of HbS and other variants. Skeletal radiographs demonstrate bone and joint deformities and flattening. Magnetic resonance imaging (MRI) may be used to diagnose a stroke caused by blocked cerebral vessels from sickled cells. Doppler studies may be used to assess for deep venous thromboses. Other tests may be indicated, such as a chest radiograph, to diagnose infection or organ malfunction.

Nursing and Collaborative Management Sickle Cell Disease

Collaborative care for a patient with SCD is directed toward (a) preventing sequelae from the disease, (b) alleviating the symptoms of the disease, (c) minimizing end–target organ damage, and (d) promptly treating serious sequelae, such as acute chest syndrome. Patients with SCD should be taught to minimize triggers of the disease by avoiding high altitudes, avoiding extreme temperatures, minimizing stress, maintaining adequate fluid intake, and treating infections promptly. Ongoing screening is also pertinent to patients with SCD. Screening for retinopathy should begin at age 10. In addition, brain scans (transcranial Doppler examinations) may be recommended. Pneumococcal, *Haemophilus influenzae,* influenza, and hepatitis immunizations should be administered.

Sickle cell crises may require hospitalization. O_2 may be administered to treat hypoxia and control sickling. Because respiratory failure is the most common cause of death, the nurse should be vigilant in assessing for any changes in respiratory status. Rest may be encouraged to reduce metabolic requirements, and deep-vein thrombosis prophylaxis (using anticoagulants) should be prescribed. Fluids and electrolytes are administered to reduce blood viscosity and maintain renal function. Priapism is managed with pain medication, fluids, and nifedipine. If it does not resolve within a few hours, a urologist may inject the corpus cavernosum with a dilute solution of epinephrine to preserve penile function.

Transfusion therapy is indicated when an aplastic crisis occurs; aggressive total RBC exchange transfusion programs may be implemented for patients who have frequent crises, serious complications such as acute chest syndrome or a brain stroke, or both. These patients, like those with thalassemia major, may require chelation therapy to reduce transfusion-produced iron overload.

Undertreatment of sickle cell pain is a major problem. Lack of understanding can lead health care providers to underestimate how much pain these patients suffer. Because of their prior opioid treatment, patients with SCD may be tolerant, and thus large doses may be needed to reduce pain to an acceptable level. During an acute crisis, optimal pain management usually includes large doses of continuous opioid analgesics along with breakthrough analgesia, often in the form of patient-controlled analgesia (PCA). (PCA is discussed in Chapter 10.)

Because patients may experience different types and sites of pain, a multimodal and multidisciplinary approach to pain management is often needed. Adjunctive measures, such as nonsteroidal anti-inflammatory agents, antineuropathic pain medications (e.g., tricyclic antidepressants, antiseizure medications), local anaesthetics, nerve blocks, transelectrodermal nerve stimulator (transcutaneous

electrical nerve stimulation [TENS]), acupuncture, or some combination of these strategies may be used.

Although pain is the most common symptom in patients with SCD seeking medical care, infection is a frequent complication and must be treated. Infections, such as chronic leg ulcers, may be treated with rest, antibiotics, warm saline soaks, debridement, or grafting if necessary. Patients with acute chest syndrome are treated with broad-spectrum antibiotics, O_2 therapy, fluid therapy, and possibly exchange transfusion. Blood transfusions have little, if any, role in the treatment between crises because patients develop antibodies to RBCs and iron overload. However, because chronic hemolysis results in increased utilization of folic acid stores, routine folic acid supplements should be taken.

Although many antisickling drugs have been tried, hydroxyurea (Hydrea) is the only one that has been shown to be clinically beneficial. This drug increases the production of fetal hemoglobin (HbF), decreases the reactive neutrophil count, increases erythrocyte volume and hydration, and alters the adhesion of sickle erythrocytes to the endothelium. The increase in HbF is accompanied by a reduction in hemolysis, an increase in Hb concentration, and a decrease in sickled cells and painful crises (Yawn, Buchanan, Afenyi-Annan, et al., 2014).

Bone marrow transplantation is the only available treatment that can cure some patients with SCD; however, it is very rarely done in Canada. The selection of appropriate recipients, the scarcity of appropriate donors, the risks involved, and the high cost/benefit ratio limit the use of bone marrow transplantation for SCD. (Bone marrow transplants are discussed in Chapter 18.) Patient teaching and support are important in the long-term care of the patient with SCD. The patient and family must understand the basis of the disease and the reasons for supportive care and ongoing screening pertinent to SCD patients, such as eye examinations. The patient must be taught ways to avoid crises, which include taking steps to avoid dehydration and reducing the chance of developing hypoxia (for example, by avoiding high altitudes and seeking medical attention quickly to counteract problems such as upper respiratory tract infections). Education on pain control is also needed because the pain during a crisis may be severe and often requires considerable analgesia. There are several smartphone applications that may help patients and support self-care. For example, a free iPhone app called sickleWell helps with maintaining medication adherence and provides information about symptoms and interventions.

Recurrent episodes of severe acute pain and unrelenting chronic pain can be profoundly disabling and depressing. Occupational therapists and physiotherapists can help the patient achieve optimum physical functioning and independence; a psychologist may be able to use cognitive–behavioural therapy to help patients with SCD cope with anxiety and depression; support groups may also be helpful. Because there are often such additional quality-of-life issues, the nurse can play an important role in ensuring that the patient's needs are met through appropriate referrals.

Genetics in Clinical Practice

Sickle Cell Disease

Genetic Basis

- Autosomal recessive disorder (see Chapter 15, Figure 15-8)
- Mutation in beta-globin gene *(HBB)*; sickle hemoglobin (HbS) on chromosome 11
- Various versions of beta globin result from different mutations in the *HBB* gene
- HbS variant involves substitution of valine for glutamic acid in the beta-globin gene

Incidence

- Most common inherited blood disorder in Canada
- More commonly affects people of African descent
- Also affects people of Mediterranean, Caribbean, South and Central American, Arabian, and Middle Eastern descent
- Affects 8 of every 100 000 people

Genetic Testing

- DNA testing is available.
- Electrophoresis of hemoglobin and sickling screening test are more commonly used.

Clinical Implications

- SCD requires ongoing continuity of care and extensive patient education.
- Sickle cell trait is the carrier state for SCD and represents a mild type of sickle cell disease.
- If both parents have the trait, there is a one in four chance that their child will have SCD.
- Management of SCD should focus on the prevention of sickle cell crisis.
- Genetic counselling is recommended for individuals with a family history of SCD; individuals should understand the risks of transmitting the genetic

mutation.

SCD, sickle cell disease.

Ethical Dilemmas

Pain Management

Situation

A 21-year-old man is admitted to the emergency department in sickle cell crisis with complaints of excruciating pain. He is known to several of the nurses and health care providers in the department. One of the nurses remarks that it must be time for his "fix" of pain medications.

Important Points for Consideration

- The experience of pain is subjective, and experts in pain management agree that "pain is what the patient says it is." The single most reliable indicator of pain is self-report.
- Pain can have serious and debilitating physical and psychological effects. The best possible pain relief should be provided in all circumstances.
- Previous episodes of acute pain or a history of chronic pain can alter physiological and psychological responses to pain and to pain medication. Care should be provided in consultation with the patient and should take into account the patient's history.
- People with pain are often stigmatized because of health care providers' lack of knowledge about pain and about long-term use of opioids or other pain medications. Competent and compassionate care should be provided to all patients.

Clinical Decision-Making Questions

1. How can the nurse educate peers regarding pain assessment and management?
2. What important factors would need to be included in the nurse's assessment and management in consultation with the patient?

Acquired Hemolytic Anemia

Acquired hemolytic anemia results from hemolysis of RBCs from extrinsic factors. These factors can be separated into three categories: (a) physical destruction, (b)

immune reactions, and (c) infectious agents and toxins (see Table 33-2).

Physical destruction of RBCs results from the exertion of extreme force on the cells. Traumatic events causing disruption of the RBC membrane include hemodialysis, extracorporeal circulation used in cardiopulmonary bypass, and prosthetic heart valves. In addition, the force needed to push blood through abnormal vessels, such as those that have been burned, radiated, or affected by vascular disease (e.g., diabetes mellitus) may also physically damage RBCs. RBCs can also be fragmented and destroyed as they try to pass through abnormal arterial or venous microcirculation. The RBCs are sheared as they try to pass by excessive platelet aggregation or fibrin polymer formation, such as seen in thrombotic thrombo-cytopenic purpura (TTP) and disseminated intravascular coagulation (DIC).

Antibodies may destroy RBCs by the mechanisms involved in antigen–antibody reactions. The reactions may be of an isoimmune or autoimmune type. *Isoimmune reactions* occur when antibodies develop against antigens from another individual of the same species—in the case of humans, that is, from another person. Blood transfusion reactions typify this response, when the recipient's antibodies hemolyze donor cells.

Autoimmune reactions result when individuals develop antibodies against their own RBCs. Autoimmune hemolytic reactions may be idiopathic, developing with no prior hemolytic history as a result of the immunoglobulin G (IgG) covering the RBCs, or secondary to other autoimmune diseases (e.g., systemic lupus erythematosus), leukemia, or lymphoma, or reactions to drugs (penicillin, ibuprofen, metformin).

Infectious agents and toxins constitute the third category of acquired hemolytic disorders. Infectious agents foster hemolysis in three ways: (a) by invading the RBC and destroying its contents (e.g., parasites such as in malaria); (b) by releasing hemolytic substances (e.g., *Clostridium perfringens*); and (c) by generating an antigen–antibody reaction (e.g., *Mycoplasma pneumonia*). Various agents may be toxic to RBCs and cause hemolysis. These hemolytic toxins involve chemicals such as oxidative drugs, arsenic, lead, copper, bee stings, and snake venom.

Laboratory findings in hemolytic anemia are presented in Table 33-6. Treatment and management of acquired hemolytic anemias involve general supportive care until the causative agent can be eliminated or at least rendered less injurious to the RBCs. Because a hemolytic crisis is a potential consequence, the nurse must be ready to institute appropriate emergent therapy. This includes aggressive hydration and electrolyte replacement to reduce the risk for kidney injury caused by hemoglobin's clogging the kidney tubules and, subsequently, shock. Additional supportive care may include administering corticosteroids and blood products or removing the spleen. For chronic hemolytic anemia, folate may have to be replaced. To suppress the RBC destruction, immuno-suppressive drugs such as rituximab (Rituxan) may be used.

Hemochromatosis

Hemochromatosis is an iron overload disorder. Although it is primarily caused by a genetic defect, hemochromatosis occurs secondary to diseases such as sideroblastic anemia. It may also be caused by liver disease and the multiple blood transfusions that are used to treat thalassemia and SCD.

The genetic disorder *(hereditary hemochromatosis)* is autosomal recessive and characterized by increased intestinal iron absorption and, as a result, increased tissue iron deposition (see the "Genetics in Clinical Practice" box). In Canada, it is one of the most common genetic disorders (Canadian Hemochromatosis Society, 2013). It most affects Canadians of Northern European descent, with an incidence of 1 in 300. One in 250 to 300 Canadians is at risk of developing the full-blown disease (homozygous with two recessive genes), and approximately one in nine is a potential carrier with one recessive gene (Canadian Hemochromatosis Society, 2013).

Genetics in Clinical Practice

Hemochromatosis

Genetic Basis

- Autosomal recessive disorder
- Caused by mutations in *HAMP*, *HFE*, *HFE2*, *SLC40A1*, and *TFR2* genes
- These genes play an important role in regulating the absorption, transport, and storage of iron
- Mutations in these genes impair the control of the iron absorption during digestion and alter the distribution of iron to other parts of the body; as a result, iron accumulates in tissues and organs

Incidence

- Most common genetic disease in people of European ancestry
- Affects approximately 1 in 300 Canadians of Northern European ancestry
- Very low prevalence in other ethnic populations

Genetic Testing

- Genetic testing is recommended for all first-degree relatives of people with the disease.

- Useful diagnostic tests include serum iron concentration, total iron-binding capacity, and transferrin saturation.
- Liver biopsy, once considered the gold standard diagnostic test, is primarily used to quantify iron deposition and estimate the prognosis and extent of the disease.

Clinical Implications

- Early treatment can prevent serious complications.
- Clinical expression is variable depending on dietary iron, blood loss, and other modifying factors.
- If untreated, progressive iron deposits can lead to multiple organ failure.

The normal range for total body iron is 2 to 6 g. Individuals with hemochromatosis accumulate iron at a rate of 0.5 to 1.0 g each year and may accumulate total iron concentrations exceeding 50 g. Symptoms of hemochromatosis usually develop between 40 and 60 years of age. Early symptoms are nonspecific and include fatigue, arthralgia, erectile dysfunction, abdominal pain, and weight loss. Later, the excess iron accumulates in the liver and causes liver enlargement and eventually cirrhosis. Patients with hemochromatosis are at increased risk for hepato-cellular carcinoma. Other organs also become affected, resulting in diabetes mellitus, skin pigment changes (bronzing), cardiac changes (e.g., cardiomyopathy), arthritis, and testicular atrophy. Physical examination reveals an enlarged liver and spleen and pigmentation changes in the skin. Laboratory values demonstrate an elevated serum iron, TIBC, and serum ferritin. Testing for known genetic mutations confirms the diagnosis. A liver biopsy can quantify the amount of iron and is the definitive way to establish the diagnosis.

The goal of treatment is to remove excess iron from the body and minimize any symptoms the patient may have. Iron removal is achieved by removing 500 mL of blood each week for 2 to 3 years until the iron stores in the body are depleted. Then, less frequent removal of blood is needed to maintain iron levels within normal limits. Iron chelating agents, which form a complex with iron and promote its excretion from the body, may also be used to remove excess iron.

Management of organ involvement (e.g., diabetes mellitus, HF) is the same as conventional treatment for these problems. Dietary modifications, such as avoidance of vitamin C and iron supplements, uncooked seafood, and iron-rich foods, may also assist in the reduction of iron accumulation.

The most common causes of death in people with hemochromatosis are cirrhosis, liver failure, hepatic carcinoma, and cardiac failure. With early diagnosis and treatment, life expectancy is normal. However, many cases go undetected and untreated.

Polycythemia

Polycythemia is an abnormal condition characterized by increased RBCs. This increase in RBCs can be so great that blood circulation is impaired as a result of the increased blood viscosity *(hyperviscosity)* and volume *(hypervolemia).*

Etiology and Pathophysiology

The two types of polycythemia are primary polycythemia (or *polycythemia vera*) and secondary polycythemia (Figure 33-4). Their etiologies and pathogenesis differ, although their complications and clinical manifestations are similar. Polycythemia vera is considered a myeloproliferative disorder arising from a chromosomal mutation (e.g., Janus kinase 2 [JAK2]) in a single pluripotent stem cell. Therefore, not only are RBCs involved but also granulocytes and platelets, leading to increased production of each of these blood cells. The disease develops insidiously and follows a chronic, vacillating course. The median age at diagnosis is 60 years old, and it has a slight male predominance. With polycythemia vera, the patient has enhanced blood viscosity and blood volume and congestion of organs and tissues with blood. These patients have hypercoagulopathies, which predispose them to clotting. Splenomegaly and hepatomegaly are common.

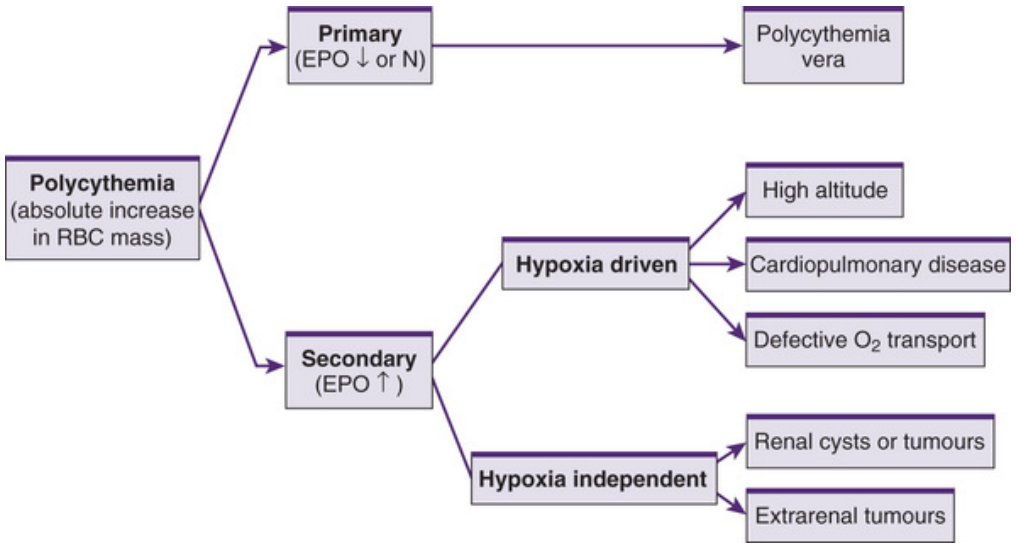

FIGURE 33-4 Differentiating between primary and secondary polycythemia. *EPO,* erythropoietin; *N,* normal; *O_2,* oxygen; *RBC,* red blood cell.

Secondary polycythemia can be either hypoxia driven or hypoxia independent. In the former, hypoxia stimulates erythropoietin (EPO) production in the kidney, which in turn stimulates RBC production. The need for O_2 may be because of high altitude, pulmonary disease, cardiovascular disease, alveolar hypoventilation, defective O_2 transport, or tissue hypoxia. EPO levels may return to normal once the Hb is stabilized at a higher level. In this situation, secondary

polycythemia is a physiological response in which the body tries to compensate for a problem rather than a pathological response. (Hypoxia-driven polycythemia is discussed in the section on chronic obstructive pulmonary disease in Chapter 31.) In hypoxia-independent secondary polycythemia, EPO is produced by malignant or benign tumour tissue. Serum EPO levels often remain elevated in these situations. Splenomegaly does not accompany secondary polycythemia.

Clinical Manifestations and Complications

Circulatory manifestations of polycythemia vera occur because of the hypertension caused by hypervolemia and hyperviscosity. They are often the first symptoms and include subjective complaints of headache, vertigo, dizziness, tinnitus, and visual disturbances. Generalized pruritus (often exacerbated by a hot bath) may be a striking symptom and is related to histamine release from an increased number of basophils. Paresthesias and *erythromelalgia* (painful burning and redness of the hands and feet caused by paroxysmal peripheral dilation of peripheral blood vessels) may also be present. In addition, the patient may experience angina, HF, intermittent claudication, and thrombo-phlebitis, which may be complicated by embolization. These manifestations are caused by blood vessel distension, impaired blood flow, circulatory stasis, thrombosis, and tissue hypoxia caused by the hypervolemia and hyperviscosity. The most common serious complication is stroke secondary to thrombosis.

Hemorrhagic phenomena caused by either vessel rupture from overdistension or inadequate platelet function may result in petechiae, ecchymoses, epistaxis, or GI bleeding. Hemorrhage can be acute and catastrophic. Hepatomegaly and splenomegaly from organ engorgement may contribute to patient complaints of satiety and fullness. The patient may also experience pain from peptic ulcer caused by either increased gastric secretions or liver and spleen engorgement. *Plethora* (ruddy complexion) may also be present. Because uric acid is one of the products of cell destruction, the increase in RBC destruction that accompanies excessive RBC production causes a similar increase in uric acid production, thus leading to hyperuricemia. This problem may cause a form of gout.

Diagnostic Studies

The following laboratory manifestations are seen in a patient with polycythemia vera: (a) elevated Hb and RBC count with microcytosis; (b) low to normal EPO level (secondary polycythemia will have a high level); (c) elevated WBC count with basophilia; (d) elevated platelets (thrombo-cytosis) and platelet dysfunction; (e) elevated leukocyte alkaline phosphatase, uric acid, and cobalamin levels; and (f) elevated histamine levels. Bone marrow examination in polycythemia vera shows hypercellularity of RBCs, WBCs, and platelets. Splenomegaly is found in 90% of patients with primary polycythemia but does not accompany secondary polycythemia.

Collaborative Care

Treatment is directed toward reducing blood volume and viscosity and bone marrow activity. Phlebotomy is the mainstay of treatment. The aim of phlebotomy is to reduce the Hct and keep it less than 45% to 48%. Generally, from the time of diagnosis, 300 to 500 mL of blood may be removed every other day until the Hct is reduced to normal levels. An individual managed with repeated phlebotomies eventually becomes deficient in iron, although this effect is rarely symptomatic. Iron supplementation should be avoided. Hydration therapy is used to reduce the blood's viscosity. Myelosuppressive agents such as busulphan (Myleran) and hydroxyurea (Hydrea) may be given to inhibit bone marrow activity. Interferon alfa may be used in high-risk patients. Targeted therapies such as ruxolitinib (Jakavi), which targets the JAK2 mutation, may be used (Griesshammer, Gisslinger, & Mesa, 2015). Antiplatelet agents, such as acetylsalicylic acid (ASA; Aspirin), may also be used for erythromelalgia or antithrombotic primary prophylaxis. Allopurinol may reduce the number of acute gout attacks, and antihistamines may be used to alleviate pruritus. Anagrelide (Agrylin) may be used to reduce the platelet count and inhibit platelet aggregation.

Nursing Management Polycythemia Vera

Primary polycythemia vera is not preventable. However, because secondary polycythemia is generated by any source of hypoxia, maintaining adequate oxygenation may prevent problems. Therefore, controlling chronic pulmonary disease, stopping smoking, and avoiding high altitudes may be important.

When acute exacerbations of polycythemia vera develop, the nurse has several responsibilities. Depending on the institution's policies, the nurse may assist with or perform the phlebotomy. Fluid intake and output must be evaluated during hydration therapy to avoid fluid overload (which further complicates the circulatory congestion) and underhydration (which can cause the blood to become even more viscous). If myelosuppressive agents are used, the nurse must administer the drugs as ordered, observe the patient, and teach the patient about medication adverse effects.

Assessment of the patient's nutritional status in collaboration with the dietitian may be necessary to offset the inadequate food intake that can result from GI symptoms of fullness, pain, and dyspepsia. Activities, medications, or both must be instituted to decrease thrombus formation. Active or passive leg exercises and ambulation, when possible, should be initiated.

Because of its chronic nature, polycythemia vera requires ongoing evaluation. Phlebotomy may need to be done every 2 to 3 months, reducing the blood volume by about 500 mL each time. The nurse must evaluate the patient for the development of complications.

Although the incidence is low, myelofibrosis and leukemia develop in some patients with polycythemia vera (10% and 5%, respectively). These occurrences may be caused by the chemotherapeutic drugs used to treat the disease, or they may be secondary to a disorder in the stem cells that progresses to erythroleukemia.

Problems of Hemostasis

Hemostasis involves the vascular endothelium, platelets, and coagulation factors, which normally function together to stop hemorrhage and repair vascular injury. (These mechanisms are described in Chapter 32.) Disruption in any of these components may result in bleeding or thrombotic disorders.

Three major disorders of hemostasis discussed in this section are (a) thrombo-cytopenia (low platelet count), (b) hemophilia and von Willebrand disease (inherited disorders of specific clotting factors), and (c) disseminated intravascular coagulation (DIC).

Thrombo-Cytopenia

Etiology and Pathophysiology

Thrombo-cytopenia is a reduction of platelets to an amount below 150×10^9/L or 150 000/mcL. Acute, severe, or prolonged decreases from this normal range can result in abnormal hemostasis that manifests as prolonged bleeding from minor trauma to spontaneous bleeding without injury.

Platelet disorders can be inherited (e.g., Wiskott–Aldrich syndrome), but the vast majority are acquired (Table 33-12). A common cause of acquired abnormalities is the ingestion of certain foods, herbs, or drugs. Although some drugs are directly myelosuppressive (e.g., chemotherapeutic drugs, ganciclovir [Cytovene]), the usual mechanism of acquired thrombo-cytopenia is accelerated platelet destruction caused by drug-dependent antibodies. Antibodies attack the platelets when the offending agent binds to a platelet surface glycoprotein.

TABLE 33-12
CAUSES OF THROMBO-CYTOPENIA

Inherited
• Fanconi's syndrome (pancytopenia) • Hereditary thrombo-cytopenia
Acquired
Immune
• Immune thrombo-cytopenic purpura (ITP) • Neonatal alloimmune thrombo-cytopenia
Nonimmune

• Shortened circulation
  • Thrombotic thrombo-cytopenic purpura (TTP)
  • Disseminated intravascular coagulation (DIC)
  • Heparin-induced thrombo-cytopenia (HIT)
  • Splenomegaly, splenic sequestration
• Turbulent blood flow (hemangiomas, abnormal cardiac valves, intra-aortic balloon pumps)
• Decreased production
  • Drug-induced marrow suppression
  • Chemotherapy
  • Viral infections (hepatitis C virus, HIV, cytomegalovirus)
  • Bacterial infection (sepsis)
  • Alcohol use disorder
  • Bone marrow suppression
  • Myelodysplastic syndrome (MDS)
  • Myelofibrosis
  • Aplastic anemia
  • Hematological malignancy (leukemias, lymphomas, myeloma)
  • Solid tumour infiltrating bone marrow
  • Radiation to the bone

HIV, human immunodeficiency virus.

A careful review of the patient's history can help to identify the causes of thrombo-cytopenia. For example, quinine may cause thrombo-cytopenia and is found in tonic water and in many herbal preparations. In addition, some drugs can affect platelet aggregation. ASA doses as low as 81 mg (a baby Aspirin) can alter the function of circulating platelets. Normal function is restored with the generation of newly formed platelets.

Immune Thrombo-Cytopenic Purpura.

The most common acquired thrombo-cytopenia is a syndrome of abnormal destruction of circulating platelets termed *immune thrombo-cytopenic purpura* (ITP). It was originally termed *idiopathic thrombo-cytopenic purpura* because its cause was unknown. However, it is now known that ITP is an autoimmune disease. In ITP, platelets are coated with antibodies. Although these platelets function normally, when they reach the spleen, the antibody-coated platelets are recognized as foreign and are destroyed by macrophages.

Platelets normally survive 8 to 10 days. However, in ITP, survival of platelets is only 1 to 3 days. Generally, the clinical syndrome manifests as an acute condition in children and a chronic condition in adults.

Thrombotic Thrombo-Cytopenic Purpura.

Thrombotic thrombo-cytopenic purpura (TTP) is an uncommon syndrome characterized by hemolytic anemia, thrombo-cytopenia, neurological abnormalities, fever (in the absence of infection), and renal abnormalities. Not all features are present in all patients. Because it is almost always associated with hemolytic–uremic syndrome (HUS), it is often referred to as TTP–HUS. The disease is associated with enhanced agglutination of platelets, which form microthrombi that deposit in arterioles and capillaries. In most cases, the syndrome is due to the deficiency of a plasma enzyme (ADAMTS-13) that usually breaks down the von Willebrand clotting factor (vWF) into normal size. (vWF is the most important protein that mediates platelet adhesion to damaged endothelial cells.) Without the enzyme, unusually large amounts of vWF attach to activated platelets, thereby promoting platelet aggregation.

TTP is seen primarily in adults between 20 and 50 years of age and has a slight female predominance. The syndrome may be idiopathic (thought to be due to an autoimmune disorder against ADAMTS-13); may be caused by certain drug toxicities, pregnancy, or infection; or may be the result of a known autoimmune disorder such as systemic lupus erythematosus or scleroderma (McCrae, Sadler, & Cines, 2013). TTP is a medical emergency because bleeding and clotting occur simultaneously.

Heparin-Induced Thrombo-Cytopenia and Thrombosis Syndrome.

One of the risks associated with the broad and increasing use of heparin is the development of the life-threatening condition called *heparin-induced thrombo-cytopenia* (HIT), also called *heparin-induced thrombo-cytopenia and thrombosis syndrome* (HITTS). Typically, patients develop thrombo-cytopenia 5 to 10 days after the onset of heparin therapy. HIT should be suspected if the platelet count falls by more than 50% or falls below 150×10^9/L. As many as 3% of patients on heparin therapy develop HIT (Warkentin, 2013).

The major clinical problem of HITTS is venous thrombosis; arterial thrombosis can also develop. Deep venous thromboses and pulmonary emboli most commonly result as a complication of the thromboses. Additional complications may include arterial vascular infarcts resulting in skin necrosis, stroke, and end-organ damage.

In HIT, platelet destruction and vascular endothelial injury are the two major responses to what is believed to be an immune-mediated response to heparin. Platelet factor 4 (PF4) binds to heparin. This complex then binds to the platelet surface, leading to further platelet activation and release of more PF4, thus creating a positive feedback loop. Antibodies are created against this complex, and they are removed prematurely from circulation, leading to thrombo-cytopenia and platelet-fibrin thrombi. Platelet aggregation also induces heparin to be neutralized. Thus, more heparin is required to maintain therapeutic activated partial thromboplastin times (aPTTs).

Clinical Manifestations.

Many patients with thrombo-cytopenia are asymptomatic. The most common symptom is bleeding, usually mucosal or cutaneous. Mucosal bleeding may manifest as epistaxis and gingival bleeding, and large bullous hemorrhages may appear on the buccal mucosa owing to the lack of vessel protection afforded by the submucosal tissue. Bleeding into the skin is manifested as petechiae or superficial ecchymoses (Figure 33-5).

FIGURE 33-5 Acute idiopathic thrombo-cytopenic purpura commonly manifests with purpuric lesions of this kind, although they may often be widespread by the time medical attention is sought. Source: Forbes, C. D., & Jackson, W. F. (2003). *Color atlas and text of clinical medicine* (3rd ed., p. 437). London: Mosby.

Petechiae are small, flat, pinpoint, red or reddish-brown microhemorrhages. When the platelet count is low, RBCs may leak out of the blood vessels and into the skin to cause petechiae. When petechiae are numerous, the resulting reddish skin bruise is called *purpura* (see Figure 33-5). Larger purplish lesions caused by hemorrhage are termed *ecchymoses* (Figure 33-6). Ecchymoses may be flat or raised; pain and tenderness sometimes are present.

FIGURE 33-6 Severe ecchymosis of the left hand.

Prolonged bleeding after routine procedures such as venipuncture or IM injection may also indicate thrombo-cytopenia. Because the bleeding may be internal, the nurse must be aware of manifestations that reflect this type of blood loss, including weakness, fainting, dizziness, tachycardia, abdominal pain, and hypotension.

The major complication of thrombo-cytopenia is hemorrhage. The hemorrhage may be insidious or acute and internal or external. It may occur in any area of the body, including the joints, retina, and brain. Cerebral hemorrhage may be fatal in people with ITP. Insidious hemorrhage may first be detected by discovering the anemia that accompanies blood loss.

Diagnostic Studies

The platelet count is decreased in cases of thrombo-cytopenia. Any reduction below 150×10^9/L or 150 000/mcL may be termed *thrombo-cytopenia*. However, prolonged bleeding from trauma or injury does not usually occur until platelet counts are less than 50×10^9/L or 50 000/mcL. When the count drops below 10×10^9/L or 10 000/mcL, spontaneous, life-threatening hemorrhages (e.g., intracranial bleeding) can occur. Platelet transfusions are generally not recommended until the count is below 10×10^9/L unless the patient is actively bleeding or critically ill with fever or sepsis.

The patient's medical history and clinical examination, along with comparisons of laboratory parameters, help to determine the etiology of the thrombo-cytopenia. Table 33-13 compares the types of thrombo-cytopenia.

TABLE 33-13
COMPARISON OF DISORDERS CAUSING THROMBO-CYTOPENIA

Laboratory Test	ITP	TTP	HIT	DIC
Platelets	↓↓↓	↓↓↓	↓↓	↓↓↓
Hemolysis				
Hb	N	↓↓	N	N, ↓
LDH	N	↑↑↑	N	↑
Reticulocytes	N	↑	N	N, ↑
Haptoglobin	N	↓	N	↓
Indirect bilirubin	N	↑	N	N, ↑
Schistocytes	N	↑↑↑	N, ↑	N, ↑
Coagulopathy				
PT	N	N	N	↑
aPTT	N	N	N	↑
D-dimer	N	N, ↑	↑	↑↑
Other Tests	ITP platelet antigen-specific assay; platelet activation/function assay, *Helicobacter pylori*, bone marrow biopsy	ADAMTS-13	Platelet activation/function assay PF4–heparin complex	

aPTT, activated partial thromboplastin time; *DIC,* disseminated intravascular coagulation; *Hb,* hemoglobin; *HIT,* heparin-induced thrombo-cytopenia; *ITP,* idiopathic thrombo-cytopenic purpura; *LDH,* lactic dehydrogenase; *N,* normal; *PF4,* platelet factor 4; ↑, increased; ↓, decreased; *PT,* prothrombin time; *TTP,* thrombotic thrombo-cytopenic purpura.

Laboratory tests that assess secondary hemostasis or coagulation, such as the prothrombin time (PT) and aPTT, can yield normal results even in severe thrombo-cytopenia. Elevated values may point toward DIC. Specific assays, such as the ITP antigen-specific assay, platelet activation/function assay, or PF4–heparin complex for HIT, can be done to assist with the diagnosis. In TTP, testing for deficiency of ADAMTS-13 is not always diagnostic, so an increase of lactic dehydrogenase (LDH) is used to help establish the diagnosis. When thrombo-cytopenia occurs with anemia characterized by altered RBC morphology, including *spherocytes* (small, globular, completely hemoglobinated erythrocytes), fragmented cells *(schistocytes),* and pronounced reticulocytosis, a diagnosis of TTP should be suspected. These findings are partially a result of intravascular fibrin deposition causing a "slicing" of RBCs. In TTP, thrombo-cytopenia may be severe, but coagulation studies are normal.

Examination of the peripheral blood smear may help distinguish acquired disorders such as ITP and TTP from congenital disorders, which may be indicated by abnormally sized platelets. Bone marrow examination is done to rule out production problems as the cause of thrombo-cytopenia (e.g., leukemia, aplastic anemia, other myeloproliferative disorders). It is performed if the other tests are inconclusive, especially in older patients suspected of having an underlying bone marrow disorder. When destruction of circulating platelets is the cause, bone marrow analysis shows *megakaryocytes* (precursors of platelets) to be normal or increased, even though circulating platelets are reduced. The absence or decreased numbers of megakaryocytes on bone marrow biopsy is consistent with

thrombo-cytopenia caused by decreased bone marrow production (e.g., aplastic anemia).

Collaborative Care

Collaborative care of thrombo-cytopenia differs according to the etiology of the thrombo-cytopenia. Discussion of management strategies for these different etiologies appears in Table 33-14.

TABLE 33-14
COLLABORATIVE CARE
Thrombo-Cytopenia

Diagnostic	***Thrombotic Thrombo-Cytopenic Purpura***
• History and physical examination	• Identification and treatment of cause
• Bone marrow aspiration and biopsy	• Plasmapheresis (plasma exchange)
• CBC including platelet count	• High-dose corticosteroids
• Specific laboratory studies	• Splenectomy
Collaborative Therapy	• Chemotherapy (e.g., vincristine, vinblastine)
Immune Thrombo-Cytopenic Purpura	• Immuno-suppressives (e.g., cyclophosphamide [Procytox], rituximab [Rituxan])
• Corticosteroids	***Heparin-Induced Thrombo-Cytopenia***
• Intravenous immunoglobulin (IVIG)	• Discontinuation of heparin
• Anti-Rho(D)	• Direct thrombin inhibitor (e.g., dabigatran [Pradaxa])
• Romiplostim (Nplate)	• Indirect thrombin inhibitor (e.g., fondaparinux [Arixtra])
• Eltrombopag (Revolade)	• Plasmapheresis (plasma exchange)
• Tranexamic acid	• Warfarin (Coumadin)
• Platelet transfusions (if life-threatening)	• Thrombolytic agents
• Vaccination (pneumococcal, meningococcal, *Haemophilus influenzae* B)	***Decreased Platelet Production***
• Danazol (Cyclomen)	• Identification and treatment of cause
• Immuno-suppressives (e.g., rituximab [Rituxan], cyclosporin)	• Corticosteroids
• High-dose cyclophosphamide (Procytox) or combination chemotherapy	• Platelet transfusions
• Splenectomy	

CBC, complete blood count.

Immune Thrombo-Cytopenic Purpura.

Multiple therapies are used to manage the patient with ITP. If the patient is asymptomatic, therapy may not be used unless the patient's platelet count is less than 10×10^9/L or 10 000/mcL. Corticosteroids (e.g., prednisone) are used to treat ITP because of their ability to suppress the phagocytic response of splenic macrophages. This suppression alters the spleen's recognition of platelets and increases the lifespan of the platelets. In addition, corticosteroids depress antibody formation and reduce capillary leakage.

Splenectomy is indicated if the patient does not respond to prednisone initially or requires unacceptably high doses to maintain an adequate platelet count. A splenectomy results in a complete or partial remission in approximately 60% to 70% of patients. The effectiveness of splenectomy is based on four factors. First, the spleen contains an abundance of the macrophages that sequester and destroy platelets. Second, structural features of the spleen enhance the interaction

between antibody-coated platelets and macrophages. Third, some antibody synthesis occurs in the spleen; thus, antiplatelet antibodies decrease after splenectomy. Fourth, the spleen normally sequesters approximately one-third of the platelets, so its removal increases the number of platelets in circulation.

High doses of IV immunoglobulin (IVIG) and a component of IVIG, anti-Rho(D) (anti-D, WinRho), may be used to treat the patient who is unresponsive to corticosteroids or splenectomy. These agents work by competing with the antiplatelet antibodies for macrophage receptors. They effectively raise the platelet count, but the beneficial effects are temporary. Rituximab (Rituxan) may be used for its ability to lyse activated B cells, thereby reducing the immune recognition of platelets.

Romiplostim (Nplate) is used for patients with chronic ITP who have had an insufficient response to the other treatments or who have a contraindication to splenectomy. As a thrombopoietin receptor agonist, this medication increases platelet production. Danazol (Cyclomen), an androgen, may be used along with steroids in some patients. Although the mechanism is not totally understood, danazol reduces the ability of the body to remove antibody-coated platelets from the blood. Immuno-suppressive therapy may be used in refractory cases (see Table 33-14).

Platelet transfusions may be used to increase platelet counts in cases of life-threatening hemorrhage. Platelets should not be given prophylactically because of the possibility of antibody formation. The usual indication for administering platelets is a platelet count less than 10×10^9/L or 10 000/mcL or the presence of bleeding before a procedure.

Thrombotic Thrombo-Cytopenic Purpura.

TTP may be treated in a variety of ways. The first step is to treat the underlying disorder (e.g., infection) or to remove the causative agent, if identified. If untreated, TTP usually results in irreversible renal failure and death. Plasma exchange (plasmapheresis) (see Chapter 16) is used to aggressively reverse platelet consumption by supplying the appropriate vWF and enzyme (ADAMTS-13) and removing the large vWF molecules binding with the platelets. Treatment should be continued daily until the patient's counts normalize and hemolysis has ceased. Corticosteroids may be added to this treatment. Monoclonal antibody therapy (e.g., rituximab), immuno-suppressants (e.g., cyclosporine or cyclophosphamide), and splenectomy have also been used with success. The administration of platelets is generally contraindicated because it may lead to new vWF-platelet complexes and increased clotting.

Heparin-Induced Thrombo-Cytopenia and Thrombosis Syndrome.

Heparin must be discontinued when HITTS is first recognized, and heparin flushes for vascular catheters should be stopped.

To maintain anticoagulation, the patient should be started on a direct thrombin inhibitor, such as dabigatran (Pradaxa). Warfarin (Coumadin) should be started

only when the platelet count has reached 150×10^9/L. If clotting is severe, the most commonly used treatment modalities are plasmapheresis to clear the platelet-aggregating IgG from the blood, protamine sulphate to interrupt the circulating heparin, thrombolytic agents to treat the thrombo-embolic events, and surgery to remove clots. Platelet transfusions are not effective because they may enhance thrombo-embolic events. Patients who have had HITTS should never be given heparin or low-molecular-weight heparin.

Acquired Thrombo-Cytopenia From Decreased Platelet Production.

The management of acquired thrombo-cytopenia is based on identifying the cause and treating the disease or removing the causative agent. If the precipitating factor is unknown, the patient may receive corticosteroids. Platelet transfusions are given if life-threatening hemorrhage develops. Splenectomy is not used because the spleen does not contribute to this type of thrombo-cytopenia.

Often, acquired thrombo-cytopenia is caused by another underlying condition (e.g., aplastic anemia, leukemia) or therapy used to treat another problem. For example, in acute leukemia, all blood cell types may be depressed. In addition, the patient may receive chemotherapeutic drugs that cause bone marrow suppression. If the patient can be adequately supported throughout the course of chemotherapy-induced thrombo-cytopenia, the thrombo-cytopenia will also resolve.

Nursing Management Thrombo-Cytopenia

Nursing Assessment

Subjective and objective data that should be obtained from a patient with thrombo-cytopenia are presented in Table 33-15.

TABLE 33-15

NURSING ASSESSMENT
Thrombo-Cytopenia

Subjective Data
Important Health Information
Past health history: Recent hemorrhage, excessive bleeding, or viral illness; HIV infection; cancer (especially leukemia or lymphoma); aplastic anemia; systemic lupus erythematosus; cirrhosis; exposure to radiation or toxic chemicals; disseminated intravascular coagulation; family history of bleeding problems *Medications:* e.g., chemotherapeutic drugs, furosemide, gold, penicillin *Surgeries or other treatments:* Recent surgery, splenectomy
Symptoms
• Bleeding gingiva; coffee-ground or bloody vomitus; epistaxis; hemoptysis; easy bruising, hematuria; dark or bloody stools; menorrhagia, metrorrhagia • Headache; fatigue, weakness, general malaise; fainting • Dyspnea • Fever
Objective Data
General
Fever, lethargy
Integumentary
Petechiae, ecchymoses, purpura
Gastro-Intestinal
Splenomegaly, abdominal distension, guaiac-positive stools
Possible Findings
Platelet count < 150×10^9/L (150 000/mcL) or prolonged bleeding time, decreased hemoglobin and hematocrit; normal or increased megakaryocytes in bone marrow examination

HIV, human immunodeficiency virus.

Nursing Diagnoses

Nursing diagnoses for the patient with thrombo-cytopenia may include but are not limited to the following:

- *Risk for impaired oral mucous membrane integrity* as evidenced by *decrease in platelets and treatment regimen*
- *Risk for bleeding* as evidenced by *inherent coagulopathy*
- *Deficient knowledge* related to *insufficient information, insufficient knowledge of resources*

Additional information on nursing diagnoses is presented in NCP 33-2, available on the Evolve website.

Planning

The overall goals are that the patient with thrombo-cytopenia will (a) have no gross or occult bleeding, (b) maintain vascular integrity, and (c) manage home care to prevent any complications related to an increased risk for bleeding.

Nursing Implementation

Health Promotion.

It is important for the nurse to discourage excessive use of over-the-counter medications known to be possible causes of acquired thrombo-cytopenia. Many medications contain ASA (Aspirin) as an ingredient. ASA reduces platelet adhesiveness, thus contributing to bleeding. It is also important for the nurse to encourage people to have a complete medical evaluation if manifestations of bleeding tendencies (e.g., prolonged epistaxis, petechiae) develop. In addition, the nurse must observe for early signs of thrombo-cytopenia in the patient receiving chemotherapeutic drugs.

Acute Intervention.

The goal during acute episodes of thrombo-cytopenia is to prevent or control hemorrhage (see NCP 33-2 on the Evolve website). In the patient with thrombo-cytopenia, bleeding is usually from superficial sites; deep bleeding (into muscles, joints, and abdomen) usually occurs only when clotting factors are diminished. It is important to emphasize to the patient that a seemingly minor nosebleed or new petechiae may indicate potential hemorrhage and that the health care provider should be notified. Bleeding from the posterior nasopharynx may be difficult to detect because the blood may be swallowed. If a subcutaneous injection is unavoidable, a small-gauge needle should be used and direct pressure applied for at least 5 to 10 minutes after injection; application of an ice pack may also be helpful; IM injections should be avoided. The patient needs to understand the importance of adherence to self-care measures that reduce the risk of bleeding (Table 33-16).

TABLE 33-16

PATIENT & CAREGIVER TEACHING GUIDE
Thrombo-Cytopenia

This instruction sheet explains precautions you should take to protect yourself when your platelet count is low. Please make sure to ask your health care provider about specific precautions you should take that relate to your bleeding risk factors.

• Notify your health care provider of any manifestations of bleeding. These include the following:
  • Black, tarry, or bloody bowel movements
  • Black or bloody vomit, sputum, or urine
  • Bruising or small red or purple spots on the skin
  • Bleeding from the mouth or anywhere in the body
  • Headache or changes in how well you can see
  • Difficulty talking, sudden weakness of an arm or leg, confusion
• Ask your health care provider about restrictions in your normal activities, such as vigorous exercise, lifting weights, and so on. Generally, walking can be done safely and should be done while wearing sturdy shoes or slippers. If you are weak and at risk for falling, get help or supervision when getting out of bed.
• Do not blow your nose forcefully; gently pat it with a tissue if needed. For a nosebleed, keep your head up and apply firm pressure to the nostrils and the bridge of your nose. If bleeding continues, place an ice bag over the bridge of your nose and the nape of your neck. If you are unable to stop a nosebleed after 10 minutes, call your health care provider.
• Do not bend down with your head lower than your waist.
• Prevent constipation by drinking plenty of fluids, and do not strain when having a bowel movement. Your health care provider may prescribe a stool softener. Do not use a suppository, an enema, or a rectal thermometer without the permission of your health care provider.
• Shave only with an electric razor; do not use blades.
• Do not pluck your eyebrows or other body hair.
• Do not puncture your skin, such as by getting tattoos or body piercing.
• Avoid using any medication (e.g., ASA [Aspirin]) or herbal product that can prolong clotting time. If you are unsure about a connection between any medication or herbal product and your thrombo-cytopenia, check with your health care provider or pharmacist.
• Use a soft-bristle toothbrush to prevent injuring the gums. Flossing is also usually safe if it is done gently using the thin tape floss. Do not use alcohol-based mouthwashes because they can dry your gums and increase bleeding.
• Women: If you are menstruating, keep track of the number of pads that you use per day. When you start using more pads per day than usual or bleed more days, notify your health care provider. Do not use tampons; use sanitary pads only.
• Ask your health care provider before you have any invasive procedures done, such as a dental cleaning, manicure, or pedicure.

ASA, acetylsalicylic acid.

In a woman with thrombo-cytopenia, the amount and duration of menstrual blood loss may exceed the usual. Counting sanitary napkins used during menses is another important intervention to detect excess blood loss. Fifty millilitres of blood will completely soak a sanitary napkin. Suppression of menses with hormonal agents may be indicated during predictable periods of thrombo-cytopenia to reduce blood loss from menses (e.g., during chemotherapy and bone marrow transplantation).

Closely monitor the platelet count, coagulation studies, hemoglobin, and hematocrit. Together these provide important information regarding potential or actual bleeding.

The proper administration of platelet transfusions is an important nursing responsibility. This is discussed under Blood Component Therapy later in this chapter.

Ambulatory and Home Care.

The patient with ITP who is receiving treatment should be monitored for response to therapy. The person with acquired thrombo-cytopenia must be

taught to avoid causative agents when possible (see Table 33-12). If the causative agents cannot be avoided (e.g., chemotherapy), the patient should learn to avoid injury or trauma during these periods and to detect the clinical signs and symptoms of bleeding caused by thrombo-cytopenia (see Table 33-16). Patients with either ITP or acquired thrombo-cytopenia should have periodic medical evaluations so the health care provider can assess the patient's status and intercede in situations in which exacerbations and bleeding are likely to occur. The impact of either an acute or a chronic condition on the patient's quality of life should also be addressed appropriately.

Evaluation.

The expected outcomes for the patient with thrombo-cytopenia are presented in NCP 33-2, available on the Evolve website.

Hemophilia and von Willebrand Disease

Hemophilia is an X-linked recessive genetic disorder caused by defective or deficient coagulation factor (see the "Genetics in Clinical Practice" box later in this chapter, and Figure 15-10). (X-linked genetic disorders are discussed in Chapter 15.) The two major forms of hemophilia, which can occur in mild to severe forms, are hemophilia A (classic hemophilia, factor VIII deficiency) and hemophilia B (Christmas disease, factor IX deficiency); von Willebrand disease is a related disorder involving a deficiency of the von Willebrand coagulation protein. Factor VIII is synthesized in the liver and circulates as a complex with vWF.

Genetics in Clinical Practice

Hemophilia A and B

Genetic Basis

- X-linked recessive disorder
- *Hemophilia A:* Caused by mutations in the *F8* gene that provide instructions for making coagulation factor VIII
- *Hemophilia B:* Caused by mutations in the *F9* gene that provides instructions for making coagulation factor IX
- Mutations in the *F8* or *F9* gene lead to the production of an abnormal version of or reduced amounts of these coagulation factors.

Incidence

- *Hemophilia A:* 1 in 5 000 to 10 000 male births
- *Hemophilia B:* 1 in 30 000 to 50 000 male births

Genetic Testing

- Possible with DNA technology

Clinical Implications

- Female carriers will transmit the genetic defect to 50% of their sons, and 50% of their daughters will be carriers.
- Men with hemophilia will not transmit the genetic defect to their sons, but all of their daughters will be carriers.
- Female hemophilia can occur if a man with hemophilia mates with a female carrier. However, it is a rare occurrence.
- Clinical manifestations of hemophilias A and B are very similar.
- Replacement therapy is available for factors VIII and IX (see Table 33-19).

Hemophilia A is the most common form of hemophilia, accounting for approximately 80% of all cases. In Canada, both hemophilia A and hemophilia B are rare disorders. About 2 500 Canadians are known to be affected by hemophilia A and about 500 Canadians by hemophilia B. von Willebrand disease is considered the most common congenital bleeding disorder and is estimated to affect as many as 1 in 1 000 Canadians (Canadian Hemophilia Society, 2016). This disease can exist in mild to severe forms; however, life-threatening hemorrhage is rare. The deficiency and inheritance patterns of these three forms of inherited coagulopathies are compared in Table 33-17.

TABLE 33-17

COMPARISON OF TYPES OF HEMOPHILIA

Disorder	Deficiency	Inheritance Pattern
Hemophilia A	Factor VIII	Recessive X-linked (transmitted by female carriers, displayed almost exclusively in men)
Hemophilia B	Factor IX	Recessive X-linked (transmitted by female carriers, displayed almost exclusively in men)
von Willebrand disease	vWF; variable factor VIII deficiencies and platelet dysfunction	Autosomal dominant, seen in both genders Recessive (in severe forms of the disease)

vWF, von Willebrand's factor.

Clinical Manifestations and Complications

Clinical manifestations and complications related to hemophilia include (a) slow, persistent, prolonged bleeding from minor trauma and small cuts; (b) delayed

bleeding after minor injuries (the delay may be several hours or days); (c) uncontrollable hemorrhage after dental extractions or irritation of the gingiva with a hard-bristle toothbrush; (d) epistaxis, especially after a blow to the face; (e) GI bleeding from ulcers and gastritis; (f) hematuria from GU trauma and splenic rupture resulting from falls or abdominal trauma; (g) ecchymoses and subcutaneous hematomas (Figure 33-7); (h) neurological signs, such as pain, anaesthesia, and paralysis, that may develop from nerve compression caused by hematoma formation; and (i) hemarthrosis (bleeding into the joints) (Figure 33-8), which may lead to joint deformity severe enough to cause crippling (most commonly in knees, elbows, shoulders, hips, and ankles).

FIGURE 33-7 Severe ecchymoses in a person with hemophilia following a fall. Source: Courtesy Peter Bonner.

FIGURE 33-8 Acute hemarthrosis of the knee is a common complication of hemophilia. Source: Forbes, C. D., & Jackson, W. F. (2003). *Color atlas and text of clinical medicine* (3rd ed., p. 441). London: Mosby.

These symptoms in children may lead to diagnosis during childhood. In adults, these developments may be the first sign of a mild form of the disease that escaped detection because of a childhood free of major injuries, dental procedures, or surgeries. All clinical manifestations relate to bleeding, and any bleeding episode in people with hemophilia may lead to a life-threatening hemorrhage.

Treatment rationales will depend on the severity of the hemophilia and the amount of the respective factor that is missing. About 80% of people with hemophilia have severe disease whereby they will have excessive bleeding after injuries or surgery and can also have spontaneous bleeding episodes. About 10% of people with hemophilia have moderate disease. Another 10% of people with hemophilia have mild disease, which may not even be detected until excessive bleeding is noted after surgery or a severe injury.

Diagnostic Studies

Laboratory studies are used to determine the type of hemophilia present. Any factor deficiency within the intrinsic system (factors VIII, IX, XI, or XII or vWF) will yield the laboratory results presented in Table 33-18.

TABLE 33-18

LABORATORY RESULTS IN HEMOPHILIA

Test	Comments
Prothrombin time	Normal. No involvement of extrinsic system.
Thrombin time	Normal. No impairment of thrombin–fibrinogen reaction.
Platelet count	Normal. Adequate platelet production.
Partial thromboplastin time	Prolonged because of deficiency in any intrinsic clotting system factor.
Bleeding time	Prolonged in von Willebrand disease because of structurally defective platelets; normal in hemophilias A and B because platelets not affected.
Factor assays	Reduction of factor VIII in hemophilia A; vWF in von Willebrand disease; factor IX in hemophilia B.

vWF, von Willebrand factor.

Collaborative Care

The goals of collaborative care are to prevent and treat bleeding. Collaborative care for people with hemophilia or von Willebrand disease requires (a) preventive care, (b) the use of replacement therapy during acute bleeding episodes and as prophylaxis, and (c) the treatment of the complications of the disease and its therapy.

Replacement of deficient clotting factors is the primary means of supporting a patient with hemophilia. In addition to treating acute crises, replacement therapy may be given before surgery and dental care as a prophylactic measure (Oldenburg & Brackmann, 2014). Examples of replacement therapy are listed in Table 33-19. Fresh-frozen plasma, once commonly used for replacement therapy, is rarely used today.

TABLE 33-19

Source: Adapted from Canadian Hemophilia Society. (2016). *Clotting factor concentrates*. Retrieved from *http://www.hemophilia.ca/en/bleeding-disorders/clotting-factor-concentrates*.

For mild hemophilia A and certain subtypes of von Willebrand disease, desmopressin acetate (also known as DDAVP), a synthetic analogue of vasopressin, may be used to stimulate an increase in factor VIII and vWF. This medication acts on platelets and endothelial cells to cause the release of vWF, which subsequently binds with factor VIII, thus increasing their concentration. It can be administered intravenously, subcutaneously, or intranasally. Beneficial effects (e.g., decreased bleeding time) of DDAVP, when administered by IV, are seen within 30 minutes and can last for more than 12 hours. Because the effect of DDAVP is relatively short-lived, the patient must be closely monitored, and repeated doses may be necessary. It is an appropriate therapy for minor bleeding episodes and dental procedures. The intranasal form may be indicated for home therapy for some patients with mild to moderate forms of the disease.

Antifibrinolytic therapy (e.g., tranexamic acid [Cyklokapron]) inhibits fibrinolysis by inhibiting plasminogen activation in the fibrin clot, thereby enhancing clot stability. These agents are used to stabilize clots in areas of increased fibrinolysis, such as the oral cavity, and in patients with difficult-to-manage episodes of epistaxis and menorrhagia. Topical thrombin and fibrin sealants may also be used for mucosal bleeding.

Complications of treatment of hemophilia include development of inhibitors to factors VIII or IX, transfusion-transmitted infectious disorders, allergic reactions, and, with the use of factor IX, thrombotic complications, because it contains activated coagulation factors. Patients with vWF may also develop alloantibodies against vWF, the infusion of which could cause life-threatening anaphylaxis; thus, replacement factors for these patients should be devoid of vWF. The most common difficulties with acute management are starting factor replacement therapy too late and stopping it too soon. Generally, minor bleeding episodes should be treated for at least 72 hours. Surgery and traumatic injuries may need more prolonged therapy. Chronically, development of inhibitors to the factor products has occurred and necessitates individualized expert patient management.

Designated treatment centres have been established in Canada as well as in many other countries to provide multidisciplinary care of hemophilia and related disorders. Gene therapy has been used on an experimental basis to treat hemophilia. (Gene therapy is discussed in Chapter 15.)

Nursing Management Hemophilia

Nursing Implementation

Health Promotion.

Genetic counselling referral is especially important now that many people with hemophilia live into adulthood. Reproductive concerns and long-term effects are issues that the nurse should include in the patient's care plan.

Acute Intervention.

Interventions are related primarily to controlling bleeding and include the following:

1. Stop the topical bleeding as quickly as possible by applying direct pressure or ice, packing the area with fibrin foam or Gelfoam, and applying a topical hemostatic medication such as thrombin.
2. Administer the specific coagulation factor to raise the patient's level of the deficient coagulation factor. Monitor the patient for signs and symptoms, such as hypersensitivity.
3. When joint bleeding occurs, in addition to administering replacement factors, it is important to totally rest the involved joint to prevent crippling deformities from hemarthrosis. Pack the joint in ice. Analgesics (e.g., acetaminophen [Tylenol], codeine) are given to reduce severe pain. However, ASA (Aspirin) and ASA-containing compounds should never be used. As soon as bleeding ceases, it is important to encourage mobilization of the affected area through range-of-motion exercises and physical therapy. Weight bearing is avoided until all swelling has resolved and muscle strength has returned.
4. Manage any life-threatening complication that may develop as a result of hemorrhage or adverse effects from coagulation factors or other medications, such as hyponatremia from use of desmopressin. For example, nursing interventions may include preventing or treating airway obstruction from hemorrhage into the neck and pharynx or assessing and treating intracranial bleeding.

Ambulatory and Home Care.

Home management is a primary consideration for the patient with hemophilia because the disease follows a progressive, chronic course. The quality and the length of life may be significantly affected by the patient's knowledge of the illness and how to live with it. The patient and family can be referred to a local treatment centre or the provincial chapter of the Canadian Hemophilia Society to encourage associations with other individuals who are dealing with the problems of hemophilia. The nurse must provide ongoing assessment of the patient's adaptation to the illness. Psychosocial support and assistance should be readily available as needed.

Most of the needed long-term care measures are related to patient teaching. The patient with hemophilia must be taught to recognize disease-related problems and to know which problems can be resolved at home and which necessitate hospitalization. Immediate medical attention is required for severe pain or swelling of a muscle or joint that restricts movement or inhibits sleep and for a head injury, a swelling in the neck or the mouth, abdominal pain, hematuria, melena, and skin wounds in need of suturing.

Daily oral hygiene must be performed without causing trauma. Understanding how to prevent injuries is another consideration. The patient can learn to participate in noncontact sports (e.g., golf) and wear gloves when doing household chores to prevent cuts or abrasions from knives, hammers, and other tools. The patient should wear medical alert identification to ensure that health care providers know about the hemophilia in case of an accident. Patients or their caregivers may also be taught to self-administer the factor replacement therapies at home.

Evaluation

The overall expected outcomes are similar to those for the patient with thrombo-cytopenia and are presented in NCP 33-2 (see the Evolve website).

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a serious bleeding and thrombotic disorder. It results from the abnormally initiated and accelerated clotting and anticlotting processes that occur in response to disease or injury. The term *disseminated intravascular coagulation* can be misleading because it suggests that blood is clotting. In fact, the paradox of

this condition is that it is characterized by the profuse bleeding resulting from the depletion of platelets and clotting factors. An underlying disease or condition always causes DIC. The underlying disease must be treated for the DIC to resolve.

Etiology and Pathophysiology

DIC is not a disease; it is an abnormal response of the normal clotting cascade stimulated by a disease process or disorder. The diseases and disorders known to predispose a patient to DIC are listed in Table 33-20. DIC can occur as an acute, catastrophic condition, or it may exist at a subacute or chronic level. Each condition may have one or multiple triggering mechanisms to start the clotting cascade. For example, tumours and traumatized or necrotic tissue release tissue factors into circulation. Endotoxin from Gram-negative bacteria activates several steps in the coagulation cascade.

TABLE 33-20
PREDISPOSING CONDITIONS TO DEVELOPMENT OF DISSEMINATED INTRAVASCULAR COAGULATION

Acute Disseminated Intravascular Coagulation	• Tissue damage
• Shock	• Extensive burns and trauma
• Hemorrhagic	• Heatstroke
• Cardiogenic	• Severe head injury
• Anaphylactic	• Transplant rejections
• Septicemia	• Postoperative damage, especially after extracorporeal membrane oxygenation
• Hemolytic processes	• Fat and pulmonary emboli
• Transfusion of mismatched blood	• Snakebites
• Acute hemolysis from infection or immunological disorders	• Glomerulonephritis
• Obstetric conditions	• Acute anoxia (e.g., after cardiac arrest)
• Abruptio placentae	• Prosthetic devices
• Amniotic fluid embolism	• Fulminant hepatitis
• Septic abortion	**Subacute Disseminated Intravascular Coagulation**
• HELLP syndrome	• Malignant disease
• Malignancies	• Myeloproliferative and lymphoproliferative malignancies
• Acute leukemia	• Metastatic cancer
• Lymphoma	• Obstetric: retained dead fetus
• Metastatic solid tumours	**Chronic Disseminated Intravascular Coagulation**
	• Liver disease
	• Systemic lupus erythematosus
	• Localized malignancy

HELLP, **h**emolysis, **e**levated **l**iver enzymes, **l**ow **p**latelet count.

Tissue factor is released at the site of tissue injury and by some malignancies, such as leukemia, and enhances normal coagulation mechanisms. Abundant intravascular thrombin, the most powerful coagulant, is produced (Figure 33-9). It catalyzes the conversion of

fibrinogen to fibrin and enhances platelet aggregation. With widespread fibrin and platelet deposition in capillaries and arterioles, thrombosis results and can lead to multiorgan failure. In addition, clotting inhibitory mechanisms, such as antithrombin III (AT III) and protein C, are depressed. This excessive clotting activates the fibrinolytic system, which in turn breaks down the newly formed clot, creating *fibrin split products* (FSPs; also called *fibrin degradation products* [FDPs]). These products have anticoagulant properties and inhibit normal blood clotting. Ultimately, with FSPs accumulating and clotting factors being depleted, the blood loses its ability to clot. Therefore, a stable clot cannot be formed at injury sites, which predisposes the patient to hemorrhage.

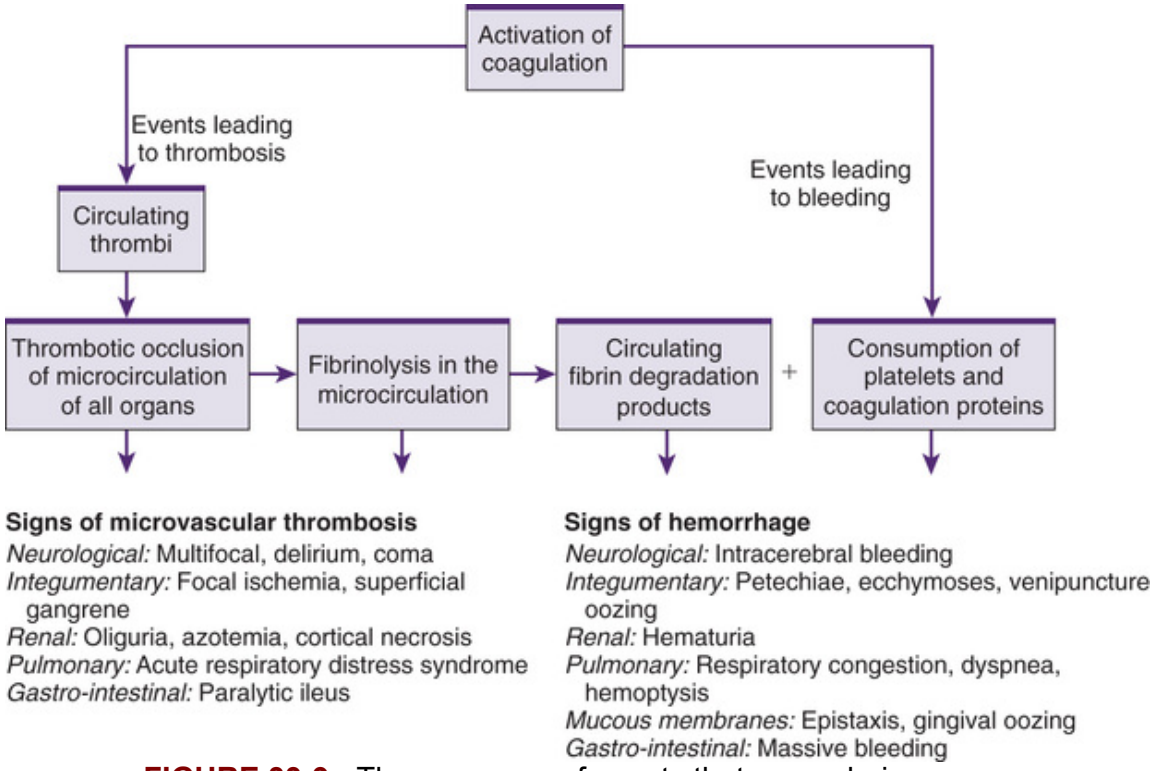

FIGURE 33-9 The sequence of events that occur during disseminated intravascular coagulation.

Chronic and subacute DIC are most commonly seen in patients with longstanding illnesses such as malignant disorders or autoimmune diseases. Occasionally, these patients have subclinical disease manifested only by laboratory abnormalities. However, the clinical spectrum ranges from easy bruising to hemorrhage and from hypercoagulability to thrombosis.

Clinical Manifestations

There are both bleeding and thrombotic manifestations in DIC. Bleeding manifestations of DIC are multifactorial (see Figure 33-9) and result from consumption and depletion of platelets and coagulation factors as well as from clot lysis and formation of FSPs that have anticoagulant properties. Bleeding manifestations include (a) integumentary manifestations, such as pallor, petechiae, purpura (Figure 33-10), oozing blood, venipuncture site bleeding, hematomas, and occult hemorrhage; (b) respiratory manifestations, such as tachypnea, hemoptysis, and orthopnea; (c) cardiovascular manifestations, such as tachycardia and hypotension; (d) GI manifestations, such as upper and lower GI bleeding, abdominal distension, and bloody stools; (e) urinary manifestations, such as hematuria; (f) neurological manifestations, such as vision changes, dizziness, headache, changes in mental status, and irritability; and (g) musculo-skeletal complaints, such as bone and joint pain.

FIGURE 33-10 Disseminated intravascular coagulation resulting from staphylococcal septicemia. Note the characteristic skin hemorrhage ranging from small purpuric lesions to larger ecchymoses. Source: Forbes, D. D., & Jackson, W. F. (2003). *Color atlas and text of clinical medicine* (3rd ed., p. 443). London: Mosby.

Thrombotic manifestations are a result of fibrin or platelet deposition in the microvasculature (see Figure 33-9). They include (a) integumentary changes, such as cyanosis, ischemic tissue necrosis (e.g., gangrene), and hemorrhagic necrosis; (b) respiratory changes, such as tachypnea, dyspnea, pulmonary emboli, and acute respiratory distress syndrome (ARDS); (c) cardiovascular changes, such as electrocardiogram (ECG) changes and venous distension; (d) GI changes, such as abdominal pain

and paralytic ileus; and (e) urinary changes, such as oliguria, leading to renal failure.

Diagnostic Studies

Tests used to diagnose acute DIC and their findings are listed in Table 33-21. As more clots are made in the body, more breakdown products from fibrinogen and fibrin are also formed. These FSPs, or FDPs, interfere with blood coagulation by (a) coating the platelets and interfering with platelet function; (b) interfering with thrombin and thus disrupting coagulation; and (c) attaching to fibrinogen, interfering with the polymerization process necessary to form a stable clot. D-dimer, a polymer resulting from the breakdown of fibrin (and not fibrinogen), is a specific marker for the degree of fibrinolysis. In general, tests that measure raw materials needed for coagulation (e.g., platelets, fibrinogen) are reduced and tests that measure clotting times are prolonged. Fragmented erythrocytes *(schistocytes),* indicative of partial occlusion of small vessels by fibrin thrombi, may be found on blood smears.

TABLE 33-21
LABORATORY ABNORMALITIES OF ACUTE DISSEMINATED INTRAVASCULAR COAGULATION

Test	Finding
Screening Tests	
Prothrombin time (PT)	Prolonged
Partial thromboplastin time (PTT)	Prolonged
Activated partial thromboplastin time (aPTT)	Prolonged
Thrombin time	Prolonged
Fibrinogen	Reduced
Platelets	Reduced
Special Tests	
Fibrin split products (FSPs)	Elevated
Factor assays (for factors V, VIII, X, XIII)	Reduced but may give misleading results, as V and VIII rise with inflammation
D-dimers (cross-linked fibrin fragments)	Elevated
Antithrombin III (AT III)	Reduced
Protein C and S	Reduced
Plasminogen, tissue activator	Reduced
Peripheral blood smear	Schistocytes present

Collaborative Care

It is important to diagnose DIC quickly, stabilize the patient (e.g., oxygenation, volume replacement), treat the underlying causative disease

or problem, and provide supportive care for the manifestations resulting from the pathology of DIC itself. Depending on its severity, a variety of different methods are used to manage DIC (Figure 33-11). First, if chronic DIC is diagnosed in a patient who is not bleeding, no therapy for DIC is necessary. Treatment of the underlying disease may be sufficient to reverse the DIC (e.g., chemotherapy when DIC is caused by malignancy). Second, when the patient with DIC is bleeding, therapy is directed toward providing support with necessary blood products while treating the primary disorder.

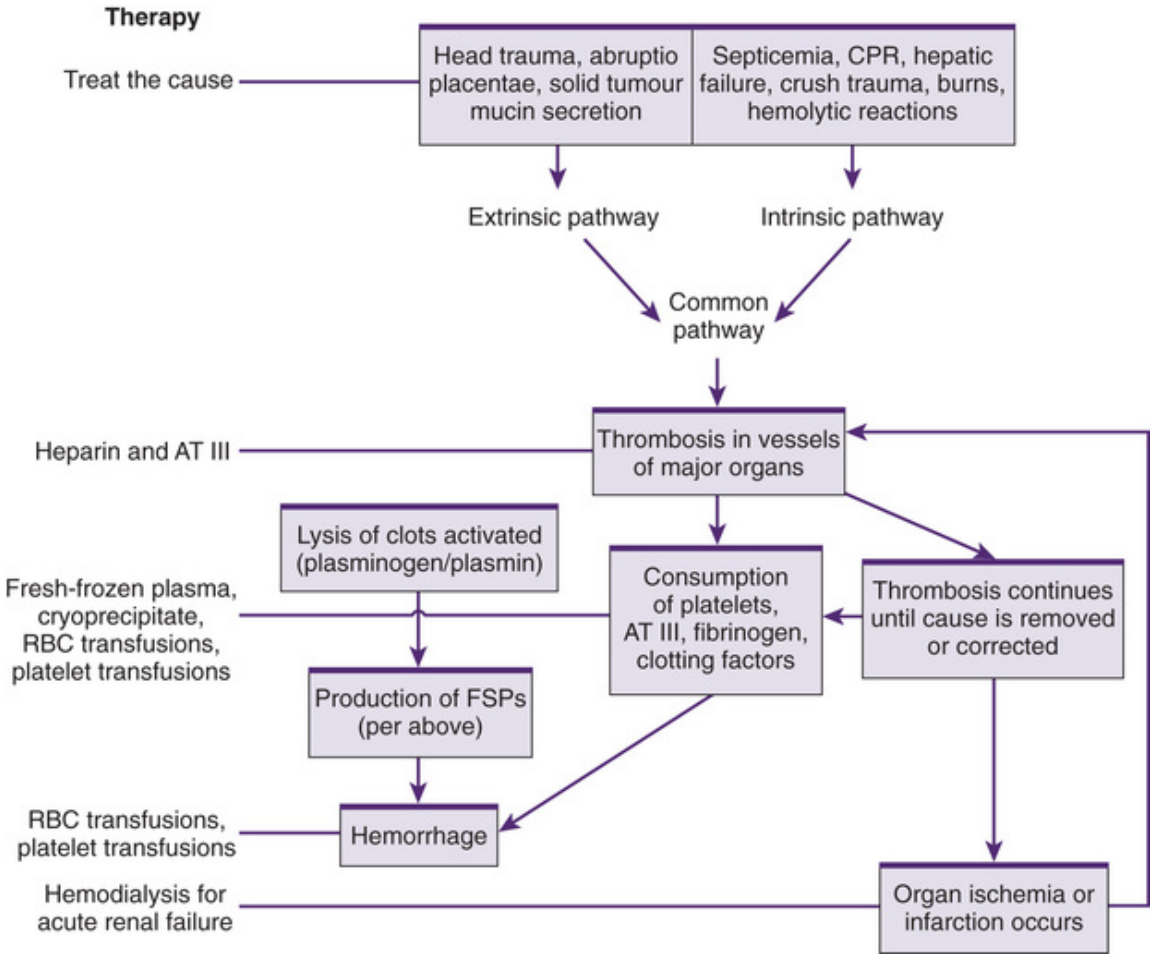

FIGURE 33-11 Intended sites of action for therapies in disseminated intravascular coagulation (DIC). *AT III,* antithrombin III; *CPR,* cardiopulmonary resuscitation; *FSPs,* fibrin split products; *RBC,* red blood cell.

Blood products are administered cautiously based on specific component deficiencies. Blood product support with platelets,
